

**American Society of Human Genetics  
69<sup>th</sup> Annual Meeting Poster Abstracts**

Abstract Topic	Abstract/Poster Board Numbers	
	Start #	End #
Precision Medicine, Pharmacogenomics, and Genetic Therapies	372	505
Prenatal, Perinatal, Reproductive, and Developmental Genetics	506	620
Genetic Counseling, ELSI, Education, and Health Services Research	621	750
Cancer Genetics	751	1082
Mendelian Phenotypes	1083	1398
Bioinformatics and Computational Approaches	1399	1746
Molecular Phenotyping and Omics Technologies	1747	1886
Complex Traits and Polygenic Disorders	1887	2297
Evolution and Population Genetics	2298	2410
Molecular and Cytogenetic Diagnostics	2411	2617
Cardiovascular Phenotypes	2618	2793
Statistical Genetics and Genetic Epidemiology	2794	3063
Molecular Effects of Genetic Variation	3064	3212
Epigenetics and Gene Regulation	3213	3364

**Posters should remain on the board for all three days (Wednesday through Friday)**

The program and abstract/poster board number next to each listing is followed by an **W** (Wednesday), **T** (Thursday), or **E** (Friday) to indicate the day on which authors must be present at their poster boards.

## PgmNr 372: A mechanism and treatment strategy for the sexual dimorphism seen in vascular Ehlers-Danlos syndrome.

### Authors:

---

We demonstrated that the PLC/IP<sub>3</sub>/PKC/ERK pathway is activated in vulnerable vascular segments in a mouse model (*Col3a1*<sup>G939D/+</sup>) of vascular Ehlers-Danlos syndrome (vEDS), a connective tissue disorder associated with spontaneous arterial rupture. Early postnatal attenuation of this signaling axis using either PKCβ (ruboxistaurin) or MEK/ERK (cobimetinib) inhibitors affords overt life-long protection in vEDS mice. Curiously, while potent inhibition of IP<sub>3</sub>-mediated PKCβ activation with hydralazine also prevented vascular rupture in early life (98% vs 50% survival at 45 days), protection was abruptly lost at sexual maturity, an event that was exaggerated in male mice (72% fatal aortic rupture between postnatal day 50 and 75 vs 15% in females). This is reminiscent of the elevated risk of vascular rupture in young men with vEDS at the end of puberty. We hypothesized that androgen signaling may contribute to puberty-associated aortic rupture. To test this, we treated vEDS mice with bicalutamide, an androgen receptor antagonist (ARA), and hydralazine. We found near-complete rescue from aortic rupture in both male and female mice (90% and 100% long-term survival, respectively). Notably, ARAs alone do not afford the same degree of protection as seen when used with hydralazine, suggesting therapeutic synergy. In anticipation of a reluctance to use potent ARAs in young men with vEDS, we considered the potential use of spironolactone, a diuretic that reduces androgen production, is a competitive antagonist of the androgen receptor and is used clinically for a variety of indications in adolescents of both sexes. Initiation of treatment with hydralazine and spironolactone at 21 days of age in vEDS mice of both sexes achieved 100% long-term survival, as compared to 45% in untreated mice. Risk correlated directly with ERK1/2 phosphorylation in the aortic wall. The vulnerability at puberty seen with hydralazine, but not ruboxistaurin or cobimetinib, positions androgen cross-talk downstream of IP<sub>3</sub> but proximal to PKCβ. Our results provide the first evidence that targetable signaling events contribute to the pathogenesis of vEDS and that puberty-associated vascular risk is androgen dependent, highlighting unanticipated therapeutic opportunities. This study may inform the mechanism for a more generalized increase in disease incidence and/or severity in males with other aortopathies including Marfan syndrome, bicuspid aortic valve with aneurysm and abdominal aortic aneurysm.

## **PgmNr 373: Elucidation of mechanism for accentuation of aortic aneurysm predisposition in males reveals a novel therapeutic strategy for heritable aortopathies.**

---

Bicuspid aortic valve (BAV) with distal ascending aortic aneurysm (DAscAoA) is the most common inherited aneurysm condition. Despite clear autosomal dominant inheritance with incomplete penetrance, very little is known regarding the etiology or pathogenesis of BAV/DAscAoA. Obstacles to progress include extreme locus heterogeneity, with currently defined genes accounting for less than 5% of disease, and the lack of robust animal models. There is a clear male bias with regard to disease incidence, penetrance, and severity that has not been mechanistically characterized. Unlike most heritable aortopathies that show restricted dilatation of the aortic root such as Marfan syndrome (MFS), Loeys-Dietz syndrome (LDS), and isolated familial thoracic aortic aneurysm (iFTAA), the aortopathy associated with BAV typically shows predominant enlargement of the ascending aortic segment distal to the sinotubular junction. We have now shown that this segmental predisposition is recapitulated in MFS mice treated with calcium channel blockers (CCBs). ERK activation and angiotensin II type 1-receptor signaling are drivers of aortic disease in this model, and Notch signaling is overtly protective as Notch antagonists dramatically accentuate the DAscAoA phenotype. Importantly, this model shows the male gender bias with regard to incidence and severity of aneurysm observed in people with BAV/DAscAoA, providing a unique opportunity to elucidate the mechanism underlying this sexual dimorphism. We performed RNA-sequencing on DAscAo specimens from male MFS mice treated with CCBs with or without rescue with ERK inhibition (ERKi). Regulation of androgen receptor activity emerged as a top enriched pathway in the filtered dataset of expression changes induced by CCBs but abrogated by addition of ERKi. We hypothesized that androgen receptor signaling may be responsible for the increased severity of the aortic phenotype in males. To test this, we treated male MFS mice receiving CCBs and Notch inhibitor with the androgen receptor antagonist Enzalutamide. Informatively, this isolated intervention completely abrogated DAscAoA formation in male MFS mice treated with CCBs and Notch inhibitors; protection was also evident in corresponding female mice, presumably due to the inhibition of female androgens. The natural protection afforded in preadolescent or female MFS mice suggests that androgen antagonism may emerge as a viable therapeutic strategy in a broader clinical context.

## PgmNr 374: Multimodal analysis in Myhre syndrome unravels potential endpoints for monitoring disease severity and efficacy of losartan treatment.

---

**Introduction:** Myhre syndrome (MS) is an ultra-rare autosomal dominant disorder due to recurrent mutations in the *SMAD4* gene encoding a member of TGF $\beta$ -SMAD4 pathway regulating extra-cellular matrix (ECM) homeostasis. The core clinical features of MS are related to progressive fibrosis and include thickening of skin and joint stiffness. Studies in fibroblasts have previously shown that losartan, an antihypertensive drug and TGF- $\beta$  antagonist, corrects the ECM deposition defect of MS.

**Materials and methods:** Five MS subjects (mean age: 22.4 years) with *SMAD4* mutations underwent clinical and laboratory evaluations including: 1. skin thickness by Rodnan score; 2. joint stiffness by goniometry; 3. speckle-tracking echocardiogram for myocardial fibrosis; 4. untargeted metabolomic GC/MS analysis in blood and urine to search for disease biomarkers.

**Results:** MS subjects were found to have increased skin thickness with an average Rodnan score of  $18 \pm 5.6$  [ranging from 0 (no thickening) to 51 (severe thickening)] and reduced joint range of motion, particularly at the ankle and knee by goniometry. Speckle-tracking echocardiogram revealed an increased strain (average  $12.5 \pm 3.2$  with normal values of  $19.7 \pm 0.28$ ) suggesting cardiac fibrosis that improved in one MS subject treated with losartan. The metabolomes of MS subjects were well separated from controls and butyric acid, ribitol and ribitol-related metabolites were found to be significantly higher in MS compared to controls.

**Conclusions:** MS patients showed multisystem involvement with fibrosis of skin, joints, and heart. A distinctive metabolomic signature involving fatty acids and polyols was detected. The present study unravels endpoints to monitor disease progression and for the evaluation of therapeutic efficacy. Preliminary data suggest that losartan can improve cardiac fibrosis in MS.

## PgmNr 375: Nanogel-mediated protein replacement therapy for Tgase-1-deficient congenital ichthyosis: Results from the proof of concept study.

---

Autosomal recessive congenital ichthyosis (ARCI) is a rare and severe disorder of disturbed cornification. Patients present with a more or less intense scaling on the entire body, often accompanied by secondary features including hair loss, ectropion, eclabion, and joint stiffness, especially in the very young. ARCI is both genetically and clinically heterogeneous. There are presently no curative therapies available, current treatment options are restricted to frequent and extended bathing, application of crèmes and scrubbing off of excess scales.

Approximately one third of ARCI cases are caused by mutations in *TGM1* making it the most common known cause. *TGM1* encodes transglutaminase 1 which is required to cross-link proteins in the outermost layer of the skin (horny layer). The disease disrupts normal keratinisation resulting in generalised scaling of the skin with notable detriments to barrier function, the latter of which leads to increased trans-epidermal water loss and a greater susceptibility to infections. In the present study, thermoresponsive nanogels (tNG) loaded with functional, recombinant transglutaminase 1 were applied to the surface of full thickness skin equivalents generated with the keratinocytes of transglutaminase 1 deficient ARCI patients. The skin equivalents demonstrated clear deficiencies in transglutaminase 1 activity and skin barrier function, in line with the pathophysiology of ARCI. Topical application of the loaded tNGs instated transglutaminase 1 activity within the viable epidermis of the mutant skin equivalents and improved skin barrier function in a manner dependent on transglutaminase 1 dose; application of the tNG alone or recombinant transglutaminase 1 alone had no impact. Toxicity studies in skin equivalents as well as keratinocyte and fibroblast monolayers confirmed the high biocompatibility of the treatment. Topical protein replacement therapy for transglutaminase 1 deficient ARCI patients appears highly promising and demonstrates a novel therapeutic approach for monogenic skin diseases.

## PgmNr 376: Protein O-GlcNAcylation is a novel mechanism regulating ureagenesis and ammonia detoxification.

### Authors:

Life-threatening hyperammonemia results from inherited defects of the urea-cycle and acquired liver diseases. O-GlcNAcylation is a dynamic post-translational modification of intracellular proteins catalyzed by the enzyme O-GlcNAc transferase (OGT) whereas the O-GlcNAcase (OGA) removes the O-GlcNAc. O-GlcNAcylation regulates liver metabolism of glucose, lipids, and bile acids. Here, we investigated the role of hepatic O-GlcNAcylation in ammonia detoxification.

Pharmacological and genetic inhibition of OGA was investigated in C57BL/6 wild-type mice with acute hyperammonemia induced by intraperitoneal injection of <sup>15</sup>N-labeled ammonium chloride. Ammonia removal was monitored by measurements of serum ammonia whereas ureagenesis was evaluated by <sup>15</sup>N-NMR spectroscopy. O-GlcNAcylated protein levels were determined by Western blot and hepatic gene expression by qPCR. Whole-liver metabolome and proteome analyses were performed by <sup>1</sup>H-NMR and mass spectrometry, respectively.

Treatment with OGA inhibitor molecules (PUGNAc and Thiamet-G) increased O-GlcNAcylation of liver proteins. Both drugs reduced concentrations of serum ammonia and increased serum levels of <sup>15</sup>N-labeled urea. Similar results were observed in mice with siRNA-induced hepatic *knockdown* of OGA. Interestingly, whole-liver metabolome was well separated between mice with enhanced O-GlcNAcylation and controls, and metabolite set enrichment analysis unravelled urea-cycle among the main implicated pathways. Neither expression of genes encoding urea-cycle enzymes nor genes involved in ammonia detoxification were affected by OGA inhibition. The protein amount of these enzymes was also unaffected, suggesting that hepatic O-GlcNAcylation regulates ammonia clearance capacity by controlling the enzymatic activity of the urea-cycle.

In conclusion, hepatic O-GlcNAcylation plays an important role in ammonia detoxification. The mechanisms underlying increased ureagenesis by OGA inhibition is under investigation. Nevertheless, OGA is a novel therapeutic target for treatment of hyperammonemia of both urea cycle disorders and acquired hyperammonemia.

## **PgmNr 377: Inhibition of Grb14, a negative modulator of insulin signaling, ameliorates insulin resistance.**

**Authors:**

Ding; R. Rugmani; Y. Zhou; C. Novotny; D. Metzger; J. Vogel; G. Swaminath; S. Talukdar

[View Session](#) [Add to Schedule](#)

---

Insulin resistance increases a patient's risk of developing type 2 diabetes, non-alcoholic steatohepatitis (NASH) and a host of other comorbidities including cardiovascular disease and cancer. At the molecular level, insulin exerts its function through the insulin receptor (IR), a transmembrane receptor tyrosine kinase. Data from human genetic studies have shown that Grb14 functions as a negative modulator of IR activity, and germline Grb14-knockout mice have improved insulin signaling in liver and muscle tissues. Here, we confirm the insulin dependent interaction between IR and Grb14 and show that Grb14 knockdown in the liver and the heart with an AAV-shRNA (Grb14-shRNA) improved glucose homeostasis and insulin resistance in diet-induced obese (DIO) mice. A previous report has shown that germline deletion of Grb14 in mice resulted in cardiac hypertrophy and decreased systolic function; effects that could severely limit the therapeutic potential of targeting Grb14. In order to understand the direct role of Grb14 in the heart, we investigated the cardiac function longitudinally for a period of four months in DIO mice treated with Grb14-shRNA. There were no significant changes in hemodynamic function as measured by echocardiography between the treated animals with respect to its control. While additional studies are needed to further establish efficacy and to de-risk potential negative cardiac effects under heart failure conditions, our data support modulating Grb14 as a bona-fide strategy to treat insulin resistance and NASH.

## **PgmNr 378: The link between low back pain and diabetes: Gene-based association study in people with comorbid diabetes mellitus and low back pain.**

### **Authors:**

---

### **Purpose**

Diabetes mellitus type 2 is a disease associated with chronic pain. Mechanisms of this association are not fully understood. Few studies have explored the genetics of this association, and an independent genetic link between diabetes and low back pain (LBP) has not been completely investigated. We hypothesize that variants in candidate genes are associated with comorbid diabetes and LBP phenotypes.

### **Methods**

This cross-sectional study is a part of a larger study of subacute and chronic LBP within the PRECISION Pain Research Registry. Subjects were recruited from the Dallas-Fort Worth Metroplex and reported LBP for at least 2 months (subacute) or 6 months (chronic) for half or more of the days with the relevant time period.

Primary outcomes were assessed using a Numerical Rating Scale (NRS) for pain intensity, the Roland-Morris Disability Questionnaire for back-specific functioning, and the Patient-Reported Outcomes Measurement Information System for quality of life measures.

Study participants self-reported diabetes. Biological samples were collected to determine participants' genotypes using the Infinium Global Screening Array. Analyses were conducted using SPSS Statistics software among 488 study participants, 109 of whom reported diabetes.

Twenty-seven candidate genetic loci concurrently implicated in both pain phenotypes and diabetic phenotypes were identified from the literature. From these loci, 35 candidate genes were used to perform a gene-based association study (GBAS) to identify their potential association with diabetes and LBP. Genetic variants were mapped to candidate genes for association with each of the pain phenotypes after adjusting for age, sex, diabetes status, and ancestry components 1-10 using MAGMA computational software.

### **Results**

GBAS results point to variants in the PRKCA gene as being associated with both NRS of LBP intensity and diabetes. PRKCA is a family of protein kinases implicated in neuropathic pain and formation of advanced glycation end products.

### **Conclusions**

Of the 35 genes tested, only variants in PRKCA are significantly associated with LBP and diabetes in the PRECISION cohort. These findings build on a framework which suggests that genetic predisposition in PRKCA may underlie diabetes and LBP.

## PgmNr 379: Does 23&Me raw data accurately detect GCK-MODY?

### Authors:

H. Zhang; T.I. Pollin

[View Session](#) [Add to Schedule](#)

**Affiliation:** Division of Endocrinology, Diabetes and Nutrition, University of Maryland, Baltimore, Baltimore, Maryland.

### Introduction

Recent studies raise a concern about the accuracy and interpretation of direct-to-consumer genetic testing (DTC-GT) raw data for health information. We have found that 23andMe raw data contains 316 variants in the *GCK* (glucokinase) gene, including 273 reportedly pathogenic or likely pathogenic variants that have been implicated in the Maturity Onset Diabetes of the Young 2 (MODY2, or GCK-MODY), a lifelong form of mild hyperglycemia which can be misdiagnosed as type 1 or type 2 diabetes but requires no treatment. In this project, we used GCK-MODY as an example to discover how many consumers may find GCK-MODY causing variants in their raw data and how many are possibly real.

### Methods

23andMe DTC-GT raw data of 3040 anonymous consumers was downloaded from openSNP and *GCK* variant genotypes extracted for analysis. Call rate and Hardy-Weinberg equilibrium (HWE) p-value were calculated. Pathogenicity of exonic/ splicing variants found in openSNP contributors was classified using 2015 ACMG/AMP guidelines. We also evaluated how many *GCK* variants identified through sequencing in the Personalized Diabetes Medicine Program (PDMP), an implementation project to demonstrate the clinical utility of monogenic diabetes diagnosis, would have been detected through from the DTC-GT raw data.

### Results and Conclusion

488 (16.1%) consumers showed a total of 18 pathogenic/likely pathogenic variants, with only 2 having a call rate >99% and HWE  $p > 0.05$ . One pathogenic frameshift allele, c.174delG, was called in 239 consumers (call rate = 14%, HWE  $p < 0.01$ ), for a MAF of 8% compared to 0% in gnomAD, underscoring the value of population data for clarifying the likelihood of false positives (apparently 99.7% in this case). Finding 2 individuals with credible GCK-MODY variants in the 3040 samples (0.07%) is consistent with a recent population estimate 0.1% for this condition. The DTC-GT raw data could potentially have identified 11 of the 21 GCK-MODY patients from the PDMP, although only 5 of the 11 variants had call rates > 99%, with the other 6 having call rates of 80%-98%, suggesting a high risk for false negatives even for variants included on the array. While actual GCK-MODY cases may have been identified, these results also support an empirically high risk of false positive and negative results from DTC-GT raw data, indicating consumers should heed disclaimers about limitations of non-medical grade genetic testing accordingly and pursue medical grade testing when indicated.

## PgmNr 380: Genome-wide association study for serum alkaline phosphatase identifies novel associations influencing metabolic disease and diverse liver-related pathways.

---

**Introduction:** Serum alkaline phosphatase (ALP) is a commonly-used indicator of liver disease. ALP levels are genetically influenced but exact genetic and biochemical etiologies underlying ALP variation are not known.

**Methods:** We carried out genome-wide association study (GWAS) of inverse normally-transformed ALP with >20 million imputed SNPs using Scalable and Accurate Implementation of GEneralized mixed model, controlling for age, sex, and principal components, in >390,000 white-British individuals from UK BioBank. We then meta analyzed these results with ALP association results from >130,000 individuals of Japanese ancestry from BioBank Japan (5,951,600 imputed SNPs) with using METAL. Cross-trait analysis was performed using GWAS of quantitatively-measured nonalcoholic hepatic steatosis (GOLD consortium) and alcoholic cirrhosis (PMID 26482880) ( $P < 0.05$  reported), and 9 targeted metabolic UK BioBank traits/diagnoses (FDR < 0.05 reported). DEPICT analyses were carried out using SNPs with ALP association  $P < 1 \times 10^{-5}$ ; we reported tissues/pathways with FDR < 0.05.

**Results:** On meta analysis of UK BioBank and BioBank Japan, 316 SNPs associated with ALP at genome-wide significance ( $P < 5 \times 10^{-8}$ ), 301 of which were novel. Many ALP-increasing SNPs affected liver-related traits: SNPs in/near *GCKR* increased quantitatively-measured nonalcoholic hepatic steatosis, and others in/near *MARC1* increased risk of alcoholic cirrhosis. A range of metabolic patterns were seen: ALP-increasing SNPs in/near *MSL2* increased body mass index, triglycerides, and LDL-cholesterol while lowering serum HDL-cholesterol; other SNPs near *GCKR* produced a mixed phenotype with higher triglycerides and LDL-cholesterol but decreased diabetes, and yet others in/near *APOC1* caused decreased both triglycerides and LDL-cholesterol. Some ALP associated SNPs were in/near genes involved in glycoprotein biology (*ASGR1*), immunity (*TIRAP*), drug metabolism (*CYP2A6*), or monogenic liver disease (*HFE*). DEPICT showed enrichment in liver, followed by adipose tissue, small intestine, and pancreas. The top enriched gene sets were PPAR-alpha, nonspecific liver, and lipid localization pathways.

**Conclusions:** We identified 301 novel ALP-increasing SNPs in UK BioBank and BioBank Japan. These variants influence hepatic steatosis, alcoholic liver disease, and diverse metabolic traits/processes. Genes associated with ALP-increasing SNPs are primarily liver-expressed and highlight multiple pathways underlying liver disease.

## PgmNr 381: Genetic variants that associate with liver fibrosis and cirrhosis have pleiotropic effects on human traits.

### Authors:

E. Speliotes<sup>1,2</sup>; V.L. Chen<sup>1,2</sup>; Y. Chen<sup>1</sup>; X. Du<sup>1</sup>; S.K. Handelman<sup>1,2</sup>

[View Session](#) [Add to Schedule](#)

1) Division of Gastroenterology and Hepatology, University of Michigan Health System, Ann Arbor, MI, USA; 2) Department of Computational Medicine and Bioinformatics, University of Michigan Medical School, Ann Arbor, MI, USA

**Background:** Cirrhosis is characterized by extensive fibrosis of the liver and is a major cause of liver-related mortality. Cirrhosis is partially heritable but genetic contributions to cirrhosis have not been systemically explored. Here, we perform an unbiased genome-wide analysis of variants for association with cirrhosis in two large biobanks and determine the effects of cirrhosis associated variants on multiple human disease/traits.

**Methods:** We carried out a genome-wide association analysis of cirrhosis (based on diagnostic codes) as a diagnosis in UK BioBank (1,088 cases vs. 407,873 controls) and then tested top associating loci for replication with cirrhosis (based on diagnostic codes and a validated text search) in the hospital-based cohort Michigan Genomics Initiative (MGI; 875 cases of cirrhosis vs. 30,346 controls). For replicating single nucleotide polymorphisms (SNPs) or SNPs previously associated with cirrhosis, we determined their effects on other diseases (phenome-wide association study), common metabolic traits, and serum/plasma metabolites.

**Results:** SNPs near the genes *PNPLA3* and *HFE* associated with cirrhosis at genome-wide significance ( $p < 5 \times 10^{-8}$ ) in UK BioBank and replicated in MGI. We confirmed that previously-reported common SNPs in *HSD17B13*, *MBOAT7*, *TM6SF2*, *SERPINA1*, *STAT4*, and *IFNL4* associate with cirrhosis in UK BioBank or MGI. Most SNPs associated with liver enzyme abnormalities. Phenome-wide association study on these SNPs identified diverse and novel associations; the cirrhosis increasing alleles at *SERPINA1* increased height and cirrhosis promoting SNPs at *STAT4* increased respiratory infection. The cirrhosis increasing allele in *HFE* increased blood pressure but decreased serum low-density lipoprotein and total cholesterol while the cirrhosis promoting allele at *MBOAT7* decreased triglycerides and increased high-density lipoprotein. The cirrhosis promoting allele at *SERPINA1* increased low-/intermediate-density lipoproteins while the cirrhosis promoting allele at *TM6SF2* decreased these.

**Conclusions:** We identified loci associated with cirrhosis at genome-wide significant and validated previously-reported common variants for association with population based cirrhosis. These variants produce diverse effects on human diseases and traits, metabolic traits/disease, and circulating metabolites.

## PgmNr 382: HMI-102, an investigational gene therapy for phenylketoneuria (PKU).

### Authors:

D. Lamppu; S. Ahmed; L. Benard; J. Ellsworth; E. Faulkner; O. Francone; M. Lobikin; T. Wright; A. Seymour

[View Session](#) [Add to Schedule](#)

**Affiliation:** Homology Medicines, Inc, Bedford, Massachusetts.

---

HMI-102 is an investigational gene therapy for PKU due to phenylalanine hydroxylase (PAH) deficiency. The PAH enzyme converts phenylalanine (Phe) into tyrosine (Tyr). PAH deficiency is due to mutations in the *PAH* gene, resulting in excess Phe. It's inherited as an autosomal recessive, monogenic defect, making it suitable for potential AAV-based gene therapy.

PAH deficiency has a continuum of clinical phenotypes characterized by elevated blood Phe, ranging from mild hyperphenylalaninemia (HPA) (Phe 120-360  $\mu\text{mol/L}$ ) to classic PKU (Phe over 1200  $\mu\text{mol/L}$ ). Current US treatment guidelines indicate treatment is not required for mild HPA. Untreated PKU in children results in severe neurological impairment. Adults treated with Phe-restricted diets as children present with higher rates of neuropsychiatric comorbidities.

HMI-102 delivers the human *PAH* gene to the liver using AAVHSC15, a clade F vector isolated from human hematopoietic stem cells. The gene is transcribed and translated into active PAH. HMI-102 was tested in  $\text{PAH}^{\text{enu}2}$  mice, a murine model of PKU with several features consistent with the human classic PKU phenotype, including blood Phe over 1200  $\mu\text{M}$ . HMI-102 normalized blood Phe within one week of administration in mice on a normal chow diet. Phe reduction was sustained for 48 weeks (lifespan of the mouse model). HMI-102 normalized blood Tyr, 5-HIAA in the brain, and darkened the mouse coat color, demonstrating restoration of Phe metabolism.

In GLP studies in non-human primates and mice, there were no adverse test-article related findings. Durable vector genomes (vg) and mRNA expression were present in the livers; vg levels were comparable in both species at given weight-based doses. Dose modeling simulations for baseline Phe up to 2400  $\mu\text{mol/L}$  were done using  $\text{PAH}^{\text{enu}2}$  efficacy data to select doses for the first-in-human (FIH) study. The modeling predicted a robust response for the starting dose (>90% of subjects would achieve Phe <360  $\mu\text{mol/L}$ ).

A retrospective chart review was conducted to characterize blood Phe control in 152 patients with HPA. The data showed high Phe levels despite dietary restriction, demonstrating an unmet need for therapies to control blood Phe. The data also confirmed the FIH study design eligibility criteria and endpoints.

Collectively, the nonclinical data and retrospective study support initiation of the FIH study, which will assess the safety, tolerability, and efficacy of HMI-102 in adults with classic PKU.

## PgmNr 383: Host genetics and gut microbiome drive individual variation in blood metabolites in a large human cohort.

---

The human blood metabolome is comprised of thousands of small molecules, many of which are associated with human health and disease. Host genetics and environmental factors contribute to the variation in the levels of some of these metabolites. While certain genetic loci have been shown to be associated with peripheral blood metabolite concentrations, the extent to which the human gut microbiome influence these variations remains understudied. In particular, gene-environment interactions with the gut microbiome are uncharacterized. In this study, we investigated the associations between host genetics and gut microbiome features with the concentrations of 943 blood metabolites in a US-based cohort of 1,675 individuals. A genome-wide association analysis using whole-genome data identified 232 metabolites associated with 141 genomic loci (genome-wide significance  $P = 5.42 \times 10^{-12}$ ). We also identified microbiome-wide associations between 191 metabolites and 49 bacteria genera (microbiome-wide significance  $P = 5.36 \times 10^{-7}$ ) using a beta-binomial model. 40 of these metabolites were significantly associated with both host genetics and microbiome. Of these associated genetic loci and associated bacteria genera, 5 metabolites (2 amino acids, 2 xenobiotics, and 1 unidentified) had significant gene-environment interactions ( $P_{\text{FDR}} < 0.05$ ) between genetic variants and either *Faecalibacterium* or *Lachnospira*, two butyrate-producing bacteria genera. Taken together, we highlight several host-microbe interactions and demonstrate a joint genetic and microbial effect on blood metabolites. Understanding these relationships provides the foundation for future applications in precision medicine.

---

Obesity is a major risk factor for chronic disease. Besides an obesogenic lifestyle, genetic factors also determine susceptibility to obesity. Using a polygenic risk score (PRS) for obesity, those in the top 10% were shown 25x more likely to be severely obese compared to the bottom 10%. Interestingly, a proportion (17%) of the top 10% were of normal weight. To gain insight into the mechanisms that determine resilience to genetic predisposition to obesity, we characterized normal weight and obese individuals with a high (top 5%) and low (bottom 5%) PRS within the UK Biobank.

Using PRSice, we built a PRS with BMI association summary statistics of 2.1 million variants (Locke et al. 2015) that we tested in 372,584 unrelated UKB participants of European ancestry. We defined 6 groups; by PRS [bottom 5%, middle 35-65%, top 5%) and BMI-category (under/normal weight [BMI: <25kg/m<sup>2</sup>, NW] and obese [BMI≥30, OB]), and compared demographics, body composition, clinical history, and measures of the obesogenic environment. All analyses were adjusted for age, sex, center, and the first ten PCs.

In the top 5% of the PRS (N=18,630), 44.5% were OB, whereas 17% were NW. In the bottom 5% PRS (N=18,628), the discrepancy was more pronounced; 53.9% were NW, and only 9% were OB. Among NW individuals, those in the top 5% PRS had ( $P<1e-3$ ) somewhat higher adiposity, lower energy intake, more sedentary time, were more often smokers, were less educated, and had more often diabetes, compared to those in the bottom 5%, though material deprivation and birth weight were

similar. Among OB individuals, we saw similar differences. In the high-PRS group, 84% of the NW reported to be thinner or of average body size at age 10, compared to 59% of the OB ( $P < 2e-16$ ). Conversely, in the low-PRS group, 27% of OB reported to be “plumper” at age 10, compared to 6% of NW ( $P < 2e-16$ ). Among the high-PRS group, NW were ( $P < 1e-3$ ) more physically active and educated, less sedentary and materially deprived, fewer had diabetes, but more were smokers, than OB. Inverse trends were observed in the low-PRS group.

Taken together, body size tracks across the life course, which seems to be largely driven by a genetic predisposition (PRS), but also by (non-)genetic factors not captured by the PRS. Moreover, material deprivation, education and lifestyle may counteract one’s genetic predisposition to obesity. Understanding the genetic and non-genetic contributors to body size can help define the scope and timing of prevention.

## PgmNr 385: Deconstructing polygenic scores for type 2 diabetes to capture etiological and clinical heterogeneity.

### Authors:

**Affiliation:** Wellcome Centre for Human Genetics, Univ Oxford, Oxford, United Kingdom

Over 400 robust signals of T2D association have been identified to date. Whilst “global” polygenic scores using all signals of T2D predisposition are appropriate for risk prediction, “partitioned” scores (pPS) that capture the etiological diversity of T2D may have more value for clinical decision-making related to the heterogeneity within T2D.

Here, we extend previous pPS analyses to an expanded set of 337 T2D signals, using clusters defined on the basis of multi-trait association patterns across 10 core traits. Fuzzy clustering defined six genetic clusters (GCs), capturing variants with primary effects on adiposity (GC1-BMI), lipids (GC2-lipids), insulin action (GC3-IA) and beta-cell function (GC4-BCF, GC5-BCF), plus a sixth with mixed features (GC6-MIX).

We considered the impact of individual T2D-pPS loadings on complication risk utilizing publicly available GWAS for CAD, atrial fibrillation (AF), hypertension, CKD, renal function (eGFR, albuminuria), stroke and fatty liver (liver fat%), and observed multiple GC-specific patterns of association with outcomes ( $p < 0.0007$ ). T2D-risk mediated by GC1-BMI was exclusively associated with AF (OR=1.3 per 1SD pPS increase), whereas GC2-Lipids associated with CKD (OR 1.4) and reduced eGFR (OR 0.95). Hypertension and CAD were most strongly associated with GC1-BMI and GC3-IA (OR>1.3). T2D-risk attributable to GC2-Lipid scores was associated with lower CAD risk (OR 0.60) but increased liver fat (OR 2.5), counter to the broader epidemiological association between them.

Next, we used available metabolomic and proteomic data to identify candidate biomarkers for each of these processes. We detected 56 protein, 83 metabolite, and 26 glycan associations ( $q$ -value<0.05 within each marker group). Many of these were associated with the GC2-Lipid pPS (including AKT2, APOB, APOE). Other candidates included IGFBP2 and APOF as markers of insulin resistance (GC3-IA). GC4-BCF and GC5-BCF pPS showed divergent associations with proinsulin (high vs low levels, respectively) pointing to distinct mechanisms of beta-cell dysfunction. Circulating levels of ATF6, a known marker of ER stress response, were associated exclusively with GC5-BCF.

Our findings demonstrate that partitioned polygenic scores capture individual differences in the etiological contributions to T2D development that can be related to clinically relevant outcomes, and which provide a mechanistic framework for understanding disease heterogeneity.

## PgmNr 386: The relationship between PCSK9 and sepsis: A genetic approach.

**Objective** Inhibition of proprotein convertase subtilisin kexin type 9 (PCSK9) decreases risk of sepsis in animal models. We tested whether functional *PCSK9* genetic variants, a *PCSK9* genetic risk score (GRS), or genetically-predicted *PCSK9* expression levels were associated with the risk of sepsis in patients admitted to the hospital with infection.

**Design, Setting and Participants** De-identified electronic health records were used to define a cohort of patients admitted to Vanderbilt University Medical Center, Nashville, Tennessee, with infection. Patients were white adults, had an International Classification of Diseases, Ninth Revision, Clinical Modification (ICD9) or ICD10 code indicating infection and received an antibiotic within 1 day of hospital admission (N=61502).

**Interventions** (1) 4 known *PCSK9* functional variants (rs11591147, rs11583680, rs562556 and rs505151, N=10922), (2) a GRS for *PCSK9* (N=7624), and (3) genetically-predicted *PCSK9* expression (N=6033).

**Main Outcomes** The primary outcome was sepsis; secondary outcomes included cardiovascular failure (use of a pressor agent) and in-hospital death.

**Results** None of the 4 functional *PCSK9* variants were significantly associated with sepsis, cardiovascular failure, or in-hospital death, with or without adjustment for (1) age and sex, or (2) age, sex, and Charlson/Deyo comorbidities. In the fully-adjusted model, the odds ratios [ORs] (95% CI) for rs11591147 were: sepsis, 0.84(0.64-1.09); cardiovascular failure, 1.24(0.82-1.85); and in-hospital death, 0.73(0.36-1.51). The ORs for rs11583680 were: sepsis, 1.01(0.93-1.10); cardiovascular failure, 0.94(0.81-1.09); and in-hospital death, 1.06(0.86-1.31). The ORs for rs562556 were: sepsis, 0.99(0.92-1.07); cardiovascular failure, 1.02(0.90-1.17); and in-hospital death, 0.99(0.81-1.21). The ORs for rs505151 were: sepsis, 0.92(0.78-1.08); cardiovascular failure, 1.05(0.80-1.37); and in-hospital death, 0.80(0.51-1.26). Similarly, the *PCSK9* GRS were not significantly associated with sepsis 1.01 (0.96-1.06), cardiovascular failure, 1.03 (0.95-1.12), and in-hospital death 1.05 (0.92-1.19). Genetically-predicted *PCSK9* expression was not associated with sepsis 1.01 (0.95-1.06), cardiovascular failure 0.96 (0.88-1.05), and in-hospital death 0.99 (0.87-1.14). All p-values>0.05.

**Conclusion** *PCSK9* genetic variants were not associated with risk of sepsis in patients hospitalized

with infection nor were they associated with the outcomes of sepsis.

## PgmNr 387: An African ancestry uterine fibroids polygenic risk score (PRS) identifies associations with other gynecologic conditions in the clinical phenome.

---

Uterine fibroids are the most common female pelvic tumor with prevalence up to 77% by menopause in African Americans. African American women have increased risk of fibroids than other continental populations, as well as larger and more numerous fibroids. The known genetic architecture of uterine fibroids currently includes ~30 loci, most discovered in European populations. We conducted a phenome-wide association study (PheWAS) of uterine fibroids polygenic risk scores (PRS) to understand the shared genetic contributions across clinical phenotypes. We constructed an African-ancestry uterine fibroids PRS of 317 SNPs using a p-value threshold of  $<1 \times 10^{-4}$ . Effect sizes were derived from imaging-confirmed uterine fibroids genome-wide association study (GWAS) of 1,272 cases and 1,379 controls from the Electronic Medical Records and Genomics (eMERGE) network. We then performed PheWAS across 6,061 independent women from eMERGE using the PRS as the predictor for clinical diagnoses adjusted for age, body mass index, and principal components. We identified 26 significant ( $p\text{-value} < 2.5 \times 10^{-5}$ ) results among 1,381 diagnoses. The top association was uterine fibroids ( $p\text{-value} = 6.42 \times 10^{-66}$ ), showing that the PRS is well-calibrated even when not restricted to imaging-confirmed cases and controls. Other top results included genitourinary conditions related to uterine fibroids, including six diagnoses related to menstrual dysregulation. There were also novel associations with other gynecological conditions including endometriosis ( $p\text{-value} = 2.51 \times 10^{-13}$ ), ovarian cysts ( $p\text{-value} = 1.26 \times 10^{-7}$ ), and abnormal Papanicolaou smear ( $p\text{-value} = 1.55 \times 10^{-6}$ ). Overall, results suggested that this imaging-confirmed uterine fibroids PRS is a valid correlate of the genetic risk underlying uterine fibroids development. We also observed associations with other gynecologic conditions, including neoplastic phenomena, suggesting shared genetic risks.

## PgmNr 388: Eculizumab therapy for protein-losing enteropathy due to CD55-deficiency: Insights from a two-years-long follow-up.

**Introduction:** The *CD55* gene encodes the decay accelerating factor, a complement system regulator. Bi-allelic loss-of-function variants in *CD55* cause an early-onset protein-losing enteropathy (PLE) syndrome, associated with intestinal lymphangiectasia and susceptibility to large-vein thrombosis. A short-term three-months-trial of eculizumab (C5-inhibitor) therapy in three *CD55*-deficiency patients showed marked improvement in disease manifestations. Here we present the two-year treatment outcomes for these patients, highlighting treatment safety and sustained therapeutic response.

**Methods:** Off-label eculizumab treatment was administered to three *CD55*-deficiency patients. Clinical treatment outcomes included frequency and consistency of bowel movements, weight, patient/parent reports of overall well-being; laboratory outcomes were underscored by serum albumin and total protein levels. Membrane attack complex (MAC) deposition on leukocytes was tested by flow cytometry, before and throughout treatment.

**Results:** All three patients had marked clinical improvement in all components, including resolution of PLE manifestations (diarrhea, edema, malabsorption), hypercoagulability, overall well-being, growth and quality of life. Correspondingly, all laboratory outcome parameters improved and normalized, including albumin and total protein levels, and up to 80% reduction in MAC deposition was observed on leukocytes ( $p < 0.001$ ). There were no severe adverse events over two years of treatment.

**Conclusions:** Patients with *CD55*-deficiency present with early-onset diarrhea, edema, severe hypoalbuminemia, abdominal pain, malnutrition and susceptibility to venous thrombosis. Previously a life-threatening condition, *CD55*-deficiency is highly responsive to targeted therapy with the terminal complement inhibitor eculizumab, with positive clinical and laboratory outcomes. This study underscores the significant role of the complement system in the gut, and warrants further studies on the function of the complement system and *CD55* in other gastrointestinal disorders.

## PgmNr 389: New frontiers to cure Alport syndrome by a personalized CRISPR/Cas9 gene editing approach.

Alport syndrome (AS) is an inherited genetic disorder characterized by clinicopathologic alterations ranging from glomerular basement membrane abnormalities to end-stage renal disease. Mutations in the collagen  $\alpha 3$ ,  $\alpha 4$  and  $\alpha 5$  encoding genes are causative of both the autosomal and X-linked forms of AS. A curative therapy for AS is still lacking, and the podocytes' functional disruption can be only partially recovered by symptomatic treatments.

Podocytes, a key component of the glomerular structure, are the only kidney cells able to produce the COLIV $\alpha 3$ - $\alpha 4$ - $\alpha 5$  heterotrimer. We have previously demonstrated that it is possible to isolate podocyte-lineage cells from urine of patients. Building upon the availability of urine-derived podocytes as an easy source of disease-relevant cells, we have established the efficiency of CRISPR/Cas9 gene therapy to restore the wild-type genotype *in-vitro*. We have engineered a two-plasmid system to correct the causative mutation in two stable podocyte-lineage cell lines, harboring a mutation in the X-linked COL4A5 (p.(Gly624Asp)) and in the autosomal COL4A3 gene (p.(Gly856Glu)). We have achieved reversion of mutations greater than 40% with undesired insertions/deletions lower than 15%. CRISPR/Cas9 gene editing experiments on urine-derived podocyte-lineage cells from a naturally occurring dog model harboring a deletion of 10 bp in exon 9 of COL4A5 replicated the results in human cells with a rate of correction greater than 50%.

In vivo experiments using our two-plasmid system to correct the COL4A5 mutation in the AS dog model are currently ongoing. A single femoral artery catheterization will be used to deliver the AAV2-CRISPR/Cas9 correction system *in-vivo*, injecting into both renal arteries. The procedure will be performed at 8 weeks of age, which is typically before the occurrence of microalbuminuria, using one of two dosages (1011-1012 and 1013-1014) in two affected males. A third affected male dog will be treated with mut-AAV2-CRISPR/Cas9 as a negative control.

The described approach can provide proof-of-principle for a gene therapy strategy for AS treatment, opening up the possibility of in-vivo clinical trials on AS patients based on personalized transformative medicine tailored to the pathogenic mechanism and able to directly act on disease-relevant cells.

## PgmNr 390: Uterine leiomyomata Polygenic Risk Scores (PRS) confer novel relationships in the clinical phenome.

Uterine leiomyomata (UL) are the most common cause of pelvic tumors in women with lifetime incidence of 70%. Little is known about the etiology of UL. Prior Genome-Wide Association Studies (GWAS) in predominately European Ancestry (EA) populations have identified ~30 loci that are associated with UL. We developed a UL polygenic risk score (PRS) and combined it with a Phenome-Wide Association Study (PheWAS) approach to gain understanding about the shared genetic contribution across many clinical phenotypes. We constructed the PRS with PRSice software using effect sizes derived from a non-Hispanic EA, imaging-confirmed UL GWAS set from the Electronic Medical Records and Genomics (eMERGE) Network (N=2,651 cases and 4,326 controls). It was optimized in an independent set of UL imaging-confirmed cases and controls (N= 429 cases, 4,750 controls) from BioVU. The PRS consisted of 4,448 linkage disequilibrium pruned ( $r^2 < 0.2$ ) variants ( $p < 0.001$ ) and the model was significant ( $r^2 = 0.0017$ ,  $p$ -value = 0.041). PheWAS analyses were performed in 53,116 non-Hispanic EA and 5,583 non-Hispanic African-American (AA) men and women from eMERGE, excluding samples used for model construction, using the PRS as the predictor for 1,738 clinical disease phenotypes adjusted for sex, age, body mass index, and 10 principal components. Our PRS PheWAS detected UL as the most significant phenotype for non-Hispanic EAs combined sexes and non-Hispanic EAs females-only test ( $p = 9.58 \times 10^{-167}$ ). We detected 40 and 47 significant phenotypes in non-Hispanic EAs and non-Hispanic EA females, respectively. Top phenotype results included dysmenorrhea, other benign neoplasms of the uterus, endometriosis, and malignant neoplasm of the uterus. Many associated phenotypes were in the genitourinary category; we also detected associations in the neoplasm and sense organ category. The sense organ phenotypes were eye diseases including astigmatism, optic atrophy, and myopia. In the non-Hispanic AA group, the PRS did not detect any phenotypes at genome wide significance, possibly due to power. Validation of the PRS is underway in the BioVU Repository (N=94,000) and Geisinger Health Systems (N=85,582). Our results indicate that UL shares biological etiology with many other diseases, most notably other

neoplasms and eye diseases. Determining the relationships between UL and these other diseases may reveal more about their molecular mechanisms and broaden our understanding about these diseases.

## PgmNr 391: Understanding intersectionality in health disparities through genetic models.

---

It is widely known that health disparities are multifactorial with origins that can be biological, environmental, social, or political. Their combined impact on marginalized groups has significantly lowered their quality of life, increased their difficulty of successful treatment and care, and impeded any positive long-term standards of living. These realizations have ignited the precision health initiative and the genetic research field has made substantial efforts to understand the underlying genetic and biological effects of these diseases. However, many of the current genetic models used to identify and analyze these effects often lack the data and statistical methods necessary to capture non-biological effects leading to misrepresented models and misinterpreted results. Disentangling these factors is crucial to understanding the structure of these disparities and we created a genetic model that allows us to analyze these effects independently. Using the Vanderbilt University Medical Center biobank (BioVU), a repository of DNA linked to de-identified electronic medical records, we observed that a high proportion of diseases significantly associated with African ancestry are confounded with race. Although genetic ancestry represents your ancestral origin and race is a social construct, these two concepts are often used interchangeably or not fully accounted for in current models. We partitioned out genetic ancestry from self-reported race by including their residuals in our phenome-wide association study (PheWAS). After adjusting for genetic ancestry, race is significantly associated with "Hypertension" ( $p=7.57e-05$ ,  $OR=1.16$ ) and "Malaise and fatigue" ( $p=2.05e-04$ ,  $OR=1.19$ ) in African Americans. After adjusting for race, African genetic ancestry is significantly associated with "Other anemias" ( $p=5.62e-07$ ,  $OR=1.32$ ) and "Disorders resulting from impaired renal function" ( $p=6.31e-06$ ,  $OR=1.70$ ). This method allows us to examine the effects of genetic ancestry and race separately which will enable us to parse out our resources and efforts to each contributing cause more effectively.

## PgmNr 392: TLA & long-read sequencing: Efficient targeted sequencing and phasing of the *CFTR* gene.

### Authors:

---

### Background

The sequencing and haplotype phasing of entire gene sequences improves the understanding of the genetic basis of disease and drug response. One example is cystic fibrosis (CF). CFTR (cystic fibrosis transmembrane conductance regulator) modulator therapy has revolutionized CF treatment, but only in a minority of CF subjects.

Observed heterogeneity in CFTR modulator efficacy is related to the range of CFTR mutations; revertant mutations can modify the response to CFTR modulators, and other intronic variations in the ~200kb CFTR gene have been linked to disease severity. Heterogeneity in the CFTR gene may also be linked to differential responses to CFTR modulators.

The Targeted Locus Amplification (TLA) technology from Cergentis can be used to selectively amplify, sequence and phase the entire CFTR gene. With PacBio long-read SMRT sequencing TLA amplicons are sequenced intact and long-range proximity information of all fragments in entire amplicons is retrieved.

### Experimental Design and Methods

TLA was performed on cell line and genomic DNA from Coriell GM12878, which has few heterozygous SNVs in CFTR, and the IB3 cell line, with known haplotypes but heterozygous for the delta508 mutation. All sample types were prepared with high and low density TLA primer sets, targeting coverage of >100kb of the (~200kb) CFTR gene. The TLA process produced amplicons consisting of 5-10 proximity ligated DNA fragments.

A multiplexed SMRTbell library of 10 TLA samples was sequenced on the PacBio Sequel System (1M SMRT cell), generating hundreds of thousands of high-fidelity single molecule reads using CCS (Circular Consensus Sequencing). CCS sequences were mapped, resulting in phased SNPs across the entire gene. Phased reads were clustered and compared between DNA samples. Additionally, we evaluated the coverage and data quality from the different sample types and TLA primer sets.

### Conclusion

We demonstrate the power and utility of TLA with long-read SMRT sequencing as a valuable research tool in sequencing and phasing across very long regions of the human genome. This process can be

done in an efficient manner, multiplexing multiple samples per SMRT cell in a process amenable to high-throughput sequencing.

## PgmNr 393: Pharmacogenomics and opioid use patterns in patients with chronic spine pain.

### Authors:

K. Fisch <sup>1</sup>; R. Gabriel <sup>2,3</sup>; B. Shahidi <sup>4</sup>; E. Said <sup>2</sup>; R. Waterman <sup>2</sup>

---

Patients undergoing spinal surgery have a higher risk of persistent opioid use compared to other surgical subtypes, with 23-52% of patients developing long term use patterns and dependence after surgery. Interindividual differences in opioid analgesia associated with genetic variability have been well-documented in surgical populations. This study aims to assess the genetic variability in a postsurgical spine surgery population through pharmacogenomics (PGx) testing on pain and opioid use outcomes. PGx testing of perioperative patients at UC San Diego Health was performed through CQuentia NGS, LLC. Under an IRB-approved protocol, diplotypes for 53 spine surgery patients were retrospectively extracted from PGx reports. PharmGKB and CPIC gene-specific information tables and EHR priority result notifications were used to distinguish Normal from Abnormal drug metabolism phenotypes for each of these diplotypes. Outcomes included baseline and three month postoperative pain intensity ratings and postoperative opioid consumption in intravenous morphine equivalents at 24, 48 and 72 hours. A Wilcoxon rank sum test was used to test for differences in outcomes in patients with clinically actionable CYP2D6 variants. Multivariate linear regression analysis was performed on each PGx gene to determine association with increased opioid use postsurgically at 48 hours controlling for sex, age and body mass index. Clinically actionable PGx variants were observed in the perioperative population (N= 3,527) at the following frequencies: CYP2D6-14%, CYP2C19-28.9%, CYP2C9-3.1%, CYP3A4-7.9%, CYP3A5-4.4%, DPYD-1.8%, TPMT-8.5%. In patients with an actionable CYP2D6 variant for opioid metabolism, 247 patients that were prescribed opioids may have benefited from a change in clinical care based on the PGx results (Hydrocodone: 115 patients; Oxycodone: 56 patients; Tramadol: 76 patients). Of 53 spine surgery patients, 11 patients (20.7%) had actionable PGx variants in CYP2D6 (2 ultra; 9 poor metabolizers), indicating an altered opioid regimen is warranted. Baseline and postoperative numeric pain rating scale and opioid consumption did not significantly differ in these CYP2D6 patients ( $p > 0.05$ ) and there were no statistically significant differences between cohorts at any PGx variant for 48 hour opioid consumption ( $p > 0.05$ ). PGx testing may benefit a clinically relevant subset of patients undergoing spine surgery to improve postsurgical pain and opioid use outcomes.

## PgmNr 394: Low dose, daily or intermittent administration of infigratinib (BGJ398), a selective FGFR inhibitor, as treatment for achondroplasia in a preclinical mouse model.

Fibroblast Growth Factor Receptor 3 (FGFR3) plays a crucial role in the process of bone elongation as genetically demonstrated by the identification of FGFR3 gain-of-function mutations in people exhibiting the most common forms of dwarfism, namely achondroplasia (ACH) and hypochondroplasia. Various therapeutic strategies have been considered, among which the most advanced treatment is to employ an analog of C-type Natriuretic Peptide (CNP) which antagonizes the MAP kinase pathway. Here, considering that FGFR3 activates many downstream signaling pathways (e.g., STAT1), we evaluated a therapeutic strategy aimed to directly target the activation of FGFR3 and all signaling pathways, not just MAP kinase. The oral tyrosine kinase inhibitor (TKI) infigratinib (BGJ398) is a potent, selective FGFR1-3 inhibitor with well characterized activity against FGFR3. We hypothesized that a very low dose of infigratinib would be able to improve the defective bone elongation. To answer this question, we treated a dwarf mouse model (*Fgfr3*<sup>Y367C/+</sup>) mimicking ACH, with subcutaneous injections of infigratinib either daily (0.2 mg/kg/day or 0.5 mg/kg/day) or intermittently (1 mg/kg, every three days) for a total treatment duration of 15 days (PND1-PND15). Results were compared to vehicle treated mutant mice. We observed a significant improvement of the upper (humerus +7%, ulna +11%) and lower (femur +11%, tibia +16%) limbs for a dose of 0.5 mg/kg, as well as improvement in the foramen magnum. The effect of the bone elongation was reduced with a lower dose (0.2 mg/kg), thus confirming a dose-response relationship. To test the hypothesis of whether daily treatment was needed, we performed intermittent injections of infigratinib (1 mg/kg, every three days). The gain of growth compared to vehicle treated mice was significant for all the long bones (+7%) and the size of the foramen magnum was increased. In addition to the gain of growth, we observed a modification of the growth plate structure, displaying a better organization of the hypertrophic zone, among other improvements. In conclusion, these data demonstrated that low, as well as intermittent dose, of infigratinib promotes growth in this ACH mouse model. No apparent toxicity of infigratinib was observed, thus suggesting that TKI therapy, as with infigratinib, has the potential to be a valuable and relevant option for children with achondroplasia.

## PgmNr 395: TGF-beta inhibition restores the responsiveness to osteoanabolic PTH treatment in the *Crtpap*<sup>-/-</sup> model of recessive osteogenesis imperfecta.

### Authors:

**Affiliation:** Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TEXAS.

Osteogenesis Imperfecta (OI) is characterized by low bone mass and fractures. Most cases are caused by dominant pathogenic variants in the genes encoding type I collagen. Pathogenic variants in *CRTAP*, involved in post-translational collagen modifications, cause severe recessive OI. Previously, we have shown that excessive TGFb signaling is an important contributor to the OI phenotype in mouse models of both dominant and recessive OI, including *Crtpap*<sup>-/-</sup> mice.

Intermittent PTH treatment increases bone mineral density (BMD) in patients with osteoporosis. In OI however, a randomized clinical trial found that PTH treatment did not increase BMD in patients with severe forms of the disorder. Others have demonstrated interactions between the TGFb and PTH signaling pathways, e.g. that TGFb signaling can reduce PTH receptor cell surface expression and thereby decrease PTH signaling. Our preliminary studies suggest that BMSCs of *Crtpap*<sup>-/-</sup> mice, cultured in osteogenic conditions, exhibit a reduced pCREB/CREB ratio, suggesting impaired PTH signaling.

Hence, we hypothesized that inhibition of the excessive TGFb signaling in *Crtpap*<sup>-/-</sup> mice restores the osteoanabolic effects of PTH treatment. To test this hypothesis, we treated 8-week-old *Crtpap*<sup>-/-</sup> and wild-type (WT) mice with PTH (40 µg/kg, 5x/week, s.c.), low-dose of the TGFb neutralizing antibody 1D11 (Genzyme/Sanofi; 1mg/kg, 3x/week IP), or control treatment (vehicle/control antibody) for 8 weeks.

MicroCT of femurs of control *Crtpap*<sup>-/-</sup> mice confirmed reduced bone mass as measured by trabecular bone volume/total volume (BV/TV; 38% of WT control; p<0.05) and cortical thickness (Cort.Th; 90% of WT; p<0.05). PTH treatment increased trabecular and cortical bone mass in WT mice, but was not effective in *Crtpap*<sup>-/-</sup> mice, consistent with the findings of the clinical PTH treatment trial in patients with more severe forms of OI. Low-dose TGFb inhibition in *Crtpap*<sup>-/-</sup> mice only moderately increased BV/TV (to 57% of WT; n.s.) and did not improve Cort.Th. Interestingly, combined PTH/anti-TGFb treatment of *Crtpap*<sup>-/-</sup> mice synergistically restored BV/TV and Cort.Th to 95% and 98% of control WT mice, respectively (p<0.05 for both).

These findings suggest that low-dose TGFb inhibition restores responsiveness to PTH treatment in the *Crtpap*<sup>-/-</sup> model of severe recessive OI. Because increased TGFb signaling also contributes to the bone phenotype in dominant OI, combined anti-TGFb and PTH treatment might be a new treatment option for patients with OI.

## PgmNr 396: Fine mapping of human leukocyte antigen complex to study asthma in African Americans.

Asthma is an inflammatory condition involving the adaptive immune system. Human leukocyte antigen (HLA) genes play a central role in inflammatory responses and in the recognition of self and foreign antigens. This region has not been extensively studied in African Americans (AA). This analysis included 4,317 AA participants (3,444 with and 873 without an asthma diagnosis) from the Study of Asthma Phenotypes and Pharmacogenomic Interactions by Race-ethnicity (SAPPHIRE) cohort. Whole genome sequence (WGS) were generated as part of the NHLBI TOPMed Program and the Asthma Translational Genomics Collaborative (ATGC). RNA-seq data were also available for 408 asthma cases and 405 controls. Single nucleotide variations (SNV) within extended major histocompatibility complex (MHC) region (chr6:27~34Mb, hg38) were generated using the WGS data, and high resolution HLA alleles were derived from both the WGS and RNA-seq data. HLA gene expression abundance was estimated from RNA-seq data. Amino acids for each MHC protein were translated from 4-digit HLA alleles. We assessed for associations between asthma and variants defined by alleles, SNVs, and amino acids. We performed an expression quantitative trait locus (eQTL) analysis for those variants significantly associated with asthma. A few SNVs were found with  $P$ -value below  $10^{-5}$  including the top one rs12215482 (OR=0.79,  $P=8.9 \times 10^{-6}$ ). We also examined two SNVs (rs9469220 and rs9273349) previously associated with IgE levels and asthma. Only rs9273349 was nominally associated (OR=1.13;  $P=0.05$ ) with asthma in our data. But both two candidate SNVs were significant eQTL (FDR  $<1.0 \times 10^{-5}$ ) for HLA-DQ genes HLA-DQB1, HLA-DQA2 and HLA-DQB2. Top associations from HLA alleles and amino acids included HLA-DQB1\*05 and a histidine at DQB1 residue 30 ( $P < 0.001$ ). HLA-DQB1 was also differentially expressed when comparing asthma cases and controls (FDR  $< 0.05$ ). In summary, this study replicated a previously described variant rs9273349 in the HLA region and verified that it was associated with HLA-DQ expression. We also identified an amino acid residue associated with asthma status in HLA-DQB1, a gene found to be differentially expressed by

asthma status. These findings require additional validation in other ATGC cohorts, as well as studies to understand the functional consequence on amino acid substitutions at position 30 in HLA-DQB1.

## **PgmNr 397: Development of a 36-gene expression panel using Nanostring nCounter to profile type I interferon signature in juvenile myositis potentially for disease stratification and guiding treatment.**

### **Authors:**

Some autoimmune diseases are notable for displaying prominent signs of type I interferon (IFN) activation. Originally, this type I IFN 'signature' was definitively characterized and confirmed in systemic lupus erythematosus based on whole transcriptome profiling of patient blood, where ~300-400 IFN responsive genes were found to be markedly upregulated. Subsequently, this signature was also observed in inflammatory myopathies (IM), including dermatomyositis and polymyositis (although only minimally so in inclusion body myositis). The signature in IM is especially prominent in skeletal muscle, which is usually (and by definition) the primary site of pathology; however, it is also observable in blood. Importantly, there is a general correlation between the magnitude of the signature with disease activity (although there is heterogeneity), and therapies targeting type I IFN signaling are either in development (e.g. anti-IFN- $\alpha/\beta$  or IFNAR antibodies) or already approved (e.g. JAK inhibitors), which show promise as treatment in IM. Thus, the development of a clinical assay measuring type I IFN signature could be useful for disease stratification, monitoring disease activity, and/or as a companion diagnostic for drugs targeting type I IFN signaling.

We use the Nanostring nCounter platform as the basis for development of a pilot type I IFN signature assay. Genes were selected by literature review from previous transcriptome studies in blood in IM; in general, those that were the most consistently and highly expressed, especially in juvenile myositis, were chosen. Our initial panel contains 32 type I IFN-inducible genes, along with 4 housekeeping genes. We present results here from 19 subjects with juvenile myositis that were in remission or had mild to moderate disease activity at time of collection along with 5 control subjects (without apparent inflammatory or autoimmune diseases). Blood from all participants were collected in PaxGene tubes, then extracted for RNA using the Promega Maxwell instrument. Oligos for nCounter Elements chemistry were designed by Nanostring and synthesized by IDT.

We observed that the magnitude of the type I IFN signature tended to correlate with disease activity. Notably, 3 subjects experiencing significant morbidity who are on multiple immunomodulatory drugs had among the highest IFN signatures observed. Translational implications of these findings as well as potential areas for refinement of the assay are discussed.

## PgmNr 398: Rare germline variant contributions to myeloid malignancy susceptibility.

---

Myeloid malignancy susceptibility alleles reported to date have largely been rare variants identified in families. With few exceptions, common variant associations have been lacking, and it is likely that as-yet undiscovered susceptibility variants are rare alleles. We analyzed whole-exome sequence from 690 individuals with myeloid malignancies to elucidate the contribution of rare (<1% population allele frequency) protein-altering alleles to disease susceptibility. We estimate that 3-4% of patients have rare variants in genes that would classify the patients as having germline predisposition under current guidelines. We also identify *MPO* as a new candidate predisposition gene, with 19 patients (2.8%) harboring rare pathogenic *MPO* variants, and significantly higher pathogenic allele frequencies in cases as compared to population controls. An elevated rare-variant burden is observed in autosomal recessive genes, particularly Fanconi anemia (FA) genes ( $P < 0.002$ ). Even accounting for high levels of rare variants, pairs of such variants in the same patient and FA gene (presumably affecting both parental homologs) occur at a rate significantly higher than would be expected by chance ( $P < 0.002$ ), suggesting that biparental inheritance of rare germline alleles in FA genes is a risk factor for myeloid malignancy. The FA gene *BRCA2* is particularly enriched for biparental inheritance, and rare germline variants in *BRCA2* are associated with poor overall survival in myeloid malignancy patients (age-adjusted HR 2.62, 95% CI 1.26-5.44).

## **PgmNr 399: The beliefs and values of patients with hemophilia and their caregivers about gene therapy and gene editing.**

**Introduction:** Hemophilia is a lifelong debilitating inherited disease that relies on factor replacement therapy to prevent bleeding. However it is not curative and there is a negative impact on emotional health and quality of life. Gene therapy and gene editing are potential curative therapies that might address current unmet needs. However, we need to know the patient's beliefs and values about these therapies before they are implemented.

**Methods:** This qualitative study uses semi structured interviews about beliefs of gene therapy/editing in patients with hemophilia A or B and their caregivers. Grounded theory was used to analyze the data.

**Results:** About gene therapy, values differ among participants. Even it is a potential curative therapy, they expect to have clearer data about efficacy, however small sample size in trials is a barrier. They expect an improvement in the factor levels and in the duration of the effect, so there is a lower risk of bleeding and factor infusions are needed only for trauma events or surgery. They expect that the decrease in their risk of bleeding will have a positive impact in their mental health and in their quality of life. Given that these therapies might be expensive, they expect that insurance companies are willing to cover for it. The fact there is a prior history of HIV and HVC blood born infections in this community makes them consider the "safety net". Their concern about liver cancer relies on the DNA change and the use of viral vectors. To accept gene therapy, they would like to know about successful cases in the short and long term. They are less optimistic about gene editing. There is a moral concern. They think that DNA defines them as humans and changing it during early life is "scary". They won't give it to their preborn child and they would prefer letting their affected child make the decision as an adult. There is a concern about safety, because CRISPR will affect other regions of DNA that might lead to cancer, autism, Down syndrome, developmental delay, etc. Finally, knowing that this therapy is delivered during pregnancy, they are concerned about the high risk of miscarriage and losing their baby.

**Conclusion:** Preliminary results indicate patients and caregivers would accept gene therapy if its efficacy and long-term safety is known. Patients are more optimistic about gene therapy than their caregivers. Overall, they are more reluctant to accept gene editing.

## PgmNr 400: Developing a genetic risk index for peanut allergy.

### Affiliations:

1) Department of Respiratory Medicine, University British Columbia, Vancouver, British Columbia, Canada; 2) Centre for Heart Lung Innovation, St. Paul's Hospital, Vancouver, British Columbia, Canada; 3) Division of Dermatology, Department of Medicine Queen's University, Kingston, Canada; 4) Division of Rheumatology, Department of Medicine, Cumming School of Medicine, University of Calgary, Alberta, Canada; 5) Department of Pediatrics and Child Health, University of Manitoba, Winnipeg, Canada; 6) Department of Pediatrics, University of British Columbia, Vancouver, BC

Over 200 single nucleotide polymorphisms (SNPs) have been found to be associated with food allergy (FA) in genome-wide association studies (GWAS). A genetic risk score (GRS), can be derived from GWAS to summarize genetic risk, risk stratification and/or prediction. Our objective was to use information from the Canadian Peanut Allergy Registry (CanPAR) GWAS study to develop a GRS using the weighted sum of the number of risk alleles (with values 0/1/2) by the natural log of their respective odds ratio (OR).

The positive predictive value of the GRS was then evaluated in an independent cohort, the Canadian Asthma Primary Prevention Study (CAPPS). The CAPPS study was initiated in 1995 and recruited 549 children at high risk for developing asthma, defined as 1 first degree (fd) relative with asthma or 2 fd with allergic disease, mothers were recruited during the second and third trimester of pregnancy, and the children have been followed until 15 years of age. Food allergy cases at the 15 year time point were determined by a pediatric allergist and controls were defined by the absence of food allergy, asthma, atopy and airway hyperresponsiveness at all time-points (12 and 24 months, 7 and 15 years of age). The CAPPS study has contributed to several asthma GWAS studies and genotypes and principal components (PCs) were extracted from the existing GWAS study.

### Methods

Models were fit with and without PC (10 for CanPAR and 5 for CAPPS). Using a p-value threshold of 1.49E-06 and LD ( $r^2 > .80$ ) pruning we identified 25 independent CanPAR SNPs for use in the GRS, of these 13 SNPs were identified (either directly genotyped, imputed, or a proxy SNP in high LD  $> .80$ ) in the CAPPS study. We then evaluated the area under the curve (AUC) which is used to determine the effectiveness of the classification and the positive predictive value (PPV).

### Results

Table 1: Summary of GRS risk models

p-value threshold	Study	Genotyped	Imputed	Total	AUC (95% CI)	PPV
1.49E-06	CanPAR	6	19	25	0.653 (0.628-0.678)	0.59

1.49E-06*	CanPAR	6	19	25	0.878 (0.862-0.894)	0.83
1.49E-06	CanPAR	5	8	13	0.638 (0.613-0.664)	0.61
1.49E-06*	CanPAR	5	8	13	0.878 (0.862-0.894)	0.84
1.49E-06	CAPPS	10	3	13	0.579 (0.404-0.754)	0.67

## Conclusions

Only minimal differences were observed between models with 13 vs. 25 SNPs and model fit was greatly improved when including PCs. Preliminary findings indicate excellent replication of the model in the CAPPS study using hyper-controls. Next steps include evaluating model fit when using asthmatic and atopic controls.

## PgmNr 401: Association between clonal hematopoiesis and non-relapse mortality after autologous hematopoietic cell transplantation.

**BACKGROUND:** Clonal hematopoiesis (CH) is an age-related condition that is characterized by somatic mutations in the blood cells of otherwise healthy individuals. In non-cancer populations, CH is associated with a higher risk of aging-related diseases such as acute myeloid leukemia (AML) and cardiovascular disease (CVD) and may be a biomarker of biologic aging. Patients who undergo hematopoietic cell transplantation (HCT) are at high risk of premature onset of aging-related conditions (subsequent neoplasms [SN], CVD) after HCT. There is a paucity of information on the impact of pre-treatment CH on aging-related conditions after HCT, including non-relapse related mortality.

**METHODS:** We used a case-control study design, and identified 10 patients who died due to non-relapse mortality (NRM; e.g., SN, CVD, organ failure) after autologous HCT at City of Hope (cases). Cases were matched (1:3) to controls (underwent HCT, alive or died of relapse-related mortality, N=29) on age at HCT  $\pm 2$  years, sex, diagnosis, and length of follow-up after HCT. We evaluated mobilized hematopoietic stem cell DNA, collected prior to HCT, using a custom 79-gene-myeloid-CH-coding-exon-amplicon-based QIAseq panel. Pathogenic and likely pathogenic CH variants (PV) above an allele fraction of 2% were used for analyses.

**RESULTS:** Patient median age at HCT was 64 years (range: 38 to 71 years), 79.5% were male, 61.6% underwent HCT for non-Hodgkin lymphoma, 17.9% for Hodgkin lymphoma, 20.5% for multiple myeloma. Among cases, causes of death were: SN (60%), CVD (10%), respiratory failure (10%), and other (20%). Due to matching, there were no differences in age, sex, or diagnosis among cases and controls. Cases were significantly more likely to have CH compared to controls (70% vs. 24.1%,  $p=0.009$ ). Cases were also significantly more likely to have multiple ( $\geq 2$ ) unique PVs (e.g. *DNMT3* and *TET2*) compared to controls (60% vs. 6.9%,  $p<0.001$ ) and significantly more likely to have PVs with high ( $\geq 10\%$ ) allelic fraction (40% vs. 3.4%,  $p=0.003$ ).

**CONCLUSION:** Our study provides preliminary evidence of an association between pre-HCT CH and adverse outcomes after HCT, irrespective of chronologic age. Integration of CH analyses into existing pre-HCT risk-prediction models may improve the accuracy of these models, setting the stage for the development of personalized risk assessment strategies and targeted treatments that optimally prevent or manage complications associated with HCT.

## PgmNr 402: Candidate gene study of adverse liver effects of methotrexate in patients with rheumatoid arthritis.

### Authors:

M. Wadelius<sup>1</sup>; J. Karlsson Sundbaum<sup>1,2</sup>; E. Baecklund<sup>1</sup>; N. Eriksson<sup>1,3</sup>; H. Kohnke<sup>1</sup>; P. Hallberg<sup>1</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Department of Medical Sciences and Science for Life Laboratory, Uppsala University, Sweden; 2) Department of Health Sciences, Luleå University of Technology, Luleå, Sweden; 3) Uppsala Clinical Research center, Uppsala, Sweden

---

**Background:** Low-dose methotrexate (MTX) is the anchor drug for the treatment of rheumatoid arthritis (RA), either in monotherapy or in combination with other drugs. MTX has proven effects on both inflammatory symptoms and signs of radiographic destruction, and early initiation improves treatment outcome. However, adverse effects on for example the liver may lead to discontinuation of MTX therapy. It would be advantageous to be able to identify patients that risk elevation of liver enzymes in order to modify treatment.

**Objective:** To investigate whether genetic variants of the candidate genes *MTHFR*, *TYMS*, *SLCO1B1* and *PNPLA3* are associated with elevation of the liver enzyme alanine aminotransferase (ALT).

**Method:** RA patients starting MTX treatment at the Rheumatology clinic, Uppsala University Hospital, Sweden in 2005-2013 were included. Clinical and laboratory data from the onset of RA until MTX was stopped or to the end of the study period were attained from medical records and telephone interviews. A blood sample was obtained, and genotyping was performed with PCR-based methods. Linear regression was used for statistical analysis of the continuous variable log transformed maximum ALT. Logistic regression was used for statistical analysis of the binary variable elevation of ALT to at least 1.5 times the upper limit of normal (ULN).

**Results:** The study comprised 207 patients with RA: 138 females (67 %) and 69 males (33%). Elevation of ALT to  $\geq 1.5 \times \text{ULN}$  was observed in 20% of the patients. *MTHFR* 677T was significantly associated with a 9.8% decrease in maximum ALT per minor allele of the variant (beta -0.0970, 95% CI -0.179, -0.0165,  $p = 0.0193$ ). No genetic variant of *MTHFR*, *TYMS*, *SLCO1B1* or *PNPLA3* was significantly associated when patients with ALT  $\geq 1.5 \times \text{ULN}$  vs.  $< 1.5 \times \text{ULN}$  were compared.

**Conclusion:** The effect of MTX is largely explained by its interactions with enzymes in the folate pathway. *MTHFR* is one of the key enzymes in the folate pathway. It is therefore of interest to study inherited variants of *MTHFR* in relation to MTX-induced toxicity. According to our results, the *MTHFR* 677T allele appears to protect against an elevation of ALT in patients with RA. We aim to verify our findings in a larger study, and to use clinical and genetic factors to develop a prediction model for elevation of ALT during MTX treatment. A robust prediction model could be a useful tool, and would be a step towards precision medicine in the field of rheumatology.

## PgmNr 403: Efficient gene editing in Rett syndrome and related disorders.

---

Mutations in MECP2 and FOXP1 genes respectively cause the classic form and the congenital variant of Rett syndrome, one of the most common genetic causes of intellectual disability in girls. Both genes are transcriptional regulators and both under- and over-expression cause disease in humans. We thus reasoned that adding a gene under a not native regulator would be a risky therapeutic strategy while gene editing would be much more effective. We present here the successful application of CRISPR/Cas9 gene editing technology in patient-specific human cellular models, namely fibroblasts, induced Pluripotent Stem Cells (iPSCs) and iPSC-derived neurons. We have engineered a two-plasmid system to correct FOXP1 (c.688C>T-p.Arg230Cys) and MECP2 (c.473C>T-p.Thr158Met) mutations. Mutation-specific sgRNAs and donor DNAs have been selected and cloned together with an mCherry/GFP reporter system. Cas9 flanked by sgRNA recognition sequences for auto-cleaving has been cloned in a second plasmid. The system has been designed to be ready for in vivo delivery via Adeno-Associated Viral (AAV) vectors. We demonstrated that different serotypes have different efficiency in different target cells, the best being either AAV9 in fibroblasts and iPSC-derived neurons or AAV2 in iPSCs. mCherry + /EGFP + fibroblasts and neurons isolated by Fluorescent Activated Cell Sorting and analyzed by Next Generation Sequencing have shown efficient gene editing via Homology-Directed Repair for both genes, with up to 80% of mutated alleles correctly reverted to the wild type sequence, outlining the relevant potentiality of the approach for Rett syndrome therapy.

## **PgmNr 404: Development of targeted genetic therapeutics and cellular models for Smith-Magenis syndrome: A proof of concept for the therapy of haploinsufficiency-based disorders.**

---

Haploinsufficiency is the primary mechanism for several genetic conditions like Smith-Magenis syndrome (SMS) and MBD5-associated neurodevelopmental disorder. In SMS, the condition is caused by either heterozygous deletion or mutation of the dosage-sensitive gene *RAI1*, proven to be the main cause of the disease. Some features of this condition include intellectual disability, early onset obesity, sleep disorders, self-injurious behaviors, and craniofacial anomalies. Currently, there is not an effective treatment for SMS or any other disorder of haploinsufficiency, and patients receive only supportive therapy. Our targeted therapeutic strategies are based in restoring the function of *RAI1* by either providing the missing copy of the gene or increasing the expression of the remaining functional allele. In the first approach, SMS patient fibroblasts were transduced in a controlled manner with lentiviral vectors containing the sequence of *RAI1*. Our results revealed that the protein *RAI1* is properly localized in the nucleus, and the expression can be increased proportionally by controlling the multiplicity of infection (MOI) to restore normal levels of *RAI1*. The second approach is based on a novel methodology using a deactivated version of the protein Cas9 fused with the viral activator VP64 (CRISPR-dCas9-VP64). NIH3T3 fibroblasts were transduced with several constructs containing different guide (g)RNAs targeting the murine *Rai1* promoter region. Our results reveal that specific constructs are able to increase *Rai1* expression, which subsequently increases the expression of the *RAI1*-regulated downstream gene *Bdnf*, which is typically reduced in expression in SMS. Finally, we developed patient-derived induced-pluripotent stem cells (iPSC) using episomal plasmids and generated neural progenitor cells (NPC) derived from these iPSC using the monolayer protocol. Immunostaining revealed that the pluripotency marker OCT4 is present in iPSC but neural differentiation marker PAX6 is absent, and upon neural induction, OCT4 is not expressed, while PAX6 is present. The combination of our targeted therapeutic strategies with the developed iPSC-NPC models will provide valuable tools with potential applications in the development of therapies for gene haploinsufficiency-based disorders.

## PgmNr 405: Specification of ACMG/AMP guidelines for standardized variant interpretation in familial hypercholesterolemia: On behalf of the ClinGen FH Variant Curation Expert Panel.

**Background:** Familial hypercholesterolemia (FH) is a heritable disorder characterized by elevated low-density lipoprotein (LDL) cholesterol levels and premature cardiovascular disease. Increasingly, patients with a clinical suspicion of FH are being offered genetic testing as part of diagnosis. However, determining pathogenicity of identified DNA variants remains a major challenge; this process may be rudimentary and often differs among laboratories. To improve accuracy, concordance and standardization, there has been increasing effort to implement the recent variant interpretation guidelines proposed by the American College of Medical Genetics and Genomics and Association for Molecular Pathology (ACMG/AMP).

**Objectives:** To further improve standardized variant interpretation, the Clinical Genome Resource (ClinGen) FH Variant Curation Expert Panel (VCEP) has been tasked with optimizing the ACMG/AMP guidelines to become disease-specific for FH.

**Methods:** Following review of ACMG/AMP criteria, the FH VCEP met through frequent emails and conference calls to propose modifications. After multiple preliminary iterations, pilot testing to identify areas for additional refinement, debate and further commentary, consensus was reached.

**Results:** Here, we propose a consensus set of FH-ACMG/AMP guidelines, which focus first on the LDL receptor gene (*LDLR*), and include: 1) functional study criteria specifications and split-weighting for three 'levels' of relevant assays; 2) alteration of control population data frequency thresholds; 3) specific use and thresholds for *in silico* prediction tools; 4) additional specifications for copy number variants; and 5) co-segregation criteria specifications and split-weighting for large versus small families. Following ClinGen approval, these guidelines will be tested in a finalized pilot study of 50 variants to demonstrate improved variant classification compared to the original ACMG/AMP criteria.

**Conclusions:** Establishment of these specified guidelines will help to achieve a more evidence-based, standardized method for the classification of variants detected in FH patients worldwide. Ultimately, all ~3000 FH-associated variants currently deposited in the ClinVar database will be re-classified

using the FH-ACMG/AMP criteria, while promoting these guidelines as the new “gold standard” for variant classification among the FH community will ensure novel variants identified in real-time are subject to an appropriate standard of evaluation.

## **PgmNr 406: Pathogenic loss of function in genes associated to monogenic pediatric disorders in healthy elderly Brazilians improves molecular diagnosis interpretation.**

### **Authors:**

---

Large sequencing datasets, including whole exomes and genomes, are an important resource to assess allelic frequency of rare variation and improve pathogenicity interpretation in molecular diagnosis pipelines. Several studies have demonstrated that unaffected individuals may harbor potentially deleterious variants in clinically relevant genes. To further assess the incidence of putative loss of function previously assigned as pathogenic or likely pathogenic variants, a census-based cohort of 1172 unrelated Brazilian individuals aged 60 or over was analyzed in search for variants in genes related to childhood disorders with Mendelian inheritance. We have filtered 924 genes associated to monogenic pediatric disorders in a whole genome sequencing dataset. Initial filtering yielded over 4 thousand putative loss of function variants in 805 genes with at least a singleton passing depth and allele balance quality criteria. Removal of putative frameshifts caused by insertions/deletions and further filtering by an allelic frequency cutoff of 1% in both cohort and gnomAD, pathogenic assertions on ClinVar and monoallelic mode of inheritance provided a high confidence list of 32 single nucleotide substitutions in 21 genes with splicing, stop gain and stop loss predicted consequences. Forty individuals carry these variants (3.4% of the cohort) with individual frequency ranging from absent to 0.14% on gnomAD. No individual was found to be homozygous following the above-mentioned criteria of variant filtering. These results are compatible with other studies, but it is noteworthy that an elderly cohort may be biased towards health fitness and overall survival. Besides potential overestimation of pathogenicity classifications, true effects of these variants might be modulated by complex gene-gene interactions resulting in reduced penetrance. In fact, half of the carriers are highly admixed with less than 70% of any single ancestry. Further investigation on biallelic disorders and occurrence of compound heterozygosity is currently ongoing. Genomic datasets of individuals without prior health complaints are becoming common both within academic and private endeavors. Pathogenicity classification of incidental findings is challenging, therefore describing the incidence of potentially damaging variants in population-based datasets is essential. Furthermore, healthy elderly cohorts can play a role as a tool for filtering candidate variants as causes to Mendelian disorders.

## PgmNr 407: Genomic survival score percentiles informed by diseases make 15-year distinctions in lifespan.

---

**Motivation:** Prediction of lifespan using genetic variants discovered by genome-wide association studies is challenging due to low power: a recent study of >1 million parental lifespans only revealed 12 genome-wide significant loci. However, many of the age-related diseases and risk factors underlying mortality each have genetic components that have been studied using large sample sizes, with many more loci identified. Carrying such variants has been shown to influence lifespan and we hypothesise that using this information can improve lifespan predictions.

**Method:** Here, we generate and test polygenic risk scores using published summary statistics for 1 million parental lifespans from UK Biobank and other European cohorts. We then assess to what extent such predictions can be improved by incorporating LD information, functional annotations, and genetic data on 16 independent diseases and disease risk factors using a Bayesian framework (bPRS).

**Results:** One standard deviation increase in bPRS (out-of-sample) associates with an increase of 1.82 (95% CI 1.63–2.01) years of life, improving upon conventional polygenic scores by more than 30%. When stratified into bPRS percentiles, parents in the top percentile live 15 years longer on average than those in the bottom percentile. The same individuals show a 30–80% decrease in the incidence of multiple age-related diseases and are 6 times as likely to survive past 90 years of age. We replicate these findings in the Estonian Biobank (N = 150,000), where mortality data are available for parents as well as subjects themselves.

**Conclusions:** Together, our findings suggest bPRS is able to make greater distinctions in long-term health and survival than conventional polygenic scores by borrowing strength from the genetic associations of multiple traits.

## PgmNr 408: A polygenic risk score to improve screening for fracture risk.

---

**Importance:** Screening programs often include large proportions of individuals at low risk of disease outcomes; polygenic risk scores of heritable risk factors could improve screening efficiency by targeting assessments to individuals at higher genetic risk. If successful, such evidence could help establish a clinical role for polygenic risk scores.

**Objective:** To test whether a polygenic risk score for heel ultrasound speed of sound (SOS) - a

heritable risk factor for fractures that is correlated with bone mineral density (BMD) - can effectively target a fracture screening program to higher risk individuals.

**Design, Setting, Participants:** 341,449 individuals from the UK Biobank were used to develop 600 polygenic risk score models for SOS with LASSO regression, with the optimal prediction model determined in a separate set of 5,335 individuals. The utility of this model in fracture risk screening was assessed on a subset of 5 validation cohorts (N=10,522) according to National Osteoporosis Guideline Group (NOGG) guidelines.

**Main Outcomes and Measures:** Performance metrics were the sensitivity and specificity to correctly identify individuals requiring treatment, with BMD-based FRAX probabilities as the reference-standard. Secondary outcomes included the proportion of the screened population requiring a clinical risk factor-based FRAX test (without BMD) and the proportion of individuals requiring a BMD-based FRAX test.

**Results:** Polygenic risk scores for SOS correlated with measured SOS ( $R^2=23.2\%$  in a testing set of 84,768 individuals). Without genetic pre-screening, guideline recommendations resulted in a high sensitivity and specificity for correct treatment assignment (99.6% and 97.1%, respectively) in the validation cohorts. However, 81% of the population required clinical risk factor-based FRAX assessments and 37% required BMD-based FRAX assessments. Limiting further assessment to individuals with a low polygenic risk score for SOS resulted in small changes to sensitivity and specificity (93.4% and 98.5%, respectively), while substantially reducing the proportions requiring clinical risk factor-based assessments and BMD-based FRAX assessments by 37% and 41%, respectively.

**Conclusions and Relevance:** The use of a polygenic risk score in fracture risk screening substantially decreases the number of individuals requiring detailed assessments, including BMD measurement, while maintaining a high sensitivity and specificity for correct treatment assignment.

## PgmNr 409: A clinical trial of intravenous 2-hydroxypropyl- $\beta$ -cyclodextrin for acute liver disease in infants with Niemann-Pick C.

---

Niemann-Pick C (NPC) is an autosomal recessive disease due to defective NPC1 or NPC2 proteins resulting in endo-lysosomal storage of unesterified cholesterol and lipids in both the central nervous system and the liver. Acute liver disease is often observed in the newborn period and may be self-limited or can be fatal. 2-hydroxypropyl- $\beta$ -cyclodextrin (2HPBCD) is a cholesterol-binding agent that reduces intracellular cholesterol accumulation in NPC, possibly by enhancing MCOLN-1 dependent secretion from the endo-lysosomal system. We are presently enrolling up to 15 infants < 6 months with direct hyperbilirubinemia due to NPC1 or NPC2 disease in clinical trial NCT03471143 , to determine whether intravenous 2HPBCD improves liver disease in NPC infants. Infants receive IV 2HPBCD twice a week for 6 weeks for a total of 12 doses, followed by monthly infusion during a 6-month extension study. Two patients have been enrolled in the study. The first patient is a 4 month old boy with NPC1 who presented with a direct bilirubin of 0.6 mg/dL, AST of 167 units/L, ALT of 94 units/L, and 5- $\alpha$ -cholan-3 $\beta$ , 5 $\alpha$ , 6 $\beta$ -triol N-(carboxymethyl)-amide ("bile acid B") of 57.2ng/mL. Direct bilirubin improved to 0.1 mg/dL two weeks after his first infusion and remained within normal limits after the 6 week infusion. AST and ALT remained elevated after 1 month at 114 units/L and 80 units/L, respectively. Bile acid B decreased to 10.5ng/mL. The second patient is a 2 month old boy who presented with a direct bilirubin of 5.7mg/dL, AST of 277 units/L, ALT of 124 units/L, and underwent his first infusion. The restoration of bile acid to within normal limits for Patient 1 suggests the drug is decreasing cholesterol storage. Additional follow-up as the patients undergo further infusions is planned.

## PgmNr 410: Systemic administration of AAV- *Slc25a46* relieves mitochondrial neuropathy of *Slc25a46* mutant mice.

---

Mitochondrial disorders could be the result of nuclear or mitochondrial DNA mutations and often affect multiple organ systems. Despite research advances in the molecular and cellular fields, the methods available for treating mitochondrial diseases are minimal. Advancements in gene therapy, however, may offer us a new opportunity to address this group of severe disorders. Mutations in the mitochondrial fusion-fission related gene *SLC25A46* cause peripheral neuropathy and optic atrophy in humans. Previously, we created a knockout mouse model that recapitulates the clinical phenotypes observed in humans. Here, we have treated *Slc25a46* mutant mice with AAV-PHP.B vector carrying the mouse *Slc25a46* gene via facial vein injection. Our results show that this AAV-PHP.B-*Slc25a46* vector is efficaciously transduced in the target organs as verified with a vector expressing eGFP. Consequently, we treated mutant mice with AAV-PHP.B-*Slc25a46* and found that treated animals have a significantly longer lifespan, improved weight gain, a reversal of central and peripheral neuropathy, and a restored mitochondrial function. Most notably, mitochondrial morphology was normalized. Overall, this study shows that gene therapy could be a practical approach to treating mitochondrial disorders caused by mutations in nuclear genes and that AAV-PHP.B is an excellent vector for delivering target genes to the central nervous system.

## PgmNr 411: Cell autonomous and cell-non-autonomous effects of NAGLU deficiency in Sanfilippo B syndrome.

### Authors:

---

Cross-correction is the transfer of soluble lysosomal enzymes between neighboring cells, and its occurrence limits our ability to discriminate between cell-autonomous and non-cell autonomous effects of enzymatic activity. The lack of understanding of the cell types primarily involved in disease complicates our ability to study its pathogenesis and hinders the discovery of potential therapies. Sanfilippo B (MPS IIIB) is a lysosomal disease caused by deficient N-alpha acetylglucosaminidase (NAGLU) enzyme, characterized by progressive neurological deterioration in childhood. We aimed to study and differentiate cell-autonomous and non-cell-autonomous effects of NAGLU deficiency by generating a transmembrane form of NAGLU. In doing this, we aimed to create a NAGLU that would remain located within the lysosome, remaining enzymatically active while bound to the lysosomal membrane, in order to prevent cross correction. We generated an expression construct consisting of the cDNA encoding human NAGLU, a 6-glycine linker, and a C-terminal murine lysosome-associated membrane protein-1 (Lamp-1). We cloned this construct into a modified pmrROSA vector. We plan to clone this construct further into a lentiviral vector to transfer NAGLU-Lamp1 into MPS IIIB human fibroblasts. We plan to assess intracellular and extracellular NAGLU enzymatic activity to determine whether our transmembrane construct can express active protein that is retained in the lysosome. We subsequently plan to generate transgenic mice, employing the Cre-lox system to target specific cell lineages. The results and conclusion of this experiment will help us differentiate between cell-autonomous and non-cell-autonomous effects of NAGLU deficiency, with implications for future therapy targets.

---

Argininosuccinic aciduria (ASA) is a urea cycle disorder (UCD) caused by deficiency of argininosuccinate lyase (ASL). Clinical manifestations of ASA occur as a consequence of impaired ureagenesis and nitric oxide depletion. We recently found that enhancement of hepatic autophagy potentiates ureagenesis and increases *in vivo* ammonia detoxification. In the present study, we investigated the efficacy of autophagy enhancement for therapy of ASA.

ASL-deficient mice were intraperitoneally (i.p.) injected with Tat-Beclin-1 (TB-1), a cell penetrating autophagy inducing peptide. Following treatment, survival and growth were evaluated along with markers of autophagy activation in tissue homogenates by Western blot. Ureagenesis was measured by stable isotope in ASL-deficient mice receiving i.p. injection of <sup>15</sup>N-labeled NH<sub>4</sub>Cl. Whole-liver metabolome analysis was performed by <sup>1</sup>H-NMR.

Compared to vehicle-controls, survival was significantly increased in ASL-deficient mice treated with TB-1. Autophagic flux was enhanced in livers but not in brains of mice injected with TB-1 as shown by reduced LC3-II and p62 protein levels, and increased fragment p10 of BHMT. Consistent with our previous studies, autophagy activation was associated with increased incorporation of <sup>15</sup>N into urea, indicating enhanced ureagenesis. Liver metabolome profiling by <sup>1</sup>H-NMR showed that autophagy activation partially rescued metabolite imbalance of ASA. Notably, argininosuccinate and citrulline which are the biochemical hallmarks of ASA, were reduced in TB-1-treated mice and levels of key compounds such as, fumarate, succinate, and glucose were rescued by enhanced autophagy. In conclusion, our data show that activation of hepatic autophagy improves survival and ureagenesis and corrects the metabolic defects of ASL deficiency. These data confirm a key role of autophagy in nitrogen homeostasis and the efficacy of autophagy enhancer molecules for therapy of UCD.

## PgmNr 413: Surrogate biomarkers to assess efficacy of liver-directed genomic therapies in methylmalonic and propionic acidemias.

Methylmalonic (MMA) and propionic acidemia (PA) are inborn errors of metabolism affecting adjacent steps in the propionyl-CoA oxidation pathway and sharing clinical and biochemical manifestations. Liver and/or kidney transplantation (LT/KT/LKT) are employed to stabilize severely affected patients, while efforts to develop genomic therapies for both disorders are underway. Disease-specific metabolites, such as serum methylmalonic and 2-methylcitric acid are highly variable and affected by dietary protein intake and renal function. With the aim of developing additional biomarkers that correlate with hepatic enzyme activity and disease burden, we have previously used a transgenic murine model of MMA (*Mut*<sup>-/-</sup>;Tg<sup>INS-MCK-Mut</sup>) to demonstrate that *in-vivo* 1-<sup>13</sup>C-propionate oxidation and plasma fibroblast growth factor-21 (FGF21) concentrations improve significantly in response to AAV8 hAAT *MUT* gene therapy. We evaluated 75 patients with MMA and 31 with PA at the NIH Clinical Center, including 20 transplanted MMA (LT/LKT, N=16 and KT, N=4) and 3 PA patients (LT, N=3). Isotopomer enrichment (<sup>13</sup>CO<sub>2</sub>/<sup>12</sup>CO<sub>2</sub> ratio) and cumulative percent of dose metabolized were measured using isotope ratio mass spectrometry in breath samples collected over two hours after an oral bolus of sodium 1-<sup>13</sup>C-propionate. Baseline VCO<sub>2</sub> production (ml/min) was measured by indirect calorimetry. The cumulative percent dose of 1-<sup>13</sup>C-propionate oxidized was 47.2 ± 7.0% (mean ± SD) in LT/LKT recipients compared to 26.9 ± 12.7 in non-transplanted MMA patients (*p*=0.008) and 67.6 ± 2.9% as opposed to 15.9 ± 13.3 (*p*<0.0001) in the PA cohort. Restored oxidative capacity post-LT/LKT was not different from healthy controls 46.81 ± 2.96% (N=16). Patients with KT (N=4) on the other hand had minimal improvement in 1-<sup>13</sup>C-propionate oxidation. Repeatability of the 1-<sup>13</sup>C-propionate breath test was tested in 6 controls and 13 MMA patients showing a coefficient of variation (CV) of 5.93 ± 3.84% and 12.87±12.53%, respectively. Serum MMA values in the same patients had a higher CV of 28.36 ± 24.90%. Circulating FGF21 concentrations were lower in LT/LKT patients 771.7 ± 822.1 vs. 6383.6 ± 8268.5 pg/ml in MMA (*p*<0.0001) and 201.1 ± 240.9 vs. 2316.8 ± 2912.9 (*p*=0.002) in PA LT recipients. 1-<sup>13</sup>C propionate oxidation and plasma FGF21 concentrations should be studied in concert with canonical metabolites to examine therapeutic effects of experimental liver-targeted genomic therapies for disorders of propionate oxidation.

## PgmNr 414: Designer triglycerides: A practical approach to deliver disease-specific alternative fatty acids, bypassing the metabolic block in patients with fatty acids oxidation disorders.

**Introduction.** Mitochondrial fatty acid  $\beta$ -oxidation (FAO) disorders are life threatening, even with optimum treatment. FAO is the major source of energy for heart and is critical for skeletal muscle especially during physiologic stress. Symptoms of FAO disorders (FAODs) include cardiac conduction abnormalities, arrhythmias, cardiomyopathy, muscle weakness, hypoketotic hypoglycemia, and/or stress-related rhabdomyolysis. MCT oil bypasses long chain FAO but patients are still at risk for rhabdomyolysis and late onset cardiomyopathy. Triheptanoin (triheptanoylglycerol) in clinical trials improves cardiomyopathy and hypoglycemia of long chain FAODs but rhabdomyolysis persists, and more effective therapy to prevent the heterogeneous symptoms of these disorders is needed.

**Methods.** Fibroblasts from patients deficient in CPT II, very long chain acyl-CoA dehydrogenase (VLCAD), long chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD), trifunctional protein (TFP), and medium chain acyl-CoA dehydrogenase (MCAD) were cultured with lipid stripped FBS. Cells were treated with heptanoic (C7), 2,6-dimethylheptanoic (dMC7), ENG05 (a designer lipid), or 4,8-dimethylnonanoic (dMC9) acids for 72 hr. Acetyl-, propionyl-, and succinylcarnitine were measured in media and TCA cycle intermediates were measured in cells.

**Results.** Media acetylcarnitine nearly doubled in VLCAD and TFP deficient cells when treated with dMC7, dMC9, or ENG05 compared to C7, while increasing in LCHAD, CPT II, and MCAD deficient cells treated with dMC9 by 10%, 25%, and 22%, respectively. With the exception of one VLCAD cell line, media propionylcarnitine was higher in C7 treatment compared to others. Media succinylcarnitine increased with dMC9 compared to C7 in all deficient cell except TFP. Intracellular succinate was higher with ENG05 treatment in two VLCAD (226% and 260%) and CPT II (161%) deficient cell lines compared to C7. Intracellular malate was higher with ENG05 in two VLCAD (22% and 90%), LCHAD (38%), TFP (210%), and CPT II (35%) deficient cells compared to C7.

**Discussion.** Persistence of rhabdomyolysis in patients treated with C7 suggests inadequate access to muscle tissue. We have shown that alternative fatty acids improve the cellular profile in fibroblasts of four key metabolites compared to C7 treatment. These findings suggest more efficient cellular utilization of the alternative fatty acids tested and potential advantage over C7. Muscle distribution in animal models remains to be demonstrated.

## PgmNr 415: The International Cantú Syndrome Registry: Patient findings and therapeutic options.

Cantú syndrome (CS), first described in 1982, is caused by pathogenic variants in *ABCC9* and *KCNJ8*, which encode pore forming and regulatory subunits of ATP-sensitive potassium ( $K_{ATP}$ ) channels, respectively. Multiple case reports of individual patients have described the various clinical features of CS, but systematic studies have been lacking. To define the effects of genetic variants on CS phenotypes and clinical outcomes, we have developed a standardized REDCap-based registry for CS patients. We report phenotypic and associated genotypes on 75 CS patients, with confirmed *ABCC9* variants in 72 of the cases. Hypertrichosis and a characteristic facial appearance are present in all cases. Polyhydramnios during fetal life, lymphedema, patent ductus arteriosus (PDA), cardiomegaly, dilated aortic root, vascular tortuosity of thoracic and cerebral arteries and migraine headaches are common features, although even with this large group of patients, there is incomplete penetrance of CS-associated features, without clear correlation to genotype.

Many patients report taking cardiac medications currently, or having taken them in the past. These include ACE inhibitors, such as quinapril and enalapril, and beta-blockers, such as atenolol and bisoprolol, as well as previous treatment for pulmonary hypertension with sildenafil. Most patients with edema report current or previous medication treatment with diuretics, including furosemide, spironolactone and amiloride. There is currently no targeted therapy for CS, and it is unclear whether the above therapies are in all cases appropriate. However, we find that CS-associated cardiomegaly in mice carrying CS mutations knocked-in to the endogenous *ABCC9* locus is reversed by the sulfonylurea glibenclamide. Sulfonylureas directly inhibit overactive  $K_{ATP}$  channels, and thus may be a viable option for directed therapy. Hence, we intend to perform a clinical trial to test glibenclamide in CS patients.

## PgmNr 416: Clinical genetic results aided by a patient-provider app intended for diverse populations.

Genomic data can optimally advance health if results are accessible and understood by patients and providers. Too often, even in advanced health care systems, genetic test results exist in complex formats that make comprehension difficult for end-users. The complexity particularly impacts individuals tested by new technologies, as genes and conditions are often rare and unfamiliar. In the UCSF P3EGS study, part of the CSER2 Consortium, we have developed a user-friendly patient-provider application that integrates genomic and other medical data into a mobile platform that supports result communication and point-of-care access in the clinic. Here we demonstrate findings from this new app that we have implemented for the return of medical genetic results. First, we defined foundational elements for return of results that can be facilitated by an app. Second, we piloted the app in clinic with patients and providers, comparing paper to electronic modalities in individuals receiving results for undiagnosed conditions. Third, we performed patient surveys, with 39 returned results to date for analysis. We show the following: 1) The genetic testing results, specifically the diagnostic conclusions, were concordant in recipients and providers in 90% of responses. 2) Recipients preferred app-based information over paper, although there were exceptions, and 3) The findings were consistent among individuals of diverse socio-economic and educational backgrounds. These data suggest that patient-provider apps may play a novel role in facilitating results communication. As more people in the population are sequenced, further implementation and expansion of similar technologies may be needed. Further collaborative efforts will encourage cross-institutional technology development, data sharing and harmonization of outcome measures.

## PgmNr 417: Utilizing gene expression to prioritize genes in medical patients.

The Undiagnosed Diseases Network (UDN) is an NIH funded study, implemented to bring together clinical and research experts from across the country. The UDN consists of 12 clinical sites across the country. At Vanderbilt, we employ a variety of methods to find the underlying causes of a patient's phenotypes. This includes on-site visits by medical staff to examine the patient and verify reported phenotypes. When a patient's disease is thought to have a genetic cause, whole-genome or whole-exome sequencing is performed in the patient and any available family members. Variants are then examined for frequency, pathogenicity, and relevance to the patient's disease to create a list of candidate mutations that may contribute to the patient's disease.

In order to gain further insight into the disease etiology of several of our unsolved cases. We performed RNA-seq on blood samples from 39 individuals whose disease etiology could not be determined. This allowed us to compare expression levels of each gene in these patients to individuals within a healthy population. We compared our patient gene expression data to that of the Gene-Tissue Expression Consortium (GTEx). Genes which appeared as outliers in the distribution of expression within the GTEx whole blood samples, became candidate genes for further study in that patient, and any known diseases associated with these genes were examined.

We also compared predicted expression, using the PrediXcan method, of each gene in our patients to predicted expression within GTEx, BioVU (electronic health records at Vanderbilt linked to DNA) and to the observed expression within that patient to look for outliers in predicted expression. Since, the elastic net models that the PrediXcan models utilize usually favor common SNPs, deviation of the observed expression from the predicted expression may indicate that a previously uncharacterized rare SNP or variant is within this gene or its regulatory components. Furthermore, genes whose expression falls outside the distribution of predicted expression in GTEx or BioVU may indicate a large genetic burden of common variants attributable to a given gene. We outline several cases in which this approach has shown promising results, leading to better patient care, and providing answers for the families involved.

## PgmNr 418: New strategies for analyzing exomes to increase diagnostic yield from patients with rare disorders.

### Authors:

---

Whole exome sequencing (WES) is becoming increasingly important in enabling tailored interventions in 'personalized' or 'precision' medicine. Recent studies suggest that in patients with suspected genetic disorders, WES should be applied as a first-tier molecular test, in parallel with standard diagnostic care, to improve the cost-effectiveness of the diagnostic process. However, limitations of the current analytical methods, genetic and phenotypic heterogeneity, knowledge gaps in the gene-disease association, and interpretation/reporting differences often hinder the identification of disease-causing variants. Ultimately, only 25-30% of families receive a diagnosis after WES, leaving the genetic basis of the remaining families' diseases unknown. We have shown recently that periodic reanalysis of negative WES data using improved bioinformatic tools and up-to-date, gene-disease databases can identify additional candidate variants, potentially increasing the diagnostic yield to 45-55%. Despite the use of these approaches, many cases remain negative after reanalysis. Thus, there is a need to develop a comprehensive strategy for reanalysing negative WES that will further improve the diagnostic yield. In addition, a lack of standardization of this process leads to high variability in diagnostic yield, as well as lack of optimum care for patients who do not receive a diagnosis. In order to improve diagnostic outcomes for these patients, we have introduced several complementary methods to our pipeline including copy number variation (CNV) analysis, UK Biobank data and a small neural network-training algorithm for the optimization of the analysis process. The incorporation of 50,000 samples with phenotypic information and whole exome/genome data from the UK Biobank with proper statistical models will certainly improve the diagnostic yield. Here we report our cumulative experience from reanalysis of a WES cohort enrolled in The Manton Center using a custom-built, comprehensive variant detection and analysis pipeline in conjunction with updated phenotypic information, literature, statistical models and databases in collaboration with an interdisciplinary team. These advances allowed us to reach a confirmed or potential diagnosis for up to a third of previously negative CES cases, demonstrating a meaningful improvement in clinical diagnostic yield.

## **PgmNr 419: Large-scale genomic characterization of pediatric patients with rare diseases at Shriners Hospital for Children's Genomics Institute (SHCGI).**

### **Authors:**

---

Shriners Hospitals for Children is a one-of-a-kind international health care system of 22 facilities dedicated to improving the lives of children by providing specialty pediatric care, innovative research and training programs. Children with orthopedic conditions, burns, spinal cord injuries and cleft lip and palate are eligible for care regardless of their ability to pay.

To expand our capabilities and develop the best tools for our patients, SHCGI has recently initiated a genomic study involving 5,000 patients and their biologic parents (15,000 subjects in total). After informed consent is obtained, their genomes will be characterized by Massively Parallel Sequencing. Diseases such as cerebral palsy, osteogenesis imperfecta, idiopathic scoliosis, metabolic bone diseases, and spina bifida are among the disorders to be investigated. Identified variants will be associated with the family history and clinical information to help fully characterize each condition and its transmission pattern. Functional validation of the identified variants and involved pathways will follow this initial discovery phase.

So far, little is known about many of these disorders, although a strong genetic component is suspected. Our network of hospitals will participate in this unique project, and the resulting outcomes should allow us to achieve better support and targeted care for our patients as better diagnostic and therapeutic tools emerge.

## PgmNr 420: Lessons from the TOTEM trial, a phase 1/2 multicentre, open-label, single-arm study of low-dose PI3K inhibitor taselisib in adult patients with PI3KCA-related overgrowth (PROS).

### Authors:

M. Luu<sup>1</sup>; P. Vabres<sup>2</sup>; H. Devilliers<sup>1</sup>; R. Loffroy<sup>3</sup>; M. Carpentier<sup>4</sup>; C. Fleck<sup>4</sup>; A. Maurer<sup>1</sup>; M. Yousfi<sup>2</sup>; M. Bardou<sup>1</sup>; L. Faivre<sup>1</sup>

[View Session](#) [Add to Schedule](#)

---

**Background:** Activating PIK3CA mutations in overgrowth syndromes provide a rationale for targeted PI3K inhibition as a drug therapy approach in PROS patients. Taselisib, a selective class I PI3K-inhibitor developed for breast cancer therapy, has been shown to suppress aberrant Pi3K hyperactivation in non-clinical pharmacological studies.

**Objective:** To establish the six-month tolerance of low-dose of taselisib in PI3KCA-related overgrowth (PROS) adult patients

**Methods:** The study was to enroll 30 adult patients with PROS in a phase IB/IIA multi-centre, open-label single arm trial. Using a 3+3 dose escalation design, a first batch of six patients received 1mg of taselisib daily before escalating at 2mg. The primary outcome was the occurrence of dose limiting toxicities defined as grade  $\geq 3$  adverse reaction (AR) during the first month of treatment. The study was to be interrupted on the occurrence of one life-threatening Suspected Unexpected Serious Adverse Reaction (SUSAR),  $\geq 2$  SUSAR, or  $\geq 5$  serious AR. All safety assessments were reviewed by an independent safety committee. Preliminary efficacy outcomes were assessed by measuring relative changes before and after treatment of a) tissue volume at affected and unaffected sites clinically and by dual energy X-ray absorptiometry, b) vascular outcomes and biologic parameters, c) quality of life. The study was conducted in accordance with the Declaration of Helsinki.

**Results:** A total of 19 patients were enrolled, 17 received taselisib and 11 completed the study. Whereas no serious AR occurred in the 1mg cohort (6 patients), the study was terminated after 11 patients were included in the 2mg cohort, due to two SUSAR (acute ileitis and a pachymeningitis). Five patients at 2mg had already completed the study, and taselisib was definitively withdrawn in the remaining 6. All the patients treated experienced at least 1 AR. Three patients had a grade 3 AR (the 2 SUSAR and 1 parvovirus infection). Gastrointestinal disorders, nervous system disorders and infections accounted for respectively 43% (43/113), 17% (19/113) and 12% (13/113) of AR. Preliminary efficacy data suggest improvement such as pain reduction, chronic bleeding cessation or

improved quality of life.

**Conclusion:** The first therapeutic trial of a PI3KCA-inhibitor in PROS patients suggests that, despite promising efficacy results, low-dose Taselisib can induce serious drug-related AR that prevent consideration of long term use.

## PgmNr 421: Adenine base editing of the *DUX4* somatic polyadenylation signal in facioscapulohumeral muscular dystrophy.

### Authors:

D. Sikrova; J. Balog; S.M. van der Maarel

[View Session](#) [Add to Schedule](#)

**Affiliation:** Human Genetics, Leiden University Medical Center, Leiden, Zuid Holland, Netherlands

Facioscapulohumeral muscular dystrophy (FSHD) is an inherited myopathy caused by sporadic expression of the transcription factor double-homeobox 4 (*DUX4*) in skeletal muscle. Expression of *DUX4* in skeletal muscle results from incomplete epigenetic repression of its locus residing within the D4Z4 macrosatellite repeat in the 4q subtelomere. Since *DUX4* is a transcriptional activator, once expressed it induces improper transcriptional changes in muscle cells, eventually leading to cell death. Interestingly, epigenetic de-repression of the D4Z4 repeat itself is not sufficient to cause FSHD as it needs to occur on a specific genetic background of chromosome 4q. There are two main subtelomeric 4q allelic variants (termed 4qA and 4qB) with only de-repression of the D4Z4 repeat on 4qA resulting in FSHD. This is due to polymorphisms between 4qA and 4qB immediately distal to the last D4Z4 repeat unit, creating only on 4qA alleles an extra exon for *DUX4* that contains a somatic polyadenylation signal (sPAS) for *DUX4* in muscle cells. It has been shown that even a single nucleotide substitution in the conserved *DUX4* PAS hexameric motif has a negative effect on the cleavage and polyadenylation of the mRNA precursor leading to gene downregulation.

Here, we wanted to explore if mutating endogenous *DUX4* sPAS would lead to reduced transcript production and thus attenuating its downstream harmful effects on myogenic cells. To achieve efficient and precise mutagenesis of the *DUX4* sPAS, we made use of CRISPR/Cas9-guided adenine base editing. The adenine base editor (ABE) allows direct conversion of targeted adenine(s) into guanine(s) and as such bypasses the need of template-dependent homologous recombination pathway which usually represents the limiting step when introducing specific nucleotide changes at the region of interest. Conveniently, the *DUX4* sPAS is a good substrate for ABE-mediated A to G mutagenesis as a nearby protospacer adjacent motif (PAM) site positions the last three adenines of the *DUX4* sPAS in the active editing window of ABE. The results of this study provide insight into the role of the *DUX4* sPAS in FSHD pathogenesis and the regulation of *DUX4* in muscle cells.

## PgmNr 422: A CRISPR-Cas13a based strategy that tracks and degrades toxic RNA in myotonic dystrophy type 1.

### Authors:

---

Cas13a, an effector of type VI CRISPR-Cas systems, is an RNA guided RNase with multiplexing and therapeutic potential. This study employs the *Leptotrichia shahii* (*Lsh*) Cas13a and a repeat-based CRISPR RNA (crRNA) to track and eliminate toxic RNA aggregates in myotonic dystrophy type 1 (DM1) – a neuromuscular disease caused by CTG expansion in the *DMPK* gene. We demonstrate that *Lsh*Cas13a cleaves CUG repeat RNA in biochemical assays and reduces toxic RNA load in patient-derived myoblasts. As a result, *Lsh*Cas13a reverses the characteristic adult-to-embryonic missplicing events in several key genes that contribute to DM1 phenotype. The deactivated *Lsh*Cas13a can further be repurposed to track RNA-rich organelles within cells. Our data highlights the reprogrammability of *Lsh*Cas13a and the possibility of using Cas13a as a means to treat other microsatellite expansion diseases.

---

**Objective:** Understanding genetic risk for Alzheimer's disease (AD) is crucial to optimizing early detection and intervention. The National Institute on Aging and Alzheimer's Association have proposed the A/T/N AD research framework for interactions between three main biomarkers of disease, amyloid plaques (A), phosphorylated tau tangles (T), and neurodegeneration (N), and how they contribute to cognitive decline associated with AD. We developed a novel polygenic risk score (PRS) based on the A/T/N framework to integrate genetic risk for AD biomarkers into the framework (the A/T/N PRS). We then compared the predictive capabilities of this PRS score for AD risk based on a case-control design. **Methods:** We used summary statistics from genome wide association studies (GWAS) of cerebrospinal fluid (CSF) phosphorylated-tau (ptau<sub>181</sub>), and amyloid- $\beta$  (A $\beta$ <sub>42</sub>), as well as late-onset AD risk genes and left hippocampal volume (LHIPV) to calculate PRS scores for 1182 subjects in the Alzheimer's Disease Neuroimaging Initiative (ADNI). The  $\alpha$ -cutoff was 0.01 for index single nucleotide polymorphisms (SNPs) and the physical distance for linkage disequilibrium (LD) clumping was 200kb. Linear regression validated performance of PRS scores for CSF biomarkers and hippocampal volume on respective outcomes with covariates for age, sex, and years of education. Additionally, CSF models were covaried for batch and LHIPV for magnet strength and intracranial volume. A generalized linear model assessed AD risk PRS performance on AD diagnosis. PRS scores were Blom transformed and averaged to calculate an A/T/N PRS. We evaluated the performance of the A/T/N PRS and AD risk PRS scores on baseline and longitudinal cognitive composites of executive function and memory by comparing p-values and R<sup>2</sup> values. **Results:** The A/T/N PRS showed superior predictive performance on executive function decline, accounting for 1.33% of the variance (whole model, 12.50%), compared to 0.40% variance explained by the AD risk PRS (whole model, 11.57%). The A/T/N PRS and the AD risk PRS performed comparably for baseline executive function, baseline and change in memory performance. **Discussion:** The A/T/N PRS was developed to model the amyloidosis, tauopathy, neurodegeneration framework that drives AD progression, and outperforms a PRS for AD risk to predict change in executive function. Integration of genetic risk across biomarkers

relevant to AD may represent a more refined strategy to model disease progression.

## PgmNr 424: Characterizing the mechanisms of *SLC35A2* epilepsy in human iPSC-derived neurons.

### Authors:

---

Germline genetic variants of *SLC35A2*, which encodes a Golgi-localized UDP-galactose transporter (UDPGaT) essential for cellular galactosylation, have been implicated in one type of congenital disorder of glycosylation associated with intractable seizures and in rare X-linked developmental and epileptic encephalopathy. Recently, we have identified post-zygotically-acquired, *de novo*, loss-of-function *SLC35A2* variants in 17% of non-lesional focal epilepsy cases, however, mechanisms of *SLC35A2* in the epileptogenic process remain elusive. This study seeks to study how pathogenic *SLC35A2* variants affect neural network activity. We have established human induced pluripotent stem cell lines (hiPSC; 713-5, isogenic control) CRISPR-edited to harbor either a pathogenic missense variant (c.910T>C p.Ser304Pro; *SLC35A2*<sup>S304P/Y</sup>) or a frameshift indel (*SLC35A2*<sup>-Y</sup>). Immunofluorescent (IF) staining for NANOG and SOX2 confirms the isogenic control, *SLC35A2*<sup>S304P/Y</sup> and *SLC35A2*<sup>-Y</sup> exhibit pluripotent characteristics. However, expression of pluripotent marker TRA1-81, which recognizes a galactose-containing keratan sulfate epitope on podocalyxin, was lost in *SLC35A2*<sup>S304P/Y</sup> and *SLC35A2*<sup>-Y</sup> compared to the isogenic control suggesting *SLC35A2* variants encode loss-of-function proteins. This was further confirmed using a MALI lectin binding assay, which detects terminal sialic acid on glycoproteins, that showed reduced binding in *SLC35A2*<sup>S304P/Y</sup> and *SLC35A2*<sup>-Y</sup> protein lysates compared to the isogenic control. Loss of transporter activity is likely due to loss of UDPGaT expression in *SLC35A2*<sup>S304P/Y</sup> and *SLC35A2*<sup>-Y</sup> hiPSCs as shown by reduced IF staining and no co-localization with GM-130 (Golgi marker) as observed in the isogenic control. To investigate how *SLC35A2* variants impact neural network activity and development, hiPSC-derived neurons were plated on multi-electrode array. Compared to the isogenic control, *SLC35A2*<sup>S304P/Y</sup> exhibit synchronous activity at an earlier onset compared to the isogenic control as quantified by the spike train tiling coefficient, mutual information, and percentage of spikes in network spikes. This suggests that *SLC35A2* variants influence the development of neural network connectivity, which may be contributing to the epileptogenic process. Further characterization of the underlying mechanisms of *SLC35A2*-associated epileptogenesis across an allelic series and the exploration of the potential of galactose treatment in this model system are underway.

## PgmNr 425: Applying genomic medicine to patients with mesial temporal lobe epilepsy: Predicting response to treatment.

---

Mesial temporal lobe epilepsy (MTLE) is the most common form of focal epilepsy in adult patients. A large proportion of patients with MTLE is refractory to treatment with antiepileptic drugs (AEDs) and may be eligible for surgical treatment, which is effective in most patients. To date, the presence of hippocampal sclerosis (HS) is the only factor used to predict poor response to AED in patients with MTLE. The long delay to indicate surgery for AED-refractory MTLE can negatively impact the quality of care offered to these patients. Recently, we proposed an algorithm to predict whether a patient with MTLE will be refractory to AED therapy combining information from clinical variables as well as SNPs in candidate genes. We were able to achieve an accuracy of 0.8177 using 56 SNPs and the presence of HS (Silva-Alves et al., doi:10.1371/journal.pone.0169214). In the present study, we aim to replicate and validate this algorithm in an independent cohort and to test whether the use of a limited number of SNPs could be enough to identify patients who are refractory to AED-therapy. For this, we selected the ten topmost significant SNPs obtained in the previous report and genotyped a total of 253 patients with MTLE, who were classified into two groups, 38 AED-responsive and 215 AED-refractory. We obtained an accuracy of 0.799, with a sensitivity of 0.92, in the prediction of AED-refractory patients. We successfully validated our previous results in an independent cohort and demonstrated that by using only 10 SNPs, it is possible to predict with high accuracy and sensitivity patients who will be refractory to AED therapy. Thus, suggesting that by incorporating genetic testing into the medical evaluation of patients with MTLE, one can indicate epilepsy surgery sooner to those predicted to be AED-refractory, which is likely to significantly improve the quality of care offered to these patients. Study supported by FAPESP, SP, Brazil.

## PgmNr 426: Zebrafish modeling for the clinic: Rapid *in vivo* functional testing of patient variants for clinical applications.

### Authors:

B. Jussila; T. Brock; C. Hopkins; R. Fekete

[View Session](#) [Add to Schedule](#)

Genomic sequencing has become more prevalent in clinical settings. The result has been a rapid increase in identification of suspect variants for causing disease. Unfortunately, many of the variants identified are either not annotated, or they are assigned a Variant-of-Uncertain-Significance (VUS) status. To improve diagnostic rates, strong (PS3) assessments of pathogenic or benign status can be obtained from functional studies. In this work, we use zebrafish (*Danio rerio*) as an intact animal model to measure the functional effects of patient-derived genetic variation. Two advantages of modeling in zebrafish are a high level of conservation with human disease associated genes (~95%) and a large clutch capacity enabling high throughput applications, such as drug testing and behavioral assessment. Using CRISPR/Cas9-mediated gene editing, we targeted the zebrafish ortholog of human syntaxin binding protein 1 (*STXBP1*), denoted *stxbp1a*, as a test case for modeling genetic contribution to pediatric epilepsy and encephalopathy. The variants chosen for the functional studies include VUS and established pathogenic and benign alleles. In a complementary approach, morpholino (MO) knock-down coupled with transient mRNA rescue with variant cDNA is being explored as a rapid assay method for detecting variant pathogenicity. The result is a toolkit in zebrafish for uncovering the functional consequence of genomic variation. The zebrafish studies integrate into our Precisome Platform - rapid, actionable, and quantifiable results for variant pathogenicity measured in disease-proxy animals ('Clinical Avatars'). The platform combines the complementary variant modeling in *C. elegans* (worms) and *D. rerio* (fish) to create a correlative body of evidence for pathogenicity that is strengthened by the conservation of biology between 3 species: worm, fish and humans. For example, the functional data presented will explore the connection of patient-specific phenotype and the conserved morphological, molecular, and behavioral activity of the Clinical Avatar animals. By including zebrafish into the Precisome Platform, strong correlative assessment is achieved for assigning pathogenicity to gene variations observed in the patient.

## PgmNr 427: Anti-sense oligonucleotide therapy delays seizure onset and extends survival in a mouse model of *Scn8a* encephalopathy.

The gene *SCN8A* encodes the voltage-gated sodium channel Na<sub>v</sub>1.6, which is localized at the axon initial segment and at nodes of Ranvier in the CNS and PNS. Exome sequencing has identified several hundred *de novo* mutations of *SCN8A* in patients with epileptic encephalopathy (MIM#614558), a severe disorder characterized by early onset seizures, developmental delay and cognitive impairment. Many patients with *SCN8A* encephalopathy are nonambulatory and nonverbal, and the condition is resistant to standard anti-epileptic drugs. Most patient mutations of *SCN8A* result in gain-of-function changes leading to elevated channel activity and neuronal hyperactivity. To test therapeutic interventions, we generated a conditional mouse model of the patient mutation p.Arg1872Trp (*Bunton-Stasyshyn, Wagnon et al, Brain 2019*). We used this model to evaluate the effectiveness of anti-sense oligonucleotides (ASOs) to compensate for neuronal hyperactivity by reducing the abundance of the Na<sub>v</sub>1.6 mRNA. *Scn8a*<sup>cond/+</sup>, *E2A-CRE* mice were treated by intracerebroventricular injection of an ASO that decreases the abundance of the *Scn8a* transcript by up to 50%. We observed a dose-dependent increase in length of seizure-free survival of the mutant mice from 2 weeks for untreated mice to 9 weeks in mice receiving two treatments of ASO. The ASO-treated mice did not exhibit any of the side effects that can result from greater reduction of Na<sub>v</sub>1.6 function, such as muscle wasting and ataxia.

These experiments provide pre-clinical evidence for the effectiveness of ASO therapy to treat an intractable childhood epilepsy. Reduction of neuronal excitability with an *SCN8A*-ASO is potentially applicable to other epilepsies. *Supported by NIH R01 NS34509.*

## PgmNr 428: HMI-202 and gene therapy for metachromatic leukodystrophy (MLD).

---

Metachromatic leukodystrophy, commonly known as MLD, is an inherited autosomal recessive lysosomal storage disorder with a great unmet medical need. This fatal neurodegenerative disease occurs in three forms: late infantile (prevalence of 1 in 40,000), juvenile, and adult. The late infantile and juvenile forms represent the majority of the MLD patients and mortality at 5 years is estimated at 75% and 30%, respectively. Most commonly, MLD is caused by mutations in the ARSA gene and patients suffering from the disease are deficient in arylsulfatase-A (ARSA) enzyme. The disease is characterized by accumulation of supraphysiologic levels of lipids (sulfatides) in the brain, spinal cord and peripheral organs, which become toxic. This excess sulfatide leads to the destruction of myelin, a key protective layer of the nerve fibers, resulting in nerve damage. Herein, we are reporting preclinical gene therapy data in a murine model of MLD where a single intravenous dose of HMI-202 (AAVHSC15-hARSA) crossed the blood-brain barrier and led to a dose-response relationship in vector genome copies, ARSA protein and ARSA enzymatic activity in the central nervous system (CNS). HMI-202 expression patterns and corresponding enzymatic activity were rapidly detected in key biologically relevant regions of the brain (brainstem, cortex, cerebellum and white matter tracks), spinal cord (gray matter and ascending white matter tracks of the posterior column) and peripheral nervous system (dorsal root ganglion and sciatic nerve) in lysosomes of both neuronal and glial cellular profiles. In summary, HMI-202 is a promising gene therapy in development for the treatment of MLD based on mouse data demonstrating its rapid onset of action and ability to achieve hARSA activity levels at or above the therapeutic threshold (10-15% of normal hARSA activity). Based on these preclinical data, IND-enabling studies of CNS gene therapy development candidate HMI-202 have been initiated.

## PgmNr 429: *PLP1* gene suppression therapy for Pelizaeus-Merzbacher disease using artificial miRNA.

---

Genomic duplication encompassing the entire *PLP1* gene is the most common cause of Pelizaeus-Merzbacher disease (PMD), an X-linked hypomyelinating leukodystrophy showing severe motor and cognitive developmental delay with various neurological phenotypes. Although the exact molecular and cellular mechanisms underlying *PLP1* duplication, which causes severe hypomyelination in the central nervous system, remain largely elusive, *PLP1* overexpression is likely the fundamental cause of this devastating disease. Here, we investigated if adeno-associated virus (AAV)-mediated gene-specific suppression may serve as a potential cure for PMD by correcting quantitative aberrations in gene products. We developed an oligodendrocyte-specific *Plp1* gene suppression therapy using artificial miRNA under the control of human *CNP* promoter in a self-complementary AAV (scAAV) platform. A single direct brain injection achieved widespread oligodendrocyte-specific *Plp1* suppression in the white matter of WT mice. AAV treatment in *Plp1* transgenic mice, a *PLP1* duplication model, ameliorated cytoplasmic accumulation of Plp1, preserved mature oligodendrocytes from degradation, restored myelin structure and expression of myelin genes, and improved survival and neurological phenotypes. Together, we provide evidence that AAV-mediated gene suppression therapy using artificial miRNA can serve as a potential cure for PMD resulting from *PLP1* duplication and possibly be applied to the development of therapies for other genomic disorders.

## PgmNr 430: Epigenome-editing of *SNCA* gene expression: A novel strategy for gene therapy of Parkinson's disease.

### Authors:

B. Kantor<sup>1,2</sup>; L. Tagliafierro<sup>3,4</sup>; E. Ilich<sup>1,2</sup>; L. Brown<sup>1,2</sup>; J. Gu<sup>3,4</sup>; O. Chiba-Falek<sup>3,4</sup>

1) NEUROBIOLOGY, DUKE, Durham, North Carolina.; 2) VIRAL VECTOR CORE, DUKE, Durham, North Carolina; 3) NEUROLOGY, DUKE, Durham, North Carolina; 4) Center for Genomic and Computational Biology, DUKE, Durham, North Carolina

**Background:** The overexpression of *SNCA* play an important role in the pathogenesis of Parkinson's Disease (PD) while, normal physiological levels of gene are crucial to maintain neuronal function. A so-far unmet need is the development of new therapeutic strategies targeting the regulatory mechanisms of *SNCA* expression to fine-tune *SNCA* levels, versus previous approaches that targeted directly the mRNA or the protein product resulting in robust reduction of *SNCA* levels associated with neurotoxicity.

**Objective:** To translate our knowledge of the mechanisms involved in the regulation of *SNCA* gene to next generation drug discovery based on tightly controlled repression of *SNCA* overexpression.

**Methods:** We developed a novel strategy to intervene with the transcription regulation of *SNCA*. The developed system based on the targeted DNA-methylation editing at *SNCA*-intron 1 and comprises of an all-in-one lentiviral vector (LV), carrying CRISPR/dCas9 fused with the catalytic domain of DNA-methyltransferase 3A (DNMT3A). Aiming to further optimize the delivery system, we created a safer integrase-deficient version of the LV.

**Results:** Applying the gRNA-dCas9-DNMT3A into human induced pluripotent stem cells (hiPSC)-derived 'aged' dopaminergic neurons from a PD-patient with the *SNCA* triplication resulted in fine-tuned downregulation of *SNCA*-mRNA and protein levels. Furthermore, the reduction in *SNCA* levels by the gRNA-dCas9-DNMT3A system rescued disease-related cellular-phenotypes characteristics of the *SNCA*-triplication/hiPSC-derived dopaminergic neurons, e.g. mitochondrial ROS-production, cell viability, and exacerbated nuclear aging signatures measured by DNA damage and abnormal nuclear envelop morphology. Next, we validated the vectors *in vivo* utilizing PD rodent models. Following the administration of LV-gRNA/dCas9-DNMT3A particles into the rat brain, we demonstrated an efficient decrease in *Snc*a-mRNA and protein levels.

**Conclusions:** Collectively, these *proof-of-concept* experiments provide the foundation and validation for advancing the novel epigenetic editing-based system further towards PD therapeutic strategy for application in a clinical setting. The system outlined here would be highly attractive for developing 'next generation drugs' as prevention and/or disease modifying interventions for PD, Alzheimer's disease and other neurodegenerative diseases and pathologies associated with dysregulation of gene expression.

---

Huntington disease (HD) is a fatal neurodegenerative disorder caused by a gain of function mutation in *HTT*. Suppression of mutant *HTT* expression has emerged as a leading therapeutic strategy for HD, with allele-selective approaches targeting *HTT* SNPs now in clinical trials. Haplotypes associated with the HD mutation (A1, A2, A3a) represent panels of allele-specific gene silencing targets for efficient treatment of HD patients of Northern European and indigenous South American ancestry. Here we extend comprehensive haplotype analysis of the HD mutation to key patient populations of Southern European, South Asian, Middle Eastern, and admixed African ancestry. In each of these populations, the HD mutation occurs predominantly on the A2 *HTT* haplotype. Analysis of HD haplotypes across all affected population groups enables rational selection of candidate target SNPs for development of allele-selective gene silencing therapeutics worldwide. Targeting SNPs on the A1 and A2 haplotypes in parallel is essential to achieve treatment of the most HD patients in populations where HD is most prevalent. Current allele-specific approaches will leave a majority of patients untreated in populations where the HD mutation occurs most frequently on the A2 haplotype, including Southern Europeans, South Asians, and patients of Middle Eastern origin. To develop strategies for allele-specific suppression of the A2 *HTT* haplotype in these patients, we demonstrate preclinical development of potent and selective ASOs targeting defining A2 *HTT* haplotype SNPs. On the basis of comprehensive *HTT* haplotype analysis, we further estimate the maximum proportion of patients that may be treated with three or four allele targets in different populations worldwide, informing current allele-specific *HTT* silencing strategies.

## PgmNr 432: Long-term effect of the gene therapy using AAV vectors with the human intrinsic GLUT1 promoter for *Glut1*-deficient mice.

**Background:** Glucose transporter 1 deficiency syndrome (GLUT1DS, OMIM #606777) is an autosomal dominant disorder caused by haplo-insufficiency of *SLC2A1*, and results in impaired hexose transport into the brain. Previously, we generated an AAV vector in which *SLC2A1* was expressed under synapsin I promoter (AAV-h*SLC2A1*), and suggested that AAV-h*SLC2A1* administration improved motor function of heterozygous knock-out *Glut1* (GLUT1<sup>+/-</sup>) mice. In this study, we developed another AAV vector that approximates human physiological GLUT1 expression.

**Methods:** We generated the AAV vector that expresses GLUT1 under the human GLUT1 promoter (AAV-GLUT1). AAV-GLUT1 was administered to GLUT1<sup>+/-</sup> mice via intra-cerebroventricular injection (CNS-local;  $6.5 \times 10^{10}$  vg/mouse,  $3.25 \times 10^{12}$  vg/kg). We analyzed GLUT1 mRNA/protein expression in the brain and other major organs and cerebral microvasculature by lectin-staining. We also examined motor function using rota-rod test and glucose levels in the blood and cerebrospinal fluid (CSF). Additionally, we confirmed that exogenous GLUT1 protein distribution in the brain and other organs after intra-cardiac injection of AAV-GLUT1 ( $7.8 \times 10^{11}$  vg/mouse,  $3.9 \times 10^{13}$  vg/kg).

**Results and conclusions:** After intra-cerebroventricular injection of AAV-GLUT1, exogenous GLUT1 was mainly expressed in endothelial cells in the brain, and partially in neural cells and oligodendrocytes. Exogenous GLUT1 also expressed in the cerebral cortex, hippocampus, and thalamus. Cerebral microvasculature was increased compared to un-injected control GLUT1<sup>+/-</sup> mice. AAV-GLUT1 improved the motor function and CSF-glucose levels of GLUT1<sup>+/-</sup> mice. Exogenous GLUT1 expression was not detected in other organs after intra-cerebroventricular injection of AAV-GLUT1. Exogenous GLUT1 expression was maintained in endothelial cells and neural cells for 24 months. After intra-cardiac injection, modest levels of exogenous GLUT1 were detected throughout the brain. Exogenous GLUT1 was also detected in the liver and in the muscle of the lower limb. AAV-based vector is a promising approach for the treatment of GLUT1DS patients.

## PgmNr 433: Loss-of-function variants in >4 million humans suggest that partial LRRK2 inhibition is a safe therapeutic strategy for Parkinson's disease.

Human genetics is a powerful tool to study the phenotypic impact of the modulation and inhibition of candidate drug targets. In particular, variants causing loss-of-function (LoF) of protein-coding genes provide natural in vivo models of gene inactivation, and are thus valuable indicators of the potential for on-target toxicity of therapeutic inhibitors.

Missense variants in *LRRK2* that cause gain of kinase function are a known cause of Parkinson's disease, suggesting inhibition of LRRK2 kinase activity as a promising therapeutic strategy. The biological consequences of such inhibition, however, have not been well characterised in humans. Furthermore, toxicity concerns have arisen from preclinical homozygous knock-out studies in model organisms, which have shown abnormal lung, liver, and kidney phenotypes.

Here, we systematically analyse predicted LoF variants across 141,456 sequenced participants in the Genome Aggregation Database (gnomAD), 49,960 exome sequenced individuals from the UK Biobank, and >4 million genotyped participants from 23andMe. After thorough manual curation, we identify 1,458 carriers of 136 unique high-confidence heterozygous LoF variants in *LRRK2*. Through Western blotting of LoF carrier lymphoblasts and CRISPR-engineered cardiomyocytes we demonstrate that six LoF variants, representing 85.2% of the carriers, result in reduced LRRK2 protein levels.

We manually curate available phenotypic data and conduct a phenome-wide association study. These analyses show that heterozygous LoF of the *LRRK2* gene is not associated with reduced life expectancy or with any specific phenotype or disease state; in particular, there is no evidence of adverse lung, liver, or kidney phenotypes.

These results suggest that partial life-long reduction of LRRK2 protein levels is consistent with a

normal, healthy lifespan, and therefore, therapeutics that downregulate LRRK2 are likely to be well-tolerated by Parkinson's disease patients. Furthermore, our results demonstrate the value of large-scale genomic databases combined with deep phenotypic characterisation of human LoF carriers to target validation in drug discovery.

## PgmNr 434: Loss of peroxisomal ACOX1 induces autoimmunity whereas a *de novo* gain-of-function variant induces elevated ROS and Schwann cell loss.

### Authors:

ACOX1 (Acyl-CoA oxidase 1) encodes the rate-limiting enzyme in very-long-chain fatty acid (VLCFA)  $\beta$ -oxidation, and produces  $H_2O_2$  in peroxisomes. We report a *de novo* mutation (p.N237S) in individuals who exhibit different phenotypes than ACOX1 deficiency patients. Loss of *dACOX1* in flies is semi-lethal, and eclosing flies exhibit progressive motor deficits and abnormal immune responses which can be rescued by Bezafibrate, an inhibitor for ELOVL1. In contrast, expression of p.N237S causes a gain-of-function that stabilizes ACOX1 as a dimer, produces elevated levels of reactive oxygen species (ROS) in insulating glia, and leads to demise of glia and neurons. Similarly, probands carrying p.N237S exhibit loss of Schwann cells, motor and sensory neurons. Treatment of flies or primary Schwann cells with an antioxidant strongly suppresses these phenotypes. Our data show that peroxisomes play a critical role in insulating glia across phyla, that loss of ACOX1 causes an autoimmune disease, and that gain of function results in ROS-driven glial death.

## PgmNr 435: A comprehensive approach to developing biomarkers tracking the progression of Parkinson disease.

Parkinson's disease (PD) is a complex neurodegenerative disorder characterized by motor and non-motor symptoms that worsen over time. Currently, there is no effective clinical and/or biological markers that can track PD disease progression.

To develop novel biological markers that can model disease characteristics, severity and progression, we are recruiting a cohort of 800 Ashkenazi Jewish individuals either manifesting or genetically at-risk for PD, and healthy controls for both cross-sectional and longitudinal studies. So far, we have recruited 620 subjects for the cross-sectional study and 135 of them will be followed longitudinally. Individuals include carriers and non-carriers of LRRK2, GBA mutations.

For all the subjects, we collected demographic data, baseline PD history and severity, clinical assessments, including MDS-UPDRS score, fluid biomarkers, digital data from wearable devices and imaging data from MRI and DaT-SPECT.

For genetic/genomic biomarker development, we collected both whole blood and peripheral blood monocytes from each subject and measured gene expression using RNA-Seq, chromatin accessibility using ATAC-Seq, and DNA methylation using MethylationEPIC BeadChip assays. Differential gene expression, chromatin accessibility and methylation will be assessed between different groups. Currently, gene expression data of whole blood and monocytes from first 400 subjects have passed quality control. Moderate correlation between gene expression and methylation with traditional measurement of PD progression (MDS-UPDRS score) was observed. The genomic biomarker candidates will be used in a multi-modal analysis with clinical, digital, imaging and fluid biomarker data in order to classify patients into subgroups that share the same characteristics and develop models that can track the severity and progression of the disease.

## PgmNr 436: Genetic spectrum of pediatric movement disorders and management implications: A single centre experience from India.

### Authors:

N. Rathod; A. Hegde; V. Patel

[View Session](#) [Add to Schedule](#)

**Affiliation:** PEDIATRIC NEUROLOGY, JASLOK HOSPITAL & RESEARCH CENTRE, MUMBAI, MAHARASHTRA, India

---

**Introduction:** The advent of next generation sequencing(NGS) has led to accurate genetic diagnosis and better understanding of the spectrum of pediatric movement disorders(MD). We aim to describe the genetic profile of our patients with Movement Disorder (MD).

**Methodology:** We analyzed 138 patients with primary MD. 89of them with suspected genetic etiologies underwent NGS. We classified them according to the International Parkinson and Movement Disorder Society Task Force recommendations. The results were correlated with their clinical profile, neuroimaging and family genetics, when available, to determine their significance.

**Results:**36/89, 32/89, 9/89, 10/89, 2/89 belonged to the dystonia, ataxia, hereditary spastic paraparesis(HSP), paroxysmal movement disorders(PMD) and parkinsonism group respectively. Causative genes were found in 55/89(61%).

Most common phenotype was dystonia with 19/36(52.7%) genetic positivity. DYT related genes(DYT5,DYT6,DYT11) were the most common while few others were PANK2, PLA2G6, GLB1 and HEXA. Large number of patients with clinically suspected neurotransmitter disorders with pharmacological responsiveness were genetically negative.24/32(75%) patients presenting predominantly with ataxia had positive results with the common genes being ATM,ITPR1,SLC2A1, APTX and POLR3A. 8/9(88%) with HSP were positive for causative genes like SPG11, SPG47, SPG3A, SPG33 and SPG7. Amongst patients with PMD, 3/10(30%) were positive with PNKD , CACNA1A , ATP1A3 gene mutations.1/2(50%) patients with parkinsonism was positivewith LRRK2 mutation.

**Conclusion:** In movement disorders, genetics helps largely with confirmation of diagnosis, prognostication, avenues for research, and antenatal protection. Genetic diagnosis provided disease specific treatment , highlighting the importance of early and specific genetic diagnosis .

## **PgmNr 437: Pharmacogenetic analysis of rs2205986 associated with glatiramer acetate-induced liver injury in multiple sclerosis patients.**

---

Multiple sclerosis (MS) is an autoimmune disease that develops when immune cells attack the myelin sheaths coating neurons in the central nervous system. Disease modifying therapies (DMT) can help reduce the frequency of demyelination events and MS severity, but are associated with a variety of adverse drug reactions (ADR), including drug-induced liver injury (DILI). Physicians often monitor liver condition for patients on DMTs with liver enzyme tests that measure patients' levels of alkaline phosphatase (AlkP), aspartate aminotransferase (AST) alanine aminotransferase (ALT), and bilirubin (TBil). A study performed by Kowalec et. al in 2018 investigated the genetic elements of DILI linked to the MS medication interferon- $\beta$  and discovered variant rs2205986 is associated with an increased DILI risk due to elevated AlkP and AST levels ( $\beta = 0.35$ ,  $\beta = 0.73$ ). Another common MS DMT known to be connected with DILI is glatiramer acetate (GA). In order to test if rs2205986 is also associated with an increased DILI risk in GA patients, 375 patients with references to GA in their electronic medical records located in Vanderbilt University Medical Center's Synthetic Derivative were manually reviewed to extract GA treatment timelines. 58 Caucasian patients had both liver lab values taken during treatment periods and genotyping information available. For each patient, the highest value for each test was identified and standardized to the upper limit of normal. With these liver enzyme values, a linear regression analysis was performed in PLINK v1.90 with patient age, sex, and first four principal components as covariates. Associations between rs2205986 and elevated AST, ALT, and TBil levels were insignificant ( $P = 0.33$ ,  $P = 0.32$ ,  $P = 0.51$ ). rs2205986, however, was significantly associated with elevated AlkP levels ( $P = 0.01$ ). With each additional variant allele, AlkP levels increase on average by 0.27 units/L (95% confidence interval: 0.09 - 0.46). This discovered association could aid physicians in screening potential GA candidates to prevent DILI, as well as contribute to the growing interest in developing personalized treatment plans accounting for patients' genetic information.

## PgmNr 438: Antisense oligonucleotide therapy in a humanized mouse model of *MECP2* duplication syndrome.

---

**Background:** Many intellectual disability disorders are due to copy number variations, and to date there have been no treatment options tested for this class of diseases. *MECP2* duplication syndrome (MDS) is one of the most common genomic rearrangements in males and results from duplications spanning the methyl-CpG binding protein 2 (*MECP2*) gene locus. Previously, we have shown that antisense oligonucleotide (ASO) therapy can successfully reduce MeCP2 levels in an MDS mouse model and reverse the disease-like phenotypes. However, our previous MDS mouse model carried one transgenic human allele and one mouse allele, with the latter being protected from human specific *MECP2*-ASO targeting. In humans, the two *MECP2* alleles are identical and because MeCP2 is a dosage-sensitive protein, one must ensure that the ASO is titrated to target the human allele such that MeCP2 levels are reduced from 2X to 1X. **Methods:** We generated a new "humanized" mouse model of MDS, that carries two human *MECP2* alleles, and no mouse endogenous allele. Moreover, we tested the effects of a human-specific *MECP2*-ASO through intracerebroventricular injection, which approximates that intrathecal delivery approach in humans. **Results:** The humanized mouse model of MDS showed elevated MeCP2 levels and using various behavioral tests we found they recapitulated the majority of the human patient phenotypes. We also found that the *MECP2*-ASO efficiently downregulates MeCP2 expression throughout the brain by quantifying the RNA and protein levels in 7 different brain regions. Furthermore, *MECP2*-ASO in a dose-dependent manner decreases MeCP2 levels in the brain. *MECP2*-ASO also ameliorates behavioral deficits including exploratory, learning and memory as well as motor coordination behavior, without any dose-limiting toxic effect or safety concern. We characterized the pharmacodynamic effect of the *MECP2*-ASO on MeCP2 and selected MeCP2-regulated genes during the duration of the treatment and found that majority normalized. **Conclusion:** Our results demonstrate that central nervous system administration of *MECP2*-ASO is well tolerated, has beneficial effects, and support a feasible translatable approach for the treatment of MDS.

## PgmNr 439: Epilepsy and autism spectrum disorder: Sequential plasmatic level and global quality of life assessment in antiepileptic drug treatment in Mali.

---

**Introduction:** Epilepsy and Autism Spectrum Disorder (ASD) are the two faces of a coin. We hypothesized that appropriate antiepileptic treatment will result in a better quality of life for epileptic patients with or without ASD.

**Aim:** To evaluate the quality of life of epileptics with/out ASD on antiepileptic drugs (AED) in Mali.

**Methods:** We followed 90 epileptics with/out ASD from October 2017 to May 2019. We recorded the duration, intensity, and the frequency of epileptic seizures before and during treatment (M1 at M3) and used the McGill to assess the global quality of life. Plasmatic AED levels were determined at first month (M1) and third month (M3) timepoints after treatment initiation.

**Results:** Comorbidity ASD/epilepsy was 8.9%. The age group 16-30 years represented 50%. Our study participants received phenobarbital (73.3%), valproic acid (7.8%) and carbamazepine (18.9%). Side effects occurred in 13.3% of participants. With 79% treatment adherence rate, the AED was under-dosed (42%), normo dosed (50%) or overdosed (8%). At M1, epileptic seizures occurred <1/month in 26.7%, had minimal intensity in 94.4%, and lasted <1 minute in 16.7 %. The global quality of life was better 94.5%. The plasmatic levels of AED were different from M1 to M3  $p < 0,000$ .

**Discussion:** The non-observance rate of the AED treatment was non-negligible. Nevertheless, our data show that AED prescription and follow up based only on body weight does not guarantee adequate plasma levels to control seizures. Epileptics with/out ASD will benefit from sequential AED, Electroencephalogram (EEG) and quality of life assessment. The occurrence of side effects should prompt for screening for known polymorphisms (SNPs) in Cytochrome CYP450 genes. Altogether, our ultimate goal is to revolutionize the EAD treatment for personalized medicine in Mali.

## PgmNr 440: A pilote animal model study for genetic vaccine of addiction, sensitivity reduction of methamphetamine by using crispr cas9 technology.

### Authors:

A. Haghighatfard; R. Ghamari

[View Session](#) [Add to Schedule](#)

**Affiliation:** department of genetic, Tehran medical sciences branch, Islamic Azad university, Tehran, Iran

Methamphetamine is a strong addictive neurotoxin that stimulates the central nervous system and affects several pathways and metabolisms in different organs. Recently, the clustered regularly interspaced short palindromic repeats-CRISPR-associated protein 9 (CRISPR-Cas9) systems was developed, which improves sequence-specific gene editing in cell lines, organs, and animals. CRISPR system would selectively disrupt the targeted location without affecting other region of DNA or other RNAs. Several long non-coding RNAs (lncRNAs) were found associated with tendency and high sensitivity to methamphetamine abuse. lncRNA named AK036791 is related to depression and sensitivity to stimulants such as methamphetamine.

We set out to design and use a CRISPR system to disrupt expression of AK036791 in a mouse model of methamphetamine exposure. Two group of male mouse were used (30 wild-type C57BL/6 mice for each group, 7-8 weeks old, male, 20-25 g). The groups of mouse were then given once-daily injections of METH (2 mg/kg) or saline for five consecutive days (day 3-7) followed by two injection-free days (day 8-9). On day 10, mouse were given a challenge injection of either 2 mg/kg METH or saline. Test group were CRISPR/Cas9 knock-in mouse model to induce doxycycline-regulated Cas9 induction that enables widespread gene disruption in multiple tissues and that limiting the duration of Cas9 expression. Forced swimming test performed in both group and expression level of AK036791 was assessed in nucleus accumbens by using quantitative Real time PCR.

Findings revealed showed three time reduction in expression level of AK036791 in nucleus accumbens of test group ( $p < 0.003$ ). Also Forced swimming test results showed depression level of knocked in mouse were significantly ( $p < 0.002$ ) lower.

It seems that designed CRISPR/Cas9 could induce reduction of expression of genes that are involved in methamphetamine sensitivity and depression. It may lead to new kind of vaccination for addiction as well as reduction of dependency and depressive symptoms. CRISPR/Cas9 also can use for developing knock-in and knock-out mice that may help to shed light to molecular mechanisms of methamphetamine in central nervous system.

## **PgmNr 441: Translating behavioral epigenetics into the primary care setting.**

The concept of screening the epigenome for patterns of methylation and unique biomarkers that underlie common disorders is advancing in the literature. Technologies such as Illumina Infinium HumanMethylation450 BeadChip array may provide a mechanism by which scientists and clinicians can collaboratively screen, diagnose, and initiate precise treatment modalities for neurodevelopmental and psychiatric disorders of childhood. In addition, the field of behavioral epigenetics provides evidence by which clinicians understand the gene by environment influences that associate with clinical symptoms of mood and behavioral disturbance. Primary care advanced practice nurses (APRN) are ideally positioned to conduct risk assessments, employ novel epigenetic screening technologies, and make diagnoses within a biopsychosocial framework that more precisely captures the dynamic course of disease and illness. In addition, APRN's are trained in therapeutic communication and may initiate counseling on the psychosocial and ethical implications of undergoing a genetic evaluation. A conceptual model for translating behavioral epigenetics into the primary care setting is proposed.

## PgmNr 442: Tryptophan hydroxylase 1 and 2 genetic polymorphisms implicated in childhood onset high-aggression.

The serotonin neurotransmission system has been implicated in childhood onset-aggression, but its role in the development of aggressive behaviours is unclear. The first and rate-limiting step of serotonin biosynthesis involves tryptophan hydroxylase (*TPH*). The purpose of this study was to investigate whether two single nucleotide polymorphisms (SNPs), rs1800532 (A218C) in the tryptophan hydroxylase 1 (*TPH1*) gene and rs4570625 (G703T) in the tryptophan hydroxylase 2 (*TPH2*) gene, are significantly associated with aggressive behaviour in a sample of children with a history of extreme, persistent and pervasive aggression. These SNPs were also assessed for possible interactions between each other, anxiety, and a history of maltreatment in association with internalizing and externalizing behaviours. From the currently compiled dataset at the Centre for Addiction and Mental Health in Toronto, Canada, the 2 SNPs were genotyped in 141 high aggression cases and 169 healthy controls. SNP genotype was analyzed for association to aggressive behaviour, anxiety, maltreatment history and internalizing/externalizing behaviours using chi-squared tests, linear, and logistic regression models. The T/T and G/T genotypes of rs4570625 were significantly associated with aggressive behaviour ( $p=0.024$ ), suggesting that T allele carriers at this SNP are at higher risk for the development of such behaviours in childhood. Externalizing behaviour in the high-aggression cases was also associated with both rs1800532 ( $p=0.006$ ) and rs4570625 ( $p=0.015$ ). In addition, for T-allele carriers of rs4570625, a history of maltreatment was associated with externalizing behaviour ( $p=0.013$ ). Although anxiety was not associated with either SNP, more females were affected by anxiety in the HA cases, suggesting that males and females have different comorbidities and different mechanisms in the development of aggressive behaviours. These results suggest that *TPH2* genetic variations and environmental factors, such as maltreatment, play important roles in the development of childhood-onset aggressive and related behaviours. More studies are required to further understand the development of such behaviours, which may lead to implications for potential means of intervention.

## PgmNr 443: A genetic screen in *Drosophila* to identify new human disease candidate genes associated with altered dopamine homeostasis.

---

The regulation of the neuromodulator dopamine (DA) is a vital component to many biological functions. In humans, dysregulation of DA leads to social and behavioral deficits as well as many debilitating neurological disorders. The genes required for DA synthesis and secretion are well-conserved, allowing model organism researchers to study the cellular and molecular processes behind DA regulation in vivo. In addition to DA's use in the nervous system, insects use DA as a precursor of melanin to color and harden their cuticle. Through a genome-wide RNAi screen in *Drosophila*, we identified 136 genes that affect cuticle pigmentation. Further experiments using the *Drosophila* activity monitor system revealed that many of these genes affect behavior when knocked down in DArgic cells, indicating they may be involved in DA signaling in the nervous system in addition to their role in cuticle pigmentation. Interestingly, ~85% of the genes identified from this screen are conserved in mammals, suggesting that defects in these genes may lead to alterations in DA signaling in humans.

In this study, we visualized the expression of a subset of our hits by using the T2A-GAL4 system to determine the expression of these genes in DArgic neurons. We expressed a CD8::GFP reporter construct in the expression domain of the genes of interest, dissected the fly brains, performed co-immunostaining with a TH antibody, and visualized the signal with a confocal microscope. For five *Drosophila* genes tested, which corresponds to eight human genes [pfk (PFKL, PFKM, PFKL), lola (ZBTB20), ctrip (TRIP12), CG4328 (LMX1A, LMX1B), and CG16758 (PNP)], expression was found in a subset of DArgic neurons. The selective expression of these genes suggests they may not have global effects on DA regulation, but may instead have cell-specific effects. As different DArgic neurons play specific roles in the brain, identifying the genes responsible for cell-specific DA regulation will allow us to examine the molecular basis behind behavioral deficits caused by defects in specific DA neuronal populations.

## PgmNr 444: Investigating the burden of treatable genetic diseases in psychiatric populations: A novel avenue for precision medicine.

### Authors:

V. Sreiretnakumar <sup>1</sup>; C. Zai <sup>1</sup>; J. Kennedy <sup>1</sup>; J. So <sup>1, 2</sup>

### Affiliations:

1) Neurogenetics Section, Centre for Addiction and Mental Health (CAMH), Toronto, Ontario, Canada;  
2) The Fred A. Litwin Family Centre in Genetic Medicine, University Health Network & Mount Sinai Hospital, 60 Murray Street, Toronto, Canada, M5T 3L9

---

Genetic diseases are individually rare but collectively common. Many genetic conditions can mimic mental health disorders, with psychiatric symptoms that are difficult to treat with regular medications. Discovery of rare genetic diseases in psychiatric patients would reveal specific management options, including treatments that may ameliorate psychiatric symptoms or help regular medications to work better, and provide information about the chances of other family members being affected. In a previous pilot study of 2046 psychiatric patients we found an enrichment of variants associated with four treatable genetic diseases, which included Niemann-Pick disease type C, Wilson disease, homocystinuria, and acute intermittent porphyria (AIP), including a 240X enrichment of AIP in comparison to the general population. In this study, we expand our investigation of treatable genetic disorders in psychiatric populations (n=2304) by screening for pathogenic variants associated with 108 treatable genetic disorders using next-generation sequencing (Illumina HiSeq 2500/NovaSeq 6000). Specifically, SCZ (n=445), bipolar (n=568), major depression (n=304), obsessive compulsive disorder (n=368) and generalized anxiety disorder (n=619) cohorts will be screened. Re-contactable patients will be prioritized to facilitate clinical molecular and biochemical diagnostic follow-up for validation of genetic screening results. We expect to see an increased prevalence of treatable genetic disorders within the psychiatric population relative to the general population. Additionally, we expect an increased carrier frequency amongst psychiatric patients that could potentially be playing a role the pathophysiology of psychiatric disorders. Importantly, patients found to be carriers or affected with treatable genetic diseases will be followed in the clinical setting and given appropriate genetic counseling, where appropriate. Discovering genetic diseases in psychiatric patients will shift how health care is delivered to these vulnerable patients by addressing underlying conditions rather than masking symptoms with medications and will especially help patients who don't respond to regular medications. This will lead to significant cost savings to the health care system. Ultimately, this study will pave the way for the identification of specific characteristics associated with psychiatric symptomatology in treatable genetic diseases that will allow for earlier targeted screening and treatments.

## **PgmNr 445: Mood stabilizing medications affect gene expression, development, and calcium signaling in iPSC derived neuronal derivatives.**

Bipolar Disorder (BD) is a genetically heterogeneous psychiatric disorder of unknown etiology that presents major challenges for the study of disease biology and drug development. Induced pluripotent stem cells (iPSCs), which can be differentiated into neurons and glia, provide a cellular model system suitable for studies of cases and controls as well as studies that assess the impact of therapeutic agents on cellular development and differentiation. As part of the Amish-Mennonite Bipolar Genetics study (AMBiGen), we are collecting clinical data, DNA, and fibroblasts from probands diagnosed with BD and their relatives, all ascertained within genetically-isolated Amish and Mennonite communities in the Americas. Fibroblasts have been reprogrammed to iPSCs with Sendai virus and differentiated into neural progenitor cells (NPCs), neurons, and astrocytes using standard protocols. Pilot studies are underway in cells from 4 probands and 4 sex-matched, unaffected siblings (2 clones each).

Assessments include morphology, action potentials, gene expression profiles, and cellular response to therapeutic dosages of established treatments such as lithium and valproic acid (VPA). Preliminary results suggest that long-term treatment with VPA, but not lithium, greatly reduced proliferation of NPCs by the MTT assay, and promoted neuronal differentiation in both cases and controls. Long-term treatment with lithium greatly reduced neuronal calcium response to glutamate stimulation in both cases and controls, based on single-cell calcium imaging. Gene expression microarray data showed that cells in different differentiation stages demonstrated the most significant differences, some genes were differentially-expressed in cases compared to controls. VPA treatment of neural progenitor cells increased neurogenesis and growth of neurites. In addition, long-term VPA treatment during the process of differentiating neural progenitor cells into neurons can greatly reduce the number of differentially-expressed genes in cases versus controls, which may reflect some therapeutic effects of VPA. These preliminary results, if replicated, could point to cell-autonomous phenotypes in neural cells derived from people diagnosed with BD

## PgmNr 446: Body mass index influences a nicotine metabolism biomarker: A Mendelian randomization study in European ancestry smokers.

---

**Background:** CYP2A6, a genetically variable enzyme that metabolizes nicotine and tobacco-specific nitrosamines, alters smoking behaviours and the risk for tobacco-related diseases such as COPD and lung cancer. CYP2A6 activity is phenotyped by the Nicotine Metabolite Ratio (NMR), a ratio of nicotine's metabolites (3'-hydroxycotinine/ cotinine). NMR is negatively correlated with body mass index (BMI), but the biology underlying this relationship is unclear. Smoking is also negatively associated with BMI; higher NMR increases smoking quantity, and could thereby reduce BMI. Alternatively, higher BMI could alter nicotine and metabolite kinetics and resulting NMR. Taylor *et al.*, 2018 provided some evidence for an influence of BMI on NMR in some but not all cohorts. Here we used Mendelian Randomization (MR) with updated instrumental variables to evaluate both potential causal influences, in order to determine whether NMR causes altered BMI or vice versa. **Methods:** Our clinical sample comprised 935 European-ancestry smokers from a cessation trial (PNAT2 NCT01314001). As an instrument for BMI, we performed LD clumping via PLINK to identify LD-independent SNPs from 941 conditional SNPs identified in a large genome-wide association study, which captured ~6% of the variation in BMI (Yengo *et al.*, 2018). As an instrument for NMR, we used our 7-variant CYP2A6 wGRS which captured ~34% of the variation in NMR (El-Boraie *et al.*, 2019). We used one-sample, bidirectional MR on individual-level data. Analyses were adjusted for relevant covariates. Sensitivity analyses were performed using MR-Egger regression to assess the validity of the resulting MR models. **Results:** LD clumping produced 334 SNPs which we subsequently used as instrumental variables for BMI in the MR models. We detected a significant causal influence for BMI on NMR ( $p \leq 0.001$ ) but no causal effect for NMR on BMI. Sensitivity analyses revealed consistent directions of effect, and the MR Egger intercept was non-significant ( $p > 0.1$ ) indicating no clear evidence of horizontal pleiotropy. **Conclusions:** Using MR we provide evidence for a causal relationship between BMI and NMR (i.e. higher BMI causes lower NMR). In contrast, we did not detect evidence that the NMR causally alters BMI. Our findings raise the possibility that BMI alters the kinetics of one or both metabolites that comprise the NMR.

## **PgmNr 447: Genetic polymorphisms in *CYP2D6*: Antipsychotic-induced weight gain in the UK Biobank sample.**

### **Authors:**

**Affiliation:** Division of Psychiatry, University College London, London, United Kingdom

---

Management of the metabolic side effects induced by antipsychotics are an important concern in the successful treatment of patients with psychosis. *CYP2D6* is a major metabolic pathway for many antipsychotics. There is growing evidence demonstrating a relationship between *CYP2D6* genotype and clinical outcomes. This study aims to consider whether *CYP2D6* metabolic status influences antipsychotic-induced weight gain.

The UK Biobank is a large, population cohort study including approximately 500,000 volunteers (age 40-70). Participants underwent extensive baseline assessments, including genome-wide genotyping and clinical interviews. We extracted genetic and clinical data for all individuals taking antipsychotics. Genetic data were phased using PHASE software to allow for star-allele allocation according to the Pharmacogene Variation Consortium guidelines. The sample was categorised into three phenotypic groups based on their Gaedigk activity score: poor, intermediate and extensive metabolisers. Ultra-rapid metabolisers were combined with extensive in this analysis. Linear regression models were conducted with *CYP2D6* metabolic phenotype as the predictor, body mass index (BMI) and waist circumference as the outcome measures, and age, sex and whether or not the drug taken was a primary *CYP2D6* substrate included as covariates.

We identified 2,863 individuals within the UK Biobank taking antipsychotics. Of these, 143 were poor metabolisers, 218 intermediate and 2,502 extensive. Overall, no significant association between *CYP2D6* phenotype and increased BMI or waist circumference was identified. We did find that taking a drug metabolised primarily through *CYP2D6* was predictive of higher BMI and waist circumference. When we conducted the analysis on 24 individual drugs rather than all antipsychotics together, we found a significant association between increased BMI and waist circumference in poor compared to extensive metabolisers for individuals taking fluphenazine.

The sample included in this paper constitutes one of the largest studies of *CYP2D6* poor and intermediate metabolisers conducted thus far. We did not identify any significant association between *CYP2D6* phenotype and increased BMI or waist circumference. Our results suggest that antipsychotic-induced weight gain is driven more by the type of antipsychotic drug than by *CYP2D6* metabolic phenotype. Further investigation of the impact of metabolic status on response to specific psychotropic drugs is required.

## PgmNr 448: X-chromosome variation influences on a nicotine metabolism biomarker predictive of smoking behaviors differ by sex in African American cigarette smokers.

### Authors:

M.J. Chenoweth <sup>1</sup>; L.S. Cox <sup>2</sup>; C. Lerman <sup>3</sup>; J. Knight <sup>4,5</sup>; R.F. Tyndale <sup>1,5</sup>

---

Cigarette smoking behaviors, which differ between men and women, are also influenced by pharmacogenetic variation. The genetically polymorphic CYP2A6 enzyme inactivates nicotine, the major psychoactive compound in cigarettes, to cotinine and then to 3'hydroxycotinine. The Nicotine Metabolite Ratio (NMR; ratio of 3'hydroxycotinine/cotinine) is a heritable (~60-80%) biomarker of the rate of nicotine metabolism. The NMR varies with sex and is associated with smoking behaviors and disease risk. Previous genome-wide association studies of the NMR that controlled for sex and examined only the autosomes (chromosomes 1 - 22) captured up to 38% of NMR variation. We investigated whether X-Chromosome genetic variation is associated with the NMR in African American smokers from two smoking cessation clinical trials (NCT01314001 and NCT00666978). Standard GWAS and X-Chromosome specific quality control steps were undertaken prior to genotype imputation. Males and females were analyzed separately. Within each trial, additive genetic models (phenotype = standardized square root NMR) adjusted for population substructure and NMR covariates (age, BMI, and use of menthol cigarettes). Results from the two individual trials were then meta-analyzed; variants with info scores >0.7 and minor allele frequencies (MAF) >1% were considered. In males (n = 351), the top variant was rs5963533 (beta = - 2.50 for A vs. G allele; P = 4.7e-9; MAF = 1.4%), explaining ~9.0% of NMR variation. The rs5963533 variant is located ~49kb downstream of *TSPAN7*, a gene previously associated with X-linked intellectual disability. In contrast to males, rs5963533 was not associated with the NMR in females (beta = - 0.22; P = 0.29). In females (n = 502), the top variant was rs148897912 (beta = 0.88 for G vs. A allele; P = 2.6e-6, MAF = 3.4%), explaining ~3.5% of NMR variation. The rs148897912 variant is located ~48kb upstream of *ENOX2*, which belongs to a family of growth-related NADH oxidases. In contrast to females, rs148897912 was not associated with the NMR in males (beta = 0.45; P = 0.21). Our findings suggest that X-Chromosome variation may represent an additional source of genomic variability in the NMR, with differing impacts in males and females. A greater understanding of the variation in this nicotine metabolism biomarker associated with smoking behaviors and tobacco-related disease risk may improve treatment strategies for both men and women.

## PgmNr 449: Evaluation of a weighted genetic risk score for the prediction of CYP2A6 activity in African-Ancestry smokers.

### Authors:

A. El-Boraie <sup>1</sup>; M.J. Chenoweth <sup>1</sup>; K. Fukunaga <sup>2</sup>; T. Mushiroda <sup>2</sup>; M. Kubo <sup>2</sup>; J. Knight <sup>3,4</sup>; J.G. Pouget <sup>4,5</sup>; C. Lerman <sup>6</sup>; N.L. Nollen <sup>7</sup>; L.S. Cox <sup>7</sup>; R.F. Tyndale <sup>1,4,5</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Department of Pharmacology and Toxicology, University of Toronto, Toronto, Ontario, Canada; 2) Center for Integrative Medical Sciences, RIKEN, Yokohama, Kanagawa, Japan; 3) Data Science Institute and Medical School, Lancaster University, Lancaster, UK; 4) Department of Psychiatry, University of Toronto, Toronto, Ontario, Canada; 5) Campbell Family Mental Health Research Institute, Centre for Addiction and Mental Health and Division of Brain and Therapeutics, Toronto, Ontario, Canada; 6) Department of Psychiatry and USC Norris Comprehensive Cancer Center, University of Southern California, Los Angeles, California, USA; 7) Department of Population Health, University of Kansas School of Medicine, Kansas City, Kansas, USA

**Background:** The Nicotine Metabolite Ratio (NMR, 3-hydroxycotinine/cotinine), an index of nicotine metabolic inactivation by CYP2A6, is associated with smoking behaviors and cessation outcomes. However, the NMR cannot be measured in non-, former- or intermittent-smokers, for example in studies of tobacco-related disease risk or for other CYP2A6 drug substrates. The NMR is highly heritable (60-80%) and we previously curated a CYP2A6 weighted genetic risk score (wGRS) for European-ancestry populations (EUR) capturing 33.8% of NMR variance. Several loss-of-function CYP2A6 alleles are unique to African-ancestry populations (AFR), and ~60% of hits identified in an AFR-stratified NMR genome-wide association study (GWAS) were not shared with EUR, warranting the need for an AFR-based wGRS.

**Methods:** Training set: N=954 AFR smokers from two trials (PNAT-II; NCT01314001) and (KIS-III; NCT00666978); replication set: N=216 AFR smokers from a third trial (Q2L; NCT01836276). Variations of the wGRS model included independent GWAS signals along with known functional CYP2A6 \* alleles, calculated as the sum of risk alleles weighted by their effect sizes.

**Results:** The final model consisted of 11 genetic variants, 8 of which are unique to AFR. In the training and replication sets, the AFR wGRS explained 32.2% ( $P<0.001$ ) and 34.3% ( $P<0.001$ ) of the variance in the NMR, respectively. The AFR wGRS demonstrated a fair ability (receiver-operating characteristic curve=0.73;  $P<0.001$ ) to discriminate NMR slow from normal metabolizers. There was a negligible influence of known NMR covariates (e.g. sex, age, BMI) and ancestral population substructure (genomic principal components) on wGRS robustness (unique variance explained=32.0%;  $P<0.001$ ), despite the geographical diversity in recruitment sites in the training set. We combined wGRSs, previously described for EUR and described here for AFR, and using wGRS-stratified analyses were able to replicate previous unique NMR-stratified cessation outcomes between metabolizer groups: the interaction between treatment and NMR metabolizer group was 2.25 ( $P=0.02$ ), compared to 2.12 ( $P=0.03$ ) for treatment and predicted wGRS metabolizer group.

**Conclusions:** We present a useful approach for translating CYP2A6 genotypes into a gene activity score in AFR populations; the wGRS is robust to non-genetic covariates and fine population

substructure. Furthermore, the AFR wGRS is comparable to its EUR wGRS counterpart in its ability to capture NMR variation.

## **PgmNr 450: Pharmacological annotation of polygenic risk in individuals to direct precision intervention in complex disorders.**

---

Individuals with complex disorders typically have a heritable burden of common variation that can be indexed by the summation of their genic risk with respect to genome-wide association summary statistics, expressed as a polygenic risk score (PRS). While each component of polygenic risk has a relatively small effect size and are small targets for therapeutic intervention, we hypothesized that some individuals may harbour significant variation that is specifically enriched in clinically actionable pathways. To test this, we developed a framework, designated the pharmagenic enrichment score (PES), to quantify common variant enrichment in pathways with known drug targets. This approach was exemplified using a cohort of schizophrenia cases, using common variants associated with drug-oriented gene-sets derived from genome wide association study summary statistics. A large proportion of individuals had elevated PES in one or more of eight candidate clinically actionable gene sets identified, including a significant proportion of patients with relatively low genome-wide schizophrenia PRS, and a subgroup displaying treatment resistance. These observations suggest that the PES approach could provide a mechanism to integrate an individual's common variant risk to inform personalized interventions, including drug repositioning for complex disorders, such as schizophrenia.

## PgmNr 451: Epigenetic modification of hypothalamic-pituitary-adrenal (HPA) axis genes *CRHR1* and *CRHR2* may be associated with treatment response in clinical depression.

### Authors:

A.J. Lisoway<sup>1,2</sup>; C.C. Zai<sup>1,2,3,4</sup>; A.K. Tiwari<sup>1,3</sup>; J.L. Kennedy<sup>1,2,3</sup>

1) Molecular Brain Science, Campbell Family Mental Health Research Institute, Centre for Addiction & Mental Health, Toronto, Ontario, Canada; 2) Institute of Medical Science, University of Toronto; 3) Department of Psychiatry, University of Toronto; 4) Department of Laboratory Medicine and Pathobiology, University of Toronto

**Background:** Stress and dysregulation of the HPA axis plays an important role in the development and severity of depressive symptoms. Epigenetic modifications are known to significantly impact the relationship between stress system genes and the environment via the HPA axis but are currently under investigated in regard to their effect on clinical depression and antidepressant treatment. Therefore, we investigated DNA methylation sites across six well-known HPA axis genes and examined their associations with antidepressant treatment response in clinically depressed patients with and without comorbid anxiety.

**Methods:** Clinically depressed patients with complete follow-up data (n=157) were selected from our naturalistically treated sample (IMPACT). Patients were referred to our study for failure to adequately respond, or intolerance to, their psychiatric medication. Saliva samples were collected at enrollment and DNA methylation levels were interrogated using the Infinium HumanMethylation450 Beadchip. Thirty CpG probes located across the promotor regions of *CRHR1*, *CRHR2*, *FKBP5*, *NR3C1*, *NR3C2*, and *SKA2* were selected to quantify methylation levels. Change in depression symptom severity, as assessed by the Beck Depression Inventory (BDI-II), was used to measure antidepressant response and remission status over eight weeks. The relationship between methylation levels and antidepressant response/remission status was investigated using non-parametric tests, linear, or logistic regression.

**Results:** DNA methylation levels at two specific CpG sites within *CRHR1* and *CRHR2* nominally differed between responders/non-responders (p=0.06) and between remitters/non-remitters (p=0.05). Furthermore, when examining these CpG sites, remitters and responders had slightly lower methylation levels as compared to non-responders/non-remitters.

**Discussion:** Lower levels of DNA methylation within HPA axis related genes may be associated with response to antidepressant treatment and improvement in clinical depression. Generally, hypomethylation in promoter regions is associated with increased gene expression. Thus, lower methylation levels across promoter regions of *CRHR1* and *CRHR2* could increase expression of these genes and influence signaling within the feedback loop of the HPA axis. Further pharmacogenetic studies, incorporating genotypes of functional SNPs within these genes, are required to fully

understand the effect of DNA methylation changes on antidepressant treatment outcome.

## PgmNr 452: High rates of genetic diagnosis in psychiatric and neurodevelopmental patient populations: A practical tool to predict and guide genetic diagnosis.

### Authors:

J. So <sup>1,2,3,4,5</sup>; J. Suddaby <sup>1</sup>; V. Sriretnakumar <sup>2,3</sup>; B. Barsanti-Innes <sup>2</sup>; H. Faghfoury <sup>1,4</sup>; T. Gofine <sup>5</sup>

---

**OBJECTIVE:** Although studies of genetic diagnostic rates have been undertaken in patient populations with neurodevelopmental disorders (NDs) and neurological disorders, there is a paucity of literature on genetic diagnosis in psychiatric populations, particularly the vulnerable population of patients with concomitant ND and psychiatric impairment. In this prospective cohort study, we investigated the genetic diagnostic rate in 151 adult psychiatric patients from two centres in Ontario, Canada, including a large subset (73.5%) with concurrent ND, and performed phenotypic analysis to determine the strongest predictors for the presence of a genetic diagnosis.

**METHODS:** Patients 16 years of age or older and affected with a psychiatric disorder plus at least one of ND, neurological disorder, congenital anomaly, dysmorphic features or family history of ND were recruited through the genetics clinics between 2012 and 2016. Patients underwent genetic assessment and testing according to clinical standards. Chi-squared test was used for phenotypic comparisons. Binary logistic regression analysis was performed to determine which phenotypic features were predictive of genetic diagnosis types.

**RESULTS:** There was an overall genetic diagnostic rate of 45.7% in the total cohort, comprising primarily single gene (18.5%) and chromosomal (15.9%) disorders. Schizophrenia was significantly more common in patients with chromosomal disorders, while mood and anxiety disorders were significantly more common in those with single gene disorders. Regression analysis using statistically significant phenotypic associations showed that presence of a single gene disorder diagnosis was best predicted by the combination of having a neurological phenotype, specifically seizures and migraines, mood disorder and family history of ND, while presence of a chromosomal diagnosis was best predicted by the combination of neurological phenotype, specifically migraines, ND and schizophrenia.

**CONCLUSIONS:** Based on the results of this study, we propose a clinical tool to aid physicians working with the psychiatric patient population to determine which individuals would benefit from genetic assessment.

## PgmNr 453: The effect of startle-related genes on anxiety symptom severity at baseline and following pharmacological treatment.

### Authors:

J. Tomasi<sup>1,2</sup>; A.K. Tiwari<sup>1,3</sup>; C.C. Zai<sup>1,2,3,4</sup>; D. Herbert<sup>1</sup>; A. Shahmirian<sup>1</sup>; N. King<sup>1</sup>; N. Freeman<sup>1</sup>; J.L. Kennedy<sup>1,2,3</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Molecular Brain Science, Centre for Addiction and Mental Health, Toronto, Canada; 2) Institute of Medical Science, University of Toronto, Toronto, Canada; 3) Department of Psychiatry, University of Toronto, Toronto, Canada; 4) Laboratory Medicine and Pathobiology, University of Toronto, Toronto, Canada

**Background:** Anxiety symptoms are observed across psychiatric disorders, with these symptoms leading to worse prognosis. Startle response magnitude increases during states of anxiety, and the presence of exaggerated startle reactivity is a strong indicator of anxiety disorder. Furthermore, initial startle reactivity predicts antidepressant treatment outcome in psychiatric populations. Several genes have shown associations with variations in startle reactivity, and the effect of these genes on anxiety symptom severity at baseline and following treatment across psychiatric patients has never been investigated. We hypothesized that startle-related genes will be associated with baseline anxiety symptom severity and/or the change in anxiety symptoms following 8 weeks of pharmacological treatment across psychiatric disorders, and in an anxiety disorder subset.

**Methods:** The sample consists of patients from the pharmacogenetic IMPACT study that provided salivary DNA samples and had anxiety symptom severity determined by the Generalized Anxiety Disorder 7-item (GAD-7) scale. We selected 19 genes and 22 SNPs associated with startle reactivity for a hypothesis-driven gene set analysis. Analyses were conducted in general psychiatric patients (N=508), and in the subsample of anxiety disorder patients (N=298). Linear regressions were performed to examine the effect of the SNPs on baseline GAD-7 score and the change in GAD-7 score after 8 weeks.

**Results:** Across psychiatric patients, two SNPs, one from *MAOA* and one from *NPSR1*, were nominally associated with baseline GAD-7 score ( $p(\text{unadjusted})=0.017, 0.023$ ). A SNP from *NLGN1* was nominally associated with the change in GAD-7 score after 8 weeks across the entire psychiatric sample ( $p(\text{unadjusted})=0.018$ ). Among anxiety disorder patients, nominally significant associations with change in GAD-7 score after 8 weeks were found for a SNP from *ANK3* and a SNP from *CNR1* ( $p(\text{unadjusted})=0.019, 0.043$ ).

**Conclusions:** A subset of genetic variants related to startle reactivity is associated with baseline anxiety severity and the change in anxiety severity following pharmacological treatment across psychiatric patients. This study provides support for exploring startle-related genes to identify biomarkers of pathological anxiety and to predict pharmacological treatment response for patients suffering with anxiety.

## PgmNr 454: Characterization of the retinal phenotype in a humanized FD mouse model with defective *ELP1* splicing.

---

Familial dysautonomia (FD) is an autosomal recessive neurodegenerative disorder caused by a splice mutation in the gene encoding Elongator complex protein 1 (*ELP1*, also known as *IKBKAP*). This mutation results in skipping of exon 20 and tissue specific reduction of *ELP1* protein levels, predominantly in the central and peripheral nervous system. Although FD patients exhibit a complex neurological phenotype due to the degeneration of sensory and autonomic neurons, progressive retinal degeneration severely impacts quality of life. Two different mouse models have been previously generated to study the retinal phenotype that results from complete loss of *ELP1*. However, neither of these models accurately recapitulates the tissue specific defective splicing observed in FD patients. Our recently developed FD mouse model, *TgFD9; Ikbkap*<sup>Δ20/flox</sup>, was generated by introducing the human *ELP1* transgene with the FD mutation into a mouse heterozygous for a hypomorphic *ELP1* allele and a knock-out allele. This mouse exhibits most of clinical features of the disease and, importantly, accurately models the tissue specific splicing defects observed in FD patients. Detailed characterization of the retinal phenotype in this FD mouse model was performed to investigate the pathology associated with the splice mutation in *ELP1*. Optical Coherence Tomography (OCT) analysis to investigate retinal thickness revealed significant reduction in the thickness of the retinal nerve fiber layer (RNFL) when compared to control littermates. Analysis of retinal morphology revealed progressive loss of retinal ganglion cells (RGC's) and significant reduction in outer nuclear layer (ONL) thickness, indicating loss of photoreceptors. RGC cell counting using whole mount retina was also performed to substantiate the loss of RGC's. Our findings suggest that our novel FD mouse model will provide a platform in which to test the *in vivo* efficacy of *ELP1* splicing modulation to increase functional *ELP1* in the retina.

## PgmNr 455: Identifying the genetic cause of retinitis pigmentosa in a multigenerational pedigree using Extremely Low-Coverage Whole Genome Sequencing (XLC-WGS).

---

Retinitis Pigmentosa (RP) is a rare, genetic eye disorder that cause progressive vision loss. RP has a slow progression and late onset and, to date, more than 60 causal genes are known. RP diagnoses are made through ophthalmological examinations. The decreasing cost of next-generation sequencing is providing opportunities to leverage precision genomics to establish molecular diagnoses for a variety of human diseases. Given RP's clinical and genetic heterogeneity, genetic screening may be able to help pinpoint a genetic cause and facilitate its diagnosis. Because whole-genome sequencing (WGS) is still cost prohibitive in a clinical setting, we investigated the utility of extreme low coverage WGS (~0.5X; XLC-WGS) as a cost-effective way to identify causal variants in a multigenerational pedigree with RP. XLC-WGS was performed in 17 members of this pedigree, including 3 individuals with clinical diagnosis of RP. The XLC-WGS data was processed using Illumina's DRAGEN pipeline and filtered using various genotype quality scores (GQX; no filter, GQX ≥ 10, or GQX ≥ 30. The resulting variants from all 3 analyses were passed to 2 independent variant interpretation tools: Expert Variant Interpreter from enGenome and Variant Interpreter from Illumina; both analyses applied ACMG-AMP guidelines. Both programs identified a nonsense mutation (c.1625C>G; p.Ser542Ter) in exon 4 of the retinitis pigmentosa 1 (*RP1*) gene on chromosome 8 as the most likely causal variant. p.Ser542Ter has previously been shown to be causative of a recessive form of RP. XLC-WGS identified 2 homozygous p.Ser542Ter carriers among the 3 sequenced RP cases. This region had insufficient coverage to identify this variant in the remaining case. In addition to these homozygous carriers, 3 non-affected pedigree members were found to be heterozygous for this variant. Improved sensitivity in detecting this variant was observed with the less stringent genotype quality score filters. Although these less stringent filters led to less confident variant calls, coupled with bioinformatic tools to guide variant interpretation, XLC-WGS was able to identify the disease-causing variant in this family. In conclusion, in the context of multigenerational pedigrees, where multiple affected and non-affected individuals are available, we have shown that XLC-WGS is a cost-effective approach that may have clinical utility in detecting pathogenic disease variants that co-segregate in families enriched for genetic disease.

---

Current universal newborn hearing screening programs do not be designed to detect mild, late-onset, and drug-induced hearing loss, nor reveal genetic etiology. The NGS-based test can identify human single nucleotide variations and viral sequence from blood, facilitating the identification of hereditary and acquired hearing loss patients.

In one of our recent study, we screened newborns for 20 hearing loss-related genetic variants from 2012 to 2017. Then, we followed 12,778 genetically non-negative newborns and revealed a higher rate of hearing loss by three months of age among referrals from the initial hearing screening (60% vs. 5.0%,  $P < 0.001$ ) and a lower rate of lost-to-follow-up/documentation (5% vs. 22%,  $P < 0.001$ ) in the genotype-positive group than in the genotype inconclusive group. Importantly, genetic screening detected 13% more hearing-impaired infants than hearing screening alone and identified 2,638 (0.23% of total) newborns predisposed to preventable ototoxicity undetectable by hearing screening. Our results proved that incorporating genetic screening improves the effectiveness of newborn hearing screening programs by elucidating etiologies, discerning high-risk subgroups for vigilant management, identifying additional children who may benefit from early intervention, and informing at-risk newborns and their maternal relatives of increased susceptibility to ototoxicity.

Besides, human cytomegalovirus (HCMV) is one of the main contributors for acquired hearing loss. Previous studies demonstrated when infants with  $>1 \times 10^4$  copies/ml of viral DNA in peripheral blood were at a higher risk for infection-related hearing loss. We then developed an NGS-based test that is capable of detecting deafness-related mutations and HCMV sequence simultaneously from a simulated dried blood spot. The availability of the test would facilitate the detection of HCMV in

newborns at birth without an extra cost. Our pilot results showed that the test is sensitive when the viral load is as low as  $1 \times 10^4$  copies/ml. Thus, we propose that the test, which concurrently detects deafness-related mutations and HCMV, is promising to compensate conventional hearing screening program. A more comprehensive clinical validity and utility analysis is warranted.

## PgmNr 457: *LTA4H* role to montelukast response in asthmatic children and young adults.

### Authors:

C. Maroteau <sup>1</sup>; G. Lassi <sup>1</sup>; S. Young <sup>2</sup>; A. Platt <sup>3</sup>; C.N.A Palmer <sup>4</sup>

[View Session](#) [Add to Schedule](#)

---

Leukotrienes play a central pathophysiological role in asthma. Recent change in NICE guidelines recommend using leukotriene receptor antagonists (LTRA) as an alternative to low dose inhaled corticosteroid (ICS) for both paediatric and adult asthmatic patients. However, 35% to 78% of asthmatics do not respond to LTRA treatment. Several studies have shown that variants in leukotriene pathway candidate genes are associated with interindividual variability in response to montelukast, a selective cysteinyl leukotriene 1 (*cysLT1*) receptor antagonist.

To test the role of one of these variants, regulatory variant rs2660845 in *LTA4H*, in the response to montelukast, we selected and genotyped 88 asthmatics starting montelukast treatment before the age of 18 from the GoSHARE study cohort of Caucasian individuals in the Tayside and Fife areas of Scotland. Non-responders were defined as being on montelukast for at least a year with more than one exacerbation or discontinuing the drug. Responders were defined as taking montelukast for at least a year with no or one exacerbation. An association analysis of the candidate SNP rs2660845 with montelukast response was performed using logistic regression and adjusted for age, gender and date of first salbutamol medication. In addition, a fixed effect meta-analysis was performed on GoSHARE, BREATHE and Tayside RCT paediatric Scottish cohorts' results.

A trend was found between *LTA4H* genotype (regulatory variant rs2660845) and exacerbations in the GoSHARE cohort ( $p=0.062$ ). Response to montelukast in the A/A group was higher (OR = 9.4, 95% CI: 0.6752 – 3.216) than those in the G allele carriers (AG+GG). Reported associations in BREATHE ( $n=210$ ) and Tayside RCT ( $n=62$ ) were respectively OR=4.4, 95% CI: 1.77 – 10.96 and OR=9.6, 95% CI: 1.00 – 92.19. Meta-analysis of those results showed a highly significant association between rs2660845 common variant ( $f_g=0.30$ ) and exacerbation responses to montelukast (OR=5.30, 95% CI: 2.38 – 11.77,  $p=4.29 \times 10^{-5}$ ).

Our study suggested that genetic variation in *LTA4H* may contribute to variability in montelukast response. Individuals under 18 years-old carrying the rs2660845 G allele are significantly less responsive to montelukast treatment, as they have increased risk of exacerbation due to the down regulation of *LTA4H* activity. These findings have the potential to help personalise therapy for individuals with asthma by identifying subgroups of responders to this commonly used medication.

## PgmNr 458: Expression of *SMARCD1* interacts with age in association with asthma control on inhaled corticosteroid therapy.

Chan School of Public Health, Boston, MA; 4) Center for Genes, Environment and Health, Department of Pediatrics, National Jewish Health, Denver, CO; 5) Department of Medicine, University of California San Francisco, San Francisco, CA; 6) Computational Health Informatics Program, Boston Children's Hospital, Boston, MA; 7) Division of Pulmonary and Respiratory Diseases, Boston Children's Hospital, Boston, MA; 8) Centro de Neumología Pediátrica, San Juan, PR

**Background:** Global gene expression levels are known to be highly dependent upon gross demographic features including age, yet identification of age-related genomic indicators has yet to be comprehensively undertaken in a disease and treatment-specific context.

**Objective:** To discover genomic indicators specific to response to inhaled steroids in individuals with asthma by accounting for age-dependent genomic interactions.

**Methods:** We used gene expression data from CD4+ lymphocytes in the Asthma BioRepository for Integrative Genomic Exploration (Asthma BRIDGE), an open-access collection of subjects participating in genetic studies of asthma with available phenotype and gene expression data. Replication population participants were Puerto Rico islanders recruited as part of the ongoing Genes environments & Admixture in Latino Americans (GALA II), who provided nasal brushings for transcript sequencing. The main outcome measure was chronic asthma control as derived by questionnaires. Genomic associations were performed using regression of chronic asthma control score on gene expression with age in years as a covariate, including a multiplicative interaction term for gene expression times age.

**Results:** The *SMARCD1* gene (SWI/SNF-related matrix-associated actin-dependent regulator of chromatin subfamily D member 1) interacted with age to influence chronic asthma control on inhaled corticosteroids, with a doubling of expression leading to an increase of 1.3 units of chronic asthma control per year (95% CI [0.86, 1.74],  $p = 6 \times 10^{-9}$ ), suggesting worsening asthma control with increasing age. This result replicated in GALA II ( $p = 3.8 \times 10^{-8}$ ). Cellular assays confirmed the role of *SMARCD1* in glucocorticoid response in airway epithelial cells.

**Conclusion:** Focusing on age-dependent factors may help identify novel indicators of asthma medication response. Age appears to modulate the effect of *SMARCD1* on asthma control with inhaled

corticosteroids.

## **PgmNr 459: Rapid and ultra-rapid whole genome sequencing in acutely ill neonates: University of California Davis experience.**

---

We report on UC Davis Genomic Medicine experience in collaboration with the Rady Genomic Institute as one of the sites for Project Baby Bear. The Division of Genomic Medicine worked closely with all the key players in NICU, PICU and UC Davis laboratory including neonatologists, intensivists, nurses, NICU and PICU nursing managers, residents, fellows and pediatric surgeons. The initial presentation was by the Rady team in August 2018 during the site visit. This was followed by individual small group presentation to NICU, PICU and Pediatric surgery teams by the UC Davis Genomic Medicine team and flyers were distributed to remind them of the opportunity to perform Rapid and Ultra rapid Whole Genome Sequencing (rWGS & urWGS) through Project Baby Bear. Our Precision Genomic group established a protocol and created flow charts and smart phrases to facilitate the process of identification, recruitment, evaluation and sending of genetic tests. As a screening process for Baby Bear, the PICU and NICU patient list was screened daily to identify potential patients. The UC Davis Children's Hospital pediatric team have in general been enthusiastic participants. Using the inclusion/exclusion criteria provided by Project Baby Bear, a total of 29 patient families have been approached thus far and 25 have consented; three families declined due to "no interest in genetic testing." The clinical presentation of the babies enrolled thus far include arrhythmias, epilepsy, skeletal dysplasia, hydrops fetalis, congenital diaphragmatic hernia, Hirschsprung disease, congenital heart defects, distinct facial features, hypocalcemia, seizures, gastroschisis, failed extubation, tracheomalacia and subdural hematoma/fluid collections. Test results in all 25 individuals have been received: positive: 8/25 (32%), variant of uncertain significance (VUS): 3/25 (12%) and negative: 14/25 (56%). Finding a positive test result made a difference in the management of all babies in whom positive test result was identified. Although negative results did not directly influence management, it prevented further workup for genetic evaluations in the immediate neonatal period for all individuals. The option of rWGS and urWGS is changing the practice of genomic medicine, moving care from symptom-based treatment of illness to targeted treatments and predictive management of potential future health care concerns.

## PgmNr 460: PubCaseFinder and PhenoTouch for differential diagnosis in rare disease.

Next-generation sequencing-based diagnostic tests have been attempted for the diagnosis of affected individuals with suspected rare diseases. The percentage of affected individuals diagnosed by clinical exome sequencing is up to 40% in several studies, unfortunately, other ~60% of affected individuals with suspected rare diseases don't receive a diagnosis. They will likely lose opportunities such as optimization of clinical management and early intervention. In this situation, phenotype-driven differential diagnosis systems such as Phenomizer and GDDP have been implemented in recent years. These systems provide a ranked list of rare diseases on the basis of the phenotypic similarity between an affected individual and rare diseases, and the top-listed diseases represent the most likely differential diagnosis. The performance of these systems is greatly influenced by the quantity and quality of both underlying databases of disease-phenotype associations (DPAs) and end-user input.

To improve the DPA databases, we developed a text mining approach to extend the coverage of DPAs and a phenotype-driven differential diagnosis system PubCaseFinder (<https://pubcasefinder.dbcls.jp>) using published case reports. A series of experiments showed that the performance of PubCaseFinder could substantially be improved thanks to the extension of the DPA database, and our proposed approach is deemed practically useful because manual curation will take enormous time and cost.

Human Phenotype Ontology (HPO) terms are the input to PubCaseFinder as affected individual's phenotypes. However, the existence of a huge number of HPO terms including synonyms and abbreviations preclude the finding of appropriate HPO terms by text search. To address this problem, we developed PhenoTouch, a new phenotype input assistant tool which was implemented in PubCaseFinder. We mapped 3,642 HPO terms to 991 FMA terms using external links, and then we mapped these FMA terms to 2,536 OBJ files of BodyParts3D/Anatomography. PhenoTouch facilitates searching for HPO terms using a human 3D model constructed by these OBJ files. In the case of selecting the region of the mandible in the human 3D model, users can easily get HPO terms related to the mandible such as retrognathia, micrognathia, narrow jaw, and broad jaw which do not include the word "mandible".

We believe our proposed approach and PhenoTouch will be valuable for improving upon phenotype-driven differential diagnosis systems for rare diseases.

## PgmNr 461: Enabling precision medicine in large exome-sequenced cohorts.

---

Precision medicine aims to leverage genetic data of patients and family members to preemptively identify disease risks, prevent or manage disease conditions, and tailor therapeutic choices. At the Regeneron Genetics Center (RGC), we are building a comprehensive database of human genetic variation which currently comprises of exome sequences of about 500,000 individuals coupled with deidentified Electronic Health Record (EHR) data. Such data allow us to identify novel and known genetic variation in the population and systematically evaluate their effect on patient health. To this end, we have implemented a scalable workflow using Spark Resilient Distributed Dataset architecture to integrate various databases of clinically relevant variants, such as ClinVar and Human Gene Mutation Database (HGMD), with RGC's ever growing sequencing and EHR data. Our workflow allows us to query genetic variant databases based on various criteria.

As an example, we discuss our survey of medically actionable variants from the exome sequencing of 50,000 individuals from the UK Biobank. We identify pathogenic (P) and likely pathogenic (LP) variants in the ACMG59 genes list; a set of genes known to cause or predispose individuals to disease and where medical intervention is expected to improve outcome(s) in terms of mortality or the avoidance of significant morbidity. Using a stringently defined "strict" set of pathogenic variants from ClinVar with an assertion criteria of  $\geq 2$  stars, we show that approximately 2% of individuals have an actionable variant. Using more relaxed criteria for defining pathogenic variants provides a larger estimate ranging from 2 -7%. We further analyze the 239 LP predicted loss-of-function (pLOF) variants from the strict set (315 carriers, 0.63%) in genes where truncation is the expected mechanism of disease. We evaluate LP pLOF variants in terms of: 1. Stop causing variants that escape NMD, affect  $< 10\%$  of the protein, 2. non-canonical splice variants, and 3. start-lost variants with alternate initiation sites downstream.

We highlight specific considerations for merging different databases of pathogenic variants, interpreting pLOF variation and the importance of systematic and scalable evaluation of genetic variants. Combining this approach with EHR data will allow us to evaluate novel variants in known disease genes, identify incorrectly reported pathogenic variants and refine pathogenic annotations in terms of penetrance and prevalence.

## **PgmNr 462: First-line preventative genetic screening: Disease penetrance in Tier 1 inherited diseases in an all-comers population is similar to family history selected populations.**

Clinical testing guidelines are focused on family history or demographic/ ethnic background as penetrance estimates for inherited genetic disease are often derived from populations with known disease. It is unknown if disease penetrance in unselected populations will be lower than in selected populations. Here we report on disease penetrance in three inherited autosomal dominant diseases: Familial Hypercholesterolemia (LDLR, PCSK9, APOB), Hereditary Breast and Ovarian Cancer (BRCA1, BRCA2) and Lynch Syndrome (MLH1, MSH2, MSH6, PSM2) in unselected adult volunteers (n = 23,709), who underwent clinical exome sequencing as a part of the Healthy Nevada Project (HNP) in Northern Nevada (Renown Health, Reno, Nevada) from March 15, 2018, to Sept 30, 2018. We identified more than 290 carriers of pathogenic/ likely pathogenic alleles, >80% of which have medical records. We report that over 90% of these carriers are undetected in the medical system with over 80% without any documented family history. In addition, 26% of these carriers have already manifested with disease, with a median age of first presentation of relevant disease at age 60, 45 and 62 for HBOC, LS and FH. When examined more closely, we find that disease penetrance in unselected carriers for LS and FH is not different from carriers identified from family history. 40% of unselected LS carriers present with colorectal or other cancers by age 40, similar to disease registries of LS patients. For FH, we estimate that 50% of unselected FH carriers will present with atherosclerotic related cardiovascular disease by age 60. We also find BRCA carriers have greatly elevated risk for HBOC. With ~90% of disease presentation occurs after 40, and 70% before the age of 65, our experience suggests that a population health based approach to genetic screening in younger patients can provide substantial clinical, economic, and patient benefit.

## PgmNr 463: Feasibility and potential impact of exon skipping as a therapeutic for neurofibromatosis type I (NF1).

---

NF1 is a rare genetic disorder affecting ~1:3000 individuals. Almost all patients develop benign cutaneous and plexiform neurofibromas, but there is also a ~10% lifetime risk for development of malignant peripheral nerve sheath tumors. In addition 40-60% of afflicted children exhibit learning disabilities. NF1 encodes neurofibromin and mutations lead to hyperactivation of the Ras pathway. Current therapeutics primarily target the Ras pathway, but these are not very effective and are limited by toxicity. NF1 is a large protein and it is unclear how critical regions and domains outside the well described Gap-related domain (GRD) are for functionality. Potentially, some are dispensable and can be deleted or skipped through exon skipping which may lead to a truncated but still functional protein, despite genetic mutation. In silico analysis has identified that 45 of 57 total exons could be skipped either as a single exon or two consecutive exons while still maintaining the translational reading frame. We performed additional in silico analysis to predict which exons could be skipped with minimal loss of NF1 function and maximum therapeutic potential. In efforts to identify exon skips that are likely to be asymptomatic we prioritized exon candidates based on: known skips in unaffected individuals, lack of skips reported in NF1 individuals, and exons that are not within critical NF1 functional domains. Next, we performed a cDNA functional screen utilizing a novel Nf1 cDNA system to determine the effects of exon skipping on in vitro NF1 expression and GRD function. Both in silico and in vitro data will be presented. We find that cDNAs representing loss of some exons are able to maintain GRD function. Furthermore, we note that deletion of some exons leads to lower levels of NF1 protein expression presumably due to loss of protein stability. We show that after both GRD function and NF1 expression levels are considered jointly, skipping of specific exons may be therapeutic. This represents a personalized medicine approach for the treatment of NF1.

## PgmNr 464: The genetic diversity gap: Precision medicine is leaving most of us behind.

### Authors:

B. Murarka; P. Fung

[View Session](#) [Add to Schedule](#)

**Affiliation:** Spectrum Bio Bank, Portola Valley, CA.

---

### The Genetic Diversity Gap

The future is here but it won't work for everyone. Specifically, Polygenetic Risk Scores are bringing precision medicine into mainstream medical practice. Unfortunately, in precision medicine, your data source is your destiny. Billions of people will get little benefits from DNA based medical breakthroughs.

Why? 85% of DNA used in research and drug development is from people of European descent. This is creating "The Genetic Diversity Gap" for the vast majority of people. The Genetic Diversity Gap has profound implications on access to precision medicine. Future generations of underrepresented communities face a rapidly compounding problem that will become insurmountable unless we start to address it today.

Spectrum BioBank is the world's only diversity-first genome database. We are a non-profit organization, funded by private donors, fixated on bridging this gap through public awareness of the problem, directly sequencing contributions from underrepresented communities, and enabling inclusive research to close this gap permanently.

Uniquely, we build direct relationships with DNA contributors from underrepresented communities so that our research partners can recontact and engage with these diverse communities. In January of 2020 we'll launch free sequencing for the major underrepresented populations and their extremely heterogeneous subpopulations (Hispanic-Latinos consists of Mexican, Puerto Rican, South American, etc. yet another reason we need this research).

We are a multidisciplinary team of experts from Consumer Genetics, Academia, Software Development, and Customer Acquisition who are passionate about eliminating The Genetic Diversity Gap.

In this talk we will share our plan to solve the gap, our initial research focuses, and a call to action for the ASHG membership to help close the gap.

## PgmNr 465: Automating analyses of high-throughput genotyping global screening array data.

**Authors:**

D.E. Condon; P.F. Cherukuri; L. Carmichael; K. Lubieniecki; J. Lubieniecka; S. Bartaria; K. Meis

[View Session](#) [Add to Schedule](#)

**Affiliation:** Sanford Health, Imagenetics, Sioux Falls, SD.

---

**Background:** Sanford Health is using the Illumina Global Screening Array (GSA) towards implementation of precision medicine and precision public health. GSA allows screening for medically actionable variants and known pharmacogenomic variants among its 661,125 assays. This system needs routine checking for proficiency of laboratory technicians, competency of the system in general, and other potential experiments involving comparisons. In order to facilitate this checking, we developed a pipeline, using Databricks as a platform, that allows concordance checks between experimental test results and known standards, confirming that the GSA is performing as expected.

**Hypothesis:** The GSA requires periodic checking to ensure that the genotyping chip is reporting correct results. We report a system which can easily run concordance using the cluster computing framework Apache Spark on Databricks.

**Methods & Results:** Genotype data is received from the Molecular Genetics Lab in a binary Illumina GTC format and is converted to a per sample Variant Call Format (VCF) file. All sample data within a directory is processed into a single dataframe, which allows for rapid concordance calculation. This allows highly parallel, fast computational analysis of large datasets. The concordance check is done with variable sets for “truth” and “test” datasets. We use the 1000 Genomes project data as a standard of truth set. However, our workflow can be used for other purposes, for example, to verify whether the GSA gives the same results regardless of source tissue, or that the GSA performs the same at different sample DNA concentrations, or whether the location of where GSA data was generated matters. GSA data is received and prepared for analyses on the Databricks platform, which allows highly parallel, fast data analysis of large data sets. The output organizes concordance according to seven types of genotype discordance and five types of genotype concordance. This can compare a single GSA run compared with the 1000 Genomes project in as little as 39 minutes. We have developed a system that automatically runs concordance checks on GSA results, and can compare with other GSA runs and against a 1000 Genomes truth set. This is beneficial for ensuring that results are being reported accurately to the patients. GSA results maintain a high concordance rate with the 1000 genomes project.

**Conclusion:** We have created a system for automated and easy concordance checking of the GSA

## PgmNr 466: Using CRISPR-Cas9 to generate zebrafish models of human disease for drug discovery.

---

Advances in next generation sequencing have greatly accelerated the identification of novel disease-associated gene mutations. However, a prevailing challenge continues to be functional validation of these variants, particularly for rare diseases. We have established the Zebrafish Genetics and Disease Models Facility that combines shared expertise and infrastructure at the Hospital for Sick Children; creating a pipeline from gene identification to functional validation and drug discovery. With a fee for service, cost recovery model, our facility aims to provide the services required to efficiently generate and analyze zebrafish models that accurately recapitulate human disease. We use a high throughput CRISPR-Cas9 mutagenesis system along with high resolution melt (HRM) analysis to generate mutations in zebrafish that are targeted to putative human disease loci. Additionally, we offer zebrafish phenotypic analysis and drug discovery services. To date, we have worked with over 29 individual labs to provide our services including generation of over 35 targeted mutations in over 25 zebrafish genes with a success rate of >85%. Here we present the results of our high-throughput mutation generation effort, as well as the preliminary characterization of our first successful zebrafish mutant strains.

## PgmNr 467: Genetic basis of pharmacokinetic variability in African Americans.

### Authors:

### Affiliations:

1) Department of Pharmacology, Northwestern University, Chicago, Illinois.; 2) University of Chicago, Chicago, Illinois

**Background:** Genetic variation contributes substantially to the differences in drug response and in particular enzyme activity within and across populations. African Americans (AAs) suffer disproportionately from adverse drug reactions. Using the unique genomic architecture of AAs and probe drugs for established drug metabolizing enzymes, we uncovered population-specific SNPs that may explain health disparity in drug response.

**Methods:** Primary hepatocyte suspension cultures derived from 60 AA were treated with four probe drugs for specific cytochrome P450 enzymes (CYPs) [midazolam (CYP3A4/5), bupropion (CYP2B6), mephenytoin (CYP2C19), phenacetin (CYP1A2)] to identify the SNPs associated with metabolite formation rate (MFR) using genome-wide association and imputed gene based methods.

**Results:** We performed four GWAS specific to each probe drug and identified rs35672164 (beta: -0.9,  $p=6.9 \times 10^{-8}$ ) and rs17882547 (beta: -1.1,  $p=2.9 \times 10^{-7}$ ) associated with hydroxy-mephenytoin MFR. Within GTEx, rs17882547 is a multiple-tissue expressed quantitative trait loci (eQTL) for *CYP2C19* and is also in linkage disequilibrium (LD) with *CYP2C19\*2*, associated with poor clopidogrel response, reduced phenytoin metabolism and acenocoumarol maintenance dose. rs35672164 is a non-coding variant within *CYP2C18* and is only found in African ancestry populations. rs73993690 (beta: -2.13,  $p=8.6 \times 10^{-7}$ ) was associated with hydroxy-midazolam MFR and is a blood eQTL for *PRKCA*, a kinase that plays an important role in hepatic CYP3A4 turnover. rs10411010 (beta: -1.15,  $p=1.97 \times 10^{-7}$ ) was associated with hydroxy-bupropion MFR. Lastly, rs264558 (beta: 1.14,  $p=2.35 \times 10^{-8}$ ) was associated with acetaminophen MFR. Gene based analysis using magma identified *CYP2C19* ( $p=1.13 \times 10^{-6}$ ), *CYP2C9* ( $p=9.34 \times 10^{-6}$ ) and *CYP2C18* ( $p=3.34 \times 10^{-6}$ ) to be significantly associated with hydroxy-mephenytoin MFR and *ZIM3* ( $p=2.44 \times 10^{-5}$ ), a Zinc finger-domain gene significantly associated with hydroxy-bupropion MFR. Zinc finger proteins are major regulators of CYP gene expression.

**Conclusion:** We identified common population-specific genetic loci that were significantly associated with probe drug MFR, a clinically relevant endophenotype. The identified genetic loci may represent regulatory variants that predispose individuals to adverse events related to several different classes of medications. Our findings may help towards predicting adverse drug events and improving treatment outcomes in AAs.

## PgmNr 468: Host genome-wide association study of infant susceptibility to shigella-associated diarrhea.

### Authors:

---

Shigella is a leading cause of moderate-to-severe diarrhea in African and South Asian children and the causative agent of shigellosis and dysentery. Associated with 80 - 165 million cases of diarrhea and up to 600,000 deaths annually, exposure to shigella is ubiquitous in many regions while colonization or infection is heterogenous. To characterize the host-genetic susceptibility to shigella-associated diarrhea, we performed two independent genome-wide association studies (GWAS) including 589 Bangladeshi infants, 429 from the PROVIDE birth cohort and 160 infants from a Cryptosporidium-focused study birth cohort in Dhaka, Bangladesh. We classified children as ever having shigella associated diarrhea or not in the first 13 months of life. A qPCR Ct distribution of the ipaH gene, carried by all four shigella species and enteroinvasive E. coli, identified a total of 143 infants with a shigella-associated diarrheal event and 446 infants with no evidence of shigella-associated diarrhea within their first 13 months of life. Host GWAS's were performed using the Illumina Infinium 5 Multiethnic Global Array and analyzed under an additive genetic model. A joint analysis (imputed variants N=6,547,362) identified loci of interest on chromosomes 11 (rs582240, within the *KRT18P59* pseudogene, average MAF=29.4%,  $P = 8.37 \times 10^{-8}$ ) and 8 (rs12550437, within the lincRNA *RP11-115J16.1*, average MAF=38.1%,  $P = 1.69 \times 10^{-7}$ ). This study suggests host genetic factors may influence the response to shigella colonization and pathogen-associated diarrhea. Additional replication and further research on the function of these genes and their association with shigellosis and other pathogen-associated diarrheal diseases is warranted.

## PgmNr 469: Prediction of personalized radiotherapy cytotoxicity score based on transcriptomics data.

### Authors:

**Background:** Radiotherapy (RT) is the one of the most commonly adopted therapeutics to treat cancer. Through ionizing radiation, RT primarily causes irreversible DNA damage to tumor cells which will lead to cell death. Although efforts have been made to improve the quality of RT, a key question remains to be answered is whether exploiting individual tumor biology could benefit patients receiving RT. To address this issue, we aimed to develop a new model to predict personalized RT cytotoxicity score (RT-CTS) using tumor transcriptomics data. This proposed model would then be able to guide the delivery of individualized treatment strategies.

**Methods:** We retrieved publicly available NCI-60 cancer cell line data, i.e. gene expression data, and survival curves. We utilized the linear quadratic (LQ) model to calculate cytotoxicity ( $\alpha$  and  $\beta$ ). First,  $\alpha$  and  $\beta$  in the 60 cell lines were calculated based on the LQ model. Then gene expression data were used to predict  $\alpha$  and  $\beta$  using linear support vector machine with 10-fold cross validation (CV). Finally, the performance of the models was validated using two independent clinical data sets of breast and lung cancer patients. Statistical analysis was based on multi-variable COX regression.

**Results:** Thirteen and seventeen highly informative genes were selected using max-min Markov blanket method to predict  $\alpha$  and  $\beta$ , respectively. The 10-fold CV R-squared was 0.82 (root mean square error (RMSE)= 0.20) for  $\alpha$  and 0.65 (RMSE= 0.03) for  $\beta$ . Using the LQ model, our predicted  $\alpha$  and  $\beta$ , and each patient's RT dosing schedule, we calculated a new score, RT-CTS, to estimate the number of clones of tumor cells killed for each individual patient in the two validation cohorts. In the lung cohort, patients with a predicted RT-CTS  $> 10^{-12}$  (RT-CTS12) had an improved 1-yr local control (LC) (84.3% vs 57.1%,  $p<0.001$ ) and overall survival (OS)(4.8 vs 1.9 yrs,  $p=0.04$ ). In the RT breast cohort, patients who achieved RT-CTS12 had superior 8 yr LC (91% vs 72%  $p=0.03$ ) that is significant on multi-variable analysis (Hazard ratio= 0.29,  $p<0.014$ ).

**Conclusion:** Based on gene expression data, we developed and validated a machine learning model that predicts RT-CTS, an individualized RT cytotoxicity score. The model can be used to provide a personalized RT dosing schedule given tumor cell expression. This study highlights the importance of transcriptomics and its impact on personalized medicine.

## PgmNr 470: Combining clinical and candidate gene data into a risk score for azathioprine-associated leukopenia in routine clinical practice.

### Authors:

P. Anandi; A.L. Dickson; Q. Feng; W. Wei; W.D. Dupont; D. Plummer; G. Liu; K.A. Barker; V.K. Kawai; K. Birdwell; N. Cox; C.M. Stein; A. Hung; C.P. Chung

[View Session](#) [Add to Schedule](#)

**Affiliation:** Vanderbilt University Medical Center, Nashville, TN

### Background/Purpose:

Azathioprine (AZA) is widely used to treat rheumatic diseases and for organ transplantation. However, serious adverse events, such as leukopenia, can limit treatment. Our ability to predict AZA-associated leukopenia is limited to the evaluation of the enzyme thiopurine methyl transferase (TPMT). We hypothesize that a risk score comprised of clinical factors and selected candidate gene variants—in addition to TPMT—could improve the prediction of AZA-associated leukopenia.

### Methods:

This is a case-control study using de-identified records from a clinical practice-based biobank at a tertiary medical center. We identified 425 Caucasian patients who received prescriptions for AZA. Subjects with a leukocyte count of  $<4,000$  WBC/ $\mu$ L while receiving AZA prescriptions were classified as cases. Subjects who did not develop leukopenia were classified as controls. We reviewed the clinical records, collected clinical variables and genotyped 71 genetic candidates of which 60 passed quality control. We built two scores using the coefficients from multivariate regressions. The first model was a logistic regression including TPMT status, age, and sex. The second model also included weight, clinical indication for AZA use, concurrent prescription of other medications, AZA daily dose, and genetic candidates. To avoid overfitting, we used ridge regression for the second model.

### Results:

216 patients had AZA-associated leukopenia and 209 were control subjects. Younger age, lower weight, a lupus diagnosis or organ transplant, and being a carrier of the *TPMT* haplotype were significantly associated with leukopenia. The area under the ROC curve (AUC) of a score based on a regression that included TPMT status, age, and sex was 0.59 (95% C.I.: 0.54-0.64). After shrinkage, the ridge model included 11 clinical and 47 genetic candidates from 8 genes (*TPMT*, *NUDT15*, *XDH*, *MOCOS*, *ABCC4*, *ITPA*, *AOX1*, and *GST*); the AUC of the score from that model was 0.77 (95% C.I.:0.73-0.82).

### Conclusion:

This proof-of-concept study investigates the utility of adding clinical and genetic variables to TPMT to improve discrimination of the risk for AZA-associated leukopenia. After shrinkage, we were able to show that a combined model, including clinical and genetic variants, improved our ability to predict leukopenia. Further studies in larger populations with independent replications are needed to further develop prediction scores that are useful for routine clinical practice.

## PgmNr 471: Implementation of pharmacogenomics into primary care across a large multi-state healthcare system.

---

Individualized medicine – the use of molecular, genetic and other patient specific features to customize patient care – is a paradigm shift in allopathic medicine. There are a number of different approaches to individualizing care, and multiple institutions throughout the United States have established programs for implementing various technologies. Pharmacogenomics (PGx) is among the most advanced and effective forms of individualized medicine to date. PGx utilizes known variation in drug metabolizing enzymes to predict and avoid certain medications based on an individual's genetic makeup. Furthermore, technologies such as programmed clinical decision support (CDS) provide prescribers with drug-gene interactions and therapy recommendations at the point of care, therefore making PGx timely, specific, and actionable.

The individualized medicine initiative at Sanford Health – named Imagenetics (merging Internal Medicine and Genetics) – began offering PGx testing in 2015 starting with *CYP2C19* for clopidogrel activity. An 8-gene prospective PGx panel consisting of *CYP2C19*, *CYP2C9*, *CYP2D6*, *CYP3A5*, *DPYD*, *SLCO1B1*, *TPMT*, and *VKORC1* was subsequently introduced in 2016. This PGx panel has allowed us to capture the majority of drug-gene interactions listed in the Clinical Pharmacogenomics Implementation Consortium (CPIC) guidelines, and additional expansion of PGx tests is currently underway.

Presently, we offer PGx testing to all patients within the Sanford Health system, which consists of more than 2 million patients across 9 different states in the upper Midwest. With a centralized genomic laboratory performing PGx testing across such a large territory, integrated technology is crucial. To maximize utility of the genomic laboratory data, PGx CDS was integrated into the electronic medical record (EMR) across the entire enterprise. Furthermore, clinical pharmacist tools and workflows were implemented to improve efficiency of review. Video conferencing, a centralized information resources (intra web), and a robust online education program are a few of the other tools used to implement and maintain this large PGx program. We present major challenges encountered during our first few years of PGx implementation, and we propose several novel solutions.

## PgmNr 472: Quantifying known and novel actionable pharmacogenetic variations in whole-exome sequencing data of 1,091 Chinese subjects.

### Authors:

Pharmacogenetics (PGx) is an important area of precision medicine. Currently, lack of large-scale exome/genome-wide data precludes clinical application of pre-emptive PGx testing in Chinese. Since whole exome sequencing (WES) data can be used to extract PGx information for individuals undergoing a diagnostic test, we analyze known and novel variants in clinically actionable pharmacogenes in a cohort recruited for the evaluation of pediatric genetic diseases in Hong Kong.

**Methods:** Sequencing data of 1,091 unrelated Chinese subjects in the HKU Pediatric Exome Cohort were analyzed using a two-tiered approach. The 1st-tier analysis targeted known PGx variants based on a curated actionable variants list (PharmGKB Level 1/ ethnic-specific high-confidence variants by literature search). The 2nd-tier analysis focused on discovery of rare, predicted deleterious variants in 121 genes with PharmGKB Level 1 and 2 evidence.

**Results:** We identified 34 PGx variants (28.3%) in the curated variant list, comprising of 41 drug-gene combinations. The most prevalent actionable variant is rs9934438 in VKORC1 (93.8%), followed by rs4244285 in CYP2C19 (40.9%) and rs2108622 in CYP4F2 (39.0%). In addition to known variants, we discovered 106 novel variants in 121 PharmGKB Level 1/2 genes that are i) not found in PharmGKB; ii) <1% in gnomAD ; and have either iii) CADD>20 or REVEL>0.7 (missense variants) or (iii) “high-confidence” annotation in LOFTEE (LOF variants). They are implicated in 125 drug-gene combinations and demonstrate diverse functional effects such as non-synonymous nucleotide substitution (n=93), premature gain of stop codon (n=9) and disruption of reading frame (n=4). Of the 1,091 Chinese subjects, 99.3% harbored at least 1 known actionable PGx variant (median=4) and 56.7% had at least 1 novel predicted deleterious PGx variant. Focusing on warfarin PGx, we observed high occurrence of VKORC1 actionable variants (rs9934438) in Chinese, while actionable CYP2C9 variants were rare compared to Caucasians.

**Conclusion:** To date, this is the largest Chinese PGx study using WES data. We have demonstrated the abundance of known and novel functional PGx variants that are potentially actionable clinically. Since existing large-scale PGx studies include mostly Caucasian subjects e.g. there are only 196 Asians in the eMERGE-PGRNseq study (2.2% of the cohort), this study addresses the unmet research gap and provides further insights into the PGx landscape of Chinese individuals.

## PgmNr 473: Utility of pharmacogenomic dosing intervention in children with chronic disease.

---

**Problem Statement:** Utilizing pharmacogenomic testing (the use of genetics to guide pharmaceutical choice and dosing) in a pediatric patient population has the ability to reduce adverse drug reactions ADRs (unexpected reactions to a drug taken at the recommended dose). This type of implementation has the ability to increase health disparities if racial and ethnic differences in allelic variation, drug utilization, and patient preferences are not part of clinical utility models. Here we determined how racial, and ethnic differences affect clinical utility of a model pharmacogenomic implementation.

**Methods:** We developed a Markov model that simulates a 15 year timeline for a cohort of children, the perspective of the model was that of the individual payer. Children were assigned to a health state with three different levels of disease state, healthy, chronic disease, or complex chronic disease. We assume that genotyping for pharmacogenomic dosing will occur at the time of diagnosis with a chronic disease. The model was interrogated for the cohort with and without a pharmacogenomic intervention. The incremental cost effectiveness ratio (ICER) was calculated. Sensitivity analysis was performed to determine highly influential variables. We further varied the rate of ADRs and the likelihood of benefit for a pharmacogenomic intervention based on racial and ethnic likelihoods.

**Results:** The cohort eligible for genotyping was 5366 individuals. With the assumption that genotyping cost was \$250, approximately 22 QALY's would be saved through genotyping, with an incremental cost effectiveness ratio (ICER) of \$46,777.18. Parameters that are sensitive to racial and ethnic background such as the likelihood that genotyping would affect prescription dosing, the number of QALYs lost from an ADR and the likelihood to have an ADR and are highly influential model parameters (ranked 1st through 3rd) in influence in the sensitivity analysis. Therefore the cost effectiveness varied with race and ethnicity when estimates of the chance of an ADR and the likelihood that genotyping would reduce an ADR were varied by racial and ethnic background. Individuals who were Black or White non-Hispanic were most likely to benefit from a pharmacogenomic intervention. The highest number of scenarios where cost effectiveness was achieved (8 and 4 scenarios) while White- Hispanic and Asian groups demonstrated poor cost effectiveness (1 and 0 scenarios).

---

UnitedHealth Group (UHG) has assembled a panel of academic researchers to assist in the development of a cohort-level pharmacogenomics program for UHG member institutions. The panel includes a synergy of medical geneticist and pharmacogeneticists, charged with identifying drug-gene pairs with potential pharmacogenetic testing to improve drug efficacy as well as economic outcomes.

A total of six working groups were created based on panel member expertise and research interest, and paired with UHG data analysts and economists. The goal was to model and compare a pharmacogenomic test-informed path versus standard care path for each candidate gene-drug pair. The desired outcome was to select one or two candidates to pilot in a randomized clinical trial across multiple sites with future studies to follow. The models were informed by published allele frequencies, evidence-based outcome frequencies, and economic data derived from UHG claims. The models included evidence provided by Clinical Pharmacogenetics Implementation Consortium (CPIC) and the Pharmacogenomics Knowledgebase (PharmGKB).

The majority of gene-drug pair candidates contained genes encoding the cytochromes P450 family of enzymes, including *CYP2D6* (opiates), and *CYP2D6/CYP2C19* (anti-depressants) with the desired outcomes of pain relief and number of prescriptions, and Hamilton depression score changes and number of prescriptions, respectively. *CYP3A5* (tacrolimus) was nominated for immune suppression and less acute rejection of transplants. *TPMT* (thiopurines), and *UGT1A6*, *SLC28A3*, and *RARG* (anthracyclines) were nominated for oncology treatment and the reduction of adverse events. Finally, the *HLA* region was nominated for abacavir, carbamazepine, allopurinol, phenytoin, and various adverse drug reactions.

Besides economic modeling, others implementation factors were considered. For instance, an alternate therapy needed to be identified for an actionable allele. The panel also identified how quickly return of results were needed for an indication, and the range of physician compliance with standard of care. National impact was also a consideration. Details of these elements will be shared. The *CYP2D6* (opiates) project was selected as the first pilot, and trial design and site selection are currently ongoing. We hope our pharmacogenomics program collaboration between academia and industry will serve as a model, and provide a template for future genomic implementation initiatives.

## PgmNr 475: *HLA-B\*51:01* and *CYP2C9\*3* are risk factors for phenytoin-induced eruption in Japanese population: The analysis in the Biobank Japan Project.

### Authors:

---

Phenytoin is one of the most widely used anti-epileptic drugs, and therefore it is important to prevent adverse reactions due to phenytoin from happening in order to provide timely therapy. In East Asians, *CYP2C9\*3* and *HLA-B\*15:02* alleles were reported to be associated with phenytoin-induced eruption; however these results were not readily applicable for Japanese population given the small sample sizes used in those previous studies for *CYP2C9* and also the extremely low frequency of *HLA-B\*15:02* in Japanese population. In this study, we aimed to investigate the risk alleles in the Japanese population using the samples and data of BioBank Japan Project. A total of 747 patients were selected for the analyses, comprising 24 cases and 723 tolerant controls. Cases are the patients who developed, and tolerant controls are those who did not develop the phenytoin-induced eruption. Among the 24 patients that had a phenytoin-induced eruption one was with erythema multiforme, four were with erythema, one with erythroderma, one with fixed drug eruption, and two with maculopapular exanthema. We genotyped DNA samples of cases and tolerant controls for *CYP2C9\*3*, *CYP2C19\*2* and *CYP2C19\*3*, by multiplex PCR, which was followed by Invader assay. *HLA-B* four-digit allele genotyping was performed on a Luminex 200 system, using a WAKFlow HLA typing kit. Subsequently, case-control association tests were conducted on the genotype data for the *CYP2C9\*3*, *CYP2C19\*2*, *CYP2C19\*3* and *HLA-B* alleles. We have found that *CYP2C9\*3* carrier status was significantly associated with phenytoin-induced eruption ( $P=0.0022$ , odds ratio 7.1, five carriers in cases (21%) and 26 carriers in tolerant controls (3.6%)). Additionally, significant association was identified for the *HLA-B\*51:01* ( $P=0.010$ , odds ratio 3.2, nine carriers in cases (38%) and 114 carriers in tolerant controls (16%)). Lastly, the area under the receiver operating characteristic curve was improved by 10% by including the *HLA-B\*51:01* as well as *CYP2C9\*3* in the predictive model to predict the risk of eruption which was developed by using multiple logistic regression analysis. Thus, we conclude that checking the carrier status of *CYP2C9\*3* and *HLA-B\*51:01* alleles before starting phenytoin administration can potentially reduce cases of eruption in clinical practice. This work was supported by JSPS Core-to-Core Program, A. Advanced Research Networks.

## PgmNr 476: A comprehensive landscape of CYP2D6 variation across 30,000 individuals.

More than one hundred CYP2D6 star alleles (haplotypes of the CYP2D6 gene) are listed in the Pharmacogene Variation Consortium (PharmVar) database, but commercial pharmacogenomic analyses only test for a minor fraction of these, often missing alleles that are common in certain populations. This is due, in part, to structural rearrangements in CYP2D6 (such as the CYP2D6\*36 and CYP2D6\*68 alleles) that require novel analytical tools and custom assay design to guarantee high confidence allele calls. These arrangements cannot typically be ascertained by off-the-shelf assays. This gap between alleles that are known to exist and alleles that are reported in tests can lead to mischaracterization of an individual's CYP2D6 genotype. In the clinical setting, this misclassification may result in prescriptions that are harmful to the patient. In the research setting, misclassification means poor quality input data for association tests. We have developed a clinically validated pipeline that calls 106 CYP2D6 star alleles listed in the PharmVar database, including CYP2D6\*36, CYP2D6\*59, and CYP2D6\*68, which occur with nontrivial frequency but are not typically reported. This pipeline is built on Helix's Exome+ assay and achieves over 99% accuracy without requiring orthogonal assay supplementation. Here we present the results of applying this pipeline to 30,000 exomes, providing an unprecedented characterization of CYP2D6 genotypic diversity in the US population.

## PgmNr 477: Analyses of core and extended pharmacogenes in sickle cell disease patients in Africa.

---

Sickle cell disease (SCD) is a multisystem genetic disorder that results in organ damage, specifically in the cardiovascular system (stroke, acute chest syndrome, and kidney dysfunctions), and increased susceptibility to infections. Thus, most SCD patients are subjected to the long term administration of hydroxyurea (HU) and opioid therapy in addition to various other medications with variable responses to such therapies. High variability in individual responses to HU treatment and other therapies of importance to SCD have been reported. The extend to which polymorphisms in genes involved in drug absorption, distribution, metabolism and excretion (ADME) contribute in-part to the high heterogeneity of drug responses has not been explored in SCD patients from African populations.

This study focuses on 32 core and 267 extended pharmacogenes from the PharmacoScan platform to systematically investigate genetic variations in ADME genes in Cameroonian population. Specifically, we (1) assess minor allele differences in SCD patients versus ethnically matched Cameroonian controls (2) evaluate variant associations to a range of clinical factors: a “long survivor group” (age over 40 years), a “stroke group” (at least one episode of overt stroke), and a “random group” (patients younger than 40 years with no cerebrovascular disease) and (3) assess correlations between variants to endophenotypes of therapeutic importance (vaso-occlusive crises (VOC), HU, fetal hemoglobin (HbF) and stroke) to variants in the core and extended genes.

No statistically significant differences in allele frequencies were detected between SCD cases and controls, also no correlation between clinical variability and variants in the core genes was detected. Two SNPs in the pharmacogenes were significantly associated with VOC (*SLCO4A1*- rs118042746,  $p=1.21e-07$ ; *UGT1A10*, *UGT1A8*- rs10176426,  $p=1.22e-07$ ). To our knowledge this is the first study to report an association between these two SNPs and VOC. In particular no correlation was detected between variants in the pharmacogenes and key therapeutic indicators such as HbF and variability in response to HU. This finding highlights the lack of influence of core and extended pharmacogenes in ADME in African populations, including SCD patients. Therefore, it supports the need to invest in research exploring population-specific drug design, targeting and efficacy, for improved clinical management of patients of African descent.

## PgmNr 478: The clinical utility of self-identified race/ethnicity compared to genetic ancestry for predicting drug response in U.S. populations.

---

The practical utility of race and ethnicity in clinical settings remains a matter of considerable controversy. We explored this issue in the context of pharmacogenomic (PGx) variants, which can be used to predict how individual patients respond to drugs. Previous studies have shown that PGx variant frequencies differ substantially among genetic ancestry groups, suggesting group-specific response probabilities for a number of commonly prescribed medications. However, the extent to which self-identified race/ethnicity (SIRE) actually serves as proxy for genetic ancestry has been called into question, particularly for modern populations with high levels of admixture. The goal of this study was to evaluate the relative utility of SIRE versus genetic ancestry for predicting drug response in a modern, cosmopolitan population. We analyzed a cohort of 8,629 individuals from the United States (US), for whom we had both SIRE information and whole genome genotypes. We focused on the three largest SIRE groups in the US: White (5,927), Black (1,527), and Hispanic (1,174). Whole genome genotypes were used to characterize individuals' continental ancestry fractions – European, African, and Native American – and individuals were clustered into three groups according to either (1) their SIRE labels or (2) their continental ancestry profiles. We then explored the extent to which PGx variant frequencies differ among the SIRE groups compared to genetic ancestry groups. SIRE and continental ancestry are highly correlated for the major US race/ethnic groups; continental ancestry alone predicts individuals' SIRE with 96.24% accuracy. The relationship between SIRE and ancestry differs among groups, with the highest correlation seen for self-identified Whites and the lowest seen for Hispanics. There is substantial variation of PGx variant frequencies among both the SIRE and ancestry defined groups, consistent with the influence of population structure on drug response. Use of continental ancestry, an objective measure of genetic diversity, does not yield an overall increase in PGx variation compared to the more subjective SIRE labels. Nevertheless, the utility of SIRE as a PGx predictor is dependent on the specific group; racial groups carry more information than the pan-ethnic Hispanic label. Our results demonstrate that SIRE contains clinically relevant information on predicted responses to certain medications, which remains useful in the absence of patient genetic data.

## PgmNr 479: Enrollment of diverse populations in the INGENIOUS clinical trial.

### Authors:

---

Recruitment of diverse populations and patients living in Medically Underserved Areas and Populations (MUA/P's) into clinical trials is a considerable challenge. For example, representation of African Americans in pharmacogenetic trials are often low and insufficient to identify genetic variation within and between racial populations. Thus, less information is often available about genetic variation that impacts drug responses in these patients. To identify variables that predict enrollment in a diverse underserved population, we analyzed the recruitment data from the INGENIOUS pharmacogenomics implementation clinical trial. We used a predictive logistic model to test variables in patients from the Eskenazi Health (EH) and Indiana University Health (IUH) care systems that predict successful enrollment into the trial, after patients were successfully contacted by research recruiters. We also evaluated the reasons why clinical trial eligible patients refused enrollment. At EH, 1) African Americans were less likely to refuse the study than nonHispanic-whites, (OR 0.68, 95% CI: 0.53-0.86),  $p=0.002$ . 2) Other minorities were more likely to refuse the study than nonHispanic-whites, (OR 1.58, 95% CI: 1.02-2.45),  $p=0.04$ . 3) When age increased by 1 year, the odds of refusing the study increased by 2%, (OR 1.02, 95% CI: 1.02-1.03),  $p<.001$ . At IUH, 1) African Americans were also less likely to refuse the study than nonHispanic-white participants (OR 0.64, 95% CI: 0.53-0.76),  $p<.001$ . 2) As age increased by 1 year, the odds of refusing the study also increased by 2% (OR 1.02, 95% CI: 1.02-1.03),  $p<.001$ . 3) Females were less likely to refuse the study than males (OR 0.81, 95% CI 0.72-0.95),  $p=0.01$  and 4) those not living in MUA/P's were less likely to refuse the study than those living in MUA/P's (OR 0.81, 95% CI 0.70-0.94),  $p=0.007$ . Barriers to enrollment from prospective patients include a lack of interest, being too busy, transportation and illness, and rarely a lack of trust. The successful recruitment of diverse patients was likely due in part to the exposure to many research studies across the sites and recruitment by diverse and skilled clinical researchers. In conclusion, diverse and underserved populations can be effectively recruited to pharmacogenomic clinical trials and addressing barriers that prospective patients reported may increase participation across all populations, even more.

## **PgmNr 480: CC-CKAT: A fast and powerful method for SNP-set joint test of prognostic and predictive effects in pharmacogenomics studies.**

**Authors:**

J. Shen; H. Zhang; D. Mehrotra

[View Session](#) [Add to Schedule](#)

**Affiliation:** Merck & Co., Inc., Kenilworth, New Jersey.

---

Many statistical methods have been developed for SNP-set analysis in sequencing studies, mainly focusing on discovering prognostic genetic markers. However, a patient's clinical outcomes may be influenced by either prognostic, predictive or both factors in pharmacogenomics (PGx) scenarios. Very few statistical methods were developed to jointly test the SNP-set-based main genetic effect and the genotype by treatment interaction effect. Here we propose a Cauchy Combined Composite Kernel Association Test (CC-CKAT), a fast and powerful composite kernel machine regression method for the joint effect test by leveraging the efficient computation advantage of the recently developed Cauchy p-value combination method. First, an adaptive weighting method is proposed to construct the multiple composite kernels capturing the potentially unbalanced strength proportions of the main effect and interaction effects and then the individual composite-kernel-level p-values are combined using the Cauchy p-value combination method. The proposed CC-CKAT method is compared with the existing method rareGE and another method CKAT we have recently developed, which adopts the same composite kernel machine regression framework; but uses the minimal p-value (minp) approach to calculate final p-value. Through analysis of extensively simulated data and the whole exome sequencing data from a Merck PGx study with the *Clostridium difficile* Infection recurrence in patients treated with bezlotoxumab, we demonstrate that the proposed CC-CKAT provides better type I error control and power performance across multiple scenarios and runs much faster than the alternative methods.

## PgmNr 481: Genetic correlations and exploration of uterine fibroid clinical phenome in black and white women.

### Authors:

B. Mautz <sup>1,2</sup>; S.H. Jones <sup>3</sup>; E.S. Torstenson <sup>1,2</sup>; J.N. Hellwege <sup>2,4</sup>; T.L. Edwards <sup>1,2,3</sup>; D.R. Velez Edwards <sup>2,3,5,6</sup>

---

Uterine fibroids affect up to 70% of women by menopause, disproportionately impacting black females. Prior studies have investigated a limited set of clinical factors associated with fibroid risk in both groups. Moreover, the genetic relationship underpinning fibroids and other diagnoses remain unexamined. Electronic health records (EHR) and publicly available genome-wide association study (GWAS) data provide a unique opportunity for a comprehensive, agnostic investigation of the fibroid phenome and genetic correlations. Utilizing the Vanderbilt University Medical Center EHR database, cases and controls in black (N = 3,568 cases; 12,521 controls) and white women (N = 7,577; 60,296) were identified using a validated method verified by imaging. We conducted race-stratified phenome-wide association studies (PheWAS) to test for association of fibroid case/control status with diagnostic code-based outcomes in models adjusted for body mass index (BMI) and age at diagnosis. We grouped outcomes into standard categories and tested for over- and under-representation and effect direction using hypergeometric and sign tests. We identified publicly available GWAS for significant PheWAS associations and known fibroid risk factors such as BMI and hypertension. Using LD Score Regression and our own fibroid GWAS summary statistics, we estimated the genetic correlation between traits. We detected 228 and 444 diagnoses that were significantly associated with fibroids in blacks and whites, respectively. Associations were over-represented in the genitourinary category (blacks  $P = 1.03 \times 10^{-20}$ ; whites  $P = 1.03 \times 10^{-14}$ ). Odd ratios of significant diagnoses in dermatological, genitourinary, endocrine/metabolic, and musculoskeletal categories trended in the risk direction. Across racial groups the most significant PheWAS associations were known fibroid symptoms (e.g. excessive menstruation,  $P < 1.0 \times 10^{-274}$ ; dysmenorrhea,  $P < 2.58 \times 10^{-152}$ ). We also detected numerous novel associations including malignant and benign cancers, endometriosis, and coronary atherosclerosis ( $P < 2.56 \times 10^{-15}$  for blacks and whites). We did not detect any significant fibroid-trait genetic correlations in either race, though we observed a suggestive negative relationship of fibroids with type 2 diabetes in blacks ( $r_g = -1.21$ ,  $P = 0.09$ ). These results provide novel insight into the fibroid phenome. More thorough analyses of genetic correlations are underway.

## PgmNr 482: Comparison of genetic testing approaches for implementation of preemptive pharmacogenomics.

---

**Background:** Preemptive pharmacogenomics (PGx) leverages lifelong reusability of genomic data to guide downstream prescribing and individualization of medications. Advancements in technologies now offer varied approaches for testing of PGx. The present study sought to evaluate performance of whole genome sequencing (WGS) and probe-based testing by concordance of variant-level calls, particularly in clinically important genes, with a CLIA-certified reference lab.

**Methods:** In an IRB-approved volunteer study, blood and saliva samples were obtained. Control DNA samples were purchased (Coriell Institute, Camden, NJ) to test rare and structural variants. Samples were blinded and analyses were performed by a CLIA-certified reference lab (n=94, OpenArray, Indianapolis, IN), ThermoFisher Scientific (n=94, PharmacoScan, Santa Clara, CA), and UPMC Genome Center (n=72, WGS, Pittsburgh, PA). Raw data, VCF files generated through Axiom Analysis Suite v4.0, and genomic VCF files were compared between labs, respectively. Concordance was determined as number of matching variant-level calls divided by total calls, excluding undetermined, failed, and no calls.

**Results:** A total of 111 and 114 variants analyzed by PharmacoScan and WGS, respectively, were evaluated for concordance with the CLIA-certified reference lab's clinical array. Variants were represented in 10 clinically important genes with high levels of evidence. *CYP2D6* copy number variation (CNV) was evaluated between PharmacoScan and the CLIA reference lab. Overall variant-level concordance between PharmacoScan and the CLIA reference lab (n=91) was 99.7% and *CYP2D6* CNV reached 100% concordance. Paired blood and saliva samples (n=20) tested on PharmacoScan were 99.7% concordant. Variant-level concordance between WGS and the CLIA reference lab (n=72) reached 96.14% and differed primarily in *CYP2D6*.

**Conclusion:** Both testing approaches had high overall concordance between platforms. PharmacoScan was also highly concordant within platform in paired blood and saliva samples. Given clinical importance of *CYP2D6*, probe-based testing may be considered more favorable than short-read sequencing for PGx testing at this time. Integration of the PharmacoScan solution for clinical implementation of PGx is underway.

## PgmNr 483: Precision medicine 2.0: Integrate precision medicine into clinical practice.

**Authors:**

Z. Gu; G. Hu

[View Session](#) [Add to Schedule](#)**Affiliation:** Admera Health, South Plainfield, NJ

---

**Background:** Physicians are becoming increasingly interested in electronic clinical decision support (CDS) for precision medicine. Improved decision support delivered through use of real-time information that combines clinical and pharmacogenomics (PGx) data has the potential to improve physicians' ability to make personalized drug therapy decisions. CDS embedded in the Electronic Health Records (EHR) systems, that connected with Laboratory Information System (LIS), might provide a potential for delivering such support of interpreting patient specific genetic data for precision medicine.

**Methods:** A PGx CDS was developed and built to support personalized drug therapy. The PGx knowledgebase was built based on FDA, CPIC, PharmGKB data to provide accurate clinical interpretation. Multiple EHR/EMR systems were integrated with LIS utilizing HL7 messages, system API, etc. The prototype CDS was developed within Cerner environment. AWS instances and S3 buckets were used to build mobile application and data warehouse for a crisp, secure, HIPAA compliant APP which can be accessed by physicians and patients.

**Results:** An active CDS was implemented with alert messages in the Cerner's medication order entry context to provide support for prescribing decisions. For a patient who had Admera's PGxOne Plus test, the patient's personal results will be incorporated within Cerner's system, where a physician would receive an alert message if the prescribing medication has a non-normal clinical interpretation, such as consider alternatives or dosage change. A semi-active CDS was implemented with drug interaction warning messages in the Admera APP's Modify Current Medication menu. A physician could modify his/her patients' current medication list to check if there would be any drug to drug interaction, drug to food interaction, drug to alcohol interaction, etc. before finalizing.

**Discussion:** With the experience of prototype CDS within Cerner environment, an improved solution to host a data warehouse with Fast Healthcare Interoperability Resources (FHIR) API that contains clinical interpretation data from LIS has been proposed. This solution can provide standardized interpretation data to different systems with minimum compatibility requirement. This in turn will constitute the core component of integrating precision medicine into clinical practice.

## PgmNr 484: Genotyping On ALL patients (GOALL): Clinical implementation of high-throughput genotyping arrays.

### Authors:

J.G.J. Rooij; J.M.H. Verkerk; B. Sedaghati-khayat; L. Broer; J.H. de Vries; G.M. van Dijk; J.B.J. van Meurs; A.G. Uitterlinden

---

**Introduction:** Genetic testing is increasingly used in standard clinical practice for most clinical disciplines. However, genetic tests are expensive and/or must be rerun when additional clinically relevant variants/genes are identified. Dense genotyping arrays (such as GSA or PMDA) cover a large portion of genetic variation and provide a cost-effective, high-throughput and highly standardized alternative. In the GOALL project, we are determining the clinical utility and applications of genotyping arrays.

**Methods:** We investigate the clinical utility of the GSAMD\_v2 and PMDA arrays by: 1) technical validation of common (vs. WES) and rare variants (vs. clinically determined genotypes by different methods), 2) prospectively offering polygenic risk scores (PRS) as primary utility in daily clinical practice, 3) prospectively counseling and testing eligibility of feeding back secondary findings (pharmacogenomics, ACMG mutations) using array based genotyping. We are piloting these applications in collaboration with the departments of Oncology (breast cancer), Ophthalmology (age-related macular degeneration), Clinical Chemistry (pharmacogenomics), Clinical Genetics (counseling) and Public Health within the Erasmus Medical Centre.

**Results:** The GSAMD\_v2 array contains 12,755 clinical variants from the ClinVar database. Our preliminary results suggest that >90% of the clinical mutations and >80% of the pharmacogenetic markers routinely determined in our hospital are covered by the array design (e.g. *APOE*, *MTFHR*, *F5* and *HLA/CYP450* etcetera). We are currently selecting carriers of clinically relevant mutations to check genotyping concordance. Comparison of array vs. WES of 197 population samples shows an overall non-reference concordance of 98%, and 95% for singletons among ~30,000 directly genotyped variants and respectively 97% and 93% among ~150,000 imputed variants (QUAL>0.8).

**Discussion:** Our preliminary results suggest that a portion of current hospital-wide clinical genetic testing can cost-effectively be replaced by array-based genotyping. In addition to reporting highly concordant results, array-based genotyping allows additional reporting of several PRS and pharmacogenomics (*HLA/CYP450*). This data can easily be stored and re-analyzed when additional genetic loci or PRS are identified, or unblinded when a patient needs further genetic testing not part of the initial primary clinical question.

## PgmNr 485: Harmonizing clinical sequencing and interpretation for the eMERGE III Network.

### Authors:

---

As Precision Medicine moves closer to routine clinical practice, new methods to produce and deliver complex, heterogeneous data to physicians and patients are required. As part of the eMERGE III project, we have built a network of eleven participant collection sites and two clinical genetic testing laboratories, which has served as an ideal environment to implement, develop and evaluate such methods. DNA capture panels targeting 109 genes and 1500 SNP sites were used for testing DNA from 25,015 participants and the sample collection, data generation, variant interpretation, report generation, report delivery and data storage were each harmonized. A compliant and secure environment was provided for storage of clinical reports, which contain participant PHI, and we employed system of ongoing review and reconciliation of clinical variant interpretations. Variant information was also deposited into ClinVar. Throughout the project, a high level of communication and data sharing between clinicians and investigators provided feedback on these systems.

Two hundred and six participants had positive diagnostic findings relevant to the indication for testing while 1,276 had additional/secondary findings of medical significance deemed to be returnable, establishing data return rates for other testing endeavors. This study accomplished the creation of harmonized structured genomic results that is enabling efforts to integrate these results into multiple electronic health record systems, setting the stage for clinical decision support to enable genomic medicine. Clinical sites also evaluated pharmacogenomic data, with one opting to incorporate it into their medical records. The established processes enable different sequencing sites to harmonize technical and interpretive aspects of sequencing tests, a critical achievement towards global standardization of genomic testing. Many eMERGE protocols and tools are available for widespread dissemination.

## PgmNr 486: Mapping impact of plasma proteins on dental diseases: A Mendelian randomization study.

### Authors:

D. Shungin<sup>1,2</sup>; G. Hindy<sup>1,3</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Broad Institute of MIT and Harvard, Cambridge, Massachusetts; 2) Umea University, Sweden; 3) Lund University, Sweden.

**Background** Dental diseases account for a large morbidity burden and healthcare spending, while their proteomics characterization remains largely unknown despite that variation in multiple plasma proteins represents a variety of important biological mechanism and is a major source for drug targets. Recently published studies identified genetic basis of human plasma proteome, potentiating studies on causal inference between proteins and complex disease traits with a help of Mendelian Randomization approach (MR). Emergence of such studies opens new horizons to generate hypotheses about potential novel drug targets for complex diseases, including for key dental diseases. The aim of the study was to assess the causal effect of plasma proteins on oral health

**Methods** We used two-sample MR approach to estimate effects of proteins for the two major dental diseases: caries and periodontitis. We utilized summary statistics from meta-analysis of GWAS with clinical and self-reported data for periodontitis and caries (Shungin et al, 2019), and summary statistics from GWAS for proteins (Sun et al, 2018). We constructed instruments for each protein using common variants (MAF > 0.01) associated with the plasma protein levels at two significance thresholds ( $p < 0.01$  and  $p < 1e-05$ ) and located in the respective encoding genes or 300 kb flanking regions followed by pruning ( $r^2 < 0.1$ ). Two sample inverse-variance weighted (IVW) MR was used to test for causal associations between proteins and dental phenotypes. Sensitivity analyses using MR-Egger and the weighted median estimator were used to correct for possible pleiotropic bias.

**Results** Around 1100 proteins had 3 or more SNPs that were used as instruments in the MR analyses. We identified several proteins implicated in caries and periodontitis at the stringent significance level ( $p < 1e-05$ ). Among the prioritized causal associations, we observed targets that have been previously implicated in etiopathology of dental diseases, such as *LCT* ( $\beta_{IVW} = 0.014$ ,  $P = 1.55e-17$ ) and *AMY1* ( $\beta_{IVW} = 0.03$ ,  $P = 9.5e-11$ ) for caries, and *SIGLEC14* ( $\beta_{IVW} = -0.01$ ,  $P = 7.2e-06$ ) for periodontitis, confirming validity of the utilized prioritization approach for pQTLs. We have further identified previously not reported proteins implicated in caries and periodontitis that might serve as potential drug targets.

**Conclusion** This study highlighted causal roles of protein biomarkers for the two key dental diseases using MR analysis, pointing at potential drug targets.

## PgmNr 487: *GRK5* polymorphism affects $\beta$ 2-agonist response in preterm labor patients.

### Authors:

J. Chung <sup>1</sup>; S. Hwang <sup>1</sup>; J. Yee <sup>2</sup>; J. Park <sup>2</sup>; K. Lee <sup>3</sup>; Y. Kim <sup>4</sup>; H. Gwak <sup>2</sup>

[View Session](#)[Add to Schedule](#)

### Affiliations:

1) College of Pharmacy, Hanyang University, Ansan, Gyeonggi-do, 15588, Korea; 2) College of Pharmacy and Division of Life & Pharmaceutical Sciences, Ewha Womans University, 52 Ewhayeodae-gil Sedaemun-gu, Seoul 03760, Korea; 3) College of Pharmacy, Chungbuk National University, Osongsaengmyeong 1-ro, Osong-eup, Heungdeok-gu, Cheongju-si, Chungcheongbuk-do 28160, Korea; 4) Department of Obstetrics and Gynecology, Ewha Womans University Mokdong Hospital, 1071 Anyangcheon-ro, Yangcheon-gu, Seoul 07985, Korea

---

**Purpose:** Ritodrine, a tocolytic  $\beta$ 2-agonist, has been used extensively in Europe and Asia despite its safety concerns. This study aimed to examine the contribution of most frequent single nucleotide polymorphisms of G-protein Kinase 5 (*GRK5*) to efficacy and adverse effect of ritodrine in preterm labor patients.

**Methods:** A total of 164 preterm labor patients were included in this study. Seven single nucleotide polymorphisms of the *GRK5* gene (rs915120, rs2230345, rs2230349, rs7923896, rs1020672, rs4752308, and rs4752292) were assessed. The primary endpoints were time to delivery and proportions of women who remained undelivered. The secondary endpoint was ritodrine-induced adverse drug events (ADEs). To predict the possible effects of given variants on splicing, *in silico* analysis was performed.

**Results:** The mutant type homozygote carriers of rs4752292 and rs1020672 had 0.6 times the hazard of delivery than those with the wild-type allele (95% CI, 0.41~0.98 and 0.38~0.97, respectively). Proportions of patients who remained undelivered at 7 days after initiation of ritodrine therapy were significantly higher in patients with variant homozygote carriers of rs4752292 and rs1020672 than the wild-type allele carriers. In addition, patients with variant homozygotes of rs4752292 and rs1020672 had 2.5- (95% CI, 1.15-5.28) and 2.3-fold (95% CI, 1.06~5.13) ADEs compared to those with the wild-type carriers. *In silico* analysis showed that both rs4752292 and rs1020672 had the potential to affect mRNA splicing by alteration of splicing motifs.

**Conclusion:** This study demonstrates that the pharmacodynamics of  $\beta$ 2-adrenergic receptor targeted therapy is associated with *GRK5* polymorphisms in patients with preterm labor.

## PgmNr 488: Leveraging tensor decomposition to extract biological processes underlying drug treatments.

---

Decomposition of transcriptome matrixes has been useful to understand the biological processes underlying tumor heterogeneity, tissue specificity and responses to perturbations. Here we apply a Bayesian tensor decomposition approach to the transcriptome (three axes correspond to individual \* drugs \* genes) measured on 60 African American (AA) primary hepatocytes before and after treating with 6 different enzyme-inducing drugs in order to understand commonalities and specificities underlying transcriptomic changes to drug exposures.

We identified 5 robust latent components (C1-C5) through hierarchical clustering of the components across 10 runs. The clustering of the robust components confirms known drug similarity (Carbamazepine and Phenytoin have a common mechanism of action for the treatment of epilepsy). Omeprazole has the largest divergence from other drug expression profiles and is enriched in C5 which was highly weighted for differentially expressed drug metabolism genes, *CYP1A1* and *CYP1B2*. *CYP1A1* is responsible for the metabolism of estrogens, which are known to differ between populations. Altered enzyme activity has been linked to breast, colon and ovarian cancers, all of which show profound health disparities. C1 highly differentiates Omeprazole from phenytoin and was enriched in genes related to response to cytokines. C3 corresponds to gender differences which feature *XIST*. Interestingly, the weight of C3 is higher in drug treatment conditions compared with baseline, suggesting that gender difference in gene expression is enlarged upon drug treatment.

We also performed genome-wide association analysis using these derived components as the phenotype. We found associations between C1 and rs2518683 and the SNP is previously associated with platelet count ( $p=2.649e-07$ ). C1 has the highest component in phenytoin which is known to cause thrombocytopenia (decreased platelet count). Importantly, this cardiovascular phenotype is highly relevant to AAs.

Together, our tensor decomposition analysis, 1) illustrates the structure of hierarchical similarity of expression profiles with drug treatment 2) extracts rich features specific to individuals and drugs as well as clinically important underlying genes. These findings highlight the potential of applying tensor decomposition to multi-omic datasets such as GTEx and CMap to deconvolute the effects of the individual, condition and their interaction with respect to the transcriptome variation.

## PgmNr 489: Multi-ethnic single nucleotide polymorphism (SNP)-based screening of pharmacogenomic HLA alleles implicated in drug-induced hypersensitivity reaction.

### Affiliations:

1) Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, New York.; 2) Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY 10029; 3) Institute for Personalized Medicine, Icahn School of Medicine at Mount Sinai, New York, NY 10029

Drug-induced hypersensitivity reactions are life-threatening adverse events that have been strongly associated with specific human leucocyte antigen (HLA) alleles. Among the reported pharmacogenomic *HLA* risk alleles, clinical practice guidelines and/or FDA/EMA testing recommendations are currently available for *HLA-B\*57:01* (abacavir), *HLA-B\*15:02* (carbamazepine, phenytoin) and *HLA-A\*31:01* (carbamazepine), and *HLA-B\*58:01* (allopurinol). However, routine *HLA* typing for pharmacogenomic risk prediction is not cost-effective due to the technical challenges with interrogating the polymorphic *HLA* gene region. To facilitate pharmacogenomic *HLA* allele screening, previous studies identified single nucleotide polymorphisms (SNPs) in linkage disequilibrium with the most relevant *HLA* risk alleles; however, these proxy-SNPs have inadequate sensitivity across multi-ethnic populations and poor specificity, which has limited their use in clinical practice. To identify a multi-ethnic panel of proxy-SNPs for *HLA-B\*57:01*, *HLA-B\*15:02*, *HLA-A\*31:01* and *HLA-B\*58:01*, publicly available whole genome sequencing and *HLA* typing data from the 1000 Genomes (1KG) Project were interrogated. The sensitivity and specificity of all SNPs in the MHC region ( $n=608,256$ ) were initially assessed across a multi-ethnic subset of 1KG subjects ( $n=1079$ ), which identified a panel of 18 proxy-SNPs that detected the four pharmacogenomic *HLA* risk alleles with a mean sensitivity and specificity of 99%. Selected false positive and negative 1KG samples were clarified by confirmatory genotyping (Agena Bioscience), which resulted in the proxy-SNP panel having sensitivity and specificity >99% for *HLA-B\*57:01* ( $N_{\text{carriers}}=69$ ;  $N_{\text{SNPs}}=8$ ), *HLA-B\*15:02* ( $N_{\text{carriers}}=65$ ;  $N_{\text{SNPs}}=3$ ) and *HLA-A\*31:01* ( $N_{\text{carriers}}=88$ ;  $N_{\text{SNPs}}=4$ ); and >95% for *HLA-B\*58:01* ( $N_{\text{carriers}}=77$ ;  $N_{\text{SNPs}}=3$ ). The validity of the proxy-SNP panel was confirmed in an independent 1KG subset ( $n=1425$ ), and in the combined cohort ( $n=2504$ ) the majority of proxy-SNPs had 100% sensitivity and 99% specificity for the four pharmacogenomic *HLA* alleles in the Asian, European and Hispanic populations. Importantly, the panel also included proxy-SNPs with 98% sensitivity and specificity for *HLA-A\*31:01* and *HLA-B\*58:01* in the African population. Taken together, these data indicate that the identified novel proxy-SNP panel could enable cost-effective and rapid genotype-based screening to predict pharmacogenomic *HLA* allele risk in diverse patient populations.

## PgmNr 490: Prioritizing drug targets from GWAS by training on Mendelian trait associations.

**Authors:**

[View Session](#) [Add to Schedule](#)

**Affiliation:** Genomics Research Center, AbbVie, North Chicago, IL.

---

Drugs with therapeutic mechanisms supported by human genetic evidence are more likely to succeed in clinical development. We have recently shown that this increase in success depends on the strength of evidence for a specific causal gene, but most significant disease-associated variants from genome-wide association studies (GWAS) occur in noncoding regions of the genome and have uncertain causal genes. Candidate causal genes may be identified through physical distance to the variant, through follow-up experiments, or through leveraging publicly available resources on variant function. However, there remains a question of how to weight different evidence sources. We sought to develop models to estimate causal probabilities using the curated set of genetic associations from the Online Mendelian Inheritance in Man (OMIM) database. We posited that modest-effect regulatory GWAS variants would to a degree be phenocopied by more severe Mendelian mutations in the relevant causal gene. We take advantage of the EFO ontology to automatically generate a set of positive labels for GWAS candidate genes with OMIM genetic associations for similar traits. We train models to predict these labels from candidate gene link properties. We find such positive labels, though only applicable to a minority of significant GWAS associations, are significantly more frequent than predicted by chance, even when excluding OMIM entries for complex diseases. We estimate a decay in causal gene probability as a function of distance from the gene boundary that is similar to the relationship between distance and regulatory QTL position. We also find a significant, positive effect of colocalization of the GWAS signal with gene expression QTL and positive effects of coding variants in the gene. We show we can outperform models in which the closest gene is assumed to be causal and models in which the causal gene is randomly selected from a set of possible candidate genes when predicting OMIM positive labels. As further validation of our approach for utility in pharmaceutical applications, we use estimated causal gene probabilities derived from the model output to quantify human genetic evidence for target involvement in a set of drug indications. We find that accounting for human genetic evidence in this way improves our ability to distinguish drug targets from non-targets and increases the estimated effect of genetic evidence on target-indication pair approval probability.

## PgmNr 491: Efficient algorithm for choosing fewest number of reference samples required to validate clinical variants for return of results.

### Authors:

N. Rafaels <sup>1</sup>; T. Brunetti <sup>1</sup>; R.A. Mathias <sup>2,3</sup>; K.C. Barnes <sup>1</sup>; K. Crooks <sup>1,4</sup>

---

### Introduction

The Colorado Center for Personalized Medicine (CCPM), has worked with Illumina to design the Infinium CU Custom MEGA-Ex (CU-MEGA) genotyping array with 45,000 custom variants, including over 200 additional pharmacogenetic variants. CCPM proposes to return pharmacogenetic results directly from the CU-MEGA chip back to patients, which requires validation from control samples with previously determined genotype calls. We've developed an algorithm that selects the fewest number of reference samples required to accomplish this goal.

### Methods

We selected a set of variants of interest from CU-MEGA in common with 1000 genomes (TGP) Phase 3 data also in Coriell (2388 samples), and then split by sample. We then calculated genotype counts per sample per variant, such that each genotype count is either 0 or 1 using PLINK/Seq. Then for every subject, "Patient 0", we chose the sample with highest number of 1's discrepant with "Patient 0", replaced 0's from "Patient 0" with 1's from "Patient X", and repeated until the number of discrepancies is 0, and tallied the number of subjects required to reach 0. For each subject, we repeated 50 times to account for random ties. We then saved the "Patient 0" with the lowest tally for a list of Coriell samples to order. To reduce the number of files generated, we deleted files for "Patient 0" if the tally is greater than the lowest tally generated thus far. If there are multiple samples with the lowest tally, we further filtered by choosing a set of samples most unrelated with most ethnic diversity.

### Results

For this experiment, we chose 169 variants from PharmGkB in common with both CU-MEGA and TGP. The algorithm produced a 5-way tie with 78 samples minimally required to view all genotypes available in the Coriell and TGP databases. The most diverse dataset included 21 AFR, 6 AMR, 19 EAS, 17 EUR, and 15 SAS.

### Conclusions

This algorithm can be expanded to any set of variants, reference samples and/or genotyping panel. This algorithm cannot validate genotypes not included in the reference dataset. CCPM plans to utilize this algorithm iteratively as new genotyping platforms and new clinical information are released.

## PgmNr 492: Homology aware design facilitates microarray CNV detection within gene families.

Detection of copy number variation (CNV) is challenging in members of highly homologous gene families. *RHD*, one of the two genes underlying the Rh blood group system, has very high homology to *RHCE*. The frequent deletion of *RHD* underlies the D-/- type, the most critical locus for red blood cell matching for transfusion after the *ABO* one. *CYP2D6*, involved in the metabolism of 25% of all prescribed drugs, is highly homologous to a pseudogene, *CYP2D7*.

Sequence similarity or identity between gene family members makes copy number calling very challenging. This is even more difficult when the off-target sequence match is to a region with its own copy number or SNP variation. *RHD* copy number calling suffers from the first problem. Although *RHCE* copy number changes are extremely rare, there are relatively few regions of *RHD* unique to this gene. *CYP2D6* copy number calling additionally suffers from the second problem, in that copy number variation in the *CYP2D7* pseudogene can be confused with copy number changes in *CYP2D6*. In both cases, careful probe selection improves results, while proactively eliminating less useful probes from the array yields better data while using less space.

Using data from the Applied Biosystems™ Axiom™ PMD Array, which has extensive coverage of both *RHD* and *CYP2D6*, we applied both empirical and analytical methods for CNV probe selection. A set of 360 samples from the HapMap and 1000 Genomes Project collections was studied. Samples were selected in part for *CYP2D6* copy number diversity, and *RHD* deletions were very common as well. Accuracy was evaluated by comparison to TaqMan assays and publicly available copy number data. We found that analytical methods that take into account the length of the genomic homology were predictive of CNV probe performance. Based on this and empirical performance metrics, we identified a reusable, space-efficient *RHD* CNV module with close to 100% accuracy in the samples studied. CNV calls in *CYP2D6* exon regions were also found to be highly accurate, validating this approach for further copy number detection-oriented arrays focused on complex gene families.

## **PgmNr 493: Genetics for pre-health undergraduate students in the era of advanced genomics and personalized medicine.**

**Authors:**

K. Makky

[View Session](#) [Add to Schedule](#)**Affiliation:** Biomedical Sciences, SC446, Marquette Univ, Milwaukee, Wisconsin.

---

In modern medicine and patient-centered treatment, clinical applications of genetics have evolved to be more than just understanding the cause of rare inherited diseases. With advancements in the field of genomics and genetic testing, many believe that future healthcare providers should also have the ability to understand and analyze personalized information based on a patient's genetic profile. This has prompted a shift in medical education, starting with pre-med pedagogy, with genetics curriculum being the center of this shift.

In the Department of Biomedical Sciences at Marquette University, we offer a human medical genetics course that follows the medical knowledge competencies proposed by the Association of Professors of Human and Medical Genetics (APHMG). Here, we discuss and share the curriculum offered by our department, which starts with an introduction to the human genomic structure and includes topics such as epigenetics, Mendelian disorders, complex genetic disorders, and pharmacogenetics. High impact teaching practices such as case studies are used, some of which will be shared. The objective is to start a conversation to solicit feedback and information from other clinicians, geneticists, genetic counselors, and educators by asking the following questions: What can biology educators do to prepare undergraduate students for their future professional career as health care providers? What educational practices will best help our pre-health undergraduate students? Do we have to reform genetics classes at the college level to better prepare our pre-health students?

## PgmNr 494: Pharmacogenetics beyond the drug label, with NIH's Medical Genetics Summaries (MGS).

### Authors:

Pharmacogenetic testing is an integral part of precision medicine. By acting on the results of a pharmacogenetics test, a clinician can identify responders and non-responders prior to or during therapy, avoid adverse events, and optimize the initial drug dose.

Currently, 262 drugs have pharmacogenetic information in the FDA label. However, this information is not provided in a standard format and may not be actionable (when to test may not be addressed, and dosing alterations may not be provided).

Because it is often at the clinician's discretion whether to test a patient before starting therapy, it is important to have access to a peer-reviewed, up-to-date summary of the latest literature, a quick review of the drug, and how to use the patient's genotype to guide therapy.

Medical Genetics Summaries (MGS, <https://www.ncbi.nlm.nih.gov/books/NBK61999>) unites the latest drug and gene information with dosing recommendations from the FDA and professional and medical societies. All 46 summaries include information from the FDA label, 18 have dosing recommendations from the Dutch Pharmacogenetics Working Group (DWPG), 14 have recommendations from the Clinical Pharmacogenetics Implementation Consortium (CPIC), and 3 have recommendations from the American Society of Clinical Oncology (ASCO).

By centralizing dosing guidelines, MGS provides supplemental information when the drug label lacks pharmacogenetic dosing recommendations. For example, for the chemotherapy drug capecitabine, both the FDA label and CPIC guidance agree there is no safe dose for individuals who lack DPD activity. However, for individuals who have partial DPD activity, CPIC provides dose recommendations whereas the FDA states there is insufficient data for dose alterations.

MGS simplifies the implementation of precision medicine by explaining the influence of genetic variant(s) on the metabolism and action of a drug, and linking to relevant tests in the NIH Genetic Testing Registry (GTR, <https://www.ncbi.nlm.nih.gov/gtr/>).

The GTR currently has 59,597 orderable genetic tests, voluntarily submitted by testing labs from across the world. Of these, 407 are pharmacogenetic tests, testing for at least one drug response, with some tests analyzing a panel of genetic variants, accounting for over 100 drug responses. Approximately 99 drugs from the FDA list have tests in GTR. There are also tests for 50 drugs not in the FDA list.

MGS and GTR are free, easy to use, and can help you optimize your care delivery.

## PgmNr 495: Family history vs. polygenic risk scores as the predictors of genetic risk.

### Authors:

R. Mägi; K. Läll; T. Laisk

[View Session](#) [Add to Schedule](#)

**Affiliation:** Estonian Genome Center, Institute of Genomics, Univ Tartu, Tartu, Estonia

---

Genome-wide association studies have discovered thousands of novel genetic associations for a wide variety of diseases. Even though most of the association effect sizes are small, genetic risk scores (GRS) combining genome-wide information into single risk estimators have shown to describe big enough proportions of genetic variability of diseases to be considered as tools for clinical practice. Despite of their prognostic abilities, GRS are still treated with skepticism in medical community and in many cases disease family history is considered to be the best possible tool for disease prediction. Also the prognostic value of GRS is disputed in the light of their low specificity.

Using Estonian Biobank data (N=150,000) which contains approximately 18,000 parent-child duos and several example disease risk scores (type 2 diabetes, coronary heart disease, early menopause), we show that even though parental GRS is a good predictor of offsprings GRS, there are cases where the offspring of high-risk parents has low genetic risk of the disease and vice versa. We studied if the offspring's genetic risks are lower compared to their parents (potentially due to prenatal purifying selection) but found no statistically significant difference. Additionally we compared the predictive values of GRSs with other risk factors already implemented into clinical practice (BMI, smoking status, concurrent diseases) and found that the predictive value of GRS is comparable with some phenotypic factors already in use.

As a conclusion we emphasize the potential of GRS in clinical practice, especially in the light of new era of precision medicine. We consider it as a cost effective tool for medical doctors for gaining additional insights into patient's possible health outcomes.

## PgmNr 496: Nashville Biosciences: Driving precision medicine with BioVU®.

**Authors:**

J. Wenke; E. Sundaram; L. Sundararajan; Y. Wu; J. Stover; L. Ekstrom

[View Session](#) [Add to Schedule](#)

**Affiliation:** Nashville Biosciences, Nashville, Tennessee.

---

The availability of genomic data has enabled the development of targeted therapies and personalized medicine. BioVU® is a biobank created by VUMC consisting of approximately 250K de-identified DNA samples linked to longitudinal electronic medical records (EMRs). BioVU® was created to enable exploration of the relationships among genetic variation, disease susceptibility, and drug responses. VUMC also has a database of approximately 3M de-identified EMRs for diverse VUMC patients called the Synthetic Derivative. Nashville Biosciences was created to expand the use of these VUMC resources to help industry advance drug discovery and development. Here, we describe three representative pharma client projects entitled: (1) Phenome wide association study (PheWASTM) drug target prioritization, (2) A synthetic control arm clinical trial, and (3) Identification of variants associated with protection from a rare disease using WES. (1) Using PheWASTM-based studies, we prioritized gene targets for early stage clinical development by identifying novel disease associations. A proprietary scoring system consisting of scientific and clinical metrics was implemented to select the strongest disease phenotype associations using a collaborative and iterative approach. We consulted published literature to develop a mechanistic hypothesis and recommend experimental next steps. (2) We created a cohort of patients with a rare lymphoproliferative disorder as a part of a synthetic placebo control arm for a phase III clinical trial. We reviewed EMRs and extracted detailed patient data including demographics, medical history, treatments, lab values, and survival data to enable analysis of treatment response, health resource utilization, and survival time. Designing a synthetic control arm for clinical studies from a rich database can reduce trial clinical costs and the time-period significantly. (3) We generated a virtual cohort of patients using clinical parameters including diagnosis codes for disease risk factors, findings from pathology and radiology reports, and lab values to sort patients into matched case and control groups for the disease of interest. Variants associated with protection from the chronic disease of interest were identified using WES. We also provided genotyping data for the de-identified patients to enable a GWAS. By leveraging real-world clinical and genomic data, we are advancing the discovery and development of personalized therapeutics and diagnostics.

## **PgmNr 497: The Taiwan Precision Medicine Initiative (TPMI): Incorporating pharmacogenetics in clinical practice.**

Advances in pharmacogenetic research have linked numerous variants to drug responses and the USFDA have required pharmacogenomic (PG) information in the labeling of over 200 medications. However, only a small number of drug labels provide clear instruction for clinical implementation. As part of the Taiwan Precision Medicine Initiative (TPMI), a pilot project to generate genetic profiles for 1 million people in the country and incorporate genetic information in clinical practice, we have translated relevant pharmacogenetic results into guidelines for medication usage and dosing for real time implementation in the clinic.

A custom-designed Taiwan Precision Medicine (TPM) SNP array based on the Applied Biosystems Axiom platform that includes probes for 3,865 PG markers was validated on >50,000 Taiwan Biobank samples and the population-specific allele frequencies of the PG markers established. The accuracy of the actionable PG panel was extremely high, with sensitivity and specificity of individual tests >99%. Our preliminary data show that more than 80% of participants have risk alleles affecting drug response. For 16 medications with clear clinical guidelines, 56% of participants harbor actionable PG variants requiring change in dosage or switching to a different medication.

The PG genotyping results become part of the patients' electronic health record, and, when a medication affected by the patient's genotype is prescribed, an alert will appear on the physician's drug ordering screen based on the guidelines from the Clinical Pharmacogenetics Implementation Consortium (CPIC) and USFDA for that medication. Implementation of pre-emptive genotyping for pharmacogenomics in a large population will improve drug safety and efficacy. Early experience based on the use of pharmacogenetics in 70,000 patients in the TPMI will be presented.

## PgmNr 498: Tissue-specific gene expression, gene expression regulation, and genetic association phenotypes improves prediction of clinical trial drug side effects.

---

Adverse side effects can account for the high failure rates associated with drug therapeutic development in clinical trials. Recent studies have shown that side effects of drugs can be predicted using genetic association loci identified from genome-wide association studies. However, these studies have been restricted due to a small number of studied phenotypes, inadequate approaches to infer causal genes and/or limited ability to identify biologically relevant tissues. Here, we overcome these challenges by utilizing co-localization of genetic association summary statistics data from a phenome-wide association study (PheWAS) of 1,435 phenotypes in 366,756 individuals from UK Biobank, and gene expression data from 48 tissues from the Genotype Tissue-Expression Project (GTEx). First, we evaluated how either testing of additional phenotypes from a PheWAS or testing of multiple tissues - which allows for identification of tissue-specific expression quantitative trait loci - can increase levels of genetic support for side effects of drugs in clinical trials. We observed that the percentage of side effects supported by a genetic association phenotype increased after sampling 10 to 440 phenotypes, and sampling 1 to 48 tissues from the GTEx project. Next, we identified five genetic features that are predictive of side effects, including: 1) Mendelian loci, 2) tissue-level effects and 3) phenotype-level effects of gene expression regulation, 4) genetic constraint, and 5) tissue-specificity of gene expression. By examining these features together, we observed that genes with all five genetic features had up to three-fold increased risk of side effect, compared to genes with no genetic support. Finally, we investigated whether side effects may arise due to a drug being delivered to non-relevant tissues. Using gene expression regulation and a genetic association phenotype as a proxy for a drug therapeutic causing a side effect, we observed that gene expression regulation found in a high number of tissues also tended to have many genetic association phenotypes. This correlation was driven by instances where the tissue and genetic association phenotype matched in terms of biological significance. These results imply that exposure of drugs to multiple tissues can induce several side effects. In conclusion, we demonstrate the utility of tissue-specific gene expression data for drug side effect prediction and the need for tissue-specific delivery of drug therapeutics.

## PgmNr 499: Predicting nevirapine concentrations using pharmacogenetics in Ghanaian HIV-infected children.

1) Pharmacotherapy and Translational Research, Center for Pharmacogenomics and Precision Medicine, College of Pharmacy, Univ Florida, Gainesville, Florida; 2) Ohio State University, Columbus, Ohio, United States; 3) Directorate of Child Health, Komfo Anokye Teaching Hospital, Kumasi, Ghana; 4) Department of Child Health, School of Medical Sciences, Kwame Nkrumah; 5) Department of Biostatistics and Computational Biology, University of Rochester School of Medicine and Dentistry, Rochester, NY, United States; 6) Department of Clinical Pharmacy, College of Pharmacy, King Khalid University, Abha, Saudi Arabia; 7) Division of Clinical Pharmacology, Department of Medicine, University of Cape Town, Cape Town, South Africa; 8) Department of Medicine, College of Medicine and Emerging Pathogens Institute, University of Florida, Gainesville, FL, United States

**Background:** Nevirapine (NVP) is a nonnucleoside reverse transcriptase inhibitor used in the treatment of human immunodeficiency virus (HIV) in young children, and is metabolized by CYP3A4 and CYP2B6 enzymes. We investigated the association of certain SNPs with NVP drug concentrations in HIV-infected children with and without tuberculosis (TB). **Methods:** This pharmacokinetic (PK)/pharmacogenetics study was performed in Ghana between 2012 and 2017. NVP-naïve patients aged 3-35 months old or weighed < 10 kg were enrolled. Patients with opportunistic infections other than TB were excluded. All parents/guardians provided written informed consent. Patients received NVP plus zidovudine and lamivudine or abacavir and lamivudine twice daily in addition to the first-line anti-TB therapy if they had TB. PK sampling was performed after at least 4 weeks of ART. Blood samples were collected at 0, 2, 6, and 12 hours after NVP dose. Drug concentration was measured using validated assay at the University of Cape Town. Minimum concentration ( $C_{min}$ ), area under the concentration-time curve from time 0 to 12 hours ( $AUC_{0-12}$ ), and apparent clearance (CL/F) were calculated using non-compartmental analysis on Phoenix v8.0. Genotyping for *rs3745274*, *rs28399499*, *rs4803419*, *rs3211371*, *rs28399433*, *rs776746*, *rs10264272*, *rs1045642*, *rs2472677*, *rs2307424*, *rs2502815*, *rs3003596*, *rs3732356*, and *rs6785049* SNPs was performed by TaqMan® allelic discrimination method. Statistical analysis was performed using JMP Pro v14.1. **Results:** A total of 53 patients were included in this study. Median (range) age and weight were 1.6 years (0.3-3.6) and 8.3 kg (4.5-12.5). Fifty eight percent (n=31) were male and 43% (n=23) had HIV/TB co-infection. The median (range) NVP dose received was 10 mg/kg (7-14). For PK parameters, the patients had median (range)  $C_{min}$  of 3.3 mcg/mL (0.0-14.0) and  $AUC_{0-12}$  56.0 mcg.hr/mL (16.7-202.6). Table below shows the SNPs which predicted the PK parameters while adjusting for age, gender, TB, and dose. Using step-wise regression, *rs3745274* and *rs6785049* predicted  $AUC_{0-12}$ ,  $C_{min}$ , and CL/F; *rs28399499* and *rs776746* predicted  $AUC_{0-12}$  and  $C_{min}$ ; and *rs28399433* predicted  $AUC_{0-12}$  only. **Conclusions:** In addition to CYP2B6, CYP3A5, and CYP2A6 SNPs, *rs6785049* (*NR1I2*) predicted NVP PK parameters.

Gene	SNP rs #	$AUC_{0-12}$	$C_{min}$	CL/F
------	----------	--------------	-----------	------

		Beta	p-value	Beta	p-value	Beta	p-value
<i>CYP2B6</i>	<i>rs3745274</i>	-26.1	0.005	-1.64	0.020	0.45	0.023
<i>CYP2B6</i>	<i>rs28399499</i>	28.10	0.150	2.87	0.047	-0.36	0.380

---

**Background:** Adverse drug events (ADEs) cause significant morbidity and mortality each year, but are highly underreported. Electronic health record (EHR) data hold a wealth of clinical information related to ADEs, but much of the relevant information is in the clinical narrative and is challenging to extract on a large scale. For example, when an ADE is suspected, often clinicians engage in a rule out trial (e.g. stop one drug at a time) to determine which drug may be responsible for symptoms. This process is documented in the clinical narrative over time and therefore necessitates manual abstraction which can be prohibitively time consuming. We outline a hybrid process of text extraction by natural language processing (NLP) followed by manual review of the extracted text to more efficiently assign the probability of an ADE for a large scale PGx study.

**Methods:** This study included 10,082 participants in the Right Drug, Right Dose, Right Time (RIGHT) study who received a new prescription between January 1, 2005 and December 31, 2017 for at least one of 20 drugs with clinically relevant pharmacogenomic interactions. ADEs associated with the drugs of interest were identified through review of EHR data for 1 year following long-term prescription medications (i.e. simvastatin) and 3 months for short-term drugs (i.e. codeine and tramadol). Using rule-based NLP methodologies we extracted all text that included the drug name (generic and trade) and any disorder term that appeared in the same sentence or adjacent sentences. Text for each medication was reviewed and assigned a 0 (no indication of problem), 1 (AE), or 2 (possible AE), with little or no additional medical record review.

**Results:** Of the 10,082 participants, we identified over 15,000 instances where a study participant had a first-time exposure to the 20 key drugs. On average, 7.6 clinical notes were identified by NLP for each patient that had both the drug mention and a MedDRA disorder term in the same sentence or adjacent sentences. Manual review of extracted sentences is currently ongoing. Clopidogrel review is complete: 562 patients were exposed, 3993 sentences were reviewed, and 9 patients had ADEs.

**Conclusions:** We have identified an NLP trigger methodology that combines NLP techniques and manual abstraction to increase the efficiency by which ADEs are identified in a large scale study of pharmacogenomics.

## **PgmNr 501: Identification and functional classification of novel variants in important pharmacogenomic genes using whole-genome sequencing data.**

Next-generation sequencing provides a more thorough assay of variants for pharmacogenetic testing in both research and clinical settings. Pharmacogenetic alleles can be assigned using available software tools without the limitation of the pre-selected sites used in array assays. Next-generation sequencing can also reveal novel variants that have not been previously identified or have not yet been included in known pharmacogenetic alleles (star alleles). In this study, we examined the novel variants in 17 important pharmacogenomic genes using 70 Illumina whole-genome sequencing samples, classified the possible functions of these novel variants, and discuss ways to report novel variants in pharmacogenetic testing. In addition, since many pharmacogenetic alleles are defined by more than one variant and the relationship among variants identified from short read sequencing is mostly unknown, we compared the pharmacogenetic diplotype calls using phased variants from trios data to allele calls without phasing to assess the accuracy of allele calls with and without phasing.

Pharmacogenomics aims at identifying and applying effective and safe ways to utilize a patient's genetic data in guiding drug selection and dosing. The Clinical Pharmacogenetics Implementation Consortium (CPIC) provides guidelines with strong evidence for genes affecting more than 50 therapeutic areas. Penn Medicine BioBank (PMBB) consists of a diverse group of ~20,000 individuals whose electronic health record (EHR) data is linked to genome-wide genotype data. A retrospective data mining of the Penn Medicine EHR, which includes ~3.6M patients showed that ~30,000 patients have been prescribed more than two CPIC Level A drugs every year from 2011- 2016. Our analyses give us a snapshot view into the distribution of important CPIC drugs in the Penn Medicine EHR. We evaluated 11 CPIC genes using PharmCAT, which can annotate genetic variants in a VCF file to identify samples with functional PGx phenotypes. Genetic analyses of 19,106 samples from PMBB, stratified by ancestry, reflect the differences in PGx phenotypes by ancestry. Among the genotyped individuals, approximately 98% of samples have at least one non-reference CPIC level A variant allele. PharmCAT annotation also identified 63% of samples are carriers of one or more PGx actionable variants. PGx actionable variants refer to genetic variations that leads to recommendations for drug dosage or alternative therapies to minimize adverse drug reactions. Linking genetic data back to EHR referenced that less than 5% of participants are prescribed the affected drugs. We identified 76.6% EA and 19.8% AA carry alleles associated with warfarin sensitivity and 390 samples that contained polymorphisms for lack of clopidogrel efficacy leading to conditions such as acute coronary syndrome, coronary artery disease, and myocardial infarction. Lastly, polygenic risk scores (PRS) calculated in PMBB population to identify the risk of coronary artery disease (CAD) also reflected 10% (1916) samples were more likely to be prescribed statins. Among these 1916, 1137 samples are already prescribed statins supporting the prediction suggested by PRS. PRS<sub>CAD</sub> was also highly associated with prescription of atorvastatin (p-value=5.2e-06). This analysis provides an overview of the distribution of carriers of PGx associated genetic variants and also identifies a target population for considering pre-emptive genotyping for PGx implementation. PRS may be useful to guide preemptive PGx interventions in the setting of preventive care.

## PgmNr 503: Polygenic risk distribution across common complex diseases.

---

Polygenic risk scores (PRS) aggregate risk for complex traits/diseases from many common variants across the genome into a single number indicative of an individual's risk of developing the phenotype in question. For any particular phenotype, there is a distribution of PRS values with those in the top percentiles at increased risk relative to those in the bottom. This information could inform screening programs, improving the accuracy of individual stratification by risk and peak risk period. While most individuals will be in the middle of the distribution for most diseases, they will likely be at extremely high or low risk for at least one disease. We used the UK Biobank (UKB) to investigate individuals in the tails of PRS distribution across common complex diseases that are a serious burden on affected individuals and the healthcare system: coronary artery disease, stroke, type 2 diabetes, rheumatoid arthritis and Alzheimer's disease. External genome-wide association studies (GWAS) were used to predict into corresponding phenotypes in the UKB. The optimal P-value threshold explaining maximum phenotypic variance was identified for each. We then built PRS scores in unrelated UKB participants of European ancestry (n=385 780) at these optimal thresholds and adjusted for batch, assessment centre and 6 principal components. The adjusted PRS were split into quantiles and different PRS distribution patterns were investigated to identify individuals at increased risk for at least one disease. Finally, we explored comorbidities between the diseases studied and stratified risk by family history. We show that 40.8%, 22.6% and 4.9% of the population studied were in the tail 10%, 5% and 1% for at least one disease. Furthermore, 9.2%, 2.4% and 0.1% of the population were in the tail 10%, 5% and 1% PRS for at least two disorders, respectively. This indicates a slight increase in the enrichment of multiple high PRS compared to chance, reflecting a moderate positive correlation between the five PRS. Individuals in the top tail of PRS distribution were more likely to have family history of the disease, excepting stroke where no strong relationship was observed. While the proportion of individuals at a level of clinically elevated risk is low for each disease alone, risk distribution across these common complex diseases could be used to inform the optimization of prevention, screening and treatment, with implications on a population scale.

## PgmNr 504: Integrating longitudinal omics for detection of adverse events in deep space missions.

Previous large scale investigations, have demonstrated the feasibility of multi-omics data generation, and their utility towards precision medicine. We will present work on the necessary next steps towards monitoring individual astronaut health in deep space missions: the development of novel algorithms that can monitoring wellness departures from individualized personnel baselines.

Our methods characterize longitudinal multi-omics signals (transcriptomes, proteomes, and physiological measures), using novel statistical algorithms based on topological properties of time series. Our methodology first analyzes individual signals based on their frequencies, accounting for underlying noise, uneven sampling rates, missing data (without imputation), and sampling over multiple time-scales for different data modalities. Our software package pyiomica uses spectral analysis to transform time signals to periodograms and classify them based on their autocorrelations. This allows the identification of temporal trends, including periodic events, constant changes, and sudden changes compared to baseline, that can correspond to adverse health events during flight. Clusters of multiple omics components are identified within each temporal class, and these collective signals are then transformed into visibility graphs, that are networks representing intensities at different timepoints of multiple omics. The network characteristics are then used to identify modules and abnormal events over time, relating to changes in physiological state of the personnel, as assessed by biological evaluation for enrichment of particular pathways. We will demonstrate the application of the algorithms using saliva data from 100 timepoints (transcriptomics, proteomics and extracellular vesicle content), as an evaluation of the utility of saliva for non-invasive monitoring of generalized health - particularly convenient for in-flight sampling of astronauts.

Personalized dynamic omics have high utility for monitoring astronauts, and our approach is an extensible prototype that can incorporate new dynamic measurements as measured during spaceflight with different monitors.

## Background

Drug targets supported by human genetic evidence for efficacy are more likely to be approved. Robust prediction of target-mediated adverse effects (AEs) early in drug development would be a valuable de-risking strategy, but the utility of genetics in doing so has not been evaluated. Using a set of curated gene-AE pairs, we assess whether common genetic evidence can retrospectively predict on-target AEs.

## Methods

We constructed a benchmark of target-encoding genes and serious AEs for which European GWAS summary statistics for the AE trait/a clinical correlate were publicly available. For each trait, we identified genetic signals ( $p \leq 5 \times 10^{-6}$ ) within 500kb of each target start site, with a subanalysis requiring  $p \leq 5 \times 10^{-8}$ . To assess whether the signal at each locus was driven by *cis* gene expression, we ran pairwise (approximate Bayes factor) colocalisation analyses against tissue-specific eQTL summary statistics for each target-tissue-trait combination (GTExV7) using COLOC. Colocalisation was declared where the posterior probability (PP) of colocalised signals (H4) was the highest of all posteriors for the five hypotheses evaluated by COLOC, with sub-analyses requiring a  $PP \geq 0.8$ . We declared genetic evidence linking target to trait when colocalisation was observed in  $\geq 1$  tissue.

## Results

Metrics of precision and sensitivity were used to assess error (enrichment analysis of genetic evidence amongst AE-annotated genes vs. controls was not feasible due to low cell counts). Of the 15 trait-geneset groups analysed,  $\geq 1$  annotated gene was correctly identified in two cardiac rhythm traits: atrial fibrillation (AF)/other cardiac arrhythmia (*NR3C1*, *ATP1B2*, *KCNN3*) and heart rate (*CALCR1*). Main analyses ( $p \leq 5 \times 10^{-6}$ , highest ranked PP) for AF showed 50% precision and 33% sensitivity, and HR 14.3% precision and 100% sensitivity. The most rigorous subanalyses ( $p \leq 5 \times 10^{-8}$ ,  $PP \geq 0.8$ ) optimised both metrics in both AF (100% precision, 40% sensitivity) and HR (50% precision, 100% sensitivity).

## Conclusion

These analyses demonstrate that drug targets known to be associated with severe AEs can be retrospectively identified using colocalisation between trait- and expression-associated variants.

Whilst results varied highly between traits, and null results cannot be interpreted as evidence in support of the absence of an association, we highlight the potential of this method to prospectively flag concerning targets.

## **PgmNr 506: Successful application of preimplantation genetic diagnosis for oculocutaneous albinism type 1 merging with preimplantation genetic testing for aneuploidy by a combination of quantitative polymerase chain reaction approaches.**

### **Authors:**

S.P. Chang <sup>1</sup>; A. Yan <sup>1</sup>; G.C. Ma <sup>1</sup>; F.P. Tsai <sup>2</sup>; M. Chen <sup>1,3</sup>

---

Autosomal recessive oculocutaneous albinism type 1 (MIM# 203100; OCA1) is one of the thousands of monogenic diseases characterized by absence of pigment in hair, skin, and eyes. Mutations of the tyrosinase (*TYR*, MIM\* 606933) gene are clinically associated with the disorder, and so far, more than 300 mutations have been described. Preimplantation genetic diagnosis (PGT-M) has been widely utilized for the affected families who wish to prevent the transmission of genetic disorders. Preimplantation genetic testing for aneuploidy (PGT-A) is also employed to improve live birth rates in IVF (In vitro fertilization) cycles for couples with advanced maternal age, repeated implantation failure, and recurrent miscarriage. More and more at-risk couples have the need to combine PGT-M and PGT-A technologies during IVF treatment. In the present study, a Taiwanese couple with a maternal age of 38 years was enrolled. Their first child with OCA1, suffering from eye problems, caused by heterozygous *TYR* mutants of paternal c.1366+3A>T and maternal c.895C>A (p.R299S). We developed and evaluated an in-house duplex-nested ARMS-qPCR technique for PGT-M, and compared it to direct sequencing. The optimized protocol was then applied clinically to detect the disease-causing mutations and to screen simultaneously for aneuploidy by a qPCR-based PGT-A. After ovarian stimulation, a total of 14 embryos with good morphology were selected and biopsied from blastocysts on day 5 to detect PGT-A and PGT-M simultaneously. The PGT-A results showed that two embryos were aneuploid and 12 were euploid, and those of PGT-M showed that three wild-type embryos without the familial mutants, three affected embryos with two heterozygous mutants, four maternal-carrier embryos, and four paternal-carrier embryos. Finally, two euploidy embryos were selected (one wild-type and one maternal carrier) for transfer at Day 6, achieving a successful singleton-pregnancy. After 38 weeks of uneventful gestation, a healthy boy was born weighing 3088g. Prenatal and postnatal genotyping confirmed the baby to be an unaffected maternal carrier. We here report a successful application for the strategy combined PGT-M and PGT-A by a combination of quantitative polymerase chain reaction approaches, resulting in the healthy boy birth. The results show that such a combination of technologies is a fast and valid screening tool and can be provided as an optimized solution for high-risk families.

## PgmNr 507: Targeted sequencing and RNA assay reveal a noncanonical *JAG1* splicing variant causing Alagille syndrome.

### Authors:

**BACKGROUND:** Alagille syndrome (ALGS), as known as congenital arteriohepatic dysplasia, is a rare autosomal dominant multi-systemic disorder. Mutations in *JAG1* or more rarely *NOTCH2* have been revealed as the cause of ALGS. In this study, a 5-year old girl with typical ALGS' feature and her pregnant mother came to our reproductive genetics clinic for counseling.

**AIM:** We aimed to clarify the genetic diagnosis and provide prenatal genetic diagnosis for the pregnant.

**METHODS:** Next generation sequencing (NGS)-based multigene panel was used to identify pathogenic variant of the proband. The candidate variant was verified by using Sanger sequencing. RNA assay was performed to clarify splicing effect of the candidate variant. Amniocentesis, karyotyping, and Sanger sequencing were performed for prenatal testing.

**RESULTS:** We identified a novel *de novo* noncanonical *JAG1* splicing variant (c.2917-8C>A) in the proband. Peripheral blood RNA assay indicated that the mutant transcript might escape nonsense-mediated mRNA decay (NMD) and encode a C-terminal truncated protein. Information of the variant led to success prenatal diagnosis of the fetus.

**CONCLUSION:** In conclusion, we clarified the genetic diagnosis of an ALGS patient and ensured utility of prenatal genetic testing.

## PgmNr 508: Mutation of *RONIN* (*THAP11*) results in a combined vitamin B<sub>12</sub> and ribosome biogenesis deficiency syndrome.

Combined methylmalonic acidemia and homocystinuria (*cb/C* type), an inherited disorder of vitamin B<sub>12</sub> metabolism, is a rare metabolic and multi-systemic disease caused by mutations in *MMACHC*. Patients with *cb/C* can have severe neurodevelopmental defects including microcephaly, hydrocephaly, and seizures as well as renal, cardiac and hematological defects. Recently, an X-linked variant of *cb/C* was discovered and termed *cb/X*. Rather than being due to mutations in *MMACHC*, *cb/X* was shown to result from hemizygous mutations in the transcription cofactor *HCFC1*, which is known to be an obligatory partner for the transcription factor *RONIN* (*THAP11*). Intriguingly, a single patient exhibiting *cb/X*-like pathology has been found to carry homozygous mutations in *RONIN*. Patients with either *HCFC1* or *RONIN* mutations were shown to have a dramatic reduction in *MMACHC* transcription. We have previously shown that the *Hcfc1*/*Ronin* transcriptional complex directly regulates mouse *Mmachc* expression. These findings suggest that *cb/X* and the new *RONIN* (*THAP11*) disorder comprise a novel family of rare and severe *cb/C*-like disorders that are transcriptional in nature. To better understand the cellular and molecular mechanisms underlying the pathophysiology of these devastating neurodevelopmental diseases, we have generated a mouse model that carries the human mutation in *Ronin* (*Ronin*<sup>F80L</sup>). Here we report the generation of the first mouse model, *Ronin*<sup>F80L</sup> along with its phenotypic and molecular characterization. *Ronin*<sup>F80L/F80L</sup> homozygous mice die soon after birth and exhibit severe brain developmental defects that recapitulate those observed in the human *cb/X* and *RONIN*-deficient patients. Moreover, consistent with an inherited vitamin B<sub>12</sub> disorder, cells from *Ronin*<sup>F80L/F80L</sup> homozygous embryos exhibit defects in cobalamin metabolism. Surprisingly however, RNA-seq and ChIP-seq analyses also revealed a role for *Ronin* in directly regulating ribosome biogenesis. Furthermore, we were able to show that there is also a functional deficit in ribosome biogenesis and hence protein translation. This identifies for the first time a role for *RONIN* in ribosome biogenesis. Together, the phenotypic and molecular data confirm that the *Ronin*<sup>F80L/F80L</sup> mouse model will serve as a powerful tool to further uncover the pathophysiology of this complex family of diseases.

## PgmNr 509: Copy number variations of the PKA catalytic subunits *PRKACA* and *PRKACB* are present in isolated micronodular adrenocortical disease (iMAD).

### Authors:

---

Genetic defects that cause abnormal c-AMP dependent protein kinase A (PKA) signaling constitute the leading cause of adrenal tumors and Cushing syndrome (CS). Inactivating *PRKAR1A* mutations are the main genetic cause of PKA pathway activation identified so far in bilateral adrenocortical hyperplasia (BAH). However, activating mutations and amplification of the PKA catalytic subunit gene *PRKACA* were recently described in cortisol-producing adrenal tumors and BAH, respectively. Herein, we studied copy number variations (CNVs) of the PKA catalytic subunits *PRKACA* and *PRKACB* in 77 patients with isolated micronodular adrenocortical disease (iMAD) that are negative for *PRKAR1A* mutations. We performed TaqMan copy number assay through ddPCR for *PRKACA* and *PRKACB* genes. We screened 69 germline samples and unilateral or bilateral adrenal tissues from 34 patients. The *PRKACA* gene was duplicated in 10 out of 69 germline samples (14.4%). We detected two heterozygous deletions of *PRKACB* gene at the germline level (2.8%); one of the two patients had also duplication of the *PRKACA* gene. At the somatic level we detected duplication or amplification (more than 3 copies) of the *PRKACA* gene in 16 of the studied tissues (47%) and one had an homozygous deletion (2.9%). In five of those 16 cases (14.7%) we detected the *PRKACA* CNVs in both adrenal glands, while absent in the germline, indicating potential mosaicism. Regarding the *PRKACB* CNVs, we found that two patients had a heterozygous deletion of the *PRKACB* gene in the germline (2.8%) one of whom had also the *PRKACA* duplicated; unfortunately, adrenal tissue was not available from this patient. Moreover, at the somatic level we found that 9 out of 34 adrenal tissues (26.4%) had deletion of the *PRKACB* gene, while 7 of them (20.5%) had also duplication or amplification of the *PRKACA* gene. These data suggest that *PRKACA* and *PRKACB* copy number variations may happen concurrently in the early stages of adrenocortical tumor development in BAH. Although the exact way these defects participate in tumor growth remains unclear, we can speculate that almost certainly they are involved in the increased PKA activation that is the hallmark of BAH and most benign cortisol-producing adrenal tumors.

## PgmNr 510: Analysis of ultrasonic manifestation of fetus with 17q12 microdeletion.

### Authors:

L. Zhang; Y. Li; E. Yuan; H. Li; P. Yang; G. Li; Y. Xu; H. Zhang; Z. Zhang; S. Cui

[View Session](#) [Add to Schedule](#)

**Affiliation:** The 3rd affiliated hosp. of Zhengzhou Univ., Zhengzhou, China

### Objectives

In our study, we firstly analyzed the ultrasonic manifestations of 25 fetus diagnosed as 17q12 microdeletion by prenatal chromosome microarray analysis (CMA).

### Methods

Cells from fetuses in amniotic fluid were collected by centrifugal method, and cell DNA was extracted for CMA. The Affymatrix CytoScan 750K chip (Thermo, USA) was used for CMA detection after confirming no maternal blood contamination by short tandem repeat (STR) locus comparison.

### Results

Among the 3,901 pregnant women, a total of 25 fetuses were detected with 17q12 microdeletion, accounting for 0.6% (25/3,901). There were 340 fetuses (8.7%, 340/3,901) showed kidney abnormality by prenatal ultrasonography, and included all the 25 fetuses with 17q12 microdeletion, accounting for 7.4% (25/340). Among these 340 fetuses with kidney abnormalities, 48 fetuses were classified as pathogenic (14.1%, 48/340), among which 17q12 microdeletion accounted for 52.1% (25/48) and chromosome aneuploidy disease accounted for 27.1% (13/48), the other 20.8% (10/48) were pathogenic chromosome microdeletion and microduplication.

88.0% (22/25) fetuses showed hyperechogenic kidney by prenatal ultrasonography in 17q12 microdeletion fetuses. Among the 22 fetuses with hyperechogenic kidney, 24.0% (6/22) had no other abnormalities except hyperechogenic kidney. Collecting system separation (28.0%, 7/25), polycystic dysplastic kidney (20.0%, 5/25), renal cysts (8.0%, 2/25) and hydronephrosis (8.0%, 2/25) were included in other fetuses. 28.0% (7/25) fetuses with only kidney abnormalities by prenatal ultrasonography, 16.0% (4/25) were combined with increased amniotic fluid, 24.0% (6/25) were combined with other system abnormalities, and the most common abnormalities was nervous system. In addition, there were hyperechogenic bowel, single umbilical artery and growth retardation. There were ten pregnant women did the parental CMA verification, four of which were inherited from mother and the other six fetuses were newly mutation. Follow-up study showed that five (20.0%, 5/25) fetuses had a family history of diabetes and there was one pregnant woman's father with renal cysts.

### Conclusion

In conclusion, hyperechogenic kidney was a common prenatal ultrasonic manifestation of 17q12 microdeletion syndrome. Hyperechogenic kidney was found at prenatal, 17q12 microdeletion syndrome should be considered and prenatal chromosome microarray analysis should be performed.

## PgmNr 511: Whole exome sequencing identifies candidate gene variants in patients with Mayer-Rokitansky-Kuster-Hauser (MRKH) syndrome.

---

Mayer-Rokitansky-Küster-Hauser (MRKH) Syndrome is a phenotypically complex condition characterized by incomplete development of the uterus and vaginal canal, and can be accompanied by unilateral renal agenesis, skeletal abnormalities, hearing impairment, and cardiac anomalies. While some large copy number variants and several mutations in *HNF1B* and *WNT4* have been identified in a small number of patients, the genetic basis remains poorly understood for most patients. To better understand genetic causes of MRKH, we performed whole exome sequencing on DNA from 111 women with MRKH to identify likely pathogenic variants (frameshift, splice site, or nonsense) and missense variants of undetermined significance (VUS) with an allele frequency of <0.01. We identified and prioritized candidate variants with the following characteristics: 1) those in murine genes known to impair müllerian development; 2) those in genes with putative disease causing variants in humans, but lacking definitive evidence; and 3) those near the breakpoints of derivative chromosomes from a patient with a t(3;16)(3p22.3;16p13.3) translocation. Among 14 human orthologs from mouse models (*EMX2*, *HOXA9*, *HOXA10*, *HOXA11*, *HOXA13*, *LHX1*, *PAX2*, *PBX2*, *RARA*, *TP63*, *WNT4*, *WNT5A*, *WNT7A*, and *WNT9B*), we found 3 heterozygous likely pathogenic variants in *EMX2*, but in none of the other genes. Among genes previously studied, but not confirmed in humans (*AMH*, *AMHR2*, *CFTR*, *CTNNB1*, *GALT*, *HOXA7*, *LAMC1*, *LRP10*, *MMP14*, *PBX1*, *RARG*, *RXRA*, *SHOX*, *TBX6*, *WT1*, and *ZNHIT3*), we identified heterozygous likely pathogenic variants in *ZNHIT3* (n = 4) and *CFTR* (n = 2). For genes located near the breakpoints on derivative chromosomes 3p22.3 (*CCR4*, *CMTM6*, *CMTM7*, *CMTM8*, *CNOT10*, *CRTAP*, *DYNC1I1*, *GLB1*, *TMPPE*, and *TRIM71*) and 16p13.3 (*IL32*, *MEFV*, *OR1F1*, *TIGD7*, *ZNF200*, *ZNF205*, *ZNF213*, *ZNF263*, *ZNF75A*, and *ZSCAN10*), *TIGD7* (n=1) and *MEFV* (n=1) had heterozygous likely pathogenic variants. We also identified heterozygous VUS with a CADD score >20 in most of the other genes, including 13 variants in 6 murine orthologs, 43 variants in 15 putative human genes, and 23 variants in 11 genes at the breakpoints of the t(3;16) translocation. Sanger sequencing is ongoing for confirmation, and *in vitro* confirmation and segregation analyses will be performed for selected variants. Our preliminary data suggests that low frequency deleterious alleles in *EMX2*, *ZNHIT3*, *TIGD7*, and perhaps *CFTR*, could play a role in the pathogenesis of MRKH.

## PgmNr 512: Utilizing CRISPR/Cas9 to study SOX9 haploinsufficiency in human iPSC-derived chondrocytes.

### Authors:

T.Y. Ha; K.K. Miu; W.Y. Chan

---

SOX9 is an important gene in development which actively involves in the differentiation of 3 germ layers and it is the master regulatory gene in chondrocyte development. Moreover, haploinsufficiency (HI) in SOX9 will result in severe developmental disorder called Campomelic Dysplasia (CD). Patients with CD suffer from bent long bones, club feet, small thoracic cavity etc. CD patients usually die shortly after birth due to respiratory failure and only very few of them could survive into adolescent years. Our study aims at elucidating the effect of different pathways which are important for SOX9 HI on chondrocytes.

To generate our desired SOX9 HI model, we utilized CRISPR/Cas9 to make a single nucleotide polymorphism (SNP) mutation at the end of SOX9 exon 2 splice site in human induced pluripotent stem cells (hiPSCs). Single clones were screened by Sanger sequencing of the PCR fragments. The SOX9 HI hiPSCs were differentiated to chondrocytes according to a well-established 14-day protocol. To validate our desired SOX9 HI mutant, RT-qPCR, immunofluorescence and Safranin O staining were performed on day 14. Our results from these experiment consistently showed that the SOX9 HI chondrocytes have decreased expression of SOX9 in terms of mRNA and protein levels.

Transcriptome analysis were then performed. By comparing wild type chondrocytes and SOX9 HI chondrocytes, we identified around 700 differentially expressed genes for each phenotype and from gene ontology analysis, binding of around 1000 genes were being affected in SOX9 HI chondrocytes. From the KEGG analysis results, notch signaling, p53 and ribosomal pathways have the highest rich factor scores.

To conclude, we had successfully generated SOX9 HI hiPSCs and differentiated them to chondrocytes. From the transcriptome analysis results, several pathways were being affected in SOX9 HI chondrocytes. Our further research would be to inhibit these pathways one by one and try to rescue the SOX9 HI phenotype with different approaches.

## PgmNr 513: The role of TWIST1 phosphorylation and miR10 in regulating neural crest cell fate and migration.

---

A wide variety of common birth defects and pediatric cancers arise from aberrations in the development of neural crest (NC) cells originating from the neural plate borders. The NC cells switch their epithelial to mesenchymal phenotype with the acquisition of migratory and plasticity properties towards the pharyngeal arches during facial and peripheral nervous system formation. This neurulation system provides an excellent *in vivo* model to uncover the mechanism(s) governing how transcription factors and microRNAs regulate NC cell specification, epithelial to mesenchymal transition (EMT), delamination, and migratory processes. The transcription factor TWIST1 is a master regulator of EMT and plays a critical role during tumor invasiveness in cancer metastasis. TWIST1 phosphoregulation in cancer cell line models showed that several critical phospho-residues regulate both protein activity and transcription of target genes including miR-10 family members. Despite its importance in NC cells, the function of Twist1 phosphoregulation and expression of the miR-10 family has not been investigated *in vivo*. Previous developmental studies suggested that conditional knockout (cko) of *Twist1* in cranial neural crest (CNC) cells increased cell death of NC cells localized to pharyngeal arches, while complete loss of *Twist1* led to failure of neural tube closure and early embryonic lethality. However, our recent quantitative data using dual fluorescent cell tracing markers and neural tube explants showed that *Twist1*cko in CNC cells significantly reduced cell delamination and disrupted the EMT process. The detached *Twist1*null CNC cells retained their epithelial signatures and migrated over a significantly less distance, providing an explanation for observed increased cell death and craniofacial abnormalities. Notably, TWIST1 is highly phosphorylated in CNC cells, while miR10a, miR10b and miR99b are temporally regulated during neurulation. To investigate the importance of TWIST1 phosphorylation in CNC cell fate, *Twist1*phospho-incompetent mice for multiple serine residues were recently generated. Our initial results showed that Tw1-S68A phospho-mutant mice have craniofacial defects and hemorrhage in the forebrain. To further investigate the importance of TWIST1 phosphorylation, EMT and migration of CNC cells are being analyzed in S18/20A and S68A mutant mice. These studies will lead to a better mechanistic understanding of the role of *Twist1* and miR10 in NC cell fate.

## PgmNr 514: *HMGA2* disruption in monozygotic twins with Silver-Russell syndrome.

---

Silver-Russell Syndrome (SRS) is a disorder characterized by prenatal and postnatal growth retardation, macrocephaly, a prominent forehead, body asymmetry and facial dysmorphisms. Epimutations at chromosome 11 and maternal uniparental disomy of chromosome 7 together explain about 60% of SRS cases. However, patients clinically diagnosed with SRS sometimes present negative results in routine genetic tests for the syndrome. This reinforces the idea that other genes may be involved in the etiology of the syndrome. We studied monozygotic twin sisters clinically diagnosed with Silver-Russell syndrome carrying a balanced translocation between chromosome 3 and chromosome 12 (46,XX,t(3;12)(q29;q14)). Chromosome microarray analysis did not identify any imbalances. Mate-pair sequencing was then performed to identify the translocation breakpoints. The breakpoint on chromosome 3 interrupts the *NAALADL2* gene. This gene has an important role in the central nervous system acting in the release of glutamate in the synaptic cleft. The breakpoint on chromosome 12 disrupts *HMGA2*. *HMGA2* gene encodes an architectural transcription factor highly expressed in embryonic development involved in cell growth and proliferation. *HMGA2* regulates expression of *IGF2*, a causative gene for SRS. Loss-of function and large deletions in *HMGA2* have been reported in a few patients with a Silver-Russell phenotype. Therefore, this study provides further evidence of the role of *HMGA2* in the etiology of Silver-Russell syndrome.

## PgmNr 515: Phenotypic and molecular characterization of orofacial development in *Mecom* loss-of-function mutants.

---

Human orofacial clefting is one of the most common human birth defects with a complex multifactorial etiology. Isolated cleft palate (CP) can arise due to abnormal growth, migration or fusion of the palate shelves caused by perturbations intrinsic to the palate shelves or as a secondary consequence of extrinsic factors. Pierre Robin sequence (PRS) is a form of CP in which individuals exhibit micrognathia and glossoptosis that leads to failed palate shelf elevation and fusion. *Prdm16* null mutant mice exhibit PRS-like cleft palate. A role for the *Prdm16* paralog, *Mecom*, in orofacial development has not been reported; however, we observe CP in the *Mecom* loss-of-function mutant, *Evi1*<sup>ko3</sup>. In contrast to *Prdm16* mutants in which palate shelf elevation is obstructed, *Evi1*<sup>ko3</sup> mutant palate shelves elevate but fail to meet and fuse at the midline. The requirement for *Mecom* appears to be intrinsic to the palate. Both genes encode zinc-finger transcription factors that regulate gene expression through both DNA-dependent and DNA-independent mechanisms. Both *Mecom* and *Prdm16* are robustly expressed in the developing craniofacial structures with partially overlapping patterns throughout the embryo. This study focuses on a targeted *Mecom* deletion allele, *Evi1*<sup>ko3</sup>, in which exon 3 of *Evi1* is removed to prevent expression of two transcripts expressed from the *Mecom* locus (*Mds1-Evi1* and *Evi1*) but not *Mds1*. We outcrossed the allele 10 generations onto the FVB/NJ strain and observed ~40% CP penetrance. We examined non-penetrant *Evi1*<sup>ko3</sup> mutants for potential “subclinical” phenotypes using SEM and histology. Embryonic day (E)16.5 mutants without CP exhibit palate rugae defects and abnormal palate morphology at the midline that warrants further characterization to identify potential submucous CP or other “subclinical” phenotypes. To assess the molecular consequences of palate-intrinsic loss of *Mecom*, we carried out transcriptional profiling via RNAseq analysis of total RNA from pooled embryonic day E13.5 *Evi1*<sup>ko3</sup> mutant and wild type palate shelves. Validation of differentially expressed genes is ongoing. These data address the hypothesis that loss of *Mecom* results in CP due to altered developmental and molecular pathways intrinsic to the palate shelves and may contribute to a greater understanding of normal palatogenesis and suggest additional contributors to the etiology of CP in mice and human.

## PgmNr 516: Involvement of transcription factors that control embryonic morphogenesis in the repair of DNA-DSBs after fetus radiation exposure.

---

In the study of Hiroshima and Nagasaki atomic bomb survivors exposed in utero, it has been noted that exposure-related small head size and intellectual impairment had increased. Thus developing central nervous system seems to be radiation sensitive. In a process of searching for specific proteins that react with unrepairable, persistent DSBs induced by radiation exposure, we have detected an ATM dependent phosphorylation of transcription factor CHD7 (chromodomain containing DNA helicase 7) which is known as morphogenesis factor of brain and neurosensory organ. Antibodies raised against the phosphorylated peptide sequence, KLEDDDKSEESpSQPEAGA, which was a putative ATM kinase target in CHD7, strongly reacted with DSBs formed by radiation exposure. The phosphorylated form of CHD7 co-localized with γH2AX, 53BP1 and p-ATM, making DSB repair-foci. Co-immunoprecipitation experiments indicated the antibody cross-reactivity with 53BP1, since both proteins share the ATM kinase target, SpSQP sequence. Thus we reconfirmed the specificity of ATM-dependent CHD7 phosphorylation under the 53BP1 null background. CHD7 is known as a transcription factor that controls cell differentiation and morphogenesis during embryonic development especially with regards to formation of brain, heart and sensory organs (eyes, ears) from the neural crest via non-canonical WNT signaling. In human, heterozygous mutation of *CHD7* causes malformation (Charge Syndrome) and results in embryonic lethality in the case of null (homozygous) mutation. Mouse fetus exposure resulted in the strong accumulation of p-CHD7 proteins at the DSB-repair foci in developing neurosensory organs. Thus we conclude that there exists molecular mechanism of morphogenesis-coupled DSB repair in the early development. This mechanism seems to be universal since (1) PTIP (Pax2 Transcription factor Interacting Protein) also participate in DSB-repair foci formation, where Pax2 is a transcription factor that control kidney morphogenesis. (2) COBRA1, a BRCA1 interacting protein which controls mammary gland morphogenesis also participates in DSB-repair foci formation, and (3) MCPH1/BRIT1, whose mutation causes microcephaly, has three BRCT domains and strongly accumulates at DSB-repair foci after radiation exposure.

---

Craniofacial dysostosis including craniosynostosis is a common birth defect that occurs in one in at least 2,000 newborns. The metopic suture, one of the major craniofacial sutures, is prematurely fused in 25% of all craniosynostosis cases. Gene mutations affecting suture growth are a significant source of calvarial pathology, but no more than 30 genes and few mouse models are known to be associated with metopic abnormalities. The metopic suture is abnormally widened in Apert and Saethre-Chotzen craniosynostosis syndromes. To characterize the transcriptome of the murine frontal suture (homologous to the human metopic suture) during embryonic development in mutants compared to wildtype (WT), we applied bulk and single-cell RNA-seq and network analysis. Bulk RNA-seq analysis was performed on laser capture microdissected tissue of 60 suture mesenchyme (SM) and osteogenic front (OF) subregions at embryonic day (E)16.5 and E18.5 of Apert *Fgfr2*<sup>+/S252W</sup> and Saethre-Chotzen *Twist1*<sup>+/-</sup> mutants, with widened frontal sutures at E18.5, and WT mice. In WT mice across both ages there were a combined 4,282 differentially expressed genes (DEGs) between SM and OF subregions. Mesenchymal gene expression signatures suggested functional roles as a mechanoresponsive connective tissue and developing stem cell niche. Across both subregions, there were 2,480 DEGs between E16.5 and E18.5, and changes were consistent with a decrease in proliferation and increase in maturation in both the SM and OFs from E16.5 to E18.5. In the *Twist1*<sup>+/-</sup> and *Fgfr2*<sup>+/S252W</sup> mice across both ages, there were 115 and 127 DEGs, respectively, compared to WT. Transcriptional changes affecting genes involved in vasculogenesis and ribogenesis distinguished the *Twist1*<sup>+/-</sup> and *Fgfr2*<sup>+/S252W</sup> mice from WT, respectively. Co-expression network analysis characterizing the transcriptional organization of the SM and OFs identified a novel SM gene expression module, from which we validated key driver genes regulating osteoblast differentiation. Single-cell RNA-seq identified at least five suture subpopulations that suggested an osteogenic differentiation trajectory within the suture. Altogether, our rich transcriptomic data with network biology analyses provided a model of frontal suturogenesis. Supported by grant NIH U01 DE024448.

## PgmNr 518: Are fetal endothelial nitric oxide synthase gene haplotypes risk factors in chorioamnionitis.

### Authors:

K. Yanamandra; D. Napper; J.A. Bocchini Jr.

[View Session](#) [Add to Schedule](#)

**Affiliation:** Pediatrics, LSU Health Science Center, Shreveport, Louisiana.

### Background:

Chorioamnionitis is an infection of chorion and amnion and has a multifactorial etiology leading to growth restriction of the fetus in utero, sepsis, and premature rupture of membranes. It could risk severe prematurity, small for gestation, and fetal distress leading to respiratory failure after birth. Animal studies suggest that NO in placental vasculature is required to facilitate fetal growth. Earlier studies showed that preterm infants with severe respiratory failure respond favorably to inhaled nitric oxide. These infants may have a deficiency in the inflammatory response, including a defect in nitric oxide generation in airspaces. We have previously reported that the mutant eNOS genotypes, leading to decreased Nitric oxide, increased the risk of respiratory distress, PPRM, and IUGR, in premature infants.

### Objective:

To study the potential association of infant eNOS genotypes and amnionitis.

### Methods:

We analyzed eNOS gene haplotypes (T786C, G894T, intron 4 VNTR b/a genotypes), in 54 preterm infants (6 amnionitis cases and 48 Non-amnionitis controls), using microplate PCR genotyping methods.

### Conclusions:

Our data on eNOS double marker (T786C/Intron4 VNTR b/a; T786C/G894T; G894T/Intron4 VNTR b/a) analysis revealed that amnionitis cases showed significantly higher 50% C-a, 38% C-T, 29% T-a mutant haplotypes compared to 19%, 19%, 14% without amnionitis history respectively. Data on triple marker (T786C, Intron VNTR b/a, and G894T) analysis revealed the mutant haplotype C-a-T significantly higher 39% vs. 17% in cases vs. controls respectively. These data suggest a significant association of eNOS mutant haplotypes in double (C-a, C-T, T-a); and (C-a-T) triple markers with the amnionitis disease condition. Infants C-T, T-a); markers and (C-a-T) triple marker with the amnionitis disease condition. Infants with amnionitis have higher frequencies of mutant haplotypes, potentially reducing the endogenous NO availability thus leading to the disease. This is the first report to suggest a role for eNOS gene haplotypes in the etiology of amnionitis in premature newborn infants.

## PgmNr 519: *In utero* endotoxin exposure decreases subsequent inflammatory bowel disease severity in mice.

---

Inflammatory bowel disease (IBD) affects 3 million adults in the US. Though its exact etiology remains unknown, IBD is characterized by excessive inflammation of the intestine, leading to fever, pain, and severe diarrhea. Current dogma implies that this inflammation is due to an aggressive immune response to gut microbes in a genetically susceptible host and specific environmental factors including antibiotic exposure. Though genes including *CARD15* have been implicated in IBD, the role of the pre-natal environment in onset of disease remains largely unknown. We hypothesize that in utero exposure to inflammation will increase responses to subsequent IBD triggers in genetically susceptible adults by altering expression of related IBD genes, protecting them from excessive inflammation and pain.

To mimic in utero inflammation, we injected 2 mg/kg of lipopolysaccharide into the uterine horns of pregnant CD-1 mice. At 5 weeks, the mice underwent a 6-day exposure to 2% dextran sodium sulfate (DSS), a chemical mimic of IBD. Analyses included body weight and colon length measurements and qPCR for IBD-associated genes. Relevant controls (e.g. no DSS) were used at both time points.

Colon lengths in controls that did not receive pre-natal LPS but received DSS were significantly shorter than in those that received neither exposure ( $p < 0.0001$ ), reflective of increased disease severity. Colon length was similar between mice that received both LPS and DSS exposure and controls that received only LPS exposure. Body weight measurements showed that mice exposed to LPS in utero gained an average of 1.8g during the model, regardless of DSS exposure status, revealing reduced disease. However, body weights of mice that did not receive LPS but received DSS decreased by 1.3g and those that received neither exposure gained 2.1g. We showed via qPCR that *Atg16l1* expression was significantly increased among mice that only received DSS exposure ( $p = 0.002$ ,  $p = 0.031$ ,  $p = 0.002$ ) compared to all other groups. *Card15* expression was significantly higher among mice that did not receive LPS but received DSS compared to two other groups ( $p = 0.01$ ,  $p = 0.004$ ).

Counterintuitively, these results demonstrate that pre-natal exposure to inflammation leads to a reduced development of IBD later in life, evidenced by a lack of physical and gene expression changes associated with DSS exposure in mice. This suggests that in utero inflammation exposure protects the gut from excessive inflammation into adulthood.

## PgmNr 520: Misregulation of growth-differentiation factor 11 (*GDF11*) in MeCP2-related disorders.

**Authors:**

S. Bajikar; H. Zoghbi

[View Session](#) [Add to Schedule](#)**Affiliation:** Molecular and Human Genetics, Baylor College of Medicine, Houston, Texas.

---

Loss-of-function mutations or duplication in methyl-CpG binding protein 2 (*MECP2*) cause two severe neurodevelopmental disorders: Rett syndrome and *MECP2*-duplication syndrome, respectively. While the genetic cause of these disorders is known, the mechanism by which disruption in MeCP2 levels leads to pathogenesis unknown. Disruption in normal levels of MeCP2 causes a mild change in expression of thousands of genes. The objective of this study is to identify robustly misregulated transcripts in mouse models of MeCP2-disorders to reveal candidate mediators of pathogenesis. I employed a meta-analysis of transcriptome profiles collected from *Mecp2*-null mouse models and identified Growth differentiation factor 11 (*Gdf11*) as a gene sensitive to MeCP2-levels. *Gdf11* is downregulated in *Mecp2*-null models, while upregulated in *MECP2*-transgenic models. Additionally, *Gdf11* expression levels are returned to wild-type levels when MeCP2 levels are normalized. The opposing regulation of *Gdf11* by MeCP2 implicates GDF11 misregulation as one potential driver of some phenotypes in Rett and *MECP2* duplication syndromes. GDF11 is a transforming growth factor beta family ligand that is a critical patterning morphogen for the skeletal system. However, despite broad expression throughout the brain, the role of GDF11 in brain development and homeostasis is unknown. On going and future work will test if modulating GDF11 levels specifically in the brain using either will on its own cause aberrant neurological phenotypes. Next, I will test if normalization of GDF11 levels rescues neurological phenotypes seen in mouse models of *MECP2* disorders. In sum, I have found that GDF11 is misregulated in *MECP2*-related disorders, and I will test its potential as a therapeutic modifier of these disorders.

## PgmNr 521: Human and mouse essentiality screens as a resource for disease gene discovery.

---

Although genomic sequencing has been transformative in the study of rare genetic diseases, identifying causal variants remains a considerable challenge that can be addressed in part by new gene-specific knowledge.

In the present study, we integrate measures of how essential a gene is to supporting life, as inferred from the comprehensive viability and phenotyping screens performed on knockout mice by the International Mouse Phenotyping Consortium (IMPC) and from human cell line essentiality screens. We introduce a novel, cross-species gene classification across the Full Spectrum of Intolerance to Loss-of-function (FUSIL) and demonstrate that genes in five mutually exclusive FUSIL categories have differing characteristics in the biological processes they regulate, tissue expression levels and human mutation rates. Most notably, Mendelian disease genes are highly overrepresented (2.6 fold-increase odds) in the developmental lethal category, representing genes not essential for cell survival but required for organism development. This enrichment is partially driven by an association with early onset, multisystemic, autosomal dominant disorders. Consistent with this, we find an even higher overrepresentation (3.3 fold-increase) of genes associated with developmental disorders. By combining this information with intolerance to variation scores derived from human population sequencing studies, we provide a framework to prioritise novel developmental disorder associated genes. To validate our approach, we screened 163 developmental lethal genes with no previous association to rare disease and highly intolerant to variation for candidate variants in unsolved developmental disorder cases from three independent disease sequencing consortia and identified potentially pathogenic, *de novo* variants shared in different patients. We describe findings for around half the genes and, in particular, highlight the evidence for a novel role for *VPS4A* and *TMEM63B* in intellectual disability, with patients exhibiting similar neurological and movement phenotypes that are partially modelled by the IMPC mouse.

In summary, in this work we demonstrate how by combining different resources, as diverse as human cell proliferation scores, mouse viability data and intolerance to variation scores derived from large sequencing programs, we can identify a set of genes more likely to be associated to disease and therefore propose FUSIL as an efficient resource for disease gene discovery.

## **PgmNr 522: When one tissue is not enough: Child with developmental delays and mosaic marker chromosome duplicating 11p12-11p11.2, present in amniocytes and buccal cells but not in blood cells.**

### **Authors:**

C. Melder; C. Motter

[View Session](#) [Add to Schedule](#)

---

We report the case of an 8 year old girl with developmental delays, who first came to our service's attention prenatally in 2010. An amniocentesis karyotype done for advanced maternal age was read as 47,XX, +mar. To further define the marker chromosome, a prenatal oligonucleotide array was performed which showed mosaicism for a 5.3 Mb gain from 11p12 to 11p11.2 in 70% of the cells studied (using FISH BAC clone from this region). Parental FISH was negative. Delivery was unremarkable, and no further testing was done after birth. The patient returned to our clinic in October 2018; her medical history is unremarkable with the exception of headaches but she has significant expressive speech delay, learning difficulty in all areas and ADHD. A SNP array on blood in our laboratory was normal, without any sign of the 11p duplication. As we suspected there might be mosaicism in other tissues, a microarray was done on buccal cells. This was positive for mosaic (approximately 57%) heterozygous 7.67 Mb duplication at 11p11.12-p12 including many genes. Although this exact duplication has not, to our knowledge, been previously reported, the size of the duplication and the number of genes involved support that it is likely pathogenic. This phenomenon of mosaic chromosomal rearrangements found in other tissues but absent in blood is described for a few other regions, but we have not been able to find cases involving this particular region. It is interesting to note that if the prenatal testing had not been done, chromosomal testing would likely have stopped with the normal study on blood and we might have gone on to single-gene testing. This raises the question of when it is necessary to obtain samples from other tissues for clinically significant mosaicism.

---

Chromosome 15q13.3 microdeletion syndrome (*MIM: 612001*), is characterized by mental retardation, epilepsy, and variable dysmorphism of the face and digits. For years, *CHRNA7* (*MIM: 118511*), encoding for the  $\alpha 7$  nicotinic acetylcholine receptor (nAChR), has been considered as the candidate gene accounting for the neuropsychiatric manifestations associated to this syndrome. However, recent studies in mouse models have shown that *OTUD7A/CEZANNE2* (*MIM: 612024*), which encodes for an ovarian tumor (OTU) deubiquitinase, should be considered as the critical gene, within the 15q13.3 region, responsible for brain dysfunction.

We performed exome sequencing in a patient presenting with severe global developmental delay, language and cortical visual impairment, infantile spasms replaced by generalized myoclonic seizures, and abnormal MRI findings.

Trio analysis allowed us to identify a homozygous *OTUD7A* missense variant NM\_130901.2:c.697C>T. The proband is the second born from consanguineous heterozygous parents, both presenting with learning disability. The brother is also heterozygous for the variant and presents school difficulties. The variant is predicted to alter an ultra-conserved amino acid, p.(Leu233Phe), lying within the OTU catalytic domain.

We are performing functional analyses on this variant which seems to be a strong candidate to explain the neuropsychiatric manifestations in this patient.

---

Brain morphogenesis is an important process contributing to higher-order cognition, however our knowledge about its biological basis is largely incomplete. Here we analyzed 118 neuroanatomical parameters in 1,566 mutant mouse lines and identified 198 genes whose disruptions yield NeuroAnatomical Phenotypes (NAP), mostly affecting structures implicated in brain connectivity. Groups of functionally similar NAP genes participate in pathways involving the cytoskeleton, the cell cycle and the synapse, display distinct fetal and postnatal brain expression dynamics and importantly, their disruption can yield convergent phenotypic patterns. 17% of human unique orthologues of mouse NAP genes are known loci for cognitive dysfunction. The remaining 83% constitute a vast pool of genes newly implicated in brain architecture, providing the largest study of mouse NAP genes and pathways. This offers a complementary resource to human genetic studies and predict that many more genes could be involved in mammalian brain morphogenesis.

## PgmNr 525: Placental epigenetic and gene expression changes associated with maternal dyslipidemia in early pregnancy.

### Authors:

M. Ouidir; P. Mendola; X. Zeng; S. Workalemahu; D. Shrestha; K.L. Grantz; C. Zhang; F. Tekola-Ayele

Although maternal lipid profiles influence placental function which may lead to early fetal programming of adult health and diseases, the underlying mechanisms remain unclear. We performed an epigenome-wide association study to identify placental DNA methylation and mRNA gene expression signatures of maternal dyslipidemia in early pregnancy.

Placental samples from the NICHD Fetal Growth Studies – Singleton cohort were profiled for DNA methylation using Illumina’s Infinium Human Methylation450 Beadchip (n=262) and RNA sequence (n=64). Maternal lipid levels were measured using blood samples collected in early pregnancy and dichotomized as high total cholesterol (TChol,  $\geq 200$  mg/dl), low high-density lipoprotein cholesterol (HDLc,  $\leq 50$  mg/dl), high low-density lipoprotein cholesterol (LDLc,  $\geq 100$  mg/dl) and high triglycerides (TG,  $\geq 150$  mg/dl). For each maternal lipid trait, we conducted epigenome-wide association analyses with covariate-adjusted robust linear regression models. Genes harboring top differentially methylated CpGs (FDR-adjusted  $P$ -value  $< 0.05$ ) were evaluated for placental mRNA gene expression.

High TChol was associated with hypermethylation of cg20637199 (*STK11*) and cg10695180 (*MOGAT2*). High LDLc was associated with hypomethylation of cg02047211 (*RPTOR*). High TG was associated with hypomethylation of cg07255925 (*HECTD2*), cg02785814 (*ALX4*) and cg04985482 (*MICA*) and hypermethylation of cg09326404 (*FAAH*). Genes annotating the top epigenome-wide significant CpGs were enriched in disease and functional pathways including cell death of mesenchymal cells ( $P$ -value =  $8.5 \times 10^{-5}$ ) and dyslipidemia ( $P$ -value =  $1.4 \times 10^{-4}$ ). High TChol, high TG and low HDLc were associated with decreased expression of *ALX4* in placenta (FDR-adjusted  $P$ -values were  $1.5 \times 10^{-3}$ ,  $1.9 \times 10^{-2}$  and  $1.3 \times 10^{-11}$ , respectively). Functional annotation found five genetic loci that regulate methylation levels (*cis*-meQTL) of cg02785814 (*ALX4*) in blood. The variants were also *cis*-eQTL with *ALX4* and *EXT2*, which are essential for fetal structure formation and angiogenesis. *ALX4* and *EXT2* exhibit the highest expression in placenta and female reproductive organs, and harbor loci associated with type-2 diabetes, hypertension, and LDLc in adults.

Our study revealed that maternal dyslipidemia in early pregnancy was significantly related to several novel placental epigenetic signatures that have been implicated in vascular and structural development and the etiology of cardiometabolic diseases in later life.

## PgmNr 526: Clustering of co-morbid conditions among *FMR1* premutation carrier women.

---

Fragile X-associated primary ovarian insufficiency (FXPOI) is seen in about 20% of women who carry an *FMR1* premutation (PM) allele (55-200 CGG repeats). These women develop hypergonadotropic hypogonadism with amenorrhea before the age of 40. A non-linear association with repeat size in the PM range and risk for FXPOI has been documented: those with a mid-range repeats are at highest risk (~70-100 repeats). Importantly, not all female carriers with 70-100 repeats experience FXPOI. Studies have also described an increased reporting of co-morbid conditions by PM women, including depression, anxiety, headaches, sleep problems, peripheral neuropathy, hypothyroidism, and many others. Furthermore, PM women are at risk for developing a late-onset fragile X-associated tremor-ataxia syndrome (FXTAS), typically after age 50. The risk for FXTAS increases linearly with repeat size, indicating a different molecular mechanism. We have collected general medical history information along with reproductive histories on 355 women with a PM, including 87 with FXPOI and 168 without FXPOI (still cycling or menopause after age 40), to more fully understand their complex health histories. Notably, anxiety, depression, tension headaches, and migraines were reported by more than 30% of all PM women. Using survival analysis to examine the age of diagnosis, adjusting for the age at evaluation, women with FXPOI compared with women without FXPOI had an earlier age at onset for anxiety, depression, tension headaches, hypothyroidism, fibromyalgia, and osteoporosis. We used cluster analysis to identify co-morbid conditions that grouped together across all PM women, and our final model consisted of eight clusters. Importantly, the majority of PM women fell into the three categories that were primarily defined by only one or a few medical issues: "Minimal conditions" (N=123), "Headaches" (N=33), and "FXPOI with minimal other conditions" (N=67). Also of note, a single cluster defined women with symptoms of FXTAS (e.g., tremor, ataxia and neuropathy), and none of these women met the criteria for FXPOI. Taking all the results together, it appears that many PM women are at risk for only minimal co-morbid conditions, and the most frequent conditions are depression, anxiety, and headaches. Further, women with symptoms of FXTAS appear to be distinct from women with symptoms of FXPOI, confirming theories that these two PM-associated phenotypes may be the result different molecular mechanisms.

## PgmNr 527: Genetic signals for vasomotor symptoms during menopause suggest potential drug targets.

### Authors:

### BACKGROUND

Vasomotor symptoms such as hot flushes and night sweats are experienced by 80% of women around menopause and can significantly affect quality of life. On average they last around 5 years with 10% of women experiencing symptoms for >10 years. Changes in hormone levels, particularly oestrogen are key factors and hormone replacement therapy (HRT) is an effective treatment. However, the publication of health risks associated with HRT in 2002 meant a substantial reduction in uptake of the treatment in the UK – from 49% of women pre-2002 to 14% of women post-2002.

### METHODS

We have used the change in HRT use since 2002 to identify genetic variants associated with vasomotor symptoms in 150,000 post-menopausal women from UK Biobank. We compared genetic variants from a GWAS of HRT use in women taking HRT before and after 2002.

### RESULTS

We identified 15 independent signals associated with any HRT use. Eleven of the 15 signals were associated with menopause timing and of these, nine were associated with raised HRT use in women taking HRT before 2002 but not after. This implies that HRT prior to 2002 was often prescribed because a woman was menopausal, rather than for specific symptoms.

In contrast, one variant was associated with raised odds of using HRT in those taking HRT before and after 2002 (OR=1.17, 95%CI=1.13,1.21 pre 2002; OR=1.20, 95%CI=1.12,1.30 post-2002). This common variant with allele frequency of 95% was in *TACR3*, the receptor for neurokinin ( $P=1\times10^{-26}$  in all women). The locus was also identified in a previous genome-wide analysis of vasomotor symptoms ever versus never (Crandall et al 2017). Furthermore, an antagonist of the neurokinin B receptor has been shown to reduce vasomotor symptoms in a randomised control trial (Prague et al, 2017).

### CONCLUSIONS

Our study uses changes in health practice to identify a genetic variant associated with vasomotor symptoms during the menopause transition. The findings strengthen the evidence that targeting neurokinin B could be an effective treatment for the millions of women who experience menopausal symptoms, without the potential side effects associated with hormonal treatments.

## PgmNr 528: The landscape of variations of embryonic mitochondrial genome.

---

**Introduction:** Maternal transmission, variant selection during gametogenesis, and propensity to accumulate mutations highlight the role of mtDNA integrity in gamete maturation, fertilization, and embryonic development. Studying variations in mtDNA and evaluating effects of these on embryo development is essential in understanding the biology and outcomes of in vitro fertilization. Sparse data available on human blastocyst mtDNA variation suggests a higher rate of de-novo mutations and occurrence of heteroplasmy as a mechanism for mt dysfunction. The purpose of this study was to evaluate sequence variation of human embryonic mtDNA, and correlate this with different infertility parameters, to study their impact on implantation and embryonic development.

**Methods:** We performed a retrospective study on known outcome selected blastocysts after single euploid embryo transfer (96 from fertile-FP and 106 from infertile patients-IFP) (92-no implantation-NI, 56-ongoing pregnancy-OP, and 54-miscarried-AB). Whole genome amplified DNA from trophectoderm biopsies of blastocysts that had undergone PGT-A were utilized for targeted mtDNA library prep, using PrecisionIDmtDNA kit on the IonTorrent PGM platform. Variant calling and data analysis was performed using IonReporter, MitoMap and Partek software. Regions with >20x mtDNA coverage were included in the analysis.

**Results:** Mt genome was sequenced at av. depth of 400x and 41.6% coverage for all embryos. Mutation frequency was similar in FP and IFP: D-loop (48.2%, 41.1%), RNR1 (22.6%, 23.2%), RNR2 (14.5%, 9.8%), ND3 (6.9%, 11%), ND1 (4.8%, 3.2%), ND4L and CO1 (1.49%). Average variant load per embryo (VPE) in FP and IFP was  $6.3 \pm 7.2$  and  $7.3 \pm 8.4$  respectively, of which disease causing mutations (DCM) were  $0.73 \pm 0.81$  and  $0.75 \pm 1.1$ , respectively. 70.4% of them were homoplasmic (>80% mutant allele), OR 8.66 [95%CI: 8.64-8.67]. Embryos that resulted in OP had lower frequency of DCM compared to embryos that AB ( $p=0.0004$ ) and NI ( $p=0.03$ ). DCM in RNR1, CO1 and ND4L genes were present only in embryos that NI or AB ( $p=0.001$ ). There was no correlation between embryonic mtDNA variant load and maternal age.

**Conclusion:** Embryonic mtDNA has a high frequency of sequence variants, D-loop being the most common. Maternal age did not impact the variation load. Integrity of RNR1, CO1 and ND4L genes determines the outcome after euploid embryo transfer, however larger sample size and a validation study are necessary to confirm their predictive value.

## **PgmNr 529: 3- Hydroxyisobutyryl-Co A hydrolase (HIBCH) deficiency: An early infantile onset leigh-like presentation with two novel mutations with c.763C>T and c.428C>A on *HIBCH* gene.**

---

3-Hydroxyisobutyryl-CoA hydrolase (HIBCH) deficiency is a rare inborn error of valine metabolism which inherited autosomal recessively involving the HIBCH gene on chromosome 2q32. HIBCH is an enzyme that catalyzes the hydrolysis of 3-hydroxyisobutyryl-CoA into 3-hydroxyisobutyric acid in the mitochondria. With a mutation in both copies of HIBCH gene, catabolism of valine would be affected, leading to accumulation of methacrylyl-CoA, a highly toxic intermediate metabolite suspected to reduce mitochondrial enzyme activities. There is by far no cure for the disease and treatment remained supportive. We present a 8 years old patient who was born at 38 weeks and 6 days with birth weight 2.46kg. She presented at the age of 3 months old with clinical features resembling Leigh syndrome, failure to thrive, developmental delay, microcephaly, hypotonia, and poor visual fixation. Whole exome sequencing found two novel mutation with a heterozygous c.763C>T(p.R255X) pathogenic variant in the HIBCH gene and a heterozygous c.428C>A (p.T143K) variant of unknown significance in the HIBCH gene. Our patient developed into a phase of progressive neurodegeneration with deteriorated swallowing function, motor function, and became ventilator dependent at around 9 months old. Echocardiogram showed hypertrophic cardiomyopathy. Magnetic resonance imaging of the brain showed T2 hyperintense and T1 hypointense signal in bilateral basal ganglia, thalami, cerebral peduncles, hippocampal regions, brainstem and deep gray matter with cavitary lesion. Acylcarnitine profile showed elevation of C4-carnitine in one sample only at the time of acute neural deterioration, and soon became normalized. Gas chromatographic analysis of urinary organic acids also showed elevated lactic acid and branched-chain ketoacid. Metabolomic profiling was performed after she had the neuroregression phase, there was no valine metabolism pathway related metabolites detected. Later, she also has autonomic dysfunction with thermolability. Valine restriction diet does not change the clinical progress of the patient. The study describes two novel mutation and the natural history of HIBCH deficiency, it expands the clinical phenotype related to HIBCH deficiency.

## PgmNr 530: Newborn screening for lysosomal storage disorders in Oregon from results to clinical findings: A 6 month retrospective.

### Authors:

---

Newborn screening for lysosomal storage disorders (LSD) has been implemented in a number of states in the U.S. However, publications about their experience from initial laboratory testing through follow-up with DNA results and clinical outcomes are rare. We describe Oregon's experience during the first six months of screening for 4 LSDs from initial testing of the dried blood spot (DBS) through clinical follow-up and outcome. From October 1, 2018 through April 30, 2019, 24,209 babies were adequately screened for enzyme activity for Pompe, mucopolysaccharidosis (MPS1), Fabry, and Gaucher using DBS on the Baebies microfluidics platform. Samples with an enzyme activity below the cut-off were sent for second tier DNA testing. Of these, 5 babies were confirmed to have disease: 2 with MPS1, 2 with Gaucher, and 1 with Fabry. The approximate incidence of disease was 1 in 12,000 for both MPS1 and Gaucher and 1 in 24,000 for Fabry. Notably, both MPS1 patients have been determined to have non-Hurler disease and the Fabry patient has a late-onset allele. None of the confirmed cases are clinically indicated at this time to be treated. Two babies without current clinical signs or symptoms are being followed: one infant with pathogenic allele and pseudodeficiency allele in conjunction with a variant of uncertain significance (VUS) in the *GAA* gene, and one infant with a VUS in *trans* with a pathogenic variant in *IDUA*, who had normal urine mucopolysaccharides screen at 9 weeks of age. Finally, accounting for all known possible pseudodeficiency alleles, the false positive rates were 0.57%, 0.04%, 0.09%, and 0.80% for Pompe, MPS1, Gaucher, and Fabry disease, respectively.

## **PgmNr 531: Cytogenetic abnormalities found in 675 Mexican patients with diagnosis associated with abnormal sexual development.**

---

Cytogenetic abnormalities found in 675 mexican patients, with a clinical diagnosis of disorders in sexual development, are evaluated. The diagnosis of each case was classified based on the sections of congenital malformations of the genital organs and adrenogenital disorders of the International Statistical Classification of Diseases and Related Health Problems of the World Health Organization.

We included 675 patients from April 2004 to March 2019with. The samples were processed according to the specifications established by The AGT Cytogenetics Laboratory Manual for obtaining metaphases stained with the GTG bands methodology. The karyotype analysis was carried out using the GEN ASIs system (Applied Spectral Imaging®).

The population was predominantly female, representing 62% of the cases, of the rest 34% corresponded to the male sex and the remaining 4% did not have data that allowed to corroborate sex. Most patients are children (0-5 years), which corresponds to 51.1% followed by adolescent (12-17 years) with 19.3%. The results of the karyotype showed that 39% of the cases present numerical and/or structural chromosomal abnormalities. According to the classification of the World Health Organization, 48.9% corresponds to Turner Syndrome, followed by indeterminate sex and pseudo hermaphroditism with 13.9%; These data coincide with that reported by other authors. The chromosomal abnormalities with greater frequency were those that presented only aneuploidies (79% of the cases) followed by aneuploidies with additional structural abnormalities (16% of the cases), those that only presented structural abnormalities represented 11% of the study population.

The sex chromosomes X and Y, presented the highest number of numerical and/or structural abnormalities. The autosome chromosomes 18, 5 and 21 showed more abnormalities than the rest of them. Of the structural abnormalities, the isochromosomes were the most frequent with 54.7% , ring chromosomes with 17%, followed by deletions and derivative chromosomes with the same number of cases represented by 9.4% for each anomaly.

Cytogenetic findings in the mexican population allow to identify the frequency of the abnormalities presented on new borns, children and young adults referred to our laboratory. The data obtained show the markers associated to the disorders of the sexual development. The information acquired has relevance of much importance for the pre and post natal medical care in our community.

## PgmNr 532: Clinical exome sequencing as a tool in prenatal diagnosis and genetic counseling: Assessment in 25 cases.

### Authors:

S. Singh; S. Thakur

[View Session](#) [Add to Schedule](#)

---

**Background-** Prenatal diagnostic testing for rare genetic disorders is a rapidly advancing field. Genetic disorders resulting in prenatal or neonatal death are rare and genetically heterogeneous. An accurate diagnosis of the index case is essential for accurate prenatal diagnosis, but testing is often limited by the availability of fetal DNA. Without a potential prenatal test, couples are left in a dilemma for future pregnancies. To help parents to make an informed decision relating to the pregnancy. We describe our novel method to use exome sequencing parental DNA samples and on the affected fetus, to identify recessive monogenic disorders in a study of 25 samples referred. We demonstrate the utility of exome sequencing in reaching an accurate diagnosis and thus helping in prenatal diagnosis and genetic counseling. **Methods-** Exome sequencing was carried out in parents or fetus affected with a lethal or prenatal-onset disorder. Heterozygous rare variants in the same gene in both parents were selected for analysis. Likely, disease-causing variants were tested in fetal DNA to confirm co-segregation. **Results-** A total of 25 parents or fetus underwent whole genome sequencing or partial exome sequencing after ante-natal genetic counseling. Consanguinity was seen among 6 (24%) of the couples. Fetal DNA samples were obtained either from amniotic fluid (n=8, 40%) or by chorionic villus sampling (n=12, 60%). Whole genome sequencing (WGS) of either or both of the parents was done in 12 (48%) couples for identification of genetic illnesses. An index genetic disease case in the family was present in 16/25 (64%) couples screened and when prior fetus or child is affected, a genetic diagnosis was obtained in 69% (n=11) of the current fetus. Two couples, one each with homozygous carrier state for retinoblastoma gene and Leber's congenital amaurosis were identified during prenatal genetic counseling and thus WGS helped in prenatal counseling for risk assessment in a future pregnancy. **Conclusion-** Genome sequencing is an important tool in diagnosing genetic illnesses in a fetus who show changes in fetal ultrasonography. It is especially important for risk assessment if a history of genetic illness is present in previous pregnancies. Whole genome sequencing is important in prenatal counseling for parents.

## PgmNr 533: Clinical utility of noninvasive prenatal testing for chromosome disease syndromes in 94,000 subjects.

**Authors:**

L. Wu; D. Liang

[View Session](#) [Add to Schedule](#)

**Affiliation:** Center for Medical Genetics, School of Life Sciences, Central South University, Changsha, Hunan, China

---

**Purpose:** To assess the clinical performance of an expanded non-invasive prenatal test (NIPT) (named as “NIPT-Plus”) for detection of both aneuploidy and genome-wide microdeletion/microduplication syndromes (MMS).

**Methods:** A total of 94,085 women with a singleton pregnancy were prospectively enrolled in the study. The cell-free plasma DNA was directly sequenced without intermediate amplification and fetal abnormalities identified using an improved copy number variation (CNV) calling algorithm.

**Results:** A total of 1128 pregnancies (1.2%) were scored positive for clinically significant fetal chromosome abnormalities. This comprised 965 aneuploidies (1.026%) and 163 (0.174%) MMS. From follow up tests, the positive predictive values (PPVs) for T21, T18, T13, rare trisomies and sex chromosome aneuploidies were calculated as 95%, 82%, 46%, 29% and 47%, respectively. For known MMS (n=32), PPVs were 93% (DiGeorge), 68% (22q11.22 microduplication), 75% (Prada-Willi/Angleman) and 50% (Cri Du Chat). For the remaining genome-wide MMS (n=88), combined PPVs were 32% (CNVs > 10 Mb) and 19% (CNVs < 10 Mb).

**Conclusions:** NIPT-Plus yielded high PPVs for common aneuploidies and DiGeorge Syndrome, and moderate PPVs for other MMS. Our results present compelling evidence that NIPT Plus can be used as a first-tier pregnancy screening method to improve detection rates of clinically significant fetal chromosome abnormalities.

## PgmNr 534: Sleep disturbances in school age children with PTHS, SMS, and MAND mirror sleep abnormalities in autism spectrum disorder.

### Authors:

A. Gandhi <sup>1,2</sup>; D. Zhou <sup>1</sup>; J. Alaimo <sup>1</sup>; E. Chon <sup>1</sup>; M.D. Fountain <sup>1</sup>; S.H. Elsea <sup>1</sup>

---

Sleep disturbance in school-age children has been studied to some extent in children with Smith-Magenis syndrome (SMS). However, for neurodevelopmental disorders such as Pitt-Hopkins syndrome (PTHS) and MBD5-associated neurodevelopmental disorder (MAND), the existence of sleep disturbance in this population is not yet defined or well characterized. We surveyed caregivers of school-age children with these 3 disorders using the Children's Sleep Health Questionnaire (CSHQ) to assess how sleep disturbance differed between groups and identify disorder-specific sleep problems. We also compared our data to existing data regarding sleep disturbance in school-aged children with autism spectrum disorders (ASD). The CSHQ provided evidence for sleep disturbance in each condition (total score > 41); however, while there were similarities, specific concerns differed. The mean total CSHQ score for MAND ( $55.33 \pm 13.26$ ) was significantly different from that of ASD ( $48.83 \pm 9.68$ ), while PTHS ( $44.67 \pm 7.91$ ) and SMS ( $51.81 \pm 8.46$ ) were not. Further, mean nighttime sleep duration in hours for PTHS ( $10.18 \pm 1.52$ ) differed significantly from SMS ( $7.84 \pm 1.52$ ), MAND ( $8.41 \pm 2.2$ ), and ASD ( $8.78 \pm 1.55$ ). Overall, data indicate that sleep disturbance in PTHS is less severe than that observed in SMS and MAND. Sleep disturbance in SMS and MAND do not significantly differ from each other based on total scores on the CSHQ. Individuals with PTHS had significantly lower scores for daytime sleepiness than the ASD group; however, MAND > ASD > SMS on the daytime sleepiness subscale. Additionally, while the PTHS group did not differ from ASD for night wakings, the SMS and MAND groups scored significantly higher. All 3 groups showed significantly higher parasomnias than the ASD group. Restless sleep and bedwetting were notably present across all disorders. Overall, only parasomnias & daytime sleepiness differed significantly between PTHS and ASD, parasomnias & night wakings between SMS and ASD, and night wakings & parasomnias between MAND and ASD, suggesting that, while different aspects of sleep disturbance in each disorder mirror the wide range found in the general ASD population, certain aspects such as night wakings and parasomnias are shared and do differ significantly from ASD. These data further illustrate the complexity of these conditions and the challenges of underlying sleep disturbance in each population, indicating the need for more support, education, and treatment for these individuals.

## PgmNr 535: *FKBP8* rare variants are risk factors for human neural tube defects.

### Authors:

T. Tian <sup>1,2</sup>; X.Y. Cao <sup>1</sup>; S.E. Kim <sup>3</sup>; Y.L. Lin <sup>1</sup>; B.J. Wlodarczyk <sup>1</sup>; Y.P. Lei <sup>1</sup>; R.H. Finnell <sup>1,3</sup>

---

**Background:** Neural tube defects (NTDs) are a group of serious congenital defects that occur due to a failure of neural tube closure during early embryonic development. The genetic etiology of NTDs remains poorly understood. *FKBP8*, an immunophilin family member that binds to FK506, is critical for proper neural tube ventralization through antagonism of the sonic hedgehog (Shh) signaling pathway during development. *FKBP8* also inhibits apoptosis by anchoring *BCL2* and *BCLXL* to mitochondrial membranes. Loss of *Fkbp8* results in increased apoptosis in the posterior neural tube. *Fkbp8*<sup>-/-</sup> mouse embryos showed NTDs consistent with a diagnosis of spina bifida. To date, no publication demonstrates any possible association between *FKBP8* and human NTD risk. Thus, this study provides the first evidence for a relationship between *FKBP8* and spina bifida in humans.

**Methods and Results:** Sanger sequencing was performed on 384 spina bifida cases. One loss of function variant (p.E140X) and four nonsynonymous rare mutations (p.S3L, p.K315N, p.A292S, p.A251G) which were predicted to be deleterious were identified. GFP-*FKBP8* was created by subcloning of *FKBP8* CDS region into pEGFPC1. Identified variants were introduced into GFP-*FKBP8* plasmids by site direction mutagenesis. Subcellular localization assay performed on HeLa cells showed that the variant p.E140X affected *FKBP8* localization from the mitochondrion in the cytoplasm into the nucleus. The other variants had no obvious effect on *FKBP8* protein localization. The *FKBP8* protein expression of variants p.S3L, p.K315N, p.A292S was decreased, and p.E140X produced a truncated form of *FKBP8* protein in 293T cells. Furthermore, *FKBP8* variants had enhanced Shh signaling activity as determined by Western Blot in 293T cells, indicating those variants may decrease the antagonism of *FKBP8* on the Shh pathway.

**Conclusion** Our study indicates that rare deleterious variants of *FKBP8* are risk factors for human NTDs. Rare variants of *FKBP8* could contribute to spina bifida via dysregulation of the Shh signaling pathway.

## PgmNr 536: Nephro-cutaneous syndrome in 21 Roma children with congenital EGFR mutation.

Background: Epidermal growth factor receptor (EGFR), a transmembrane glycoprotein, mediates many cellular growth and differentiation processes, through its tyrosine-kinase activity. Acquired activating mutations are common in malignant transformation processes of various tumors. Unique loss of function, homozygous mutation is congenital and causes a distinct phenotype.

Cohort study: We report on the largest cohort of 21 Roma children with EGFR deficiency. Perinatal course involved polyhydramnios, intrauterine growth restriction and significant prematurity, followed by the development of specific skin condition initially with thin and fragile skin, later with persistent desquamative ichtiosiforme dermatitis prone to inflammation. Some children had progeroid facial features. Early postnatally recurrent infectious complications (presented as sepsis in 47 % of the cases) appeared. The prognosis was poor, all children beside one died before 6 months of age. Additionally we present the longest surviving, 13 year old boy, who developed previously unreported renal impairment with Fanconi-like syndrome and secondary hyperaldosteronism.

Results: Homozygous c.1283G>A (p.Gly428Asp) mutation in *EGFR* was confirmed in 16 of the 21 reported cases due to retrospective patient analysis.

Discussion: Severely underdiagnosed EGFR deficiency, prevalent in the Roma population, is a crippling disorder, presenting with repeated infections and ichtiosiforme dermatitis. Apart from the largest reported cohort of 20 children, we present a long-term surviving patient, who, apart from typical epidermal features, suffers from previously undescribed, severe combined renal glomerular and tubular dysfunction, which turned up to be survive limiting since infancy and may contribute to chronical growth retardation.

### Affiliations:

1) Medical Ethics and Medical Genetics, Kyoto University School of Public Health, Kyoto, Japan; 2) Clinical Genetics Unit, Kyoto University Hospital, Kyoto, Japan; 3) Health Informatics, Kyoto University School of Public Health, Kyoto, Japan

**Objectives:** Trisomy 21 (T21) is one of the major concerns in prenatal genetic testing. In the past few decades, the overall mortality and morbidity of T21 have improved through intensive management, but little is known about prognosis of very low birth weight (VLBW) infants with T21. Our purpose was to investigate mortality and morbidity of VLBW infants with T21 in Japan, compared with those of VLBWI infants with no birth defects (BD-).

**Method:** Maternal and neonatal data were collected prospectively for infants weighing less than 1,501 grams who admitted to centers of the Neonatal Research Network of Japan (NRN-J) during the period of January 2003 to December 2016. Statistical significance for unadjusted comparisons was determined using Fisher's exact test, Pearson's chi-square test, Wilcoxon test and logistic regression analysis. This study was approved by Ethics Committee of Kyoto University Graduate School and Faculty of Medicine.

**Results:** Of 60,136 VLBW infants, number of T21 was 328 (0.55 %). The frequency of maternal complications and the use of antenatal steroid was significantly low in T21 compared with BD-, except for diabetes mellitus. Cesarean section, male contribution, outborn and gestational age were significantly high in T21 compared with BD-. About two third of T21 VLBW infants were small for gestational age. Although non-reassuring fetal status was significantly high in T21, there was no significant difference in Apgar Score either at 1 minute or 5 minutes. The rates of respiratory distress syndrome, chronic lung disease and retinopathy of prematurity were significantly low in T21 compared with BD-. Mortality rate in NICU was 22.9 % for T21, compared with 5.6 % for BD-, respectively. Mean length of hospital stay for survivors was 123.1 days for T21, compared with 93.8 days for BD-.

**Conclusion:** NRN-J database contains about two third of VLBW infants born in Japan and our data is the first national survey for VLBW infants with T21. Although there is limitation that no data exists about the timing of diagnosis, which may affect the plan for care, our data showed that more than three forth of VLBW infants with T21 could achieve to go home. This will be a meaningful data for prenatal counseling, perinatal management and treatment.

## PgmNr 538: Genome sequencing analysis of fetuses with increased nuchal translucency.

---

**Background:** Increased Nuchal Translucency (NT) is an important biomarker which is associated with higher risk of fetal structural anomalies. It is known to be contributed by different genetic etiologies ranging from single-base mutations to those affecting millions of base-pairs. Currently, prenatal diagnosis is routinely performed by karyotyping and chromosomal microarray analysis (CMA), however, both of them are limited in resolution. The diversity of the genetic etiologies warrants an integrated assay such as genome sequencing (GS) for comprehensive detection of genomic variants. Herein, we aim to evaluate the feasibility of applying GS in prenatal diagnosis for the fetuses with increased NT.

**Methods:** We retrospectively applied GS (>30-fold) for the fetuses with increased NT ( $\geq 3.5$ -mm), which were undergone routine prenatal diagnosis. Detection of single-nucleotide variants, copy-number variants and structural rearrangements were performed simultaneously and the results were integrated for interpretation in accordance with the guidelines of American College of Medical Genetics and Genomics. Pathogenic or likely pathogenic (P/LP) variants were selected for validation and parental confirmation, if available.

**Results:** Overall, 50 fetuses were enrolled, including 34 isolated and 16 with reported fetal structural malformations. Routine CMA/karyotyping reported eight P/LP CNVs, yielding a diagnostic rate of 16.0% (8/50). In comparison, GS provided a 2-fold increased diagnostic yield (32.0%, 16/50), including one mosaic turner syndrome, eight cases with microdeletions/microduplications and seven cases with P/LP point mutations. Moreover, GS identified two cryptic insertions and two inversions. Follow-up study further demonstrated the potential pathogenicity of a balanced insertion disrupting an OMIM autosomal dominant disease-causing gene at the inserted site.

**Conclusions:** Our study demonstrates that applying GS in fetuses with increased NT is able to comprehensively detect and delineate the spectrum of genomic variants contributory to the diseases. Importantly, prenatal diagnosis by GS doubled the diagnostic yield compared with routine protocols. Given a comparable turn-around-time and less DNA required, our study provides a strong evidence to facilitate GS in prenatal diagnosis, particularly in fetuses with increased NT.

## PgmNr 539: HCFC1: A new transcriptional regulator coupling vitamin B12 metabolism to neural crest development.

---

Recently, patients with *cbIX*, an X-linked variant of the *cbIC* cobalamin (vitamin B12) deficiency syndrome, were discovered. While *cbIX* phenocopies most of the clinical symptoms observed in *cbIC*, the disease is caused by mutations in the transcription cofactor *HCFC1* (*Host Cell Factor C1*). Previous research has determined that *HCFC1*, along with the transcription factor *RONIN* (*THAP11*), directly regulates the expression of *MMACHC*, which encodes an enzyme essential for cobalamin metabolism and is mutated in *cbIC* patients. Thus, the origin of the *cbIX* phenotype is likely in part due to transcriptional reduction of *MMACHC* during development.

In order to address this possibility and to define the exact pathophysiology of *cbIX*, our group has generated the *Hcfc1 A115V* mouse model, which carries the most frequent missense mutation observed in *cbIX* patients. Unexpectedly, the *A115V* hemizygous mice exhibit a fully penetrant skin hypopigmentation phenotype and craniofacial dysmorphia, indicating a potential defect in neural crest cell (NCC) development. These data have led us to hypothesize that *HCFC1* functions in a transcription factor complex to regulate NCC development through regulating *Mmachc* and cobalamin metabolism.

We have determined that, analogous to *cbIX* patients, *A115V* hemizygous mice have a dramatic reduction of *Mmachc* levels in embryonic tissue. Moreover, the hypopigmentation phenotype is rescued by over-expressing *Mmachc* in these mice. These data suggest that we have uncovered a new transcriptional program influencing NCC development and raises the intriguing possibility that disrupted cobalamin metabolism may also play a role. Current efforts are aimed at determining the specific requirement for cobalamin during NCC development.

## PgmNr 540: Placental transcriptome analysis using RNA sequencing in monochorionic twin pregnancies complicated by selective growth restriction.

**Authors:**

T. Leung

[View Session](#) [Add to Schedule](#)

**Affiliation:** Obstetrics & Gynaecology, The Chinese University of Hong Kong, Hong Kong, China

---

**Objective:** to investigate if there any difference in placental gene expression between the selective intrauterine growth (sIUGR) twin and the normally growing co-twin in monochorionic diamniotic (MCDA) twin pregnancies

**Method:** This was a prospective study on differential gene expression in MCDA twin placenta complicated by sIUGR. The normally growing twin of MCDA pairs with sIUGR was used as a reference for control genetic factors of the fetus and maternal factors of the mother. This study is divided into 2 stages: (1) Gene discovery phase: Placental tissues from 5 sIUGR and 2 control pairs were sampled for transcriptome profiling. (2) Validation phase: Placental tissues from 13 sIUGR and 6 control pairs were collected for RNA and protein validation. Placental biopsies were obtained from women with sIUGR and matched controls in the delivery ward. In the gene discovery phase, the transcriptome profiling was discovered by RNA sequencing (RNA-seq). In the validation phase, RNA and protein expression level of candidate genes were determined by quantitative real-time PCR (qRT-PCR) and immunohistochemistry (IHC) staining.

**Result:** A total of 2455 transcripts were differentially expressed in placenta of all sIUGR-MCDA pairs, where 1043 were up-regulated and 1412 down-regulated. OS9 and M6PR were expressed in the trophoblasts of chorions. RNA and protein expression were significantly upregulated in sIUGR ( $p < 0.05$ ).

**Conclusion:** Endoplasmic Reticulum Lectin (OS9) and Mannose-6-Phosphate Receptor (M6PR) were increased in placenta of sIUGR-MCDA twin, but not in their normal growth co-twin.

## **PgmNr 541: Exome sequencing analysis, based on bioinformatics scores for prioritizing variants before fetal reverse phenotyping, optimize diagnosis and identify novel candidate genes in fetuses with multiple congenital abnormalities.**

Singleton exome sequencing (sES) harbors a diagnostic yield in fetuses with multiple congenital abnormalities (MCA) almost 10% lower than in live birth individuals. Such difference is largely explained by a poor knowledge of the fetal clinical hallmarks associated with pathogenic variants in morbid genes, which hinders the ability to establish an exact genotype-phenotype correlation. We gathered a large prospective multicentric cohort of 95 MCA undiagnosed fetuses, and deployed a multistep sES analysis approach to facilitate the identification of causative variants and of novel candidate genes. In the first step, we prioritized variants making use of a genotype-first approach based on bioinformatics scores and variant annotation databases, blind to fetal phenotypes. We selected in OMIM genes associated with developmental anomalies (OMIM-da): (a) high-confidence (likely)pathogenic annotation in ClinVAR, compatible with the expected inheritance model; (b) truncating variants in genes being intolerant to loss-of-function (LoF-I) and autosomal dominant inheritance, (c) predicted damaging recessive variants in autosomal recessive or X-linked OMIM-ad. Causality was confirmed by reverse phenotyping on autopsic findings. In the second step, the remaining negative fetuses were analysed according current clinical practices based on phenotype-genotype correlations. Lastly, we analysed LoF variants in all OMIM genes not related to human diseases so far, prioritizing: (1) LoF variants in LoF-I genes; (2) recessive LoF (homozygous of compound heterozygous) variants. Family segregation of the selected variants was ascertained by Sanger sequencing. The first step resolved 18/95 patients, while the second step allowed the identification of 5 additional cases (global yield 24%). Variants of Unknown clinical Significance (VUS) in OMIM-ad genes were retained as candidates for 18/95 additional patients (18.9%). Among these, 2 strong candidate variants could not be classified as causal because of the poor fetal phenotype-genotype correlation. The third step identified eight novel candidate genes (8.4%). Our approach shows that a genotype-first approach followed by reverse phenotyping seems to be a valid alternative to a phenotype-driven variant hunting in sES data prioritization, in the context of low or partial genotype-phenotype correlation., This approach owns the potential to fill in the gap between fetal and

postnatal diagnostic yield when trio analysis is not available.

---

Rubinstein-Taybi syndrome (RSTS; OMIM 180849) is an autosomal dominant developmental disorder characterized by facial dysmorphism, broad thumbs and halluces associated with intellectual disability. RSTS is caused by alterations in *CREBBP* (about 60%) and *EP300* genes (8%). RSTS is often diagnosed at birth or during early childhood but generally not suspected during antenatal period. We report nine cases of well-documented fetal RSTS. Two cases were examined after death in utero at 18 and 35 weeks of gestation and seven cases after identification of ultrasound abnormalities and termination of pregnancy. On prenatal sonography, a large gallbladder was detected in two cases, and brain malformations were noted in four cases, especially cerebellar hypoplasia. However, the diagnosis of RSTS has not been suggested during pregnancy. Fetal autopsy showed that all fetuses had large thumbs and/or suggestive facial dysmorphism. A *CREBBP* gene anomaly was identified in all cases. Alterations were similar to those found in typical RSTS children. This report will contribute to a better knowledge of the fetal phenotype to consider the hypothesis of RSTS during pregnancy. Genotyping allows reassuring genetic counseling.

## PgmNr 543: Clinical utility of a 12-gene Noonan spectrum disorders panel in prenatal and postnatal cohorts.

---

Noonan spectrum disorders are a clinically overlapping group of autosomal dominant diseases caused by germline mutations in genes involved in the RAS-MAPK signaling pathway with a prevalence at 1/1000-2500. This study evaluates the clinical utility of a 12-gene Noonan spectrum disorders panel in prenatal and postnatal cohorts. Two hundred thirty-four fetal samples and 113 postnatal specimens were sequenced in our laboratory between 2014 and 2019. In the prenatal cohort, the average gestational age at testing was 16.2 weeks (range: 11.1-25.3). Increased nuchal translucency (NT) was the most common prenatal ultrasound finding, present in 71.4% of the fetuses, followed by cystic hygroma (13.2%). Pathogenic or likely pathogenic variants were detected in four genes in the prenatal cohort: *PTPN11* (n=4), *RIT1* (n=2), *SOS1* (n=1) and *RAF1* (n=1). Among these eight positive cases, three fetuses showed solely cystic hygroma, two showed increased NT, one showed cardiac defect and facial dysmorphism, and two had unspecific ultrasound findings. In the postnatal cohort, 55 patients harbored a pathogenic or likely pathogenic variant spread amongst eight genes: *PTPN11* (n=29), *SOS1* (n=11), *BRAF* (n=4), *RIT1* (n=4), *HRAS* (n=3), *SHOC2* (n=2), *KRAS* (n=1) and *RAF1* (n=1). The average age at testing for the patients with positive results was 4.8 yrs (range: 0-18.8). Facial dysmorphism was the most common clinical phenotype, present in 61.8% of patients with positive results and specified clinical indications, followed by cardiac defects (47.1%), developmental delay (44.1%) and short stature (35.3%). The overall diagnostic yield was 3.4% (n=8/234) for the prenatal cohort and 48.7% (n=55/113) postnatally. Three genes, *PTPN11*, *SOS1* and *RIT1*, comprised 87.5% (n=7/8) of total disease-causing variants in the prenatal cohort and 80.0% (n=44/55) in the postnatal cohort, suggesting that the pattern of specific gene involvement is similar between the two groups. Of note, our diagnostic yield of 48.7% (n=55/113) in the postnatal cohort was significantly higher than that in two recent reported postnatal cohorts: 21.3% (n=87/409) and 21.7% (46/212). Different patient cohorts may explain the higher diagnostic yield in our test. Another contributing factor might be the inclusion of the *RIT1* gene, as it was not present in the NGS panel in one study and only tested in a very limited number of samples in the other.

## PgmNr 544: Tandem whole genome analysis enables comprehensive family planning.

**Authors:**

N. Neerman; R. Jyoti; A. Kaplun; J. Hogan

[View Session](#) [Add to Schedule](#)

**Affiliation:** Variantyx Inc., Framingham, Massachusetts.

---

**Background:**

A variety of carrier screening tests are offered with the promise of helping young couples with family planning. Available tests generally focus on a small subset of specific conditions and genes. While these tests are able to detect the most common causes of selected recessive conditions, they are unable to provide information about the large number of rare disorders that are less common. On the surface, when looked at on an individual basis, these disorders are deceptively rare. It's only when the set of more than 5,000 diseases with a genetic basis are considered as a whole, it becomes apparent that the impact is significant. Whole genome sequencing (WGS) provides the ability to detect variants that cause these conditions, as well as the ability to identify complex variants that cause the more commonly screened conditions but go undetected with other tests. Tandem analysis of reproductive partner genomes via WGS has the potential to provide a comprehensive assessment of shared carrier risks.

**Method:**

To test the tandem analysis approach, we started with our clinical WGS pipeline which has been validated for detection of small sequence changes, mitochondrial variants, structural variants and more than 20 tandem repeat expansions. This is the same pipeline that is currently used for the clinical WGS tests performed in our lab, including our Genomic Inform™ test for healthy individuals - a physician-ordered clinical test that includes carrier status analysis and reporting. We then adapted the annotation filters and variant interpretation workflow to additionally process and analyze whole genomes of potential reproductive partners in tandem, evaluating more than 50 paired genomes.

**Result:**

Identified variants included small sequence changes in commonly (i.e. CFTR: cystic fibrosis) and uncommonly (i.e. SEPN1: multiminicore disease; congenital myopathy with fiber-type disproportion) screened genes, large structural variants as well as premutation alleles of tandem repeat genes like FMR1 which is responsible for Fragile X syndrome. The tandem analysis workflow successfully identified dual carrier genome pairings with the potential to produce offspring inheriting two copies of the same deleterious variant. It also identified dual carrier pairings that involved the potential to inherit compound heterozygous variants in the same gene, including examples of structural variants paired with small sequence changes. We will present examples for each case type.

## PgmNr 545: Haploinsufficiency of *PRR12* causes a congenital multiple-malformation neurodevelopmental syndrome with a wide phenotypic spectrum.

---

*De novo* heterozygous truncating mutations in the proline rich 12 (*PRR12*) gene have been reported in three patients with global developmental delay, intellectual disability, eye and vision abnormalities and other features. Consistently, expression pattern of *PRR12* supports its role in brain and eye development. However, the disease-association of *PRR12* and the disease-causing mechanism have not been well established. In this report, we describe 15 additional unrelated individuals with neurodevelopmental issues who carry 14 rare and damaging variants in *PRR12*. These variants were found to be *de novo* in all cases where parental samples were available (n=13). All variants were apparently loss-of-function (7 frameshift, 5 nonsense, 1 splice site), except for one *de novo* missense variant. In addition, a 3.3 Mb deletion encompassing the entire *PRR12* gene, which was a recombination product of a maternal balanced insertion, was identified in one patient. The phenotype varied among the 19 patients with defects in *PRR12*. The major clinical features were developmental delay (84%), eye and visual abnormalities (68%), cognitive impairment (63%), behavioral problems (58%), and growth retardation (53%). The congenital ophthalmic anomalies included coloboma of the iris, lens, retina and/or optic nerve, microphthalmia, anophthalmia, and cryptophthalmos. The less frequent features included abnormal outer ears (47%), congenital heart defects (37%) and tone abnormalities (37%). Notably, variations in eye anomalies were also observed in the two patients carrying the same p.Lys1092Argfs\*131 variant; one patient had a unilateral iris, chorioretinal and optic nerve coloboma with ipsilateral microphthalmia; while the other one only presented with oblong optic nerves and bilateral ptosis. The common features in patients with *PRR12* sequence variants, including iris coloboma and intellectual disability, were also observed in the patient with a large

deletion including *PRR12*, supporting that haploinsufficiency of *PRR12* is the disease-causing mechanism. In summary, our studies demonstrated that *PRR12* haploinsufficiency leads to a multi-system neurodevelopmental syndrome with a wide clinical spectrum and variable phenotypic expressivity.

### Objectives:

To determine the utility of exome sequencing as an adjunct to perinatal post mortem for congenital anomalies.

To model the likely outcome of exome sequencing as a prenatal test in the same setting

### Method:

Probands with congenital anomalies were referred by perinatal pathologists. They were enrolled for sequencing if their microarray analysis was negative and their anomalies were considered to have a monogenic cause. Singleton or trio exome sequencing was performed as an adjunct to routine perinatal autopsy and the diagnostic outcomes were compared. A geneticist independently reviewed the probands' antenatal imaging findings and recommended a phenotype specific gene list to model the clinical utility of prenatal exome sequencing.

### Results:

A prospective cohort of 131 probands was referred. Forty-nine (37%) were unsuitable for inclusion. The parents of 5 (4%) declined enrolment and 10 (8%) could not be consented. Sixty-seven probands (52%) were enrolled. One proband could not be sequenced due to a degraded DNA sample. Results are available for 65 probands (32 singletons and 33 trios).

Specific diagnoses were identified at autopsy in 11 cases (17%) including 2 cases with negative sequencing. Sequencing identified specific diagnoses ('pathogenic' or 'likely pathogenic' variants) in 23 cases giving a diagnostic rate of 35%. The combined diagnostic rate of autopsy and exome was 38%. The individual autopsy and genomic diagnostic rates were highest in probands with significant skeletal findings (39% and 61% respectively, n=18). Genomic diagnoses were obtained from 34% of singleton exomes, with segregation when required, and 36% of trio exomes.

Variants of uncertain significance (VUS) were reported in 13 cases (20%). In four, a strong phenotype-genotype match together with plausible candidate variants indicated a need for additional studies. The combined rate of diagnostic or suspicious variants was 42%. The use of antenatal sequencing in this cohort using a candidate gene list approach would have identified a specific genomic diagnosis in 78% (18 of the 23 cases).

**Conclusion:**

Clinical Exome sequencing doubles the diagnostic rate of perinatal autopsy for congenital anomalies and supports the prenatal use of genomic sequencing

## PgmNr 547: *PRNP* gene deletion by CMA in a fetus with congenital abnormalities: First case report.

[View Session](#) [Add to Schedule](#)

**Affiliation:** Department of Pathology and Laboratory Medicine, University of Rochester Medical Center, Rochester, NY.

---

Mutations in the *PRNP* gene located at chromosome 20p13 band are associated with neurodegenerative spongiform encephalopathies also known as prion disease. We report a 21-year-old pregnant woman (G4P2A1) with a history of ADHD, bipolar disorder, chronic depression, smoking and use of THC during pregnancy referred for fetal congenital anomalies including bilateral clubbed feet, rocker bottom feet and absent cavum septum pellucidum as well as intrauterine growth retardation (IUGR) identified at 29-week ultrasound. Amniocentesis revealed a normal karyotype of 46,XX by routine G-banding. A follow up chromosome microarray comparative genomic hybridization (CMA) using 4 × 180K + SNP v2.0 platform (Agilent Technologies) revealed a 759 Kb loss at 20p13 from 4053819 to 4813038 base pairs encompassing the *PRNP* morbid gene, confirmed by FISH with RP11- 960N2(20p13, SO) and Tel 20p(SG) probes. The mother had an uncomplicated C-section at 37w0d. Her APGAR scores were 9 at 1 minute and 9 at 5 minutes. Neonatal evaluation revealed that the baby was small-for-gestational-age. Her birth weight was 1.810 kg (0.3 percentile), length was 41.0 cm (0.1 percentile) and head circumference was 33.0 cm (39. 7 percentile). Her left foot revealed rocker-bottom appearance with dorsal deviation. Additionally, right foot was dorsiflexed with resistance to extension of the ankle. No cardiac or respiratory abnormalities were seen and neurologic reflexes including Moro, pupillary, fair suck were normal. This report describes the first prenatal case with a *PRNP* gene deletion and highlights the value of CMA as a highly sensitive assay in detecting critical gene deletions/disruptions which can help establish important genotype-phenotype correlation. Our case also highlights the possible role of *PRNP* in ultrasound abnormalities observed in the fetus. Additional similar cases will be helpful in elucidating role of *PRNP* in early embryogenesis.

---

Mosaic expression of the c.49G>A, p.(E17K) *AKT1* variant causes Proteus syndrome. To create a mouse model of the disorder, we made a CRE conditional *Akt1*p.(E17K) allele. To test the Happle hypothesis, which states that the Proteus syndrome variant only survives by mosaicism, we activated the variant allele by crossing *Akt1* conditional and ACTB-Cre mice which express Cre ubiquitously. Embryos from this cross were not viable and died between E11.5 and E17.5, confirming the Happle hypothesis. Mutant embryos were pale, had fewer visible blood vessels and increased hemorrhage in the skin. Whole-mount immunostaining of E14.5 and E15.5 mutant skin showed no mature arteries or veins in the vasculature, suggesting a vascular remodeling defect. To determine the extent of the vascular defects in these embryos, we used the iDISCO clearing method to perform whole mount immunolabeling and volume imaging on mutant and wild type E11.5 – E14.5 embryos. Examination of E12.5 embryos showed that the vertebral arteries failed to complete formation with heterogeneous, abnormal connections of the basilar artery to the aorta. In E13.5 mutant embryos, several vessels including the thoracic and external carotid arteries were missing, underdeveloped, or had abnormal patterning. In addition, hematoxylin and eosin staining of sections from E11.5 – E14.5 embryos showed heterogeneous blood-filled spaces that when visualized by whole mount immunolabeling were shown to be vascular channels surrounded by alpha-smooth muscle actin-positive cells. Taken together, we conclude that constitutive AKT signaling impairs the remodeling of the developmental vascular capillaries into a hierarchical vascular network, and leads to structural vascular anomalies. We speculate that at a cellular level, these vascular anomalies are due to abnormal endothelial cell behaviors such as sprouting, migration, and subsequent endothelial cell fusion, and that disconnection of major arterial networks may cause abnormal circulation, resulting in defective vascular remodeling in peripheral vasculature.

## PgmNr 549: An infant with ambiguous genitalia and complex mosaicism for Y-chromosome abnormalities not detected by prenatal cell-free fetal DNA testing.

---

Analysis of cell-free fetal DNA has become a commonly-used prenatal diagnostic test. We report an infant whose cell-free fetal prenatal study was “normal”, but who has ambiguous genitalia and was found to be mosaic for a complex Y-chromosome abnormality. The mother, age 30 years, presented for screening ultrasonography at 12 weeks gestation because of apparent increased nuchal translucency on an earlier ultrasound examination. Exam at 12 weeks showed a 5 mm nuchal translucency (increased). A maternal blood sample was sent for cell-free fetal DNA studies, the results of which were “consistent with a female fetus”. The fetal DNA fraction was estimated by the lab to be 4%. Follow-up prenatal ultrasound examinations at 17 and 20 weeks post LMP were unremarkable, without increase in the nuchal translucency, and were consistent with female genitalia. The baby was born at term, weighing 3.02 kg. Physical exam was unremarkable other than prominent ears and ambiguous external genitalia. She had a hooded phallus, measuring 1.7 cm, with a meatus at the tip and another small opening at the base. The labioscrotal folds were fused and slightly rugated. There were no palpable gonads. Pelvic ultrasonography demonstrated a uterus thought to be appropriate in size for age, but identified no gonads. Her state newborn screen was unremarkable, including normal 17-hydroxyprogesterone. Serum electrolytes were normal. At 8 days of age, serum DHEA SO<sub>4</sub> was 99.7 ug/dl (normal 108-6-7), 17-hydroxypregnenolone 129 ng/dl (normal 229-3104), and total testosterone 55 ng/dl (normal 7-20). Lymphocyte karyotype from a peripheral blood sample showed complex mosaicism: 45, X[20]/46,X,psu idic(Y)(q11.222)[1]/47, X ,psu idic(Y)(q11.222)X2[1], ish psu idic(Y)(q11.222)SRY++nuc ish(DXZ1X1)[84]/DXZ1x1,SRYx4[13]/(DXZ1X1,SRYx2)[1]

The infant with unanticipated ambiguous genitalia whom we present illustrates some of the limitations in using cell-free DNA for prenatal diagnostic studies. It is possible that the combination of low-level mosaicism for the abnormal Y chromosome and the relatively low amount of fetal DNA in the cell-free DNA pool resulted in a “falsely normal” result. It is important that patients and providers be aware of the potential limitations of this methodology.

## PgmNr 550: Diagnosis of fetal structural abnormalities using whole exome sequencing: A single centre study.

### Introduction

Ultrasound screening (US) in pregnancy is recommended by the WHO and is undertaken to monitor maternal and fetal health; approximately 2-5% of pregnancies display anomalies of fetal development. Current testing strategies demonstrate a genetic aetiology in around 40% of cases, leaving the majority of cases without a diagnosis.

Accurate diagnosis in the prenatal period is valuable; it provides information for prenatal, perinatal and postnatal management and treatment and can enable accurate assessment of the recurrence risk for future pregnancies. Provision of an additional comprehensive test would likely extend this benefit to a significant portion of the 60% of cases currently undiagnosed by conventional methods.

Recent published evidence has demonstrated the utility of exome sequencing for improved diagnosis in fetuses with structural anomalies; a recent review by Best et al (2018) showed reported diagnostic rates of between 6.2-80%.

### Objective

To provide a molecular diagnosis for cases of unexplained fetal US anomalies using whole exome sequencing, with phenotypes derived from ultrasound and/or post-mortem investigation.

### Methods

Fetuses with an abnormality detected on US were referred to Clinical Genetics at St George's Hospital, London. Fetal DNA was obtained from CVS, AF, fetal blood or post-mortem tissue and maternal cell contamination was ruled out where relevant. DNA was enriched using Agilent SureSelect CREv2 and sequenced using Illumina NextSeq 500. Secondary and tertiary analysis of sequencing data and variant review was performed using the Congenica clinical decision support platform.

### Results

Whole exome sequencing established a diagnosis in 24/62 cases (39%); phenotypes with causal variants included skeletal dysplasia (33.3%), fetal hydrops (20.8%), brain structural abnormalities (16.7%), cardiac structural abnormalities (12.5%) and multisystem anomalies (16.7%).

Updated figures will be presented and variants of uncertain clinical significance (VUS) of note in the *ALPL*, *KCNJ2* & *KMT2D* genes will be discussed.

### Conclusions

The diagnostic yield in this selected case series is higher than published unselected cohorts.

Molecular diagnosis was not always concordant with the primary clinical diagnosis highlighting both the challenge of reduced phenotype detail in this cohort and the importance of expanding prenatal genotype-phenotype correlations. Positive diagnostic rate was higher in cases with fetal hydrops

## **PgmNr 551: When to test fetuses for Noonan spectrum disorders? Proposition from a systematic analysis of 260 cases.**

**Affiliation:** Medical Genetics, CHU Sainte-Justine, Montréal, Quebec, Canada

---

Noonan spectrum disorders (NSD) are common genetic syndromes encountered at pre and postnatal evaluations, occurring in 1:1000-2500 live births. In recent years, studies have identified some evocative ultrasound findings for these syndromes, e.g. lymphatic dysplasia (increased nuchal translucency (NT), increased nuchal fold (NF), cystic hygroma (CH), hydrops, effusions, ...); congenital heart disease (valvular dysplasia or hypertrophic cardiomyopathy (HCM)); hydramnios and renal anomaly. The aim of this study was to establish which of these US findings are the most suggestive of NSD in an effort to better define the prenatal indications for NSD testing.

Retrospective review of 260 charts from 2012 to 2018 and review of literature. Inclusion criteria: (1) chromosomal anomalies excluded (by array-CGH), (2) prenatal cases with NSD evocative US findings (n=206) or pediatric cases with clinical suspicion of NSD (n=54), and (3) molecular genetic testing for NSD performed. Most of the patients had at least 11 NSD genes tested: BRAF, HRAS, KRAS, MAP2K1, MAP2K2, NRAS, PTPN11, RAF1, RIT1, SHOC2, SOS1. Prenatal ultrasound findings in positive and negative cases were compared. A stratified analysis of some ultrasound features was conducted.

A pathogenic or likely pathogenic variant was identified in 21% (55/260) of cases. 17/141 cases of CH and increased NT (12%) had a disease-causing variant. The rate of detecting a NSD variant was 40% for thoracic effusions, 28% for hydrops, 28% for congenital heart disease and 27% for increased NF. As for the stratified analysis, the detection rates were significantly improved in cases of persistent CH (16%), NT > 6 mm (23%), when CH was associated with another evocative US finding (21%) or when a cardiac defect was combined with HCM (100%) and in cases of persistent hydrops (36%). There was also improvement of the detection rate when US findings were found in combination with hydramnios (49%), renal anomaly (36%) or macrosomia (54%). 45/151 cases with two or more US findings (30%) had a NSD diagnosis vs 9% for cases with only one US finding.

**Conclusion:** after normal array-CGH, Noonan spectrum disorders should be considered when any prenatal finding of lymphatic dysplasia or suggestive congenital heart disease is found alone OR in association. Polyhydramnios, renal anomalies and macrosomia are frequent, significantly associated findings of NSD. Only severe prenatal ultrasound findings predict an unfavorable postnatal outcome for NSD.

## PgmNr 552: Likely pathogenic *de novo* variants in congenital diaphragmatic hernia patients are associated with clinical outcomes.

---

Congenital diaphragmatic hernia (CDH) is a major congenital abnormality that is associated with significant mortality, long term morbidity, and neurodevelopmental impairment in some but not all individuals. To identify classes of genetic variants associated with an increased risk of severe clinical or developmental outcomes of CDH patients, we prospectively enrolled neonates with CDH and followed them for up to five years. We performed whole genome or exome sequencing in 463 parent offspring trios to identify *de novo* single-nucleotide variants (SNVs), indels and copy number variants (CNVs). We classified CDH patients into two groups: (a) cases with likely pathogenic (LP) variants, including *de novo* likely gene disrupting (LGD) variants or predicted deleterious missense variants in constrained genes with high diaphragmic expression or known risk genes of CDH or common comorbid disorders, deletions in constrained genes, or CNVs implicated in known syndromes (LP-group, n=100); (b) other cases (nonLP-group, n=363). We assessed seven outcomes: pulmonary hypertension at one month (n=335) and three months of age (n=269), mortality prior to initial discharge (n=461), Bayley Scales of Infant Development (BSID-III, n=190) and Vineland Adaptive Behavior Scales (VABS-II, n=240) at two years of age, Wechsler Preschool and Primary Scale of Intelligence (WPPSI-IV, n=70) and VABS-II (n=88) at five years of age. LP-group patients have significantly lower developmental

scores than non-LP group at age of two (motor:  $p=4\times 10^{-5}$ ; cognitive:  $p=1\times 10^{-4}$ ), with a similar trend in complex CDH (with additional anomalies,  $n=69$ ) and isolated ( $n=123$ ) cases. LP-group also have a trend of higher mortality rate prior to initial discharge (29.3%,  $p=7\times 10^{-3}$ ) and severe pulmonary hypertension rate at 1 month (67.7%,  $p=1\times 10^{-2}$ ) than non-LP group. Overall, complex cases in LP-group had the worst survival rate and two-year developmental outcome. Isolated cases in nonLP-group had developmental outcome similar to population average and the best survival rate, and isolated cases in LP-group and complex cases in non-LP group had similar intermediate survival rate and developmental outcome. In summary, we found *de novo* likely pathogenic variants and CNVs to be associated with worse survival, more severe pulmonary hypertension, and worse developmental outcomes. These results have important implications for counseling about prognosis, potential intervention, and long term follow up for children with CDH.

## PgmNr 553: Homozygous mutations in *SPEF2* induce multiple morphological abnormalities of the sperm flagella and male infertility.

---

Infertility has become one of the major issues of human health, affecting 10% –15% of the general population worldwide. Male factors are identified in approximately half of the infertile couple, and the diagnosis and treatment of male infertility therefore elicit an increasing interest. Male infertility due to multiple morphological abnormalities of the sperm flagella (MMAF) is a genetically heterogeneous disorder. Previous studies revealed several MMAF-associated genes (*DNAH1*, *CFAP43* or *CFAP44*, *CFAP69*, et al), which account for approximately 60% of human MMAF cases. The pathogenic mechanisms of MMAF remain to be illuminated.

In our study, whole-exome sequencing was conducted for genetic analyses of a cohort of 65 Han Chinese men with MMAF. Two homozygous stop-gain variants c.910C>t (p.Arg304\*) and c.3400delA (p.Ile1134Serfs\*13) of the *SPEF2* (sperm flagellar 2) gene were identified in two unrelated consanguineous families. Consistently, an Iranian subject from another cohort also carried a homozygous *SPEF2* stop-gain variant c.3240delT (p. Phe1080Leufs\*2). All of the *SPEF2* variants found in three unrelated individuals were absent or extremely rare from control sequence databases (1000 Genomes Project, ExAC and gnomAD). Previous animal studies reported spontaneous mutations of *SPEF2* causing sperm tail defects in bulls and pigs. Consistently, our further functional studies using immunofluorescence assays showed the absence or a remarkably reduced staining of *SPEF2* and of the MMAF-associated CFAP69 protein in the spermatozoa from *SPEF2*-affected subjects. Together, our findings revealed a new human MMAF-associated gene, which will be informative in the molecular diagnosis and genetic counselling of infertile men with oligoasthenoteratozoospermia.

## PgmNr 554: Carrier screening for spinal muscular atrophy in 10170 pregnant women in China.

---

**Background** Spinal muscular atrophy (SMA) is a genetic neuromuscular autosomal recessive disease characterized by muscle atrophy and weakness. SMA is one of the most common rare diseases. One in 6,000 to one in 10,000 children are born with the disease. One in 25 to one in 50 people are carriers of the SMA gene, so American College of Medical Genetics has recently recommended routine carrier screening for SMA. Large studies are needed in China to determine the benefits and costs of SMA carrier screening.

**Objective** To screen the carriers of spinal muscular atrophy (SMA) among pregnant women in Jiangmen area of Guangdong Province China, and to provide information for genetic counseling and further prenatal diagnosis, in order to reduce SMA newborns.

**Methods** From January 2017 to February 2019, this a prospective population-based cohort study of 10170 pregnant women from Jiang Men city in China. Exons 7 and 8 of SMN1 were amplified by real-time multiplex fluorescence quantitative PCR, and the copy number was quantitatively detected. Multiplexed-dependent probe amplification (MLPA) was used to verify the abnormal results of SMN1 gene screening. If the pregnant women are heterozygous for SMA, the husband is requested test. If both partners were SMA carriers, prenatal diagnostic testing is necessary performed.

**Results** Among 10170 pregnant women, 165 were carriers of heterozygosity deletion in exon 7 and 8 of SMN1 gene, 6 were carriers of heterozygosity deletion in exon 7 of SMN1 gene, and 55 were carriers of heterozygosity deletion in exon 8 of SMN1 gene. The carrier rate was approximately 1/59 (1.69%). 3 couples were determined to be at high risk for having offspring with SMA and prenatal diagnostic test. Prenatal diagnostic result show 3 fetuses are normal.

**Conclusion** Carrier screening and carrier rate determination are of great clinical significance for follow-up genetic counseling, disease prevention and reduction of birth defects. SMA carrier screening has reduced the burden of SMA newborns.

## PgmNr 555: A late-onset Alzheimer's disease associated gene *TM2D3* is required for neural maintenance and developmental Notch signaling in *Drosophila*.

---

Alzheimer's disease (AD) is the most prevalent neurodegenerative disorder in the aging human population. Mutations in the genes *APP*, *PSEN1*, and *PSEN2* have been found to cause familial, early-onset forms of the disease; however, about 95% of AD cases are late-onset (after age of 65) and of sporadic nature and the genetic factors that may contribute are steadily being uncovered. Large human genetics studies in the past decades have identified several loci associated with risk of late-onset Alzheimer's disease (LOAD). However, the molecular functions of many of the genes within these loci remain to be elucidated. To develop therapeutics for AD it is crucial to understand the molecular players that contribute to AD pathogenesis.

Here, we describe our efforts to functionally characterize *TM2D3*, a gene previously associated with increased risk of LOAD (7.45 OR). Using the highly tractable model organism *Drosophila melanogaster*, we have generated a null allele of the fruit fly ortholog of *TM2D3*, *almondex* (*amx*). Importantly, we have found that *amx* mutants are short lived and exhibit climbing deficits, indicative of neuronal dysfunction. Functional studies in the *Drosophila* giant fiber system and the use of electroretinogram (ERG) have uncovered defects in proper neuron function in *amx* mutants. Interestingly, introduction of wild-type human *TM2D3* in *amx* mutants suppresses lifespan and climbing defects, indicating that the human protein can functionally replace Amx and function *in vivo* in *Drosophila*. This gives us a platform to probe the molecular function of *TM2D3*, as well as the effect of the LOAD linked variant of *TM2D3* (p.P155L).

Additionally, embryos from *amx* mutant females exhibit a neurogenic phenotype, indicative of loss of proper Notch signaling during embryonic development. Past epistasis experiments have suggested that *amx* is genetically involved in the proteolytic processing of the Notch receptor. Since the metalloprotease ADAM10 and the intramembrane protease complex γ-secretase are both involved in the processing of Notch receptors and APP, we hypothesize that *TM2D3* (and Amx) acts as a regulator of ADAM10 and/or γ-secretase. Taking advantage of genetic epistasis experiments that are possible in *Drosophila*, we aim to precisely determine at what step *TM2D3* acts genetically to understand its molecular function in the context of LOAD.

## PgmNr 556: Exome sequencing in 400 individuals with malformations of cortical development reveals wide genetic heterogeneity.

### Authors:

U. Kini <sup>1</sup>; A. Pagnamenta <sup>2</sup>; M. Hashim <sup>2</sup>; R. Tripathy <sup>3</sup>; D. Keays <sup>3</sup>; J. Taylor <sup>2</sup>; DDD. Study <sup>4</sup>

---

Malformations of cortical development (MCD) are congenital anomalies that result from abnormal proliferation, migration and organisation of fetal neurones during brain development causing brain anomalies such as primary microcephaly, lissencephaly, periventricular nodular heterotopia (PVNH), cortical dysplasia and polymicrogyria (PMG). Over the past 2 decades a large number of novel genetic causes have been described. **Aims:** To study the spectrum of genetic pathways involved in cortical development and examine genetic heterogeneity in a cohort of 400 individuals with MCD. **Methods:** Patients with MCD who had undergone exome sequencing were identified from 2 sources: (1) DDD (Deciphering Developmental Disorders) study: Exome sequencing was carried out on 13,451 individuals with suspected rare genetic disorders. A comprehensive list of 21 HPO (human phenotype ontology) terms related to MCD were used to identify a subset of 294 patients and their exome data was accessed through a filtered list of candidate variants provided by DDD (2) Genetics of Structural Brain Abnormalities and learning difficulties (GOSBA) study: Trio exome sequencing data from 106 probands were examined for known and novel genetic variants. The phenotype was assessed in detail via a bespoke clinical questionnaire, review of MRI brain scans and neuropathological findings and studying facial dysmorphism. **Results:** 68 individuals with MCD (68/400 or 17%) were found to have a reportable genetic variant in a gene previously reported to cause a brain phenotype (n=39 genes); the most common being *DYNC1H1* (n=8 affected individuals). An additional 17 patients had variants in novel genes (n=9 genes, published) causing a specific brain phenotype - *PGAP3*, *PIGY*, *DENR*, *SOX11*, *ERMARD*, *PI4KA*, *HNRNPK*, *NEDD4L* and *CCND2*, taking the diagnostic yield up to ~27%. Putative candidate variants that need further exploration have been identified in an additional 150 patients. Cellular genetic pathways such as microtubule, GPI anchor and *AKT-PI3KA* pathways were identified as critical for cortical development. **Conclusion:** Our study demonstrates a wide genetic heterogeneity in MCD - 48 different genes accounted for the MCD in 85 patients. A large proportion of MCD cases (~70 %) therefore remain unsolved despite using newer testing technology such as exome sequencing. Due to the wide genetic and phenotypic heterogeneity reporting of novel genes can be slow and labour-intensive.

## PgmNr 557: Mutations in *RFX* family members are a common cause of autism and ADHD.

---

Regulatory Factor X (RFXs) proteins are a family of developmentally important transcription factors that share highly-conserved DNA binding domains. Knockout studies of *Rfx2*, *Rfx3*, *Rfx4*, and *Rfx7* in mice and *Xenopus* demonstrate important roles for these genes in embryogenesis, central nervous system development and ciliogenesis. Expression patterns of human *RFX2*, *RFX3*, *RFX4* and *RFX7* show strong tissue specificity to human brain, and are under marked haploinsufficient constraint in human populations. We report a total of 31 patients (28 probands) with *de novo* or inherited

heterozygous mutations in *RFX* family members in association with autistic features and other neurobehavioral abnormalities: *RFX3* mutations (17 patients), *RFX2* (2), *RFX4* (3), and *RFX7* (9). These cases share in common neurobehavioral features including autism spectrum disorder (ASD), ADHD, and mild intellectual disability. Other frequent features included hypotonia, subtle dysmorphisms, and sleep disorder. Functional analysis of the spectrum of mutations encountered is consistent with a loss-of-function mechanism. Collectively, *de novo* mutations in *RFX* family members may comprise one of the more common genetically identifiable causes of ASD, and point to a network of brain-expressed targets that illuminate critical disease-associated neurobiological pathways for this disorder.

## PgmNr 558: Associated anomalies in cases with agenesis of the corpus callosum.

### Authors:

Agenesis of corpus callosum (ACC) is an uncommon congenital anomaly, its etiology is unclear and its pathogenesis is controversial. Cases with ACC often have other non-ACC associated congenital anomalies. The purpose of this study was to assess the prevalence and the types of these associated anomalies in a defined population. The associated anomalies in cases with ACC were collected in all livebirths, stillbirths and terminations of pregnancy during 29 years in 387,067 consecutive births in the area covered by our population-based registry of congenital malformations. Of the 99 cases with ACC, representing a prevalence of 2.56 per 10,000, 73 (73.7%) had associated anomalies. There were 16 (16.2%) cases with chromosomal abnormalities, and 13 (13.2%) nonchromosomal recognized dysmorphic conditions including syndromes 2 each: Aicardi, Dandy-Walker, and fetal alcoholism. Forty four (44.4%) of the cases had non syndromic multiple congenital anomalies (MCA). Anomalies in the musculoskeletal, the urogenital, the central nervous, the cardiovascular, and the digestive systems were the most common other anomalies in the cases with MCA. The anomalies associated with ACC could be classified into a recognizable malformation syndrome in 29 out of the 73 cases (39.7 %) with associated anomalies. This study included special strengths: it is population-based, each affected child was examined by a geneticist, all elective terminations were ascertained, and the surveillance for anomalies was continued until 2 years of age. In conclusion the overall prevalence of associated anomalies, three of four cases, emphasizes the need for a screening for other anomalies in cases with ACC.

## PgmNr 559: The nuclear receptor co-regulator RERE is required for development of the cerebellar vermis and midbrain.

### Authors:

Deletions of chromosome 1p36 are the most common terminal deletions in humans and associated with high incidence of the brain defects. The arginine-glutamic acid dipeptide repeats gene (RERE) is located in a proximal critical region on chromosome 1p36. Pathogenic mutations in *RERE* have been identified as causative variants for defects seen in individuals with proximal 1p36 deletions. Cerebellar vermis anomalies are documented in 50% of individuals with these mutations in *RERE* and *RERE*-deficient mice show incomplete foliation in the vermis. Although *RERE* play a critical role in the vermis development, morphogenic and molecular mechanisms by which tissue specific depletion of *RERE* causes in the vermis are not clearly described in early embryonic cerebellum. The development of midbrain and cerebellum is initiated by the isthmus organizer (IO) located in the midbrain-hindbrain junction at E9.5. A bilateral, wing-like shaped cerebellar primordium transforms into cylinder-shaped morphology along the medial-lateral axis between E12 and E15.5. In this study, floxed *Rere* allele is excised in the midbrain-hindbrain junction by Pax2-Cre recombinase. The bilateral wings of the cerebellum are fused in medial region in control embryos at E13.5. In contrast, midline fusion of these wings is failed in Pax2-Cre;*Rere*<sup>F/F</sup> embryos. Even though medial region of Pax2-Cre;*Rere*<sup>F/F</sup> embryo cerebellum is fused at E15.5, development of midline fusion is limited in comparison with control embryos. At E18.5, four fissures are not formed in the vermis primordium of Pax2-Cre;*Rere*<sup>F/F</sup> embryos while these fissures appear in control embryos. In addition, development of the inferior colliculus in the midbrain is attenuated in mutant embryos while the inferior colliculus is completely developed in control embryos. We also showed that expression of *Wnt1*, *Fgf8*, *En1* and *En2*-which are known to be key regulators for development of the midbrain and the cerebellum- is downregulated in the mutant embryo cerebellums in comparison with that of the control embryos at E14.5. Taken together, these results suggest that tissue-specific ablation of *Rere* is enough to lead abnormal development of the vermis and *Rere* regulates expression of genes that are important for development of the midbrain and the cerebellum during the early embryonic period.

## PgmNr 560: Genetic and clinical spectrum of neurodevelopmental disorder with microcephaly in a Chinese cohort.

### Authors:

[View Session](#) [Add to Schedule](#)

**Affiliation:** Hunan Provincial Maternal and Child Health Care Hospital, Changsha, China

---

**Background:** Microcephaly is a complex and multifactorial birth defect with occipital frontal circumference (OFC) of  $>2$  SDs below the population mean. There is a growing number of researchers focusing of the genes linked to the disease. To date, almost 800 genes related to microcephaly have been identified including 18 pathogenic genes of microcephaly primary hereditary (MCPH). Only 3 cohorts using exome sequencing to identify genes linked to microcephaly.

**Methods:** We included 80 patients with microcephaly. CNV-seq and whole-exome sequencing (WES) were performed on the patients. Relevant clinical profiles of each patient was collected by experienced neurologists.

**Results:** We identified 8 CNVs and 34 genes related to microcephaly. The top 6 common genes in our cohort was *DYRK1A* (5 patients), *ASPM* (4 patients), *TUBA1A* (3 patients) and *CASK*, *FOXP1*, *PNKP* (2 patients). Other genes were found in only one patient, respectively. Among the 34 genes, there were 26 reported genes for microcephaly (76.5%), 3 unreported genes for microcephaly (*ARF1*, *MPDZ*, *ZNF462*; 8.8%) and 5 candidate genes for microcephaly (*SMG6*, *BTBD9*, *FOCAD*, *TMEM147*, *THSD7A*; 14.7%). These patients presented with clinical features such as developmental delay, seizures, dysmorphic feature.

**Conclusion:** Our research included the largest cohort with developmental disorder and microcephaly and clarified the genetic and clinical spectrum of the disease to date. We also identified genes with novel clinical phenotypes as microcephaly and several novel candidate genes. Our research contributed to the understanding of genetic etiology of microcephaly and provided clues for genetic counseling.

## PgmNr 561: Investigating evolving interactions between Zika virus and host pathways using *Drosophila*.

---

Spread of Zika virus (ZIKV) is linked to an increase in neurological diseases including Guillan-Barré syndrome and congenital microcephaly, yet the underlying molecular mechanisms are mostly unknown. Recent work suggests increased pathogenicity of the Puerto Rican ZIKV strain is associated with missense mutations that occurred in pre-Membrane protein (prM) and NonStructural protein 1 (NS1). These changes make Puerto Rican ZIKV strains distinct from those isolated in Central Africa and Southeast Asia and may contribute to worsening outcomes of ZIKV infection. To better understand how ZIKV causes neurological sequelae in humans, and why Puerto Rican strains appear more pathogenic, we are using the fruit fly *Drosophila melanogaster* to assess the interactions between ZIKV proteins and host cellular pathways. We have also investigated if more ancient versions of ZIKV proteins elicit the same effects on these pathways as the modern Puerto Rican strain. We generated transgenic flies that allow expression of individual ZIKV proteins under the control of a UAS element to determine the effect of ZIKV protein expression in diverse tissues *in vivo*. Interestingly, using the sequences from the Puerto Rican strain, we found that most factors exhibited a scorable phenotype when expressed in the nervous system or developing tissues. Some phenotypes such as reduced brain size and sensory bristle loss suggest that multiple ZIKV proteins can modulate neurodevelopment. We have also generated transgenic flies expressing the more ancient and less pathogenic Cambodian strain ZIKV proteins. Interestingly we found the Cambodian strain NS1 protein does not display the phenotypes caused by the Puerto Rican NS1 suggesting that a single missense mutation in NS1 may contribute to the worsening outcomes of ZIKV infection in the Puerto Rican strain. This study demonstrates the value of *Drosophila* in the functional characterization of viral factors and has allowed us to begin to unravel the mechanism of ZIKV mediated neurological disease. It has also given early insight into the evolution of ZIKV pathogenicity and identified possibly causative missense mutations explaining worsening outcomes of ZIKV infection in South America.

## PgmNr 562: Preimplantation genetic testing for Schaaf-Yang syndrome using karyomapping.

---

**Introduction:** Cerebral palsy (CP) is the most common severe motor disability in children. It's not a disease but a combination of signs and symptoms. Different patterns of inheritance and genetic heterogeneity are known to CP. Some neurologic and metabolic genetic disorders which mimic the clinical characteristics with CP are more likely to be misdiagnosed. Whole exome sequencing (WES) for a patient, initially diagnosed as CP, revealed a nonsense variant in the *MAGEL2* gene. *MAGEL2* is a maternally imprinted, paternal-only expressed, gene located in the Prader-Willi critical region 15q11-15q13. Loss-of-function variants in paternal allele of *MAGEL2* has been described in Schaaf-Yang syndrome (SHFYNG), which is a neurodevelopmental disorder shared partial phenotypes overlap with Prader-Willi Syndrome, including neonatal hypotonia, feeding problems, and developmental delay/ intellectual disability. Male individual with *MAGEL2* pathogenic variant is at 50% risk for producing an affected child. Here we report the first successful preimplantation genetic testing for monogenic defects (PGT-M) for SHFYNG using Karyomapping.

**Materials and Methods:** A Chinese family with 5 patients initially misdiagnosed as CP was recruited in our Reproductive Genetic Clinic. Four of the patients died after birth due to atelectasis. WES was used to identify pathogenic variant of the only survive 11-year-old proband. Karyomapping, a method employing genome-wide analysis of SNP, was used as PGT-M protocol. Analysis of DNA from the proband and his parent revealed informative SNPs linked with the *MAGEL2* pathogenic variant. These SNPs were subsequently used for embryo diagnosis.

**Results:** The WES for the proband, misdiagnosed and treated as CP, revealed a novel nonsense pathogenic variant of c.2895 G>A (p.Trp965\*) in the *MAGEL2* gene. The variant was inherited from his unaffected father and paternal grandmother. Five embryos underwent trophectoderm biopsy followed by vitrification in the second cycle. Through Karyomapping analysis, 2 embryos without inheritance of the *MAGEL2* pathogenic variant haplotype were diagnosed as unaffected. One unaffected embryo was transferred, with one healthy baby was born at 38 gestational weeks.

**Conclusions:** This is the first report of Karyomapping-based PGT-M for a SHFYNG family initially misdiagnosed as CP. Karyomapping could be used to identify embryos with monogenic defects.

## PgmNr 563: Hippocampal transcriptome changes associated with long-term cognitive effects of gestational air pollution toxicity in mouse.

---

Air pollution adversely alters the early phases of human development. Gestational air pollution exposure is associated with long-lasting neurodevelopmental effects including increased risk of autism, depression, and decreased intellectual capacity. The molecular mechanisms for this toxicity have not been examined at the transcriptomic level. In this study, pregnant dams were exposed to urban derived nanosized particulate matter (nPM). Three-month male and female offspring were studied for cognitive changes using forced swim and elevated plus behavior tests. At 4.5 months of age, hippocampal transcriptomic changes were analyzed by RNAseq to identify the genes associated with the observed behavioral changes. Male offspring showed increased immobility time in the forced swim test and increased open arm entry in the elevated plus test, which indicates increased depressive behavior and decreased anxiety, respectively. Weighted gene co-expression analysis of the hippocampal transcriptome changes identified a module of 43 genes with sex-specific gene responses to gestational nPM exposure. These genes were enriched for several nervous system pathways, including G-protein coupled receptor, GABA receptor, and Opioid signaling pathways. The identified genes were tested for association with the observed behavioral changes. The forced swim was associated with several nPM responsive genes related to synaptic long-term potentiation and CCR5 signaling pathways. The genes associated with elevated plus were enriched for immune-related pathways such as GP6 signaling and pattern recognition pathways. In conclusion, this study identified several transcriptomic profiles for further study on gestational air pollution toxicity on the brain. Understanding the causal relationship of the identified genes with depressive and anxiety-like behaviors may have important implications for therapeutic and intervention development research.

## **PgmNr 564: Evidence of pervasive anxiety-related symptoms in 47,XXY (Klinefelter syndrome) and the potential impact of hormonal replacement therapy (HRT).**

### **Authors:**

C. Samango-Sprouse <sup>1,2,4</sup>; A. Gropman <sup>3,2</sup>; P. Lasutschinkow <sup>4</sup>; T. Sadeghin <sup>4</sup>

[View Session](#) [Add to Schedule](#)

### **Affiliations:**

1) George Washington University School of Medicine and Health Sciences, Washington, DC; 2) Department of Human and Molecular Genetics, Florida International University, Miami, FL; 3) Children's National Medical Center, Washington, DC; 4) The Focus Foundation, Davidsonville, MD

47,XXY (Klinefelter syndrome) is the most common X&Y chromosomal variation (1:660 males). The phenotype includes accelerated height, language-based learning disorders, motor delays & behavioral problems. Past studies demonstrated hormonal replacement therapy (HRT) may improve neurodevelopment of boys with 47,XXY. The progression of anxiety related symptoms throughout childhood & the potential impact of HRT at each age has not been investigated.

Parents of 48 toddlers (group A), 44 boys between 6 & 10 years (group B) & 42 boys between 11-18 years (group C) with 47,XXY completed Child Behavior Checklists. 58.3% of A, 61.4% of B & 72.6% of C received HRT (T). The rest were untreated (U). HRT was based on an evaluation by a pediatric endocrinologist. Hotelling's T-squared distributions were completed to analyze differences between U&T groups.

In group A, 10% of non-HRT (A-U) showed symptoms above the 97<sup>th</sup> percentile (clinically elevated) in internalizing & externalizing problems. 3.57% of A-T had clinically elevated symptoms in externalizing & total problems. A-T had fewer symptoms in affective ( $P=0.017$ ) & total problems ( $P=0.03$ ) compared to A-U.

23.53% of B-U were clinically elevated in internalizing & total problems. 11.76% of B-U were clinically elevated in anxious/depressed, somatic complaints, thought, externalizing & affective problems. B-T had fewer symptoms but were clinically elevated in internalizing (14.81%), externalizing (11.11%) & total problems (11.11%). B-T had fewer symptoms in somatic complaints ( $P=0.01$ ), thought ( $P=0.07$ ) & somatic problems ( $P=0.01$ ).

C-U group was clinically elevated in internalizing (60%), anxiety (50%), & anxious/depressed (40%). 30% of C-U was clinically elevated in somatic complaints, total & affective problems. 21.88% of C-T was clinically elevated in internalizing & total problems. 12.5% were elevated in affective & anxiety problems. C-T had less symptoms in anxious/depressed ( $P=0.01$ ), thought ( $P=0.03$ ), externalizing ( $P=0.04$ ), total ( $P=0.03$ ), & affective problems ( $P=0.02$ ).

Our findings demonstrate anxiety related symptoms appear to be a penetrant aspect of the 47,XXY phenotype as early as 3 years, with severity possibly increasing with age. This research supports the potential positive effect of HRT on neurodevelopment in boys with 47,XXY with less reported

symptoms in HRT-boys at all ages. Further studies should explore the impact of HRT on specific symptoms of anxiety to develop more personalized & precise treatments.

## **PgmNr 565: Combinatorial overexpression of transcription factors *Atoh1*, *Gfi1* and *Pou4f3* enable the conversion of Greater Epithelial Ridge (GER) cells into ectopic hair cells in the neonatal mouse cochlea.**

### **Authors:**

---

Hair cells in the inner ear enable the perception of sound through the process of mechano-transduction, rendering them indispensable for hearing. Regeneration of these hair cells occurs naturally in non-mammalian vertebrates like fish, amphibians and birds. In mammals, hair cells can regenerate at young ages to a minimal extent, in response to specific genetic interventions. One such intervention is the ectopic expression of transcription factor *Atoh1*. It is known that the expression of a transcription factor cocktail comprising *Atoh1*, *Gfi1* and *Pou4f3* can reprogram the transcriptomic signature of mouse embryonic stem cells towards that of inner ear hair cells. However, the effects of these transcription factor combinations on the underlying hair cell genetic network, and the relative responsiveness of 'non-hair cells' to such reprogramming signals remain unknown.

We targeted the *Rosa26* locus to allow conditional overexpression of *Atoh1* alone (*Rosa26-A*), *Gfi1*, *Atoh1* (*Rosa26-GA*) and *Gfi1*, *Atoh1*, *Pou4f3* (*Rosa26-GAP*) each. Mice harboring these conditional alleles were bred with *Sox9-CreER* mice to achieve overexpression in the greater epithelial ridge (GER) cells of the neonatal mouse cochlea after tamoxifen administration at birth. Immunostaining for hair cell markers showed the presence of a large number of ectopic hair cells in the GER of these cochleae in comparison to the wild type control animals, by one week of age. Further, these ectopic hair cells stained positive for Vglut3, an inner hair cell marker and not for Prestin, an outer hair cell marker.

Our next steps include the extensive characterisation of these ectopic hair cells by performing a single cell RNA seq followed by a bulk RNA seq. Through the single cell RNA seq, we aim to understand which cell population these ectopic hair cells most closely resemble. Once the cell population type is determined, we plan to perform a bulk RNA seq on this population to understand the difference in transcriptomic signatures of each conditional overexpression case with respect to the wildtype. Through this work, we aim to compare and understand the effect of additional transcription factors *Gfi1* and *Pou4f3* with *Atoh1*, in turning on specific gene networks to reprogram the GER cells in the neonatal mouse cochlea into hair cells. Understanding the principles governing mammalian hair cell regeneration will enable the achievement of efficient therapeutic strategies for treating human hearing loss in future.

## PgmNr 566: *MAB21L1* demonstrates a conserved role in vertebrate development.

### Authors:

---

The male-abnormal 21 family has three members, *MAB21L1*, *MAB21L2* and *MAB21L3*, with their corresponding roles in development only beginning to be understood. *MAB21L1* shares 94% protein identity with *MAB21L2*, a protein previously shown to have a role in vertebrate eye development and human disease. Recent reports have also described homozygous *MAB21L1* mutations in humans associated with ocular abnormalities including corneal dystrophy, and systemic features such as facial dysmorphism, scrotal agenesis and cerebellar malformation. Null *Mab21l1* mice likewise display developmental eye defects affecting the optic cup and anterior chamber structures. Using zebrafish and human patient DNA, our study expands on the developmental role of *MAB21L1/mab21l1* along with the spectrum of phenotypes associated with its deficiency.

To study the role of *mab21l1* in development, we utilized the zebrafish model. TALENs were used to generate a genetic mutation, *mab21l1 c.107delA p.[K36Rfs\*7]*. This line was examined for ocular anomalies using gross imaging, histology, immunohistochemistry and electron microscopy. Homozygous adult fish 1-2 years of age display ocular abnormalities including cornea, lens and other anterior segment defects, microphthalmia, and retinal degeneration. Craniofacial anomalies and reduced survival were also noted. To determine age of onset, we collected specimens at 5-days post fertilization (dpf), 8-dpf, 10-dpf, 14-dpf, 1-month post fertilization (mpf), and 2-mpf. The phenotype is first observed 5-dpf (abnormally thin cornea) with additional progressive changes identified at later stages.

To evaluate *MAB21L1*'s contribution to human disorders, we screened DNA samples from patients with various developmental ocular conditions by Sanger sequencing of the *MAB21L1* coding region. This revealed two variants, *c.184C>T*, p.[Arg62Cys] and *c.658G>C*, p.[G220R], in two unrelated patients with colobomatous microphthalmia. The pathogenicity of these variants was unclear and functional tests performed to understand their effects, including protein stability, localization and complementation assays. While protein stability and localization are undisrupted, complementation assays using zebrafish mutants suggested mild functional deficiency. Additional studies are ongoing to identify new human variants. Studies are also in progress to elucidate the molecular function of the protein to aid in functional testing of newly identified human variants.

## PgmNr 567: Insights of the role of *FOXC1* gene in ocular development using a double *foxc1a/foxc1b* knockout zebrafish line.

The gene forkhead box C1 (*FOXC1*) encodes a forkhead/winged helix transcription factor involved in embryonic development. Mutations in *FOXC1* cause developmental eye disorders like Axenfeld-Rieger syndrome type 3 or anterior segment dysgenesis, usually following an autosomal dominant inheritance pattern. Some patients also present other non-ocular defects like cardiac and craniofacial abnormalities. There are two zebrafish orthologous genes, *foxc1a* and *foxc1b*. Both zebrafish genes demonstrate evolutionary conservation with the human ortholog, especially in the forkhead and activation domains. The lack of *foxc1a* in zebrafish produces defects in somitogenesis, heart and craniofacial region. In this study we use the zebrafish as an animal model to further study the role of *FOXC1* in the eye development.

Using CRISPRs we generated single *foxc1a* and *foxc1b* knockout zebrafish lines, carrying p.[D71\*] and p.[A86Dfs\*30] alleles correspondingly, and used them to obtain *foxc1a/foxc1b* double knockout embryos (D-KO). Both *foxc1* mutations are predicted to produce complete loss-of-function alleles because of an early truncation affecting the forkhead and C-terminal domains.

*foxc1a*<sup>-/-</sup> homozygous embryos showed anomalies in blood flow, microphthalmia and periocular edema, as well as embryonic lethality, while heterozygous *foxc1a*<sup>+/-</sup> and heterozygous or homozygous *foxc1b* embryos did not display any visible phenotype and survived to adulthood. To further evaluate *foxc1a/b* dosage requirements and to generate D-KO embryos, we raised adults carrying heterozygous *foxc1a* and homozygous *foxc1b* alleles. The *foxc1a*<sup>+/-</sup>;*foxc1b*<sup>-/-</sup> fish demonstrated reduced survival, craniofacial, skeletal and ocular defects, thus displaying a dominant phenotype for the *foxc1a* mutation in *foxc1b*-deficient background and exposing a role of *foxc1b* in the development/maintenance of the affected structures. Embryos with deficiency for a single (*foxc1a*) or both (*foxc1* D-KO) genes were examined by histology and showed similar ocular defects; also, analysis of eye vasculature was performed using Tg(*fli1a*-GFP)/*foxc1a*<sup>+/-</sup> animals and showed severe abnormalities. To identify downstream effects of *foxc1* deficiency, D-KO eye samples were collected at different developmental stages, RNAseq was performed and results will be presented. Our data show that *foxc1* is necessary for the proper eye development in zebrafish and that the developed zebrafish lines serve as a suitable model for *FOXC1*-related human ocular disease.

## PgmNr 568: cfDNA screening in triplets: A clinical laboratory experience.

### Authors:

---

**Introduction:** Cell-free DNA (cfDNA) aneuploidy screening in multifetal pregnancies has been validated and clinically available since 2012. Since that time, over 900 samples from triplet gestations have been submitted for screening to one laboratory. Here, we describe the laboratory experience of the MaterniT<sup>®</sup>21 PLUS test in triplets.

**Methods:** Maternal blood samples submitted to Sequenom Laboratories<sup>®</sup> for MaterniT<sup>®</sup>21 PLUS testing were subjected to DNA extraction, library preparation, and genome-wide massively parallel sequencing as previously described by *Jensen et al.* Data analysis was performed on samples submitted for testing with a fetal number of 'three' indicated on the test requisition. Outcome data were elicited by phone or email from the ordering provider.

**Results:** From 2013 to 2019, 932 triplet samples were submitted for cfDNA screening. The majority of samples (79.2%) received a reportable result (i.e. positive or negative); the average fetal fraction (FF) in the reportable samples was 13.8%. This triplet cohort had a higher non-reportable (NR) rate due to low FF (20.2%) when compared to singleton pregnancies (<1%). In triplet samples that were NR due to low FF the average FF was 8.3%, well within the reportable range for a singleton, however the FF requirements for triplets are approximately three fold. Very few NRs were due to technical reasons (0.6%). The overall positivity rate for trisomy 21, 18, 13 in this cohort was <1% (n=7). Results of diagnostic testing were available for two of the seven positive cases, and both cases confirmed the cfDNA finding. Two additional cases had significant clinical findings consistent with increased risk for trisomy. No false negatives were reported to the laboratory. For the overall triplet cohort, the average turnaround time was 5.74 calendar days. Average turnaround times continue to decrease; in triplet samples resulted in 2018 and 2019 the average turnaround time improved to 3.8 and 3.15 calendar days, respectively.

**Conclusions:** cfDNA screening and ultrasound represent the only options for aneuploidy screening in triplets and other higher order multiples since serum screening is only available for singletons and twins. Higher NR rates are largely attributed to more stringent signal-to-noise ratio and higher FF requirements in multifetal pregnancies. Outcome information submitted from ordering providers suggest that cfDNA screening is an accurate and reliable screening method for triplet gestations.

## PgmNr 569: A novel universal PCR-based library preparation for PGT-A allowing cross-platform NGS sequencing.

Single-tube PCR-based Library Preparation (PCRLP) for Preimplantation Genetic Testing for Aneuploidy (PGT-A) by Next Generation Sequencing (NGS) is a new technology that has advantages over traditional two-step approaches, including protocol time efficiencies and reduced hands-on time. Validation of new technologies is important, and a powerful way to do this is with cross-validation. However, this is challenging with trophectoderm (TE) biopsies that typically provide limited sample template. Embryos can be re-biopsied, but biological variation in the form of mosaicism complicates data reporting. An alternative approach is possible using a novel single-tube PCRLP for PGT-A, developed based on the PerkinElmer DOPlify® WGA kit. This approach has the traditional advantages of PCRLP approaches but also allows cross-validation from a single TE biopsy.

Here, we describe the development of a novel approach for PCRLP of TE biopsies that allows cross-platform NGS using either Illumina® or Ion Torrent® sequencing technology.

Five-cell samples resembling TE biopsies were manually sorted from aneuploid cell lines (Coriell Institute). Cell lysis and WGA were performed using a modified DOPlify® kit protocol (PerkinElmer). WGA DNA was split and a second round of PCR was performed for incorporation of either Illumina® or Ion Torrent® specific adapter sequences. Amplified, indexed cell samples were purified, quantified and pooled before sequencing. Illumina® sequencing was undertaken on the MiSeq® instrument (Illumina®) while Ion Torrent® sequencing was performed on the S5 instrument (Thermo Fisher®). Sequencing data was analysed for correct aneuploidy calling using PG-Find™ software (PerkinElmer). Illumina® samples yielded an average of 580,000 reads per sample with 98.2% of reads mapping to hg19. Ion Torrent® samples yielded an average of 470,000 reads per sample with 97.9% of reads mapping to hg19. All samples passed quality control and displayed the expected karyotype when analysed by PG-Find™ software.

This novel PCRLP workflow provides rapid, scalable and economical sequencing for PGT-A and provides the capability for cross-platform sequencing validation of a single embryo biopsy for PGT-A. This flexible workflow also allows customisable throughput and tailorable resolution to detect smaller segmental aberrations. Large-scale cell-line validation of both the Illumina® and Ion Torrent® workflows are underway.

For research use only. Not for use in diagnostic procedures.

## PgmNr 570: Mathematical modeling reveals non-independence of meiosis I and meiosis II errors during human oogenesis.

---

Approximately 10% of women world-wide experience pregnancy difficulties. Aneuploidy is a major contributor of pregnancy problems in women, resulting in pregnancy loss and *in vitro* fertilization (IVF) failure. Although most aneuploid conceptions are thought to originate from female meiotic division errors, quantitative studies that formally link the observed phenotypes to underlying error mechanisms are lacking. The goal of this project is to classify mechanisms of erroneous chromosome segregations underlying the production of poor-quality eggs.

Using mathematical modeling we investigate the rates of chromosomal mis-segregations that lead to aneuploid conceptions. In the model, the probabilities of all gamete outcomes are modelled as the combination of different types of errors. We consider the probability of non-disjunction (NDJ) errors in both Meiosis I (MI-NDJ) and Meiosis II (MII-NDJ), and premature separation of sister chromatids (PSSC) in Meiosis I (MI-PSSC). The rates were parameterized based on published preimplantation genetic testing for aneuploidy (PGT-A) results performed on trophectoderm cells during IVF procedures. Our results demonstrate that we can model all possible conception outcomes with five parameters that approximated the observed data. Using our modeling strategy, we observed MI-PSSC to be more prevalent than MI-NDJ across all the ages, a result that has long been speculated. The modeling also revealed the non-independence of Meiosis I and Meiosis II errors. Namely, abnormal secondary oocytes were more likely to suffer from additional segregating errors during Meiosis II. We show how the model can be used to identify IVF patients that are outliers for the number of aneuploid embryos based on their PGT-A results. Overall, the dynamic nature of the mathematical model makes it a potential tool for predicting the outcomes of assisted reproduction. This in turn could help to improve implantation success rates which have lingered at 30% for the past 20 years.

## PgmNr 571: Preimplantation genetic testing for aneuploidies (PGT-A) by metabolomic profiling of spent culture media using Raman spectroscopy.

### Background:

With the improvement of Preimplantation Genetic Testing for Aneuploidies (PGT-A) in live birth rate, this intervention has been widely used but controversial on its potential effect by biopsy and cost-effectiveness. The application of spent culture media (SCM) from blastocysts for aneuploidy screening by Raman spectroscopy has been reported to be success recently and we are interested to assess its performance.

### Methods:

A total of 239 SCM samples from 63 cycles were collected from 2018 to 2019. The collected media has both G1/G2 and GTL as base media from blastocyst in PGT cohort (230 SCM from 55 cycles) and were separately trained and tested. There were 111 SCM have done PGT-A on blastocyst biopsy, SCM and Raman parallelly. Nine SCM from 8 cycles have reproductive outcomes in non-PGT cohort. PGT-A results was regarded as the standard and reproductive outcome using clinical pregnancy as cutoff, Raman spectra of SCM of the corresponding embryos were classified into normal or abnormal. The algorithms were trained by a set of known PGT-A samples, and then tested the rest blindly. The spectra data were predicted by 5 machine learning algorithms: Convolutional Neural Networks (CNN), k-nearest neighbors (kNN), random forests (RF), extreme gradient boosting (XGB), and stacking.

### Results:

There were 84 abnormal and 46 normal SCM from G1/G2 group, while 34 abnormal and 28 normal from GTL group. At the first phase, all SCM in both groups were analyzed. The best prediction model was stacking for both G1/G2 and GTL groups, with an overall (GTL+G1/G2) 95.41% positive predictive value (PPV), and 53.1% negative predictive value (NPV), with 93.24% specificity and 63.03% sensitivity. The testing duration of each sample was around 5 minutes, enabling a fast turnaround time. In phase two, by further excluding segmental, subchromosomal, mosaic and sex chromosomal aneuploidies, leaving only single/multiple numerical aneuploidies and euploid to analysis on 136 samples. The best prediction model was XGB, with an overall PPV of 93.33% and NPV of 76.90%, with specificity at 95.89% and sensitivity at 66.67%.

### Conclusion:

Raman spectroscopy on spent culture media for PGT-A has a good performance on positive predictive value. Although the nature of Raman spectrum has a relatively low sensitivity, its ease of use, quick turn-around time, and non-invasiveness merits. Raman spectroscopy as a first-tier screening test for excluding single and multiple numerical aneuploidies.

## PgmNr 572: Gene discovery informatics toolkit defines candidate genes for unexplained infertility and prenatal or infantile mortality.

---

Despite a recent surge in novel gene discovery, genetic causes of prenatal-lethal phenotypes remain poorly defined. To advance gene discovery in prenatal-lethal disorders, we created an easy-to-mine database integrating known human phenotypes with inheritance pattern, scores of genetic constraint, and murine and cellular knockout phenotypes—then critically assessed defining features of known prenatal-lethal genes, among 3187 OMIM genes, and relative to 16,009 non-disease genes.

While around one-third (39%) of protein-coding genes are essential for murine development, we curate only 3% (624) of human protein-coding genes linked currently to prenatal/infantile lethal disorders. 75% prenatal-lethal genes are linked to developmental lethality in knockout mice, compared to 54% for all OMIM genes and 34% among non-disease genes. Genetic constraint correlates with inheritance pattern (autosomal recessive << autosomal dominant < X-linked), and is greatest among prenatal-lethal genes. Importantly, over 90% of recessive genes show neither missense nor loss-of-function constraint, even for prenatal-lethal genes. Detailed ontology mapping for 624 prenatal-lethal genes shows marked enrichment among dominant genes for nuclear proteins with roles in RNA/DNA biology, with recessive genes enriched in cytoplasmic (mitochondrial) metabolic proteins.

We conclude that genes without genetic constraint should not be excluded as potential novel disease genes, and especially for recessive conditions (under 10% constrained). Prenatal lethal genes are 5.9-fold more likely to be associated with a lethal murine phenotype than non-disease genes. Cell essential genes are largely a subset of mouse-lethal genes, notably under-represented among known OMIM genes, and strong candidates for gamete/embryo non-viability. We therefore curate 3435 'candidate developmental lethal' human genes: essential for murine development or cellular viability, not yet linked to human disorders, presenting strong candidates for unexplained infertility and prenatal/infantile mortality.

## PgmNr 573: Localization of beta and gamma actin in early fetal brain development.

Actin is an ubiquitously expressed protein and plays a tremendous role in multiple cell functions. The family of Actin consists of 6 isoforms, whereby only the two cytoskeletal isoforms  $\beta$ CYA and  $\gamma$ CYA are expressed in adult as well as in fetal brains. The distribution of  $\beta$ CYA and  $\gamma$ CYA in the human cortex is not yet known. We analyzed the enrichment of these two isoforms in early fetal corticogenesis. In sections of 12 weeks post conception (wpc) neocortex,  $\gamma$ CYA is the predominant isoform in all layers except the adhesion junction belt of the ventricular zone (VZ) and marginal zone (MZ) where  $\beta$ CYA represents the major actin isoform. At 16 wpc the expression pattern changes.  $\beta$ CYA becomes the predominant isoform in the cortical plate (CP) and MZ. Additionally, we analyzed the intracellular distribution of the two isoforms in *in vitro* differentiated neural progenitor cells (NPC) and neurons. In NPC, both isoforms are concentrated to the cell periphery rather than the lumen. Neurons show an increased enrichment of  $\beta$ CYA in neurites and cell processes of single cells, whereas  $\gamma$ CYA prevails in the cell body. In migrating neurons,  $\beta$ CYA is the predominant actin isoform of the cell lumen. We will present a detailed assessment of differential enrichment of the two cytoskeletal actin isoforms during early human corticogenesis on cellular and subcellular levels.

## **PgmNr 574: Motor planning deficits in a prenatally diagnosed population of 47,XXY (Klinefelter syndrome) and the variable impact of hormonal replacement therapy (HRT).**

### **Authors:**

P. Lasutschinkow <sup>1</sup>; A. Gropman <sup>2</sup>; T. Sadeghin <sup>1</sup>; C. Samango-Sprouse <sup>3,4,1</sup>

47,XXY is the most common X&Y chromosomal variation (1:600) & the motor planning deficits have not been investigated. Specific motor planning deficits & potential impact of Hormonal Replacement Therapy (HRT) was investigated.

80 boys with 47,XXY were evaluated with Amsterdam Neuropsychological Test (ANT), Beery Buktenica Developmental Test of Visual-Motor Integration (BEERY-6), Bruininks-Oseretsky Test (BOT-2), Comprehensive Trail Making Test (CTMT) & Weschler Intelligence Scale for Children (WISC-IV &V). There were four groups: non-HRT, early hormonal therapy (EHT), hormonal booster therapy (HBT), or EHT&HBT (EB). 45 did not receive HRT; EHT-11; HBT-14; EB-10. HRT was given based on participant's pediatric endocrinologist's evaluation.

All groups had below to low average scores on fine motor precision & manual dexterity on BOT-2 & depressed scores in visuomotor & motor planning on ANT. Scores were below average on CTMT. On Beery-6, all groups had below average motor coordination (MC) discrepant to visual motor integration (VMI) & visual perception (VP). On WISC, the lowest scores were in coding.

ANOVA testing revealed significant differences for treatment groups in fine motor integration(FMI) on BOT-2 ( $p=0.031$ ), block design(BD) ( $p=0.049$ ) & matrix reasoning(MR) ( $p=0.047$ ) on WISC & VP on Beery-6 ( $p=0.013$ ). Post-hoc comparisons using Holm procedure indicated significant difference in FMI ( $p=0.022$ ) between non-HRT ( $M=12$ ) & EHT ( $M=15$ ). Significant differences for BD & MR existed between non-HRT ( $M=11.09$ ;  $10.21$ ) & EB ( $M=13.8$ ;  $13.6$ ) ( $p=0.029$ ;  $p=0.016$ ). Significant differences in VP ( $p=0.022$ ) were evident between non-HRT ( $M=100.1$ ) & EHT ( $M=114.1$ ).

This is the first study to identify motor planning deficits in boys with 47,XXY and the findings begin to delineate various aspects of motor planning dysfunction in 47,XXY. Paper & pencil tasks consistent with dysgraphia are the weakest aspect of motor planning in 47,XXY as evident from scores on the WISC, Beery-6, ANT, CTMT & BOT-2. These results demonstrate that HRT may have a positive response on perceptual capabilities, with EHT treated boys performing better than non-HRT in VP & FMI & EB performing better in BD & MR. This study supports previous research that HRT has a positive impact on specific aspects of neurodevelopment in 47,XXY & also identified a selective response to treatment within motor planning.

## PgmNr 575: Preconception carrier screening yield: Effect of variants of unknown significance in partners of carriers with clinically significant variants.

### Authors:

H. Fridman <sup>1,2,3</sup>; D.M. Behar <sup>4</sup>; S. Carmi <sup>1</sup>; E. Levy-Lahad <sup>2,3</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Braun School of Public Health and Community Medicine, The Hebrew University of Jerusalem, Jerusalem, Israel; 2) Medical Genetics Institute, Shaare Zedek Medical Center, Jerusalem, Israel; 3) Faculty of Medicine, The Hebrew University of Jerusalem, Jerusalem, Israel; 4) Igentify, Tirat Hacarmel, Israel

**Purpose:** Expanded preconception carrier screening (ECS) identifies couples at risk for multiple diseases. ECS reports currently include only pathogenic/likely-pathogenic (P/LP) variants. Variants of unknown significance (VOUS) are not reported, unlike genomic or chromosomal-array test results in other post- or pre-natal settings. This policy omits pairings of P/LP carriers with VOUS carriers (P/LP\*VOUS), who may be at-risk. This situation is expected to be particularly common in genes with high P/LP carrier rates. We examined the possible contribution of P/LP\*VOUS matings to the yield of ECS in an Ashkenazi Jewish (AJ) cohort, a population with well-established preconception screening.

**Methods:** We analyzed 672 AJ genome sequences (225,456 virtual matings) for variants in three different gene-sets, using automated and manual ACMG classification. Gene-sets analyzed were an AJ (55 genes), pan-ethnic (168 genes) and combined (180 genes) sets.

**Results:** Across 180 genes, we identified 4671 variants: 144 (3.1%) P/LP and 1963 (42%) VOUS. The proportion of P/LP\*P/LP and P/LP\*VOUS couples at-risk was 2.7-3.8% and 17-20% respectively (for different gene-sets). Considering only coding-VOUS (i.e. exonic non-UTR VOUS), the proportion of P/LP\*cVOUS couples at-risk was  $\approx 7\%$ . Most (65-70%) P/LP\*VOUS matings were at risk for severe/profoundly-severe diseases.

We also modeled different scenarios of VOUS reclassification, based on hypothetical fulfillment of specific ACMG criteria. Hypothetical fulfillment of the PS4 criterion (significantly greater prevalence of the variant in affected individuals vs. controls) would reclassify 89.2% of VOUS to P/LP. In contrast, hypothetical fulfillment of the PM2 criterion (absence of the variant in controls) would reclassify only 1% of VOUS to P/LP.

**Conclusions:** Disregarding VOUS in ECS may miss couples at-risk for severe diseases. Even if only 10% of couples currently classified as P/LP\*cVOUS are ultimately reclassified as P/LP\*P/LP, ECS yield would increase by  $\approx 20\%$ . This suggests that VOUS in current ECS genes are more likely to affect ECS yield than sequencing an ever greater number of rare disease genes.

These results should not be interpreted as a call for including VOUS in ECS reports, but rather as evidence for the importance of addressing variant classification in ECS-panel genes. Further data collection on variants in affected individuals is likely to have the greatest impact on such reclassification.

## PgmNr 576: Expanded carrier screening using next generation sequencing: An experience from India.

### Authors:

S. Sharda; S. Nair; P. Palan; T. Geetha; A. Arunkumar; V. Ramchander; V. Gopalan; L. Mahadevan; S. Murugan; R. Vedam

---

Carrier screening of couples is currently limited to genetic disorders with a high frequency, a positive family history or is majorly ethnicity based. Couples may not even be aware that they could be carrying a genetic variant, which could lead to their unborn child developing a genetic disorder. In most cases, carriers of a genetic disorder are asymptomatic and may have no family history and unfortunately their carrier status is often confirmed only after an affected baby is born.

With the availability of advanced molecular technologies, like massively parallel sequencing, expanded genetic screening aims to identify carriers for a much larger group of genetic diseases, not limited to ethnicity or a positive family history. There is no carrier screening program available in India, at present except for limited screening for thalassemia. Expanded carrier testing is the need of the hour in a country with high population, high birth rate and a high rate of consanguinity.

Medgenome Labs have tested around 2000 Indian couples for their carrier status, using Next Generation Sequencing and MLPA technology. We have screened couples for Autosomal and X-linked recessive disorders and have provided clinically significant results, based on which the couples went ahead for prenatal diagnosis. The most common indications for referral were previous child affected or suspected to be affected with a genetic disorder [known/unknown], consanguinity, bad obstetric history including recurrent pregnancy and IVF loss or a family history of suspected genetic disorder. Carrier screening provides the couple an opportunity to take informed reproductive choices, including prenatal diagnosis, pre-implantation genetic diagnosis or even preparedness for the newborn.

The data would also help to know the most common genetic disorders with their carrier frequency in the Indian population and if there is any difference compared to the western literature. Most of the carrier frequencies of genes and common variants is available from the western literature and ethnicity based frequency of many genetic disorders are not available for Indian population. This information can be used to counsel couples regarding their risk as well as help them take an informed decision. This retrospective analysis will certainly help the primary care providers make guidelines for primary as well as secondary prevention of rare genetic disorders which have an emotional and financial burden on the parents and society

## PgmNr 577: Autozygosity mapping and its relation to the timing of birth in Norwegian family trios.

Long autozygous (homozygous IBD segments) are enriched in low frequency and rare deleterious variants. Its mapping in genotyping array studies captures the effects of non-genotyped variants with recessive effects that may lie within these segments. Birth timing has a broad-sense heritability ranging between 25-40%, and maternal and dominance components account for 15% and 11% of its variance, respectively.

Here, we leveraged the relationship between parental genetic relatedness and offspring runs-of-homozygosity (ROH) in 15000 family-trios to estimate autozygosity while avoiding the arbitrary selection of calling parameters. We estimated the maternal, paternal and fetal effects of genome-wide autozygosity and identified regions with recessive effects on spontaneous delivery risk.

DNA from 15000 triades from the Norwegian Mother and Child cohort was genotyped using different Illumina arrays. We called ROH in the offspring multiple times varying the parameters used, and selected, within each batch, those parameters that maximized the coefficient of determination between offspring ROH and parental genetic relatedness. Autozygosity was then estimated in each member of the family trios as the fraction of genome covered by autozygous segments. Genomic regions with recessive effects were identified by autozygosity mapping. Cox proportional hazard regressions were fitted in mothers, fathers and offspring to estimate the effect of genome-wide and regional autozygosity on spontaneous delivery risk.

We observed differences in  $R^2$  ranging from 0.01 to 0.75 between offspring ROH and parental genetic relatedness using different parameters, which were highly dependent on genotyping platform. Genome-wide autozygosity analysis suggested a modest effect of maternal autozygosity on spontaneous delivery risk (HR: 1.04 [95%CI: 0.99,1.09]) and gestational age (beta: -0.6 [-1.0, -0.1]). We observed no effect of fetal nor paternal autozygosity on birth timing. We identified 259 maternal and 280 fetal variants with a false discovery rate  $<0.3$  in at least two of the 3 batches studied (lowest p-values  $4.9 \times 10^{-09}$ ) in 7 protein coding genes (RELL1, TBC1D1, PGM2, RPTOR, CARD14, SLC26A11 and

GRHL2).

Genome-wide autozygosity in the mother is associated with modest effect on birth timing, but not in the offspring nor father. Autozygosity mapping highlighted loci in glucose, insulin and cell differentiation and growth pathways associated with spontaneous delivery risk.

## PgmNr 578: Expanded carrier screening research using a unique multiplex targeted sequencing panel.

---

To create a sample-to-answer workflow with flexible throughput for expanded screening research of carrier variants, we designed a multiplex next generation sequencing (NGS) panel targeting 99.96% of coding bases plus flanking regions for 420 genes implicated in Mendelian disorders. This panel includes several complex, high-value targets that are historically difficult to assess by NGS, including the *GBA*, *SMN1*, *CYP21A2*, and *HBA1/2* loci. Eight unlinked, non-exonic, high minor allele frequency SNP markers were also included in the panel to generate a unique sequencing ID for each research sample. Panel performance was tested against cell lines containing known variants, and under-performing regions were iteratively redesigned to optimize a variety of parameters, including percentage of bases covered within the targeted loci, evenness of target coverage, and ability to call SNV, indel, and CNV variants. Libraries were created from as little as 20 ng of input DNA, yielding >99% library success rate from cell line, blood, and buccal-swab samples tested. Libraries were individually barcoded and then pooled to yield on average ~3M reads per library at up to 32 libraries per each three hour semi-conductor-based sequencing run. At this read depth, analytical sensitivity and specificity for key variants were >99% for SNV detection, and >98% for CNV detection, as empirically determined using samples with known-truth variants. Analytical reproducibility of key called-variants was >99% and no-call rate for key hotspot SNVs was <0.4%. Reporting software was also created to provide functional context for, and rapid reporting of, identified variants.

## PgmNr 579: It's not all about the extra X: The potential role of copy number variants (CNVs) in the neurodevelopmental variability of 47,XXY (Klinefelter syndrome).

### Authors:

---

**Background:** 47,XXY (Klinefelter syndrome) is the most commonly occurring sex chromosomal aneuploidy (1:650). The phenotypic profile of this syndrome ranges widely but is often associated with executive dysfunction, speech and motor delay, and language-based learning disorders. Recent research has shown that copy number variants (CNVs) may be associated with neurodevelopmental disorders. However, the prevalence of CNVs in conjunction with 47,XXY, and subsequent effects on neurodevelopmental variability, is not clearly defined. This study investigated the potential impact that CNVs may have in boys with 47,XXY.

**Method:** Six boys (47-CNV) with 47,XXY and varying CNVs (1p36.22 duplication (dup), 2p23.3 dup, 5q35.1 dup, 8q22.3 dup, 15q21.1 deletion (del), Xp22.31 dup) were compared to eleven boys (47) with 47,XXY across cognition (COG), motor (MOT), auditory comprehension (AC), expressive communication (EC), and expressive (EL) and receptive language (RL). Domains were evaluated using the Bayley Scales of Infant Development (BSID), Preschool Language Scales (PLS), Expressive One Word Picture Vocabulary (EOWPVT), and Receptive One Word Picture Vocabulary (ROWPVT). Ages for all ranged from 24-59 months ( $M=29.7 \pm 9.5$ ).

**Results:** On the BSID, no significant differences were found in COG. There was a significant difference in MOT ( $P=0.05$ ), where the 47-CNV boys had lower MOT. Scores for EC on the PLS did not reveal significant differences, but there was a difference between the 47-CNV boys and the 47 boys regarding AC on the PLS ( $P=0.48$ ), as the 47 boys exhibited higher capabilities. 47 boys had greater EL ( $P=0.043$ ) and RL ( $P=0.019$ ) than the 47-CNV boys on the EOWPVT and ROWPVT.

**Conclusion:** The 47-CNV boys presented with lower capabilities in MOT, EL, RL, and AC than the 47 boys within the first 5 years of life. Research has shown that these domains are generally areas of weakness for 47,XXY, and these results suggest that CNVs may be an underlying genetic component contributing to the neurodevelopmental variability often seen in 47,XXY. When boys with 47,XXY exhibit a greater degree of difficulty in their neurodevelopment, further genetic testing should be considered to look for the presence of CNVs. Lastly, the CNVs described in this cohort are currently reported to be of unknown clinical significance; thus, more research is warranted to determine if these CNVs are also linked to neurodevelopment, and how these CNVs manifest themselves in

conjunction with 47,XXY.

## PgmNr 580: The molecular characterization of genetic pre-disposition to fibroid growth in black women attending the Centre Hospitalier de Recherche en Chirurgie Endoscopique et Réproduction Humaine(CHRACERH)-Yaounde, Cameroon.

### Authors:

M.S.B.E Ngwafor<sup>1</sup>; J.P. Chedjou<sup>2</sup>; N. Nguediak Kaze<sup>1</sup>; H. Dongmo<sup>2</sup>; C. Tah<sup>2</sup>; A. Noubom<sup>3</sup>; S. Biboum<sup>3</sup>; C. Noa<sup>3</sup>; E. Belinga<sup>1,3</sup>; M. Toukam<sup>1,3</sup>; W.F. Mbacham<sup>1,2</sup>; J.M. Kasia<sup>1,3</sup>

### Affiliations:

1) Faculty of Medicine and Biomedical Sciences-University of Yaounde I, Yaounde, Center , Cameroon;  
2) Laboratory for Research and Public Health Biotechnologies-Biotechnology Center, University of Yaounde I , Cameroon; 3) Centre Hospitalier de Recherche en Chirurgie Endoscopique et Reproduction Humaine, Yaounde-Cameroon

Fibroids are the most common benign gynecological tumors of the uterus accounting for 20-50%. It's pathogenesis is poorly understood. It has been hypothesized that diet, lifestyle, immunological and inflammatory processes may influence genetic polymorphisms of growth factors of uterine leiomyoma. With paucity in data in Africa and Cameroon in particular, the *VEGF* -460 C/T is known to pre-dispose women to fibroids where as *FGF2* 754C/G mutation has been shown to pre-dispose women to adenomyosis even though its gene is implicated in the onset of fibroids. Thus we embarked on studying the presence of these mutations that could be associated to the development of fibroids in women of childbearing age attending CHRACERH in order to establish an association of these of markers likely to contribute to fibroid growth. We conducted a case-control study, with the recruitment of women aged 20 and above; 30 cases of USS diagnosed fibroma. In the control arm, we had 10 women with no fibroids. Prior to this, participants signed an informed consent and completed a questionnaire. Thereafter, a physical examination was done and blood samples collected on 3MM filter paper (dried blood spots-dbs) was taken to LAPHORB for genomic analyses. The Chelex 100 method for DNA extraction. The determination of the 754 C/G and 460 C/T polymorphisms of the *FGF2* and *VEGF* genes by PCR-RFLP using the endonucleases *HhaI* and *BshI*2361 respectively. This was carried out during a period of two months. At the end of the study we obtained 95% genotype GG (mutant) for the *FGF2* 754 gene with a preponderance of the G allele-97.5%. In the case of positive fibroids we obtained 93% GG genotype with 7% CG in the control group. We obtained 100% TT genotype (mutant) for the *VEGF* gene in both groups similar to studies done in Chinese women with T allele predisposing women to fibroids and the C allele with less exposure to fibroids. With respect to the association between fibroids and gene 754C/G mutation, we obtained an OR of 1.071 on a 95% CI of 0.974-1.179 with a p value of 0.402 which reflects no association between the mutation and occurrence of fibroid. It should be noted this mutation has not been studied as a biomarker pre-disposing women to fibroids but its gene *FGF2* has been implicated in fibroid development. Given no association was found between the mutations and onset of fibroids in this African population, a basis is set for the investigation of other putative fibroid biomarkers.

## PgmNr 581: Integration of genetic ancestry with DNA methylation identifies novel placental epigenetic signatures implicated in birthweight and adult complex diseases.

### Authors:

F. Tekola Ayele; X. Zeng; T. Workalemahu; M. Ouidir

**Affiliation:** Division of Intramural Population Health Research, NATIONAL INSTITUTES OF HEALTH (NIH), BETHESDA, Maryland.

---

Integrating genetically derived ancestry estimates with DNA methylation (DNAm) in fetal tissues from diverse populations may give clues about early developmental mechanisms and later life health disparities. Here, we report a study that interrogated multi-omic data on placenta collected from ethnically-diverse individuals aiming: 1) to identify ancestry-specific as well as shared DNAm signatures of genetic ancestry composition; 2) to test whether these DNAm signatures of ancestry are associated with fetal growth; and 3) to test for enrichment of ancestry-associated CpGs with mQTLs implicated in adult diseases. Placental biopsies were collected during delivery from 312 self-identified Black, White, Hispanic, and Asian women in the U.S. DNA and RNA isolated from placental samples underwent genotyping on the Illumina 2.5M array, DNAm on Illumina 450k array, and RNAseq on Illumina HiSeq2000. The percentages of African (AF), European (EU), Native American (NA) and East Asian (EA) ancestries were estimated using ADMIXTURE. Covariate-adjusted linear regression models tested associations between genetic ancestry percentage and DNAm. Analyses were performed for: EU, AF, and NA ancestry percentages in Hispanics; and AF, EU, and EA ancestry percentages in Blacks, Whites, and Asians, respectively. A total of 18 CpG sites were significantly (FDR  $P < 0.05$ ) differentially methylated with AF ancestry percentage in Blacks; 91 CpGs with EU ancestry percentage in Whites, 68 CpGs with EA ancestry percentage in East Asians; and 234 CpGs, 12 CpGs, and 6 CpGs with NA, EU, and AF ancestry percentage in Hispanics. Five CpGs (*ERI1*, *GCC2*, *BMF*, *PGAM5*, *NARFL*) showed directionally consistent associations with both NA ancestry in Hispanics and EA ancestry in East Asians. Among the top hits, 5 EU ancestry CpGs in Whites, 3 EA ancestry CpGs in Asians, and 8 NA ancestry CpGs in Hispanics were negatively correlated with the expressions of their respective genes. An EU-ancestry CpG (*SLC16A3*) and an NA-ancestry CpG (*IER3*) showed Bonferroni-corrected significant association with higher birthweight. Several ancestry-associated CpGs were enriched with mQTL SNPs in blood across the life span, including more than 50 GWAS SNPs associated with 24 adult traits. This novel study demonstrates that links between genetic ancestry and epigenetic marks in diverse populations may underlie differences in early growth, the developmental origins of health and disease, and health disparities.

## PgmNr 582: Exome sequencing expands knowledge of early phenotypes in well-known genetic conditions.

### Authors:

---

Increased utilization of exome sequencing (ES) in infants has led to earlier diagnoses of well-known genetic conditions. Such diagnoses expand knowledge of early phenotypes and presentations which may not fulfill clinical diagnostic criteria (CDC). We identified several such cases as part of UCSF's Program in Prenatal and Pediatric Genomic Sequencing (P3EGS) study.

Patient 1 is a 16mo female of European ancestry who was evaluated at 2mo for failure to thrive, mild hypotonia, and multiple congenital anomalies including persistent left superior vena cava, hypoplastic kidneys, ventricular septal defect, bilateral ear pits, congenital sacral dimple, tethered cord, and a history of single umbilical artery. At 5mo she was also noted to have developmental delays (DD). ES identified a *de novo* variant in *KMT2D* predicting p.Met999\*fs. The patient did not meet CDC for Kabuki syndrome, which emphasize facial features that are difficult to appreciate in infancy, and had not yet been noted to have DD, which is also important for CDC, when first seen by genetics.

Patient 2 is a 11mo Latina female seen by genetics at 3mo during a hospitalization for respiratory failure. She also had a history of hypotonia and dysphagia. At 8mo, ES revealed a *de novo* variant in *MECP2* predicting p.Arg168\*. She did not meet CDC for Rett/Atypical Rett syndromes, as she was too young to manifest regression or stereotypic hand movements. While respiratory problems have been described in Rett syndrome, the severity and timing were atypical.

Patient 3 is a 15mo Latino male seen by genetics at 5mo due to cleft lip/palate and microcephaly. He also had a history of DD, feeding difficulties, hearing loss, and a patent foramen ovale. The patient's physical exam was notable for plagiocephaly/brachycephaly, upslanting palpebral fissures, and thickened eyebrows. His mother had history of cleft lip and an atrial septal defect. ES showed a maternally inherited *RAD21* variant predicting p.R478\*. CDC for Cornelia de Lange rely heavily on facial features—particularly synophrys—not present in our patient, and as such he did not meet criteria.

ES is providing infants with diagnoses of classic genetic conditions for which infantile phenotypes may not be well-described and the cardinal features emphasized in CDC may onset later. These cases suggest diagnostic utility of ES for infants with suspected genetic conditions who may not meet CDC and suggest CDC may need to be expanded to encompass infantile presentations.

## PgmNr 583: Toll-like receptor 6 (*TLR6*) SNPs P249S rs5743810 and Intron rs1039559 strengthen the association of *TLR6-TLR1-TLR10* gene cluster with preterm birth in Wisconsin cohort.

### Authors:

D.M. Pillers<sup>1</sup>; J. Eickhoff<sup>2</sup>; M. Baker<sup>3</sup>; B.R. Pattnaik<sup>4</sup>; W. Luo<sup>1</sup>

**Background:** Preterm birth (PTB) occurs in 11% of US births, causing significant morbidity and mortality. A subset of PTB is complicated by infection and potential aberrations in the microbiome. The Toll-like receptors (TLR) of the innate immune system are integral to pathogen recognition and susceptibility to infection. We speculated that SNPs in fetal TLR genes may be associated with the subset of PTB with underlying infection as an etiology. We have previously reported results for SNPs in three TLRs (1, 2, and 4) in Wisconsin infants, with only *TLR1* SNPs associated with PTB. *TLR1* is in the *TLR6-TLR1-TLR10* gene cluster that functions in inflammation and infection. We tested SNPs in *TLR6* and *TLR10* and found that *TLR6* SNP P249S also associates with PTB.

**Objective:** SNP associations with PTB have not been easily replicated in prior published works. Thus, we sought to validate our results with additional SNPs at discrete positions in the *TLR6* gene. We hypothesized that *TLR6* SNP intron rs1039559 would similarly mark an increased risk for PTB.

**Design/Method:** Residual newborn screening DNA was tested with IRB approval. 3000 samples were used for *TLR1* SNP (N248S) analysis, with 866, and 1926 samples adequate for subsequent *TLR6* (P249S; rs5743810), and *TLR6* (intron rs1039559) testing. SNP genotype was performed by TaqMan SNP Genotyping Assay (Lifetechnologies, CA). Ancestral background was by maternal declaration.

**Results:** The *TLR6* SNP (P249S; rs5743810) minor allele T was associated with preterm gestational age (GA) < 34 wks, Odds Ratio (OR) 1.41 (95% CI: 1.15-1.72, P<0.00087) and with GA < 37 wks, OR 1.30 (95% CI: 1.02-1.67, P<0.032). However, in GA subset < 28 wks, the *TLR6* SNP (P249S) minor allele T findings were not consistent with those in the older GA < 37 wks and GA < 34 wks. The *TLR6* SNP (intron rs1039559) major allele A was associated with preterm GA < 28 wks, OR 1.21 (95% CI: 1.04-1.40, P<0.013) and with low birthweight (<1250g), OR 1.24 (95% CI: 1.08-1.42, P<0.0025).

**Conclusion:** We propose that in addition to *TLR1*, *TLR6* is another gene in the *TLR6-TLR1-TLR10* gene cluster that is associated with preterm birth. *TLR1* and *TLR6* are part of a tightly linked cluster of TLR genes that act as co-receptors with TLR2, a key step in the inflammation cascade. We speculate that aberrant *TLR1* and *TLR6* may lead to PTB via an altered downstream pathway causing disturbed commensal homeostasis leading to an altered microbiome and finally, to pathogen invasion.

## PgmNr 584: The bad, the ugly, and the good of direct to consumer genetic testing.

**Authors:**

P. Bitoun

[View Session](#) [Add to Schedule](#)

**Affiliation:** Groupe Medical Jarente, Medical Genetics, Paris, IDF, France

---

The author presents 3 cases of paternity search performed using Direct to Consumer Tests (DCT) from the searcher's point of view for one family, from the father's side in another family and from a relative in the third.

The first case presents to the clinic with results of his abnormal spermogram from which he is convinced that he may not be the father of his previous born son. He went on to present the DCT result of his 2 further born children, his wife, his previous born son. The discussion was about the understanding of these tests results, detailed presentation of the results data, the validity of commercial genetic tests and the psychological reasons for these tests.

The second family presents with a man whose 2 cousins who had previously performed DCTs and were later contacted by email about an unknown adopted individual claiming he had matched with them as possible cousins using the DCT databank family search tool. The man at first had not answered these emails from his cousins he thought were a joke until they called him informing him he may have been the father of this unknown individual from temporal and geographical evidence. The reaction, action and results of these will be presented in details.

The third case is a classic issue of an individual who posted his genome in the public space of 23 and me and Ancestry DNA and was contacted by a distant adopted relative searching for his father.

These cases are iconic examples of what geneticists may expect to be confronted with as the use of DCT are becoming commonplace and with their various impact on individuals and families.

# PgmNr 585: Utility of whole genome sequencing in an undiagnosed fetus with increased nuchal translucency: A case illustration.

## Authors:

M.M. Shi; Z.R. Dong; H.K. Chau; Z.J. Yang; K. Kwok; K.W. Choy

[View Session](#) [Add to Schedule](#)

**Affiliation:** Department of Obstetrics & Gynaecology, The Chinese University of Hong Kong, Hong Kong, China

## Background:

Increased nuchal translucency (NT) in the first trimester is highly associated with chromosomal abnormalities. Karyotyping and chromosomal microarray (CMA) have been routinely performed for these cases, but only yield a diagnosis rate less than 20%. Monogenic syndromes such as Noonan syndrome are also related with increased NT but could not be detected by routine tests. Therefore, it warrants an integrated platform for comprehensive investigation of point mutations, structural variants (SVs) and copy number variants (CNVs). Whole genome sequencing (WGS) offers the potential of a single test detecting nearly all genomic variations. Herein, we retrospectively recruited an undiagnosed fetus with increased NT, and applied WGS for the investigation of its genetic etiology.

## Methods:

The case was recruited from Prenatal Genetic Diagnosis Centre in the Chinese University of Hong Kong. The fetus presented with increased NT (4.18 mm) at 13 gestation weeks and no other abnormalities were detected prenatally. Both karyotyping and CMA were normal. Clinical follow-up showed the fetus was live birth with multiple malformations (low set ears, increased nuchal fold, right hand single transverse crease, bilateral clinodactyly) and mild hearing loss. DNA was extracted from stored chorionic villi. WGS approach (30-fold) was performed for the fetus only to save the cost. Point mutations, CNVs and SVs was analyzed by our in-house pipeline and interpretation was performed according to the ACMG guidelines. Selected putative mutations were validated among the fetus and parents.

## Results:

No pathogenic CNVs and SVs were identified, but we detected a heterozygous frameshift mutation (NM\_0012561 82: c.2404dupC (p.L802fs)) of *ANKRD11* gene, which could cause KBG syndrome (OMIM: #148050). This mutation could result in a truncated protein and lead to nonsense mediated decay. Subsequent parental validation suggested that it arouses *de novo*. Since the child presented with clinical features associated with KBG syndrome, we classified this mutation as pathogenic. In addition, we detected a secondary finding of *GJB2* homozygous pathogenic mutation (NM\_004004 c.G109A (p.V37I)), which is consistent with hearing loss findings.

## Conclusion:

Our study demonstrated that WGS was feasible to investigate the genetic etiology of prenatal cases, and dual molecular diagnosis of KBG syndrome and *GJB2*-related hearing loss could be detected among undiagnosed fetuses with increased nuchal translucency.

## PgmNr 586: Accurate quantification of copy number of the $\alpha$ -globin genes using CarrierScan™ Assay.

### Authors:

S. Mohan<sup>1</sup>; L. Le<sup>1</sup>; R. Varma<sup>1</sup>; D. Behar<sup>2,3</sup>; C. Bormans<sup>2</sup>; J. Winters<sup>4</sup>; L. Hasadsri<sup>4</sup>; P. Lundquist<sup>4</sup>; A. Roter<sup>1</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) ThermoFisher Scientific, Santa Clara, CA.; 2) . Gene by Gene, Genomics Research Center, TX; 3) Igentify, Tirat HacCarmel, Haifa, Israel; 4) Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN

---

Copy number variations in the two alleles of the  $\alpha$ -globin genes *HBA1* and *HBA2* on chromosome 16p13.3 lead to varying degrees of severity of the  $\alpha$ -thalassemia trait. The most common deletion alleles of  $\alpha$ -thalassemia are found in up to 80% of the individuals in some Middle Eastern, sub-Saharan African and South East Asian populations. In the most severe form, called Hb Barts hydrops fetalis syndrome, fetuses lacking all copies of the  $\alpha$ -globin genes cause serious health complications for women during pregnancy and are usually stillborn. While treatments for managing disease symptoms in adults are available, high-throughput, reliable and cost-effective genetic carrier detection is critical to alleviating the burden of the disease during pregnancy and childbirth. Methods developed for quantifying the number of copies of *HBA1* and *HBA2* genes for the Applied Biosystems™ CarrierScan™ Assay have identified 15 previously undetected  $\alpha$ -thalassemia carriers in research samples obtained from the Coriell Institute for Medical Research Cell Repository. Among 96 samples tested during product development, a loss of copy in the *HBA2* gene was detected in 11 samples, and a gain in copy in 4 samples. Two additional samples, previously annotated as carriers, were also detected. The copy number status of the samples was verified by multiplex ligation-dependent probe amplification (MLPA) at Mayo Clinic and Gene by Gene. Additionally, the remaining 79 samples were confirmed as carrying 2 copies each of *HBA1* and *HBA2* genes, indicating that the algorithm performed with 100% analytical sensitivity and specificity in this verification study. Samples analyzed by the Genomics Laboratory at Mayo Clinic identified an additional 27  $\alpha$ -thalassemia carriers across 4 96- format CarrierScan plates; the results were confirmed with MLPA, showing 100% concordance between the assays.

The CarrierScan assay is a microarray-based technology that detects sequence and structural variants in approximately 600 genes. Deletions and duplications at the gene or exon level are identified by calculating a copy-number score across selected copy-number-responsive probesets, including those that target the  $\alpha$ -globin gene loci. This provides important information that may assist in research evaluating  $\alpha$ -thalassemia copy number variations across populations.

## PgmNr 587: Genome-wide association study of female infertility in >36,000 women.

### Authors:

G. Galarneau <sup>1</sup>; P. Fontanillas <sup>2</sup>; C. Clementi <sup>1</sup>; D.E. Parfitt <sup>1</sup>; J.Y. Tung <sup>2</sup>; P. Yurttas Beim <sup>1</sup>; the 23andMe Research Team, the Celmatix Research Team

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Celmatix, New York, NY; 2) 23andMe, Inc., Mountain View, CA

On average, women of reproductive age having timed intercourse are able to establish pregnancy within 6 months, but ~15% take longer than a year or are unable to conceive. We conducted the first genome-wide association study (GWAS) on female infertility in women of European ancestry who used 23andMe's genetic services and consented to participate in research. Cases were women who reported trying to conceive for  $\geq 13$  months in their first pregnancy attempt ( $n=9,822$ ). Controls were women with  $\geq 1$  biological child who reported conception in  $< 6$  months in their first pregnancy attempt ( $n=26,947$ ). We used LDHub to identify genetically correlated traits and MAGMA to perform a gene-set analysis.

Two loci showed genome-wide association. The first locus includes *CDC42* and *WNT4* ( $rs61768001$ ,  $p=4.6 \times 10^{-10}$ ,  $OR=1.16$ , 95% CI [1.11, 1.22]). *CDC42* controls the activation of primordial follicles and *WNT4* is a regulator of endometrial decidualization. The second locus is ~25 kb upstream of *FSHB* ( $rs11031006$ ,  $p=3.6 \times 10^{-8}$ ,  $OR=1.14$ , 95% CI [1.09, 1.19]). *FSHB* encodes the  $\beta$ -subunit of follicle stimulating hormone (FSH). The variants  $rs11031006$  and  $rs10835638$ , both in the credible SNP set, have been associated with nulliparity and lifetime parity. The variant  $rs10835638$  is in the *FSHB* promoter within an 11-bp binding site of the LHX3 transcription factor. The  $rs10835638$ -T allele has been found to reduce the binding affinity of LHX3 and reduces *FSHB* transcription in gonadotrope cells. Six additional loci showed suggestive association ( $p < 1 \times 10^{-6}$ ): *GLYR1*, *FAM168A*, 2q14.3, *HLA-A-TRIM26*, *DUSP10-HHIPL2* and *THADA-PLEKHH2*. Two of these, *GLYR1* and *FAM168A*, include genes that interact with the FSH signaling pathway, which induces ovarian follicles maturation. *GLYR1* mediates the stress activation of MAPK14, which is involved in oocyte meiotic maturation. *FAM168A* activates AKT1, which initiates oocyte growth.

The most genetically correlated traits with female infertility were number of live births ( $p=0.0002$ ,  $r_g=-0.35 \pm 0.10$ ) and lung forced vital capacity ( $p=0.0017$ ,  $r_g=-0.18 \pm 0.06$ ). The most enriched gene-set was NF- $\kappa$ B-driven pro-inflammatory genes that are negatively regulated by glucocorticoids ( $p=3.4 \times 10^{-5}$ ). Interestingly, our study implicates multiple pathways and processes known to be important for reproduction in delayed time-to-first-conception and infertility. This subclinical insight will be key to earlier detection, more efficient patient journeys, and novel therapeutics.

## PgmNr 588: Genetic evidence on the role of maternal vitamin D status during pregnancy in obstetric outcomes.

### Authors:

M.C. Borges <sup>1,2</sup>; A.L.G. Soares <sup>1,2</sup>; Q. Yang <sup>1,2</sup>; F. Kilpi <sup>1,2</sup>; M. Taylor <sup>1,2</sup>; J. Brand <sup>1,3</sup>; D.A. Lawlor <sup>1,2</sup>; MR-PREG Group

1) MRC Integrative Epidemiology Unit at the University of Bristol, Bristol, United Kingdom; 2) Population Health Sciences, Bristol Medical School, University of Bristol, Bristol, United Kingdom; 3) Clinical Epidemiology and Biostatistics, School of Medical Sciences, Örebro University, Örebro, Sweden

### Background/Aims

Vitamin D deficiency or insufficiency is common in pregnancy. However, it is unclear whether vitamin D supplementation should be an integral part of routine antenatal care given the scarcity of evidence from high-quality randomized controlled trials (RCTs). Mendelian randomization is a method that uses genetic variants robustly associated with modifiable exposures to generate more reliable evidence regarding which interventions should produce health benefits. We have used Mendelian randomization to interrogate the effect of maternal vitamin D status during pregnancy on several obstetric outcomes (i.e. miscarriage, stillbirth, need of labour induction, C-section, gestational diabetes and birth weight).

### Methods

We selected six independent genetic variants strongly associated with vitamin D status, proxied by circulating 25-hydroxyvitamin D (25(OH)D), in the general population. These genetic variants were tested for replication in an independent cohort of pregnant women (N = 4,819 from ALSPAC study). Mendelian randomization analysis was conducted using inverse variance weighted method in up to 207,565 women from UK Biobank. Sensitivity analyses were performed to explore bias due to invalid genetic variants. Results are expressed as odds ratio (OR) or mean difference in outcome per unit increase in natural log 25(OH)D.

### Results

The associations of genetic variants with 25(OH)D largely replicated in pregnant women. In the Mendelian randomization analysis, there was no clear evidence that maternal 25(OH)D concentration was related to the incidence of miscarriage (OR=1.03; 95%CI: 0.88, 1.22; P=0.70), stillbirth (OR=1.31; 95%CI: 0.80, 2.13; P=0.28), need of induction (OR=0.93; 95%CI: 0.44, 1.97; P=0.85), C-section (OR=0.93; 95%CI: 0.44, 1.97; P=0.85), gestational diabetes (OR=1.43; 95%CI: 0.37, 5.53; P=0.60), or birth weight (0.03 kg, 95%CI: -0.01, 0.07, P=0.15). However, effect estimates were imprecise for several outcomes.

### Conclusion

Overall, there was no strong evidence that maternal 25(OH)D status affects any of the assessed obstetric outcomes in the target population. We have requested and will soon receive data from several additional studies to increase power and to include a broader range of outcomes in our

analyses. Mendelian randomization can be a valuable tool to probe the putative effect of pregnancy exposures on obstetric outcomes and to inform clinical practice and public health policies in the absence of high-quality RCTs.

## PgmNr 589: Placental microRNAs in the regulation of fetal growth: A meta-analysis of two independent mother-infant cohorts.

---

The placenta is the master regulator of fetal growth and development. During implantation, the trophoblast invades the extracellular matrix (ECM) of the decidualized endometrium into the uterine wall. The trophoblast then differentiates and proliferates into a network of branching villi – the functional units of the placenta that facilitate exchange of gases, nutrients and waste for the growing embryo. Poor placental function is the most common cause of intrauterine growth restriction, which is associated with perinatal morbidity, mortality and long-term health outcomes. MicroRNAs (miRNA) are non-coding RNAs that regulate gene expression through targeted silencing of target mRNAs, based on sequence complementarity. Placental miRNAs associate with fetal growth, and are linked to the basic processes of trophoblast biology, but the pathways and molecular mechanisms by which miRNAs regulate birth weight are not fully known. To assess the role of miRNAs in placental function and fetal development, we have utilized small RNA sequencing to profile placental miRNAs from two independent mother-infant cohorts: the New Hampshire Birth Cohort Study (n=317) and Rhode Island Child Health Study (n=225). We modeled miRNA counts on infant birth weight percentile in each cohort, while accounting for race, sex, parity and technical factors, using negative binomial generalized linear models. We aggregated cohort-specific results via inverse variance weighted fixed-effects meta-analysis. We identified 62 miRNAs that were differentially expressed (DEmiRs) with birth weight percentile at false discovery rate (FDR)<0.05. Our DEmiRs were predicted to target 1130 mRNAs, among which, 90 were predicted mRNA targets of more than two DEmiRs. These 90 targets are enriched for pathways involved in ECM organization, including collagen formation (FDR=4.4e-4) and degradation (FDR=6.9e-6). Our findings support the idea that placental miRNAs control trophoblast proliferation and differentiation, apoptosis, cellular metabolism, as well as vasculo- and angio-genesis. Further, our results suggest that placental miRNAs are involved in the metabolism of the ECM protein, collagen, which may influence the invasive behavior of trophoblasts during implantation. In the largest RNA-Seq based, genome-wide miRNA profiling study conducted in human placenta to date, we implicate potential molecular mechanisms underlying the role of miRNAs in placental development, placental function and fetal growth.

## PgmNr 590: Increasing incidences of musculoskeletal abnormalities in a large population of boys with 49,XXXXY.

### Authors:

G. Porter <sup>1</sup>; C. Samango-Sprouse <sup>1,2,3</sup>; P. Lasutschinkow <sup>1</sup>; T. Sadeghin <sup>1</sup>; A. Gropman <sup>4</sup>

49,XXXXY is the rarest chromosomal variation, with 1:80,000-100,000 live male births. Case studies indicate increased incidences of musculoskeletal abnormalities in these boys, including knee subluxation, congenital talipes equinovarus, scoliosis, kyphosis, and genu valga. These issues, combined with testosterone deficiency, may lead to decreased participation in physical activity and additional complications to health and well being. The elucidation of the orthopedic profile of 49,XXXXY is necessary in order to provide health care providers with accurate information on which to base the development of care and treatment plans.

This study collected data from an international cohort of more than 100 boys with 49,XXXXY over ten years. The data was collected based on evaluations by a multidisciplinary team consisting of a pediatric orthopedist and two physical therapists. The data was segregated into three categories: under 5 years, 5-10 years, and over 10 years old. Participants with a copy number variant or mosaicism were excluded.

Boys with 49,XXXXY presented with increased incidences of torticollis (29.2%), scoliosis (20.1%), leg length discrepancy (35.9%), gait abnormalities (83.0%), genu valgum (39.1%), hamstring tightness (41.2%), ligamentous laxity (67.4%), radioulnar synostosis (66.2%), clinodactyly (66.7%), abnormal shoulder range of motion (36.8%), gunstock deformity (21.6%), foot pronation (42.4%) and eversion (22.8%), pes planus (25.8%), tight heel cords (21.3%), and feet abnormalities (87.9%).

The incidences of these anomalies appeared to increase with age, specifically scoliosis, kyphosis, number of hip surgeries, leg length discrepancy, gait abnormality, hamstring tightness, ligamentous laxity, pes cavus, and club foot.

These results indicate the high rate of musculoskeletal anomalies in boys with 49,XXXXY, and the increasing incidence of these abnormalities with age. Such findings may indicate that orthopedic issues become more complicated with time, and these boys will benefit from early targeted treatment on specific vulnerable areas. Given the rare incidence of this disorder, the investigation of associated clinical symptoms is essential to determine and establish appropriate care and treatment. This research further supports the necessity for the comprehensive treatment of boys with 49,XXXXY by a multidisciplinary team of specialists, including, among others, a pediatric orthopedist, pediatric physical therapist, and occupational therapist.

## PgmNr 591: Cell-free DNA analysis in twin pregnancies after reduction because of fetal aneuploidy.

### Authors:

---

**Background:** In multifetal pregnancies, cell-free DNA from a non-viable conception may lead to a non-invasive prenatal test result that is discordant with the viable fetus. However, few studies have examined changes in cell-free DNA over time in pregnancies with an aneuploid fetal demise.

**Objectives:** Using elective fetal reduction as a model for natural demise, we examine the results of targeted cell-free DNA analysis at multiple points after reduction of an aneuploid twin.

**Methods:** Two twin pregnancies, each with one aneuploid fetus (one trisomy 21 and one monosomy X), were included in the study. Maternal blood was collected at multiple time points prior to and following reduction and studied using targeted cell-free DNA analysis. Proportion values were calculated for chromosomes 21, X, and Y. The chromosome 21 and X aneuploidy values represent the relative signal from the chromosome of interest compared to that expected in disomy. The chromosome Y value represents the presence of Y signal. Fetal fraction was also determined for all samples.

**Results:** In the first pregnancy with a male fetus with trisomy 21 and one female euploid fetus, the aneuploidy values from chromosome 21 moved towards the expectation for euploidy over 13 weeks following reduction. The chromosome Y value followed a similar pattern. In the second pregnancy with a fetus with monosomy X, the aneuploidy value from chromosome X moved towards the expectation for euploidy over the 8 weeks following reduction. However, the trends were not linear: both cases showed a transient increase in the level of aneuploidy 3 to 8 weeks following reduction. Fetal fraction also increased and then decreased again over several weeks. Notably, the aneuploidy values never reached 0 (the euploid state) even months after the reduction.

**Conclusions:** These study results demonstrate the complexity of cell-free DNA analysis in multifetal pregnancies with reduction. The unpredictable patterns for both aneuploidy and fetal fraction after fetal reduction do not support cell-free DNA testing at any given interval following a fetal demise.

## PgmNr 592: Cell-free DNA testing for prenatal aneuploidy assessment: An analysis of international professional society statements.

### Authors:

R. Jones; K. White; A. Batey; E. Kostenko; M. Schmid

[View Session](#) [Add to Schedule](#)

**Affiliation:** Medical and Scientific Affairs, Roche Sequencing Solutions Inc., San Jose, CA

---

**Introduction:** Prenatal assessment for fetal aneuploidy using cell-free DNA analysis (also called non-invasive prenatal testing or NIPT) is clinically available throughout the world. The objective of this study was to obtain a global perspective on approaches to clinical implementation by reviewing practice guidelines and recommendations published by international and national professional societies.

**Methods:** Position statements and practice recommendations were located by searching PubMed, Embase, and examining public websites available in English. Key content and themes were captured from each document.

**Results:** Twenty documents were identified from international as well as national societies from Europe, the Americas, the Middle East, Asia and Pacific regions. Statements were from 28 organizations representing medical genetics (9), obstetrics (15), prenatal ultrasound (5) and counseling (1), with some societies representing more than one area. The statements were consistent in stating: NIPT is not diagnostic (20), NIPT is an accurate screening test (20), and patient pre and post-test counseling, including test features and limitations, is recommended (19). Differences were found in three areas: which patients should be offered NIPT, what fetal conditions should be on the test panel, and what information should be on the test report. Fourteen of twenty documents focus on NIPT for patients with an increased risk for fetal aneuploidy. Eight of the statements have been issued or revised since 2017. Of 13 statements that addressed expanded panels, 9 societies expressly say that cell-free DNA screening should not be used for copy-number variants or whole genome analysis. Test report recommendations were found in 4 of 20 professional statements.

**Conclusions:** Professional societies involved in prenatal care have different recommendations regarding the incorporation of NIPT into clinical practice. Although societies agree that NIPT has high accuracy for prenatal risk assessment of common aneuploidies, confirmation of 'high-risk' results with diagnostic testing is critical and patient counseling is important, differences exist around which patients should be offered NIPT, what fetal conditions beyond common aneuploidies should be added to the testing panel and what information should be included on the test report. Less than half of the statements have been issued or revised since 2017.

## PgmNr 593: Clinical performance of noninvasive prenatal testing in high risk pregnancies.

### Affiliations:

1) Department of Obstetrics and Gynaecology, The Chinese University of Hong Kong, Hong Kong SAR; 2) Shenzhen Research Institute, The Chinese University of Hong Kong, Shenzhen, China; 3) Department of Fetal Medicine and Prenatal Diagnosis, the Third Affiliated Hospital of Guangzhou Medical University, Guangzhou, 510150, China; 4) Genetics and Prenatal Diagnosis Center, The First Affiliated Hospital of Zhengzhou University, Zhengzhou, 450052, China; 5) Baoan Women's and Children's Health hospital, Jinan University, Shenzhen, 518101, China

### Background

Noninvasive prenatal testing (NIPT) has greatly advanced prenatal screening for aneuploidies since its implementation for clinical use. Genome-wide NIPT allows for screening of rare aneuploidies and copy number variants (CNVs), but the clinical performance of such expansion remains unknown and invasive diagnostic testing is warranted for confirmation of the positive results. Chromosomal microarray analysis (CMA) shows superiority over conventional karyotyping in detecting a wide spectrum of chromosome abnormalities including pathogenic CNVs through the genome. In this study, we aimed to evaluate the clinical performance of genome-wide NIPT in detecting chromosomal abnormalities in high risk pregnancies by comparison with CMA, so that we can provide valuable information for genetic counselling and clinical management of high risk pregnancies.

### Methods

Pregnant women with high risk for chromosome abnormalities were retrospectively enrolled from four prenatal diagnosis centers between 2015 and 2018. Pregnancies with both NIPT and CMA performed during pregnancies were included for further analysis. The results were categorized into common trisomies, sex chromosome abnormalities, rare aneuploidies and CNVs. Positive predictive value (PPV) and false positive rate (FPR) were calculated, and the discordant results between NIPT and CMA were also analyzed.

### Results

A cohort of 675 singleton pregnancies were included in this study. Of these, the majority (74.7%, 504/675) were referred by advanced maternal age. Overall, 77.8% (525/675) of the cases were reported to be positive by NIPT. A positive CMA result was detected in 278 of 675 (41.2%) cases. Among NIPT positive cases 43.0% (226/526) were confirmed to be true positives. PPV estimates for rare aneuploidies and CNVs of NIPT were 17.5% and 33.9%, respectively. Importantly, 62 (of 675, 9.2%) additional chromosomal aberrations were detected by CMA but not reported by NIPT, including 45 CNVs smaller than 5Mb, 12 CNVs larger than 5Mb, and other 5 whole chromosomal abnormalities (Trisomy 18, 47,XXY, mosaic Monosomy 9 and 22, triploidy, uniparental disomy 4).

### Conclusion

NIPT shows high false positive rates for the detection of rare aneuploidies and CNVs in high risk pregnancies, which will increase potentially unnecessary invasive confirmatory testing and maternal anxiety. CMA is able to provide comprehensive genetic information and should be offered for high risk pregnancies undergoing invasive diagnostic procedures.

## PgmNr 594: Combined preimplantation genetic testing for *CFTR* gene mutations and aneuploidy using a single WGA PCR and amplicon panel-specific enrichment.

### Authors:

M. Jasper <sup>1</sup>; C. Robinson <sup>1</sup>; J. Nehyba <sup>2</sup>; R. Hrdlickova <sup>2</sup>; A. Kothandaraman <sup>2</sup>; S. Myers <sup>1</sup>

### Affiliations:

1) PerkinElmer Health Sciences (Australia) Pty Ltd, Thebarton, Australia; 2) PerkinElmer, Inc., Austin, TX

Cystic Fibrosis is one of the most common indications reported for Preimplantation Genetic Testing (PGT) for monogenic disorders (PGT-M) (ESHRE PGD data collection). The ability to target the *Cystic Fibrosis Transmembrane Conductance Regulator (CFTR)* gene with PCR primers during whole genome amplification (WGA), achieving concurrent PGT-M and PGT for aneuploidy (PGT-A) in a single PCR reaction represents a unique approach to maximise the screening opportunity for a single embryo biopsy.

The aim of this study was to demonstrate a novel protocol for concurrent PGT-A and PGT-M in a single PCR, using a *CFTR*-specific primer panel in combination with WGA, and analysed by Next Generation Sequencing (NGS).

Five-cell samples sorted from a 48,XXY,+21 cell line (Coriell Institute) were subjected to WGA using the DOPlify® TSE (Target Sequence Enrichment) protocol (PerkinElmer) with the inclusion of either NEXTFLEX® Cystic Fibrosis Amplicon Panel kit primer mix 1 or 2 (PerkinElmer). Further enrichment of the 31 *CFTR* target regions was achieved following reamplification of the enriched WGA using *CFTR*-specific PCR with the inclusion of gDNA (control). The *CFTR* amplicons generated were subsequently pooled with the original TSE WGA to allow single sample indexing (PG-Seq™ kit, PerkinElmer) and MiSeq® instrument (Illumina®) sequencing.

Whole chromosome aneuploidy concordant with the expected sample karyotype was achieved and 68% (23/31) of *CFTR* target regions were represented for 5-cell samples, with read depths of up to 200x. Of the 8 most common *CFTR* mutations, accounting for 75% of all mutations (CF Genetic Analysis Consortium, 1994), all were amplified from gDNA and 4/8 from 5-cell samples. An additional 13 Single Nucleotide Polymorphisms (SNPs) were identified that could potentially be used for linkage analysis.

The DOPlify® WGA kit provides a flexible technology to amplify and sequence whole genomes and relevant sequences in parallel using PerkinElmer's TSE protocol, offering a streamlined solution for combined PGT-M and PGT-A. The system accommodates the addition of multiple primer sets targeting specific sequences, allowing numerous sites to be analysed at once. Further optimisation of primer concentration and pooling will achieve improved coverage for all target regions. The workflow also provides an opportunity to generate PGT results using a variety of different NGS indexing and or NGS platform approaches.

For research use only. Not for use in diagnostic procedures.

## PgmNr 595: Discordant NIPT (non invasive prenatal test) result: Clinical review and validation.

---

**Objective :** To confirm the reliability of NIPT and to discuss about the discordant cases.

**Methods :** This test results in large single center from 1, 2015 to 12, 2018 were analyzed. The patients who referred from other hospital due to abnormal NIPT result were included. Karyotyping was done by CVS and amniocentesis. Microdeletion test was added in case of showing abnormal sonographic soft marker.

**Results :** Total 1607 single pregnancy cases who performed NIPT were enrolled. Among the 1562 cases(97.2%) reported as low risk, 1 case revealed as false negative which showed z-score 2.49 on chromosome 18 and finally diagnoses as true trisomy 18. Forty-two cases(2.6%) reported as high risk; Trisomy 21(n=22), trisomy 18(n=2), trisomy 13(n=1), monosomy X(n=4), sex chromosome anomaly including XXX, XXY(n=7), triploidy(n=1) and 22q11.2 deletion(n=1). In massive parallel sequencing method, other uncommon trisomy such as trisomy 7(n=1), 14(n=1) and 15(n=2) was incidentally detected. Thirty-four cytogenetic confirmation tests were done in NIPT high risk group. Among the 17 karyotype tests in NIPT trisomy 21 group, all 17 cases revealed as trisomy 21(100%). One karyotype test in NIPT trisomy 18 group showed trisomy 18(100%). In NIPT monosomy X group, 3 cases showed discordancy resulting as normal karyotype and 1 case was mos45,X[14]/46,X,i(X)(q10)[6] which regarded as monosomy X(25%). The 22q11.2 deletion case had no sonographic cardiac anomaly and confirmed as false positive. Three 47,XXX and 3 46,XY were diagnosed in sex chromosome high risk group(50%). The NIPT result of triploidy was due to effect of vanished fetus in DCDA twin pregnancy. Both trisomy 15 NIPT cases showed discordancy but interestingly one of the cases was finally diagnoses as maternal uniparental disomy 15 which implies the further diverse way of interpretation in case of uncommon trisomy in NIPT. There were 3 uninformative results(0.2%); 1 case due to low fetal fraction, 1 case due to repeated CNVs on X chromosome which finally diagnosed as exon 1-29 duplication of dystrophin gene on Xq21.2 and 1 case with unknown cause.

**Conclusion :** In the present study, clinical review and validation of both discordant and general cases are introduced based on single institution's results. As the use of NIPT as a prior screening test increases, the systematic discussion of discordant cases should be conducted between the laboratories.

## PgmNr 596: Spectrum and features of clinically significant copy number variants in prenatal diagnosis: Implications on genome-wide noninvasive prenatal testing.

### Affiliations:

1) Department of Obstetrics and Gynaecology, The Chinese University of Hong Kong, Hong Kong, China; 2) Warwick Medical School at the University of Warwick, Coventry, UK; 3) Department of Central Laboratory, Bao'an Maternity and Child Healthcare Hospital, Jinan University School of Medicine, Key Laboratory of Birth Defects Research, Birth Defects Prevention Research and Transformation Team, Shenzhen, China; 4) Shenzhen Research Institute, Department of Obstetrics and Gynaecology, The Chinese University of Hong Kong, Shenzhen, China; 5) The Chinese University of Hong Kong-Baylor College of Medicine Joint Center for Medical Genetics, Hong Kong, China

**Background:** Chromosomal microarray analysis (CMA) is widely utilized for the detection of pathogenic copy number variants (pCNVs) in prenatal diagnosis. Implementation and widespread use have expanded our understanding, curation and delineation of CNVs and the related genomic disorders. On the other hand, noninvasive prenatal testing (NIPT) is well established for the screening of common aneuploidies. More recently, efforts have been made to expand the scope of NIPT for the detection of fetal microdeletion syndromes. Expanding NIPT for microdeletions and microduplications is controversial as there are no consensual recommendations by professional societies. The spectrum and features of pCNVs including the size, genomic distribution and mode of inheritance are important considerations before genome-wide NIPT is implemented into clinical practice.

**Methods:** We retrospectively analyzed the pCNVs (<10Mb) in 1,510 pregnancies with standard indications for prenatal diagnosis from Jan 2012 to Dec 2017 at our prenatal genetic diagnosis laboratory. We have combined pCNV data from 14 published studies including of 22,355 fetuses undergoing CMA testing. Summarizing this data, we describe the spectrum and features of pCNVs including the prevalence, size, and mode of inheritance.

**Results:** Overall, 375/23,865 (1.6%) fetuses carried pCNVs (<10Mb), and 44 (11.7%) fetuses involved 2 or more pCNVs. A total of 428 pCNVs were detected in these fetuses, of which 280 are deletions and 148 are duplications. 360 (84.1%) were less than 5Mb in size and 68 (15.9%) were between 5-10Mb. The incidence of carrying a pathogenic copy number variant in the high-risk group (abnormal ultrasound finding, high risk down's screening, family history, NIPT positive) is 1 in 36, and the low-risk group (advanced maternal age ≥35, maternal anxiety, others) is 1 in 125. Parental inheritance study results were available for 311 pCNVs, 204 (65.6%) occurred *de novo*, 71 (22.8%) were maternally inherited and 36 (11.6%) were paternally inherited.

**Conclusion:** Collectively, pCNVs are common in all pregnancies. High-risk pregnancies should be offered invasive testing with CMA for a comprehensive investigation. Detection limits on size, genomic distribution, mode of inheritance should be carefully considered before implementing copy number variant screening in genome-wide NIPT.

## PgmNr 597: The application of ACMG variant classification guidelines for the variant assessment of non-invasive prenatal sequencing (NIPS).

**Background** Classification of prenatally detected sequence variants plays a critical role in pregnancy management. Limited fetal phenotypic data and maternal admixture complicate NIPS analysis. To share experience and help improve data analysis in NIPS, genetic variants detected from a NIPS for single or multiple dominant monogenic disorders were retrospectively assessed for the performance of ACMG guidelines in this test. **Methods** A total of 73 variants with potential pathogenicity in 19 dominant monogenic disease-causing genes (*BRAF*, *CBL*, *CDKL5*, *CHD7*, *COL1A1/2*, *FGFR2/3*, *JAG1*, *KRAS*, *MAP2K2*, *MECP2*, *NIPBL*, *PTPN11*, *RAF1*, *RIT1*, *SOS1*, *TSC1/2*) were evaluated and classified by following ACMG guidelines. The strength of certain criteria was assessed and tuned for more accurate as well as efficient data interpretation. **Results** By following the ACMG guidelines, 52 variants were classified as pathogenic (P), 9 were classified as likely pathogenic (LP), and 12 were variants of uncertain significance (VUS). With certain criteria (e.g. number of patients reported in literature, applicable fetal/familial phenotypic evidence, etc.) tuned, however, 8 likely pathogenic variants could be upgraded to pathogenic, which included four that had multiple patient reports and were well-recognized as disease-causing variants. Reasonable specificity of ultrasound indications was required to fully appreciate *de novo* variants' pathogenicity. With 64.4% (n=47/73) of variants in this NIPS were *de novo*, the specificity of fetal ultrasound information impacted significantly on the accuracy of NIPS variants' classification. The importance of the phenotypic information was also reflected by the 12 VUSs that either due to early gestational ages (14.1±3.9 weeks) that precluded sonographic findings or maternal mosaicism compounded with the lack of clinical and/or scientific evidences, or evidences which were not concordant with the disease caused by the gene bearing the variant under assessment. **Conclusion** ACMG guidelines are helpful in the NIPS variant classification; however, given the nature of this test and the targeted genes, certain criteria need fine-tuning. Reasonably specific fetal ultrasound information at appropriate gestational ages, and the family medical histories significantly impact classification accuracy.

## PgmNr 598: A retrospective study of the application of chromosomal microarray analysis in prenatal diagnosis.

During the last decade, Chromosomal microarray analysis (CMA) was recommended by a few communities in different countries as a first-tier technique for genetic follow up of fetal structural anomalies identified by ultrasonography. With the accumulation of cases and experiences, it's the time to take a second look on the application and consider if we are abusing this technique. In this retrospective study, we present a comprehensive overview of 2363 singleton prenatal cases out of 4266 cases which were referred for CMA during 2014 to 2018.

The overall pathogenetic findings account for 10.41% (246/2363) of the cases, among which 49.6% (122/246) could be detected by karyotyping analysis. In those chromosomal normal cases, CMA made a further 5.53% yield. These data are perfectly in accordance with previous perspective researches. Multiple abnormalities (37%), pleural effusion (25%), cystic hygroma (23.5%) and gastral intestinal abnormalities (19.35%) were most associated with genetic abnormalities. For submicroscopic anomalies, multiple abnormalities (15.1%), pleural effusion (14.3%), gastral intestinal abnormalities (10.7%) and urinary system abnormalities (9.1%) were most relevant indications. The most striking finding is that 41.67% (6/13) cases of echogenic kidney(s) with or without size change were associated with pathogenic copy number changes (CNV). Another interesting finding is the high detection rate (50.8%) of variance of uncertain significance in fetus with growth retardation and other minor ultrasound findings. On the other hand, if there's no clinical indication for prenatal diagnosis, little benefit would be obtained from CMA, with only 1 pathogenic CNV in 110 cases.

## PgmNr 599: Disorders of sex development in a multigenerational family: Oligogenic causes, reduced penetrance and blended phenotypes with combined pituitary hormone deficiency.

---

Disorders of sex development (DSD) represent a heterogeneous group of congenital genital anomalies. We report a family presenting DSD in three generations. The three probands were first cousins (P1, male, XY, 13 yrs; P2, male, XY, 18 yrs) diagnosed with cryptorchidism, severe penoscrotal hypospadias, small testicles, azoospermia; and their joint first cousin once removed (P3, male, XY, 30 yrs) with cryptorchidism and cryptozoospermia. Familial anamnesis also included other reproductive disorders, such as cases with ambiguous sex, prostate cancer, stillbirth, induced termination of mid-pregnancy and diagnosed premature placental ageing. Whole-exome sequencing (WES) of eight family members detected a splicing variant in *NR5A1* gene (c.G991-1C; p.Val331Ilefs) as the most likely cause of DSD in P1 and P2. The variant is not reported in human genome databases, but was shown in a Belgian patient with cryptorchidism (Robevska et al 2018, Hum Mutat). As several family members were asymptomatic carriers, the estimated penetrance rate was < 50%. In depth WES data analysis of P1-P2 and their parents uncovered oligogenic contribution as a potential modulator of the penetrance of the *NR5A1* variant. Both, P1 and P2 had inherited rare variants in genes implicated in combined pituitary hormone deficiency (CPHD) – *OTX2* p.Pro134Arg (P2), *PROP1* p.Leu102Cysfs and *GLI2* p.Arg131His (P1) from the other parent. Hormonal profiling supported the blended phenotype of DSD and CPHD in this family. P3 carried neither the *NR5A1* splicing variant nor any of the CPHD variants. The highest prioritized candidate variant responsible for his condition was p.Glu60Ter in the *DMRT2* gene located in the genomic region linked to gonadal dysgenesis. Due to complex family history, WES data were also screened for secondary findings. P2, P3 and other family members were detected as the carriers of the p.Ile157Thr variant of *CHEK2*, implicated in familial prostate cancer. The grandfather of P1-P2 and father of P3, who had been diagnosed with prostate cancer, were identified as the obligate carriers of the *CHEK2* variant. Our study demonstrates heterogeneity and oligogenic contribution to the penetrance of DSD mutations and the value of in-depth WES analysis in the pedigree to uncover the genetics of multiple segregating clinical conditions. Detailed profiling of pathogenic variants facilitates high quality counselling of index patients and their family members. Grant: Estonian Research Council IUT34-12.

## PgmNr 600: Insights from the largest genetic study of sporadic and recurrent miscarriage.

### Authors:

**Introduction:** Miscarriage is a common complex trait that affects 10-25% of all clinically confirmed pregnancies. Miscarriage is associated with excessive bleeding, infection, depression, infertility and an increased lifetime risk of cardiovascular disease. A variety of predisposing factors have been associated with increased miscarriage risk, and it has a genetic component that thus far has remained poorly characterized. Our aim was to discover and map the maternal genetic susceptibility and underlying biology of sporadic and recurrent miscarriage.

**Materials and methods:** We performed a genome wide association study including up to 69,054 sporadic miscarriage cases from seven different ancestries, 750 recurrent miscarriage cases of European ancestry, and up to 359,469 female controls. We investigated the genetic architecture of miscarriage with biobank-scale Mendelian randomization, heritability, genetic correlation and functional annotation analyses.

**Results:** We identified one and four loci significantly ( $p < 5 \times 10^{-8}$ ) associated with sporadic and recurrent miscarriage, respectively. Following functional annotation linked these associations with genes related to gonadotropin regulation, placental biology and progesterone production. We found a heritability of 29% (95%CI 20%-38%) for miscarriage. Consistent with observational associations, we found significant genetic correlations between sporadic miscarriage and number of children ( $p = 7.2 \times 10^{-9}$ ).

**Conclusions:** Our results confirm miscarriage as a complex partly heritable phenotype and implicate novel biology through regulation of genes involved in gonadotropin regulation, placental biology and progesterone production.

## PgmNr 601: Maternal blood mRNA profiles associated with spontaneous preterm birth in maternity log study.

---

**Objective:** Despite the seriousness of pregnancy complications including preterm birth (PTB), their mechanisms of pathogenesis or progression have not been well elucidated. Pregnancy complications are multifactorial diseases caused by complex interactions of genetic and environmental factors. Messenger RNAs (mRNAs) in maternal blood can be affected by both factors. Several studies investigated maternal whole-blood gene expression profiles associated with spontaneous PTB (SPTB), *i.e.* non-induced delivery before 37 gestational weeks. However, these studies used microarray to analyze mRNA expression, and significance of their results were not clear. In this study, we used RNA-seq to investigate blood mRNA profiles associated with SPTB.

**Methods:** We used maternal peripheral blood samples collected in the Maternity Log Study, which is a prospective cohort study of pregnant Japanese women. In this study, pregnant women were recruited in the first or second trimester of pregnancy at Tohoku University Hospital. These samples were collected at the first term (between 12 and 23 gestational weeks) and the second term (between 24 and 34 gestational weeks) from 301 women using PAXgene Blood RNA Kit, and subjected to RNA-seq using the HiSeq sequencer. Multivariate logistic regression model was used to evaluate association between mRNA expression and SPTB.

**Results:** After correcting multiple testing by FDR, we identified over 900 genes which showed significantly different expression levels between the SPTB group (N=14) and the healthy control group (N=182) at both first and second terms. Especially, the expression of a gene associated with maternal placenta development was significantly higher in the SPTB group than in the control group.

**Discussions:** We identified maternal blood mRNA profiles associated with SPTB, indicating possible biomarkers for SPTB detectable in the early phase of pregnancy. Further research may lead to elucidation of molecular mechanisms and development of prevention measures for SPTB.

## **PgmNr 602: The impact of delayed evacuation after pregnancy termination on fetal tissue quality for diagnostic and research applications.**

### **Authors:**

**Background:** In the United States, potassium chloride (KCl), digoxin and other agents are commonly used to arrest fetal circulation prior to pregnancy termination during the second trimester, largely for medico-legal and social reasons. The effects of induced demise prior to pregnancy termination on fetal tissue quality for subsequent diagnostic and research applications have not been characterized in detail. This is a critical knowledge gap, since high-quality fetal tissue is required for the accurate clinical diagnosis of fetal anomalies, and for biomedical research purposes.

**Objective:** To determine the effects of delayed evacuation after pregnancy termination on tissue quality for clinical and research purposes

**Study Design:** To compare tissue quality from second trimester fetuses terminated with and without injection of digoxin or KCl, 19-25 hours before dilation and evacuation (D&E), we obtained fetal tissue from terminations with and without prior injection of digoxin or KCl. We assessed: 1) cellular morphology by hematoxylin and eosin staining, 2) cell proliferation by Ki67 staining, 3) apoptosis by the TUNEL cell death assay, 4) tissue viability by cell culture, and 5) nucleic acid quality by integrity scores and the polymerase chain reaction (PCR).

**Results:** Tissues from fetuses after delayed evacuation demonstrated: 1) greater cellular morphology disruption, 2) decreased proliferation, 3) greater apoptosis, 4) diminished cell culture viability, 5) lower RNA quality; however, all samples yielded DNA of adequate quality for PCR.

**Conclusion:** Delayed evacuation for >18 hours is associated with fetal tissue quality unsuitable for most clinical and research applications except DNA diagnostics. Limiting the interval between arrest of fetal circulation and D&E could improve the quality of fetal tissue for clinical and research purposes.

## PgmNr 603: Transitions in transcriptome and composition of maternal peripheral blood through pregnancy.

---

**Introduction:** Throughout pregnancy the maternal body facilitates conditions allowing development and growth of the fetus. The maternal bloodstream plays an essential role not only in accommodating the increased metabolic demands and requirements for nutrients, but also in hormonal signaling and in a complex regulation of immunity. We studied the associated mechanisms in maternal blood through a detailed characterization of the transitions in the transcriptome across pregnancy.

**Methods:** We enrolled 31 pregnant women (at gestational age 4 – 25 weeks) and sampled peripheral blood on a weekly basis through pregnancy and once postpartum. We sequenced ribosome depleted total RNA in 531 discovery samples from 21 pregnant women and 271 replication samples from 10 pregnant women. The samples were sequenced at an average of 25 million reads per sample and in total the mapping (STAR v2.5.3a to GRCh38/GENCODEv28) yielded >13 billion uniquely mapped reads. This extremely dense sampling allowed analysis of changes in genetic expression at an unprecedented fine scale, carried out using a longitudinal mixed effects model.

**Results:** In a strict discovery/validation design, we identified 704 transcripts with robust pregnancy-specific expression patterns. We used expression correlation analysis to cluster these pregnancy-specific patterns in modules. These showed significant enrichment for multiple biological pathways, including Defense response to virus, T-cell activation, Defense response to bacterium/fungus, Hemoglobin metabolism, and Mast cell activation. Deconvolution into cell-types revealed consistent changes in cell populations, with 11 of 19 quantified cell-types showing robust alterations through pregnancy, including a steady increase in the fraction of hematopoietic progenitor cells up to week 35. Although these patterns demonstrate an altered regulation of the immune system during pregnancy, changes in the viral load through pregnancy were not detectable among RNA reads mapped to virus genomes for these 31 women.

**Conclusion:** We provide a comprehensive characterization of the changes in transcription and cell-type composition in maternal blood through pregnancy, which highlights its systemic role in healthy gestation. These data will be useful as a reference for future studies of transcription dynamics and changes in cell populations in pregnancies complicated by, e.g., preeclampsia, preterm delivery or gestational diabetes.

## PgmNr 604: Expanded carrier screening benefits as it relates to test enhancements and variant reclassification.

The American College of Obstetrics and Gynecology (ACOG Committee Opinion 691) recommends discussing carrier screening options, including expanded carrier screening options (ECS) with all women who are pregnant or are considering pregnancy. With regards to repeat screening, the opinion states “the decision to rescreen a patient with previous carrier screening should be undertaken only with the guidance of a genetics professional who can best assess the incremental benefit of repeat testing for additional mutations.”

Sema4 began offering its comprehensive expanded carrier screening panel in 2015. The original panel screened for 281 genetic conditions (260 autosomal recessive disorders and 21 X-linked). In 2018, a newer version was launched that included multiple enhancements: the addition of 21-hydroxylase related congenital adrenal hyperplasia (*CYP21A2*), full gene sequencing for *HBA1* and *HBA2*, full gene sequencing for *GBA* (genotyping was performed previously) and the addition of copy number variant (CNV) detection via a bioinformatics algorithm of the NGS data. For patients with a history of testing on the previous platform, the option of an “upgrade”, which included repeat analysis of the NGS data (which was rerun both for the purposes of CNV detection and variant reclassification), as well as the other previously described enhancements, was offered.

Since June 2018, our lab has completed 847 upgrades for patients previously tested on the 281 platform. Of those, there were 143 new variants reported due to a new feature of the test (133 *CYP21A2* and 9 large deletions or duplications of other genes). Another 48 new variants were reported due to classification changes and 7 variants were removed due to downgrading.

From our current data, new information regarding carrier status was reported in 22% of individuals pursuing the upgrade, 6% being solely due to variant reclassification. Importantly, utilizing ancillary assays and technology to increase detection rates, 17 new carrier couples were identified. Post test telegenetic counseling is offered for positive ECS results through our laboratory, and as such, we include a discussion on how evolving genetic knowledge and testing impact family planning and pre and postnatal care as well as disease and carrier-state identity.

## PgmNr 605: Non-invasive prenatal testing using a novel, clinic-friendly digital PCR platform.

Noninvasive prenatal genetic testing (NIPT) describes the detection of fetal chromosomal aneuploidies using cell-free fetal DNA found in the blood of a pregnant woman. The fetal fraction of the total maternal cell-free DNA (cfDNA) varies among pregnant women but ranges from 0.5% to 19%. In 2007 a group first showed the general feasibility of using digital PCR (dPCR) for NIPT, but their assay required an unreasonably high 25% fetal fraction in the cfDNA tested. Improvements in modern dPCR make it the new ideal technology for NIPT. To address the needs of using dPCR as a routine tool for NIPT, a novel dPCR platform was developed. The dPCR platform consists of a cost-effective, micro-molded plastic consumable and a fully-integrated instrument that combines consumable sample loading, thermal cycling and 5-color fluorescence detection. The consumable partitions a 10 microliter sample into 20,000 micromolded wells without requiring valves, films or any moving parts. The instrument is 100% dry, contamination-free and requires no routine maintenance. The platform achieves sample-to-answer in less than 90 minutes using a simple, qPCR-equivalent workflow. Of the 10 microliters loaded into each well on the consumable, over 95% of the sample is analyzed. Here we show the dPCR platform's ability to accurately conduct NIPT fetal genotyping of trisomies 13 (Patau syndrome), 18 (Edwards syndrome) and 21 (Down syndrome). A commercially available assay was used that exploits primers and probes against conserved regions of the chromosomes of interest (13, 18 and 21). In a non-trisomy DNA sample, the ratio of any of these 3 chromosome markers against the other should be 1:1. If cfDNA from both the mother and fetus are non-trisomy, all possible copy number ratios will be 1:1. If any of these ratios are elevated significantly above 1, this signals that the fetal DNA may have a trisomy and the patient would be advised to undergo more rigorous testing. This assay was run on the novel dPCR platform for 8 previously characterized maternal cfDNA samples that had a range of fetal fractions. The dPCR platform was able to accurately determine the fetal trisomy genotype in all cases. The platform presented here offers qPCR equivalent workflow, affordability and 90 minute time-to-answer while maintaining high precision and unbiased, absolute chromosome tag quantification for precision NIPT.

## **PgmNr 606: A comprehensive evaluation of the importance of follow-up prenatal diagnostic testing in the era of increased utilization of non-invasive prenatal screening.**

---

As the use of non-invasive prenatal screening (NIPS) has become widespread, multiple studies have substantiated its superior performance in relation to traditional screening approaches, including demonstrating its significant predictive value. However, studies estimating the false positive (FP) and false negative (FN) rates and predicting pregnancy outcomes based on confirmatory results from prenatal diagnostic testing (PDT) have been limited.

**Method:** We examined 1766 consecutive singleton pregnancies referred to our laboratory with documented NIPS results, including 73 cases with one or more NIPS failures or inconclusive NIPS results. Karyotype and/or microarray analyses were performed on amniotic fluid and/or chorionic villi samples.

**Results:** Among cases for which both NIPS and PDT results were available (1693), the overall concordance between those results was 81% (1374/1693). Specifically, of the 894 cases reported as abnormal by NIPS, 63% (559/894) had concordant PDT results, representing true positives (TP). An additional 4% of these cases (33/894) showed partial concordance. The discordance rate for this subgroup of cases was therefore 33% (299/894) (FP). Conversely, NIPS was reported normal in 47% of cases (799/1693) and follow-up PDT demonstrated 98% (779/799) concordance, representing true negative (TN) results, while 2% of cases (15/799) with normal NIPS results yielded abnormal PDT results (FN). An additional 5 cases with normal NIPS results showed a sex chromosome discrepancy.

Considering specific abnormalities, the NIPS FP rate was highest for triploidy (78%; 25/32), followed by other autosomal aneuploidies (71%; 27/38), monosomy X (70%; 65/93), trisomy 13 (56%; 48/86), segmental deletions and duplications (55%; 36/66), trisomy 18 (26%; 40/151), other sex chromosome abnormalities (17%; 9/53), and trisomy 21 (13%; 49/375). The NIPS TP rate was highest for trisomy 21 (87%) and lowest for triploidy (22%). These TP rates include cases with additional findings identified by PDT and cases with partial concordance (PC); PC rates ranged from 0%-11%.

**Conclusion:** Our data demonstrating low false negative rates supports professional society recommendations for the use of NIPS as the primary screening test for detecting fetal aneuploidies. However, the considerably high false positive rates for abnormal NIPS results, other than for trisomy 21, strongly support the use of follow-up prenatal diagnostic testing, irrespective of risk estimated solely from NIPS.

## PgmNr 607: Evaluation of non-linear comorbidity structure and genetic risk for classification of preterm birth from electronic health records.

### Authors:

A. Abraham; C. Bejan; D.R. Velez-Edwards; J. Capra

[View Session](#) [Add to Schedule](#)

**Affiliation:** Vanderbilt University, Nashville, Tennessee.

---

**Background:** Preterm birth (PTB) is the leading cause of infant mortality worldwide and increase risk for immediate and long-term morbidities. Although there is a substantial heritable component to PTB, its genetic etiology remains poorly understood. Many different factors influence PTB risk. The relationships between these comorbidities, their genetic drivers, and their effects on PTB outcome remain largely unknown. Electronic health records (EHR) are a rich resource to characterize this phenotypic complexity. We hypothesize that accounting for the phenotypic complexity will reveal clinically relevant sub-phenotypes and yield insights into the genetic architecture of PTB.

**Methods:** In our delivery cohort, we define preterm from non-preterm deliveries using billing codes and estimated gestational age. First, we test ICD9 codes for association with PTB to characterize the clinical phenome. We then explored how well billing codes (other than those related to delivery status), demographic, and clinical features could classify deliveries as preterm or non-preterm using boosted decision trees. To evaluate the classification performance of genetic risk and detect any interaction benefits, we compared models with and without PTB genetic risk scores (GRS). Performance was evaluated using ROC/PR curves and top features were extracted by mean absolute SHAP value. We then used unsupervised clustering on the feature importance values to discover sub-phenotypes of deliveries and quantify their risk for PTB.

**Results & Conclusions:** Within our delivery cohort (n=11,270 PTB; 41,793 non-PTB), 298 codes were enriched for PTB and identified known reproductive and systemic comorbidities. Decision trees accurately identified PTB using billing codes (AUC=0.92) and the addition of GRS did not improve performance. To evaluate the potential for predicting PTB, we trained decision trees on features available 90 days before delivery. This algorithm accurately predicted PTB (AUC=0.82). Clustering on feature importance values yielded 12 sub-phenotypes, three of which had significantly increased risk for PTB, with distinct enrichment of comorbidities (diabetes + psychiatric traits vs. hypertensive + PTSD vs. thyroid + infectious agents). These sub-phenotypes provide interpretability and reveals non-linear combinations of comorbidities influencing risk for PTB.

## PgmNr 608: Parents' satisfaction and emotional responses to newborn genomic sequencing: The role of uncertainty.

### Authors:

M.K. Uveges<sup>1,2</sup>; L.A. Frankel<sup>3</sup>; I.A. Holm<sup>2,4</sup>; A.L. McGuire<sup>5</sup>; S. Pereira<sup>5</sup>; A.H. Beggs<sup>2,4</sup>; R.C. Green<sup>1,2,6</sup>; K.D. Christensen<sup>1,2</sup>

---

### Purpose

Genomic sequencing results can generate findings with variable actionability, and individuals who dislike uncertainty may be less enthusiastic about learning this information. We sought to understand the association between parents' tolerance of uncertainty and their emotional responses and satisfaction to receiving genomic information about their newborns.

### Methods

The BabySeq Project was a randomized clinical trial of newborn genomic sequencing (nGS) in sick and well babies. At baseline, parents completed the 12-item Intolerance to Uncertainty Scale (IUS). At three months after results disclosure sessions, parents completed the 10-item Patient Health Questionnaire (PHQ) and the 7-item General Anxiety Disorder scale (GAD), scales that assessed symptoms of depression and anxiety, respectively. At 3 months post-disclosure, parents also completed a 9-item scale assessing satisfaction with disclosed results.

### Results

337 parents completed the 3-month follow-up survey. In regression analyses that controlled for baseline scores and cohort (sick or well newborns), a one-point increase in IUS scores was associated with a 0.4 point increase in PHQ scores and a 0.3 point increase in GAD scores (both  $p < 0.001$ ). No interactions were observed between IUS scores and randomization status on either outcome (all  $p > 0.10$ ). No association was observed between IUS scores and satisfaction with results among fathers. However, among mothers, a one-point increase in IUS scores was associated with a 0.3 point decrease in satisfaction scores if newborns did not receive sequencing ( $p = 0.015$  for interaction between IUS and randomization status), but was unassociated with satisfaction scores if newborns received sequencing.

### Conclusion

Parents with more intolerance of uncertainty had more symptoms of anxiety and depression regardless of whether or not their newborn received genomic sequencing. When results were broken down by gender, mothers who reported more intolerance of uncertainty were also less satisfied with disclosure, but only when randomly assigned to the non-genomic sequencing condition. Findings highlight the importance of considering dispositional characteristics when discussing health information about newborns with parents, and suggest that newborn genomic sequencing may satisfy parents' questions about the health of their newborns rather than raise more concerns.

## PgmNr 609: Genetic burden and gestational age accurately predict complications in preterm infants.

---

**OBJECTIVE:** Premature infants are at increased risk for neonatal complications (NC) including: bronchopulmonary dysplasia (BPD), necrotizing enterocolitis (NEC), intraventricular hemorrhage (IVH), and retinopathy of prematurity (ROP). Moreover, many of these conditions can lead to long-term disability. However, even among preterm infants, there is still remarkable variation in the presence and severity of NC. We hypothesize that the accumulation of evolutionarily conserved variants (i.e. genetic burden) in Non-Hispanic White preterm infants influences the risk for NC.

**METHODS:** We analyzed the whole-exome sequences (WES) of 131 Non-Hispanic White preterm infants born between 28-31 completed weeks. Fifty-six infants denoted resilient (RES) did not develop severe complications (BPD  $gr \geq 3$ , IVH  $gr \geq 3$ , NEC  $gr \geq 2$ , and ROP  $gr \geq 2$ ) while 75 infants denoted susceptible (SUS) developed at least one severe complication. All preterm infants were extensively phenotyped, and cared for in the same time period, and hospital environment. We performed logistic regression across 24,254 genes to test burden for association to NC; gestational age was included as a covariate in the analysis. In a *post hoc* analysis, we also examined the predictive power of the polygenic risk score (PRS), which we computed from the genetic burden of 10 genes showing the largest evidence for association.

**RESULTS:** Our genetic burden analysis (which included gestational age as a covariate) showed that genetic burden is associated with NC at the exome-wide level ( $p = 0.05$ ). After using a 10-fold cross-validation procedure to protect against over-fitting, we also showed that PRS predicts NC (average AUC=67%,  $p = 0.01$ ). Note that, no single gene was statistically significant at the exome-wide level. Furthermore, our results confirm that gestational age is associated with NC ( $p = 7.31E-12$ ), and that prediction accuracy improves when gestational age and genetic burden are combined into a single composite predictor (average AUC=87%).

**CONCLUSIONS:** Genetic burden in evolutionarily conserved regions of the genome is contributing to the heritability of NC in Non-Hispanic Whites, with excess variation leading to increased risk. Therefore—similar to our composite predictor of NC—it should be possible to construct improved biomarkers that integrate information from the genetic burden of associated genes.

## PgmNr 610: The fate of paternal mitochondria during early embryonic development.

### Authors:

---

Paternal mitochondria are eliminated through different mechanisms in different animals in order to make sure that strict mitochondrial maternal inheritance is maintained. However, the elimination mechanism of paternal mitochondria in mice has been somewhat controversial, and the mechanism in humans has not yet been fully defined. Therefore, to better understand this process, we have conducted a close examination of the changes of paternal mitochondrial DNA (mtDNA) during early embryonic development. Mice and human embryos were obtained by intracytoplasmic sperm injection (ICSI), and single molecular, long-read sequencing was used to detect and analyze the percentage of sperm mitochondria in unfertilized oocyte and different development stages of embryos. In this way, we obtained the abundance of paternal mtDNA during the development of mice and human early embryos. The results provide a further clue to elucidate the molecular mechanisms of mice and human paternal mitochondria during fertilization and early embryonic development, as well as the elimination during oocyte meiosis.

Somatic mutations are defined by their presence in only a fraction of the cells that comprise a tissue – a phenomenon that is referred to as mosaicism. Within the individual, in which mosaic variants arise, they have been connected to a range of diseases – including cancer or dementia. However, if these mutations occur prior to the specification of or within the germline, they have the potential to be transmitted to offspring. In a cohort of 8 families with 14 children, we previously described that 4% of 501 apparent *de novo* single nucleotide variants (dSNVs) on the paternal haplotype were in fact mosaic in father's sperm. Moreover, the majority of these variants was not detectable in blood or only at significantly lower levels. These data and additional analysis of untransmitted SNVs suggested that sperm and by extension the spermatogonial stem cells harbor a rich collection of somatic mutations that allow insights into the early embryonic development and the establishment of the germline; moreover, understanding the extent and patterns of sperm mosaicism allows for the refinement of clinical risk assessment of recurrence and *de novo* transmission.

Here, we extend our analysis to a cohort of 12 individuals aged 18-22 years (young), and 4 between the ages of 48-62 years (old). We performed at least 300x whole genome sequencing on the sperm and blood of each individual to reliably detect mosaicism down to 2% with a low false-positive rate (<10%). In addition, for the majority of the young cohort we collected additional time points for a total of 16. This comprehensive data set allows us to determine the inter- and intra-subject variability of sperm mosaicism, within and across age groups. We find that each individual harbors around 20 sperm-mosaic variants with around two-third being only detectable in sperm. Across our data sets, allelic fractions of mosaic variants suggest that a restricted founder population of 3-6 cells dominates the germline. Furthermore, the mutational signatures reveal mutagenic processes that are distinct between early embryonic development and post germline establishment and differ from those mutations that are accumulated in the germline with age. In addition, we predict that our framework has the ability to detect clinically relevant mosaicism that conveys significant risk to inherit a potential or observed pathogenic mutation.

## PgmNr 612: Pedigree analysis of rare variants identified in monozygotic concordant transgender twin males through whole genome sequencing.

### Authors:

---

**Introduction:** Transgender identity (TGI) occurs in 0.3% of the population and is associated with both significant societal discrimination and even frequent discrimination within the healthcare system. One root cause of this discrimination is a lack of understanding regarding its etiology. While prior studies have suggested a genetic contribution, no candidate genes have yet been verified through pedigree or functional analysis. We hypothesized that rare variants in genes involved in sexually dimorphic brain development contribute to TGI, and that these variants would follow known Mendelian patterns of inheritance upon segregation analysis.

**Methods:** Whole genome sequencing was performed on the genomic DNA of a family with monozygotic concordant transgender male (natal female) twins as well as their cisgender parents and sister. Variants were considered if they met the following criteria: 1) not present in 88 cisgender controls, 2) frequency  $\leq 0.01$  in the ExAC, Yale, and 1000 Genomes databases, 3) predicted to have a functional effect compared to the wild-type gene. Segregation analysis was then performed on the remaining variants, and those consistent with either paternal-dominant, recessive, or *de novo* inheritance pattern of TGI were considered for further evaluation.

**Results:** Whole genome sequencing, with an average coverage of 99.18% and average read depth of 33 demonstrated 50,715 genetic variants. After filtering and pedigree analysis, there were 119 remaining variants showing patterns consistent with either paternal-dominant ( $n=100$ ), recessive ( $n=13$ ), or *de novo* ( $n=6$ ) inheritance. A compelling heterozygous variant in *MAP4K3* was noted in both twins as well as their father, while their mother and sister were both identified as wild type. Our prior research has identified *MAP4K3* as a candidate gene that may play a role in the development of gender identity in humans, making it interesting for further investigation.

**Conclusion:** In this family, whole genome sequencing identified 119 rare variants with inheritance patterns that would be consistent with either paternal-dominant, recessive or *de novo* inheritance of TGI. While we believe that TGI likely has multifactorial genetic and environmental contributors, these findings add to the growing body of knowledge regarding the understanding of its genetic etiology. This is especially true in the case of *MAP4K3*, which we previously identified as a candidate gene, potentially affecting gender identity in the brain.

## PgmNr 613: Accurate fetal sex determination from maternal blood at 8 weeks gestation.

### Authors:

**Affiliation:** Gateway Genomics, 7590 Fay Ave. La Jolla, CA. 92037

---

**Background:** Prior studies have shown that SneakPeek® Early Gender Test can accurately determine fetal sex as early as 9 weeks gestation using a qPCR-based assay. The purpose of this study was to evaluate the clinical performance of SneakPeek® for noninvasive prenatal testing (NIPT) to determine fetal sex at an earlier time point: 8 weeks gestation.

**Methods:** A multicenter blinded study was conducted at five ultrasound clinics. Maternal blood samples were collected from 108 pregnant women between 7.00 and 10.57 weeks of gestation. Plasma was separated from whole blood by centrifugation. A commercial DNA extraction kit (MagMAX® Cell-Free DNA Isolation Kit) was used to isolate circulating cell-free DNA from maternal plasma. Real-time quantitative PCR was used to detect fetal DNA using a multi-copy sequence on the Y-chromosome. Total cell-free DNA (maternal and fetal circulating free DNA) was measured using an autosomal control gene.

**Results:** Male Y-chromosome DNA was detected in all samples from women carrying a male fetus. SneakPeek® correctly identified fetal sex in 107 of 108 pregnancies. Four of the 108 samples initially yielded an inconclusive result. A second sample was collected from the four participants and a result was obtained on the second round of testing. Fetal sex for all samples were unknown prior to genetic testing and confirmed through a sonogram. In this study, SneakPeek® accuracy, sensitivity, and specificity were 99.1%, 100%, and 98.2% for fetal sex identification, respectively.

**Conclusion:** This study showed that SneakPeek® Early Gender Test is highly accurate for fetal sex determination in pregnancy as early as 8 weeks gestation.

**Keywords:** SneakPeek, NIPT, Early Gender Test, Pregnancy, Fetal Sex, Maternal Blood, Maternal Plasma, Cell-free Fetal DNA

# PgmNr 614: Fast and accurate SNP discovery and allele frequency estimation from large-scale low-pass NIPT genome sequencing.

## Background

Non-invasive prenatal test (NIPT) for fetal trisomy by sequencing of maternal plasma cell-free DNA to 0.06 – 0.3 fold has become the fastest adopted molecular test in history. Nowadays, over ten millions of NIPT tests have been carried out globally, representing a data set with a sample size capacity similar to world-wide array data. The NIPT sequencing data, when combined with clinical records from the hospitals, are valuable for genome-wide association studies of many important maternal and child's traits. However, SNP discovery from the NIPT sequencing remains difficult since traditional multi-sample variation calling algorithms are incapable of fast and accurate variation calling from large-scale low-pass genomes although it is the first step for downstream genetic analysis.

## Findings

In our study, we present a novel and highly efficient approach that integrates maximum likelihood estimation and multiple likelihood ratio tests for SNP discovery and allele frequency estimation for massive amount of NIPT genomes. The algorithm can not only detect and estimate allele frequency for bi-allelic SNPs but also multi-allelic SNPs. Analysis on simulation data suggests a close-to-zero false positive rate for SNP discovery and negligible difference on allele frequency estimation. Comparison on the speed and accuracy for variation discovery and allele frequency estimation on hundreds of thousands and up to million of individuals between our method and the traditional bayesian approaches implemented in GATK and Samtools suggests that our method is more than 20 times faster while maintains similar accuracy given the same computational resource. Genome-wide association analysis using variations called from our approach indicates greater power than directly using the known polymorphic SNPs from the reference panel. The method so far has been applied on the study of more millions of NIPT individuals and can be downloaded from <https://github.com/ShujiaHuang/BaseVar>.

## Conclusions

We present an important algorithm that can be used for accurate SNP discovery and allele frequency estimation from up to millions of NIPT sequencing data. Evaluation on simulation and massive amount of real data prove its largely improved efficiency and accuracy compared to traditional variation calling approaches. Our approach supports the great potentiality of the continuously accumulating and improving NIPT data for genome-wide association mapping of important complex traits.

## PgmNr 615: Fetal fraction cutoff established for NIPS accuracy may not predict higher risk of trisomy.

**Introduction:** The ability to isolate cell free DNA (cfDNA) from the maternal bloodstream is a powerful tool for noninvasive prenatal screening (NIPS) of trisomies 13, 18, and 21. Accurate prenatal assessment depends largely on the fraction of fetal cfDNA present in the maternal serum sample. Recently published findings revealed that the presence of trisomies is associated with decreased fetal fraction, prompting guidelines for women with failed NIPS testing due to inadequate fetal cfDNA to undergo invasive testing. In the current study, we aimed to determine whether decreased fetal fraction was associated with trisomy in our cohort, and if NIPS failure due to a fetal fraction below the established clinical cut off of 4% is an indicator of risk.

**Methods:** Information including maternal BMI, maternal age, fetal sex, gestational age, fetal cfDNA fraction, and NIPS results was collected on a cohort of 2,374 pregnancies referred to the Mayo Clinic Genomics Laboratory between January 2016 and September 2018. Additional clinical information was available for 1,181 patients who delivered at Mayo Clinic, including fetal outcome, fetal and maternal complications, and maternal smoking status. We determined the success rate of retesting after initial failure due to low fetal fraction and conducted linear and logistic regressions to investigate associations between fetal fraction and the aforementioned variables.

**Results:** Consistent with previous reports, fetal fraction was positively associated with gestational age ( $p < 0.001$ ) and negatively associated with BMI ( $p < 0.001$ ). Fetal fraction was negatively associated with the presence of trisomy ( $p = 0.031$ ) and intrauterine fetal demise (IUFD;  $p = 0.046$ ), controlling for BMI and gestational age. However, the proportions of trisomies or IUFD were similar in women who had fetal fraction below and above 4%. Fetal fraction was not associated with maternal age, fetal sex, pre-eclampsia, gestational hypertension, or maternal smoking status. 66% of redraws were successful.

**Conclusion:** Although decreased fetal fraction is associated with fetal trisomy and IUFD, failure to meet the clinical cutoff of 4% fetal fraction established for NIPS accuracy does not suggest increased risk for these characteristics. Because most redraws were successful and the majority of failed NIPS were explained by high BMI and low gestational age, a redraw may be a more appropriate next step before invasive screening due to concerns of trisomy risk.

## PgmNr 616: Single circulating trophoblast testing provides a new window for detecting placental mosaicism.

Confined placental mosaicism (CPM) and true fetal mosaicism are known to occur in human pregnancy. Mosaicism, mostly CPM, is detected with cell-free DNA-based noninvasive prenatal testing (NIPT), but there is limited information with cell-based NIPT. We have been developing Single Circulating Trophoblast (SCT) testing as a novel form of noninvasive prenatal diagnosis. Trophoblasts obtained after immunomagnetic enrichment from 30-40 mL of maternal blood are analyzed for copy number variants by single cell whole genome next-generation sequencing. Since June 2017, we have analyzed 247 samples for which at least one isolated trophoblastic cell was scorable for fetal aneuploidies, with a median of 3 scorable cells/case (sequenced up to 5 cells/singleton case). Evidence for CPM was found in 5/247 cases (2.0%).

CPM in CVS samples can be divided into three categories: abnormal cells confined to the cytotrophoblast layer (CPM I, direct preparation), confined to the mesenchymal core (CPM II, long-term culture) or found in both lineages (CPM III); only CPM I & III would be detected by our SCT testing assay. The frequency observed is 2-fold higher than the reported combined frequency for CPM I & III (0.78% and 0.22%, respectively, in CVS samples from first-trimester pregnancies). The chromosome imbalances in the analyzed SCT cells from each case (shown as abnormal cells/total cells analyzed) were monosomy X (3/7), trisomy 13 (2/2), trisomy 15 (1/1), trisomy 4 (3/3) and gain and loss of 13q (4/4). In four of the five SCT CPM cases, CVS and/or amniocentesis testing revealed normal cytogenetic results, consistent with CPM I. For one case, CVS analysis indicated very low-level mosaicism, but follow-up amniocentesis showed a normal profile.

These results suggest that CPM I may be a more common phenomenon than currently recognized, which is perhaps not surprising given the high-frequency mosaicism seen in day 3 embryos and day 5 blastocysts. It is possible that the detection of CPM I by direct CVS biopsy is an underestimate given the tiny fraction of the placenta sampled. It is also of note that uniparental disomy (UPD) 15, causing Prader-Willi or Angelman syndrome, is assumed to occur through trisomy and monosomy rescue, respectively; yet this hypothesized mosaicism has rarely been seen in CVS samples leading to UPD15. These data have important implications for normal human biology and for disease states that might be caused by mosaicism that has been undetected to date.

## PgmNr 617: A pilot study of exome sequencing of cell free fetal DNA for detection of pathogenic variants.

---

Prenatal genetic diagnosis provides earlier results and expanded testing options over traditional newborn screening, promoting more effective treatment in the immediate newborn period. Expanding the scope of prenatal genetic testing will enable additional treatment options, especially with the ongoing development of gene therapies. The most comprehensive genetic testing requires obtaining a direct fetal sample, either through amniocentesis or chorionic villus sampling, with risk for pregnancy loss and other complications. While the overall risk of these procedures is low, we aim to eliminate invasive procedures by interrogating fetal-derived cell-free DNA fragments in maternal blood. As a pilot study, we performed whole-exome sequencing (WES) on cell-free DNA in three pregnant women -- two with structurally anomalous fetuses, and one with previous pregnancies affected by Menkes syndrome. We focused our analyses on high-quality single-nucleotide polymorphisms (SNPs), cross-referencing SNPs identified in maternal cell-free DNA with likely- and known-pathogenic SNPs listed in the NIH ClinVar database. In case one, we identified a recessive causal variant c.1120 G>T (p. Glu374Ter) for type VIII osteogenesis imperfecta in the *P3H1* gene. The variant fit with the sonographic findings of shortened long bones, bowed femurs, and hypoechogenic bones. The homozygous variant in *P3H1* was confirmed by amniocentesis and Sanger sequencing. The minor allele frequency for the *P3H1* variant was 53%, which, despite sequencing coverage >200x, would have been insufficient to suggest fetal homozygosity without the sonographic findings. Case two occurred in a mother with five prior pregnancies affected with X-linked recessive Menkes syndrome; we did not find any SNPs within the *ATP7A* gene. Case two did reveal the mother, but not the fetus, carries the c.1187G>A (p.Gly396Asp) variant in the *MUTYH* gene for MYH-associated polyposis. In case three, the fetus had arthrogryposis with clubbed feet and elbow contractures on sonography. We did not find any likely- or known-pathogenic SNPs via cell free DNA analysis or via whole exome sequencing from the direct fetal sample. Taken together, these results demonstrate some ability to identify causal variants from WES on cell-free DNA, but illustrate the need for greater efforts.

## PgmNr 618: Single circulating trophoblast testing for noninvasive prenatal diagnosis.

Cell-based noninvasive prenatal testing (NIPT) as a novel form of prenatal diagnosis has been explored for decades. We have developed a Single Circulating Trophoblast (SCT) testing method for the analysis of trophoblasts from maternal blood during the late 1st/early 2nd trimester to reliably detect  $\geq 1$  Mb fetal copy number variants (CNV) (PMID 27616633, 27761919). We here report on 1) the results of two pilot studies in preparation of a more rigorous CAP/CLIA validation study, 2) data from additional samples collected at early gestational age (GA), and 3) our experience with multiple pregnancies.

1) A total of 95 samples (30-40 ml) were collected at 8w2d-20w6d GA in the two pilot studies. After enrichment, putative trophoblasts were picked to undergo CNV analysis by low coverage single-cell whole genome next generation sequencing (NGS). Overall, an average of 0.20 cells/ml was identified. About 55% of all sequenced trophoblasts were of high quality (scorable for both aneuploidy and CNV), and with up to 5 sequenced cells/case, there were on average 1.93 high-quality cells/sample. This corresponded to 53% of cases having  $\geq 2$  high-quality cells.

2) An additional 44 samples were collected specifically at 6w4d-10w6d GA. An average of 0.12 cells/ml were identified by microscopy. For 8 samples no trophoblasts were available for analysis, but NGS data are available for 29 cases and still pending for 7 cases. Of all sequenced cells, 47% were of high quality, and for 12/29 cases  $\geq 2$  high-quality cells were available.

3) When considering multiples, 26 twins and 1 triplet case were recruited since June 2017 and yielded higher cell numbers compared to singletons. An average of 0.42 trophoblasts/ml was identified, yielding on average 3.6 high-quality cells per case with NGS analysis and 75% of cases having  $\geq 2$  high-quality cells. For the confirmed opposite-sex twins, cells from both fetuses were recovered in 6/8 cases, and also for the triplet (2 male and 1 female), both normal male and female cells were recovered.

In conclusion, SCT testing is a rapidly evolving technique with strong potential as a clinical test in the near future. We show that SCT testing is also feasible at early GA, although the yield is less than at 10-15w GA. Increasing the trophoblast yield would allow earlier prenatal testing and possibly earlier pregnancy management than conventional testing methods. Additionally, the ability to recover cells from separate fetuses is an advantage over cell-free NIPT.

## PgmNr 619: Sex differences in gene expression found in term uncomplicated human placentas.

Pregnancy complications vary based on the genetic sex of the fetus. Pregnancies with a male fetus are more likely to be delivered by cesarean section and delivered preterm. Subchorionic hemorrhage is the most common pregnancy complication occurring in ~25% of pregnancies and is 6.8 times more likely with a male fetus than pregnancies with a female fetus. Pregnancies with a female fetus, on the other hand, are more likely to experience intrauterine growth restriction in which the fetus does not grow to normal healthy weight. The placenta, which is the genotype of the fetus, is critical for sustaining and maintaining a healthy pregnancy by acting as an immune modulator to protect the developing fetus from the mother's immune system. Improper placenta function can result in pregnancy complications and may be driven by changes in gene expression. Indeed, several studies have shown that placenta gene expression differs between healthy term placentas and placentas from pregnancies characterized by preeclampsia and intrauterine growth restriction. While these studies enhanced our understanding of these phenomena there was limited sample size, and sex differences were not analyzed. Here we fill this gap by characterizing genome-wide expression differences and similarities between 30 male XY and 30 female XX placentas from term uncomplicated pregnancies to create an overview of typical sex differences in one of the earliest developed tissue, the placenta. Our preliminary results show that genes that are more highly expressed in the female samples are involved in the stimulation of the ovaries to synthesize steroids for sustaining the pregnancy whereas higher expressing genes in male placental samples are involved in T cell differentiation in immune response. Further characterizing sex differences in these full-term placentas will provide the groundwork for future studies to investigate sex-specific disease-related gene expression.

## PgmNr 620: X chromosome inactivation is heterogeneous in the human placenta.

In mammals, genetic females (XX) have two X chromosomes while genetic males (XY) have one X chromosome. To equalize dosage between males and females, one of the X chromosomes in XX females is silenced through a process called X chromosome inactivation (XCI).

Previous studies of patterns of XCI in the placenta were either in non-human placentas, or only examined a few SNPs and genes in humans. In addition to the patchiness of X-inactivation across regions of the placenta, XCI is not complete in humans; as many as one-third of the genes on the X chromosome escape XCI. It is not known whether the same genes escape XCI in the same tissue across multiple individuals, and gene-specific escape in the placenta has not been investigated.

To better understand the patchiness, or potential maternal or paternal bias in XCI in the placenta, and whether genes escape XCI vary between individuals, we sequence 30 placenta tissues from 30 full-term, healthy pregnancies with female offspring. This is important because the placenta is the genotype of the fetus. Importantly, for each placenta, we collect extract RNA from two different sites. We choose the placenta in this study because heterogeneity in patterns of XCI can give us insights into when during development the X chromosome is silenced, and because understanding heterogeneity in this early-formed tissue is important for its downstream developmental effects. We perform whole-exome DNA sequence of each individual and RNA-seq for each extraction site. We quantify XCI for each extraction site from the same placenta to understand how heterogeneous XCI is in the placenta. For each gene on the X chromosome, we determine if it escapes XCI across all 30 placentas or the pattern of escape genes is heterogeneous. We discuss our findings on the heterogeneous patterns of XCI within and between individuals and their clinical implications.

## PgmNr 621: A *BRIP1* likely pathogenic variant and a *CDH1* variant of uncertain significance in a patient with lobular breast cancer.

We present the case of a 48-year old female with lobular breast cancer and a family history of breast and gastric cancer. In 2016, the patient underwent genetic testing utilizing a multi-gene panel. This testing revealed a likely pathogenic variant (LPV) in the *BRIP1* gene, *c.206-2A>G* and a variant of uncertain significance (VUS) in the *CDH1* gene, *p.T285I*. The patient's father passed away from gastric cancer with signet ring cell features (pathology confirmed). Following the patient's testing, a paternal aunt developed breast cancer and was also found to carry the *CDH1* VUS, confirming paternal inheritance. According to the International Gastric Cancer Linkage Consortium Guidelines, identification of a *CDH1* VUS in the setting of a family history consistent with hereditary diffuse gastric cancer (HDGC) should prompt consideration of endoscopy with multiple random biopsies, although this has not been proven to reliably detect this cancer at an early stage. *CDH1* mutations are also associated with about a 56% lifetime risk for breast cancer, often lobular. *BRIP1* mutations are associated with about a 6% lifetime risk for ovarian cancer and possibly a modestly increased risk for breast cancer. The patient recently opted for a total hysterectomy. A sister with LCIS was also found to carry the *BRIP1* LPV, but not the *CDH1* VUS, which was a finding of particular interest, given the association between lobular breast pathology and *CDH1* pathogenic mutations. A second sister was also found to carry the *BRIP1* LPV and *CDH1* VUS and developed breast cancer a year after testing positive. The identification of the *CDH1* VUS and confirmation of paternal inheritance has proven to be more distressing for this family than the identification of the *BRIP1* LPV, a result with an established NCCN recommendation for prophylactic oophorectomy. The uncertainty of screening for HDGC and the possibility that this variant may be reclassified as pathogenic has significantly raised the cancer related anxiety in this family. However, the patient and her relatives have been counseled that only if the *CDH1* VUS is upgraded, would this prompt a consideration of prophylactic gastrectomy. This case illustrates the complexity of multi-gene panel results, the importance of dynamic family history as a contributor to result interpretation, and the intricacy of genetic counseling for variants of uncertain significance, in particular in families consistent with a high-risk cancer susceptibility syndrome.

## **PgmNr 622: Towards equity in precision medicine: Population differences in the use of genetic testing for cancer in a regional hospital system.**

---

Precision Medicine centers around the use of biomarkers as diagnostic, prognostic, treatment predictive, and risk-based tests. These genetic tests are the *defacto* gateway to precision medicine. However, the lack of diversity in genetic research, the demonstrated differences in clinical utility, and limited access to clinical genetic tests in some disease areas suggests that precision medicine may exacerbate existing disparities. There has been a major push to increase the diversity in genetic research through programs like the *All of Us Program* and *Million Veteran's Program*. There is growing concern that even if the differences in utility are resolved, the genomic tests necessary for precision health care will not be available to all. Complicating the issue is the lack of data on use of genetic testing across diverse racial groups. Using a hospital system-wide centralized clinical data registry and warehouse with more than 1 million patient notes from more than seven hospitals, we examined the demographic characteristics of select cancer focused genetic tests from (1988-2019). Specifically, we conducted a cross-sectional study of genetic testing for select hereditary cancers, select heme malignancies, as well as testing for select genes involved in targeted cancer therapy in the Partners' Research Patient Data Registry. Our study shows large significant population differences in cancer testing for pharmacogenetics [84.9% White, 3.8% Asian, 3.5% Black, and 2.0% Hispanic]; heme malignancies [82.5% White, 2.4% Asian, 4.9% Black and 2.1% Hispanic], as well as hereditary cancer [88.6% White, 2.7% Asian, 2.5% Black and 1.7 % Hispanic]. In the more than 20,000 patient notes with genetic testing more than 80% were for White patients. Most of these patients received testing at large hospitals (> 750 beds), with fewer patients receiving genetic testing at smaller community hospitals (< 200 beds). Although these findings are limited to a single hospital system and are not nationally representative of all genetic testing, these data show the problem may be pervasive in all types of genetic testing for cancer. A national study on use of genetic testing for cancer diagnosis, prognosis, treatment, and disease management is needed. Furthermore, investigation into the potential cause of these differences in use, as well as solutions including public advocacy, patient engagement and provider education is required.

**Affiliation:** MD Anderson Cancer Center, Houston, TEXAS.

---

Familial communication of pathogenic *BRCA1* results is needed to maximize the clinical utility of sequencing and its public health benefits. Cascade *BRCA1* genetic testing is suboptimal and practical strategies for promoting familial testing are needed. Disclosure of *BRCA1* results present opportunities to counsel probands about familial communication. Little is known about what familial communication recommendations are offered to probands by genetic counselors (GCs). We examined differences in how GCs discussed familial implications of pathogenic *BRCA1* results based on: specificity of familial risk-messaging; offer of logistical help for relatives; and, provision of family letters. We completed structured content analysis of 159 *BRCA1* result disclosure notes, abstracted from electronic medical records (EMRs), for probands seen at MD Anderson Cancer Center from 2014-2019. Probands were 94% female, median age of 48.6 years, 52.3% non-White, and were counseled by 20 unique GCs with mean post-graduate experience of 4.2 years. 53.3% of notes described specific at-risk relatives who would benefit from genetic counseling; the remainder described familial implications more generically. The practice of including specific information differed widely among individual GCs [range: 6-88%]. 27% provided information on logistical genetic counseling assistance for relatives (e.g., targeted testing cost, assistance locating GCs or testing services for underinsured). More experienced GCs were more likely to provide detailed familial implication information ( $p=0.001$ ) and offer logistical help ( $p=0.04$ ). Presence of an accompanying relative to an in-person appointment ( $n=34$ ) did not change the specificity of familial implications offered, compared to unaccompanied ( $n=48$ ) or telephone disclosures ( $n=73$ ) ( $p=0.91$ ). The provision of family letters was mentioned in 48.4% of notes, but the intended recipients or purpose were frequently not specified. Some notes indicated familial communication primarily as a means to determine paternal or maternal inheritance of mutation. Although there may be discordance between EMR disclosure notes and actual counseling, findings suggest that offering specific risk-messaging, logistical help and explaining intended recipients of family letters are opportunities for improving familial communication. Counseling to determine inheritance patterns of *BRCA1* can be framed as opportunities to promote familial communication and cascade genetic testing.

## PgmNr 624: The Gene Machine: Exploring the road less traveled.

**Authors:**

[View Session](#) [Add to Schedule](#)

**Affiliation:** Auburn Univ, Auburn, Alabama.

---

Robert Frost inspired the world by taking the road less traveled. Interpret as you may, he claimed it made all the difference. New perspectives are gained from breaking away from the norm, yet today, as scientists, we find ourselves continuously following the path of least resistance regarding the recruitment of human subjects into research. We are all aware of health disparities in the U.S. and the recruitment bias towards urban-living Caucasians. Individuals living in rural America, as well as those of ethnic minorities, are the most susceptible to health disparities but the most underrepresented in research. As geneticists, particularly in the era of precision medicine, we hold the power to influence change. We need to step outside our comfort zones and make a concerted effort to include vulnerable populations in our research.

The back roads of Alabama are secluded, winding through hardwood and pine forests and open arable land. One can also see pockets of housing, some beautifully kept and others that truly do not seem habitable. The Gene Machine — a mobile recruitment and enrollment bus — witnesses this first-hand as its travels through the state to secure study participants for hereditary breast cancer genetics research. This eye-catching pink bus is a part of an IRB-approved community-based recruitment (CBR) protocol centered on overcoming barriers to research participation. We previously published our rudimentary strategies to recruit in the rural and medically underserved state of Alabama, which also has nearly double the national percentage of Black/African American individuals. Including underrepresented individuals in research is an arduous process, but it is also gratifying, and we are now implementing modifications to enhance enrollment based on lessons learned.

Overall, the Gene Machine brings research opportunities to the underrepresented, along with the option to receive genetic research reports. To date, 99% of the CBR study probands have chosen to be informed of clinically relevant findings; only 41% previously had clinical genetic testing. Notably, we established a collaborative telegenetic counseling project to provide local services to mutation carriers; interestingly, upon receiving a report, to date, only Caucasians have accepted the service, indicating adjustments are necessary. Overall, we all can learn from exploring the road less travelled, and we hope the Gene Machine can inspire a movement towards true inclusion.

## PgmNr 625: A modern approach to cascade genetic screening: Use of a chatbot to enable family sharing.

---

**Introduction:** Cascade screening is an ideal way to target healthy at-risk individuals, but suboptimal family communication, reliance on paper documents, and downstream geographic barriers all make the execution challenging. There is a need to develop novel approaches to family sharing that leverage modern societal communication modalities.

**Methods:** In collaboration with board-certified genetic counselors, Clear Genetics, Inc. developed a Family Sharing Tool that patients can use to share genetic test results with at-risk relatives using a “cascade chatbot” via email, text, or Facebook private message. We assessed the ability of a BRCA1 Cascade Chatbot to communicate genetic information to hypothetical at-risk relatives. The chatbot—named GIA for Genetic Information Assistant— was programmed to describe the familial mutation, relay associated disease risk, and facilitate next steps, including triage to telephone genetic counseling. The tool was tested on 100 users, ages 45-55 with at least a high school degree, to assess ease of use, satisfaction and comprehension.

**Results:** When asked about ease of use, 96% said the tool was “easy/very easy” to use, and 92% felt it was an effective way to get information. Only 3% would have preferred a call with a genetic counselor, and 4% would prefer a letter in the mail. When given the option to describe GIA’s personality, the top 3 descriptors were: “Informative” (84%), “Friendly” (63%), and “Professional” (52% ). To understand satisfaction levels, users were asked to describe how the interaction with GIA made them feel: 91% of reported “Informed”, 58% felt “Engaged”, and 34% “Empowered.” Other feelings were “Grateful” (23%), “Scared” (9%), and “Uncomfortable” (7%). Finally, 99% understood that testing was necessary to determine personal risk, and 76% understood that a positive result would stratify them as high-risk.

**Conclusion:** Preliminary data suggests that offloading the burden of family sharing to a chatbot can facilitate effective communication to at-risk relatives. This mode of communication alleviates many of the logistical barriers of cascade screening, while ensuring the delivery of authoritative genetic information to targeted relatives. Testing of this tool in a clinical setting is the next step to determining whether it can optimize cascade screening and change patient behaviors.

## PgmNr 626: Telegenetics: A new method for genetic counseling.

**Authors:**

A. Radfar <sup>1</sup>; I. Filip <sup>2</sup>

[View Session](#) [Add to Schedule](#)

**Affiliations:**

1) Encino, California.; 2) Kaiser , California

---

**Objective:** Telegenetics allows physicians to provide medical genetic care and counseling services remotely through audiovisual technology. Telegenetics may address many challenges facing our society in Middle -Eastern population living in U.S. Due to high level of genetic diseases in this population, telegenetics can increase detection , diagnosis and treatment of disorders in the young and aging population and decrease healthcare cost. With this work, we attempt to evaluate how telegenetics can effect a change in these challenges, and evaluate what obstacles prevent some providers from using it.

**Methods:** In this work, the cost-effectiveness, success of telegenetic care, usefulness in reaching developing and underdeveloped areas, dif?culties preventing the use of telegenetics, and proposals to overcome these challenges were reviewed and analyzed.

**Results:** Cost of telegenetics was reported 19% less expensive than traditional face-to-face care. In several studies, telegenetics was documented to have had equal or better outcomes than face-to-face encounter. Dif?culties in using telegenetics include affordability of equipment, lack of technical support in developing or underdeveloped areas, legality of licensure and patient privacy and satisfaction.

**Conclusions:** Although cost savings and convenience are major advantages of this technology, concerns with delivery barriers and challenges require cautious embracement of telemedicine. A great deal of research is needed to show that telegenetics improves patient centered outcomes.

## PgmNr 627: In the age of Twitter, email still works to engage clinicians in genomics education.

### Authors:

K. Reed <sup>1</sup>; P. Tanner <sup>1</sup>; L. Steinmark <sup>1</sup>; E. Edelman <sup>1</sup>; J. Lillpopp <sup>2</sup>; T. Ingram <sup>1</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Clinical and Continuing Education Program, The Jackson Laboratory, Bar Harbor, Maine.; 2) Genomics Office, Connecticut Department of Public Health

---

For genomic medicine to have an impact on public health, clinicians without formal training in genomics need to incorporate genetics/genomics into their practice. While dissemination of genomic education is recognized as an important aspect of reducing practice gaps, it has received limited study. The Jackson Laboratory Clinical Education Program (JAX) with support from the Connecticut Department of Public Health Genomics Office (DPH) developed and implemented a marketing strategy for *Cancer Genetic Clinical Education*, a well-tested set of 11 online, interactive modules on cancer genetics. This program seeks to train primary care providers (PCPs) to use evidence-based guidelines about Tier I cancer genetic applications. The goal was to enroll 100 new CT clinicians in the program as part of the larger DPH effort to help clinicians identify and manage patients at risk for hereditary cancer. **Methods:** Based on initial consultation with external and institutional marketing experts, JAX implemented a strategy including in-person presentation, email campaign, social media, and content marketing. **Results:** From Feb-Sept 2018, JAX sent 25 emails to CT licensed PCPs, posted 135 tweets on JAX channels, provided 58 posts for DPH's Facebook page, posted 7 paid social media ads, and gave 5 presentations to 133 clinicians. 133 new clinicians enrolled in 170 modules with 12,522 pageviews, including 70% PCPs and 7.5% oncology clinicians. Email was most effective in increasing enrollment in a module, paid ads in exposing a large number of individuals to the program, and social media in raising awareness of the program, defined by page views. Few social media users enrolled in modules and presentation attendance was not associated with module enrollment, suggesting presentations and online modules reached different audiences. **Conclusion:** Genomic educators often have limited resources and expertise to support dissemination, but it is critically important. To our knowledge, this is the first study reporting on dissemination of genomic education to a general population of clinicians. Our results suggest that different channels may be useful to achieve outcomes of awareness and enrollment, although the impact of awareness needs further study. Frequent email communication and local presentations were the most effective methods to reach clinicians with genetic education. These preliminary findings should be confirmed through study in other populations.

## PgmNr 628: Identification of *RECQL* pathogenic variants in women undergoing multi-gene panel testing.

### Authors:

K. Theobald <sup>1</sup>; S. Hiraki <sup>1</sup>; E. Sutcliffe <sup>1</sup>; P. Murphy <sup>1</sup>; K. Hruska <sup>1</sup>; R.T. Klein <sup>2</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) GeneDx Inherited Cancer, GeneDx, Gaithersburg, Maryland.; 2) My Gene Team, Miami, Florida

---

**Background:** The *RECQL* gene, a member of the DNA helicase family, has been reported as a candidate gene for hereditary breast cancer. While initial publications support a significant association with breast cancer risk, subsequent authors demonstrate conflicting evidence and the penetrance of the gene has yet to be delineated. Phenotypic variability, including possible associations with ovarian and colorectal cancer, is not well-defined. We aim to describe the spectrum of *RECQL* variants identified in our testing cohort, and to characterize the clinical phenotype of women with *RECQL* pathogenic and likely pathogenic variants (collectively denoted PV).

**Methods:** We performed a retrospective review of 11,449 women undergoing multi-gene hereditary cancer panel testing for up to 64 genes, including *RECQL*, between December 2017 and February 2019. Personal and family histories of cancer were evaluated. Women with a PV in another gene were excluded from analysis.

**Results:** Among all women tested for *RECQL*, the positive yield was 0.3% (35/11,449). Fourteen different PV were identified among the 35 women. Over half had a recurrent variant: sixteen with the Polish founder variant (c.1667\_1667+3delAGTA), and three with the French Canadian founder variant (c.643C>T). Of the 35 positive women, 37.1% (13/35) had breast cancer with an average age at first diagnosis of 57.7 years. There were 3 patients with ovarian cancer (8.6%), with an average age of diagnosis of 50.3 years, and none with a personal history of colorectal cancer. Family histories of breast, ovarian or colorectal cancer were reported by 26/35 (74.3%), 7/35 (20.0%), and 8/35 (22.9%) women, respectively. Almost half of all women (n=5,452) had a personal history of breast cancer, in whom the positive yield for *RECQL* was 0.24% (13/5,452).

**Conclusion:** PV in *RECQL* are identified in a small proportion of patients undergoing panel testing and with breast cancer. The inclusion of *RECQL* in multi-gene panels may enhance cancer risk screening opportunities. While this case series may be supportive of a potential association with breast cancer, larger, diverse case-control investigations will help to clarify the risk estimations from prior studies and delineate the role of *RECQL* in female breast and other cancers.

## PgmNr 629: Population-based cancer predisposition testing as a component of newborn screening: A cost-effectiveness analysis.

### Authors:

J.M. Yeh <sup>1,2</sup>; N.K. Stout <sup>1,3</sup>; A.B. Chaudhry <sup>2</sup>; M. Gooch <sup>1,3</sup>; P. McMahon <sup>1,3</sup>; K.D. Christensen <sup>4</sup>; L.R. Diller <sup>5</sup>; A.C. Wu <sup>1,3</sup>

1) Harvard Medical School, Boston, MA; 2) Boston Children's Hospital, Boston, MA; 3) Harvard Pilgrim Health Care Institute, Boston, MA; 4) Brigham and Women's Hospital, Boston, MA; 5) Dana-Farber Cancer Institute, Boston MA

---

**Background:** The role of population-based newborn genetic testing for pediatric cancer predisposition has not been studied, despite the availability of cancer surveillance guidelines for early detection in high-risk infants and children.

**Methods:** We developed the Precision Medicine Policy and Treatment (PreEMPT) Model to estimate the value of population-based newborn genomic sequencing (NBS) for a select panel of genes associated with early onset pediatric malignancy. Cohorts of US newborns were simulated under NBS screening vs. usual care, from birth to death. Eleven pediatric cancer predisposition syndromes were included, with mutations in *RET*, *RB1*, *TP53*, *DICER1*, *SUFU*, *PTCH1*, *SMARCB1*, *WT1*, *APC*, *ALK*, *PHO2XB* assigned at birth, using pathogenic/likely pathogenic (P/LP) variant prevalence and disease risks drawn from clinical studies and SEER, ClinVar and gnomAD databases. Newborns with mutations underwent cancer surveillance based on established guidelines. Survival benefit was modeled as a reduction in proportion of advanced disease, cancer deaths, and treatment-related late mortality risks. Costs were based on published literature and national databases. To capture uncertainty, we conducted 100 simulations in which each parameter was sampled from its underlying distribution, and report the mean and 95% uncertainty interval (UI) for all outcomes.

**Results:** In a typical US birth cohort of 4 million newborns, we estimated 3208 (95% UI, 2988-3426) P/LP variant carriers and 2167 (95% UI, 2123-2212) cancer cases in the malignancies associated with this gene panel before age 20 under Usual Care, resulting in 507 (95% UI, 494-519) cancer deaths and 842 (95% UI, 821-867) living with radiation exposure risks. NBS would prevent 8 (95% UI, 6-10) cancers (in *RET* carriers), avert 41 (95% UI, 28-60) deaths via surveillance, and result in a 7% (95% UI, 4-10%) reduction in adult survivors at risk for radiation-associated late mortality. Given a sequencing cost of \$55 (e.g., \$5/gene), the incremental cost-effectiveness ratio (ICER) for NBS was \$218,500 per life year (LY) gained; if sequencing cost declined to \$10 for the gene panel, the ICER fell to \$50,800 per LY.

**Conclusions:** Population-based genetic testing of newborns may reduce mortality associated with pediatric cancers and could potentially be cost-effective as sequencing costs decline. Decision modeling provides a novel approach for understanding the potential benefits and costs of newborn genomic screening.

## PgmNr 630: Implementation of genetic cancer risk assessment (GCRA) in Monterrey, Mexico: Increasing reach, cascade testing and access to risk reduction surgery.

### Authors:

D. Aguilar <sup>1,2</sup>; J.N. Weitzel <sup>3</sup>; K.R. Blazer <sup>3</sup>; D. Castillo <sup>3</sup>; J. Herzog <sup>3</sup>; R. Mejia <sup>3</sup>; J.C. Garcia Marrufo <sup>2</sup>; S. Cardona <sup>1</sup>; C. Villarreal Garza <sup>1</sup>; Clinical Cancer Genomics Community Research Network

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Centro de Cancer de Mama, Tec Salud, Monterrey, Nuevo León, Mexico; 2) Tecnológico de Monterrey, Escuela de Medicina y Ciencias de la Salud; Ave. Morones Prieto 3000, Monterrey, NL, México, 64710; 3) City of Hope Cancer Center, Beckman Research Institute, Division of Clinical Cancer Genomics, 1500 E. Duarte Rd , Duarte, CA, USA, 91010

**Background:** In limited-resource countries like Mexico, GCRA is not routinely provided due to lack of public insurance coverage for counseling, testing and prophylactic surgeries. There is limited infrastructure of clinicians with GCRA expertise, and little awareness among providers and patients. Thus, GCRA services in Mexico are 20 years behind higher income countries, resulting in suboptimal care and missed opportunity for prevention.

The Breast Cancer Center TecSalud established formal GCRA services for underserved patients by recruiting a cancer geneticist who provides *pro bono* care for patients, building academic collaborations for training and research with City of Hope, and enabling free genetic testing through the Clinical Cancer Genomics Community Research Network, supported in part by the Breast Cancer Research Foundation.

**Aim:** To report the uptake of the GCRA program by patients and relatives and of risk reduction surgery at TecSalud from January 2016 - May 2019.

**Methods:** Eligible probands are Mexican women who meet hereditary breast cancer testing criteria and at risk relatives of mutation carriers. Risk reduction procedures (Risk reduction mastectomy: RRM; Risk reduction salpingo-oophorectomy: RRSO) are covered by Seguro Popular and/or the NGO Fundación Santos y de la Garza Evia.

**Results:** GCRA was offered to 317 patients and 96 at risk relatives, with an increasing reach (proportion of those eligible who access the program). There is a significant growth of cascade testing and receipt of risk reduction surgery over time

	2016	2017	2018	2019
<b>Patients tested</b>	71	86	98	62
<b>Relatives tested</b>	0	6	68	22
<b>Prophylactic surgeries</b>	0	4 2 RRM; 2 RRSO	17 5 RRM; 12 RRSO	4 3 RRM; 1 RRSO

**Conclusion:** Increasing GCRA visits represent improving reach, due in part to integration of a skilled multidisciplinary team, outreach at the hospital and increased patient awareness. The expansion of cascade testing and performance of risk-appropriate surgeries reflects a maturing prevention

program. Key determinants of our progress are collaborations that provided us with crucial mentorship, access to genetic assays, as well as the increasing support of local leaders, administrators and benefactors. Sustainment of progress requires increased multilevel efforts and establishment of GCRA as a supported standard of care, so the opportunity for prevention is not missed for vulnerable and underserved high-risk patients and families.

## PgmNr 631: Universal tumor screening for Lynch syndrome: Qualitative perspectives from newly diagnosed colorectal cancer patients.

---

Lynch syndrome (LS) is an inherited cancer syndrome, caused by pathogenic variants in the four mismatch repair (MMR) genes (MLH1, MSH2, MSH6 and PMS2) and EPCAM. Individuals with LS are at increased risk of colorectal cancer (CRC), endometrial cancer and other cancers, and their first-degree relatives are at 50% risk to carry the identified variant. Increasingly, health care systems are implementing universal programs for LS which screen all patients newly diagnosed with CRC for molecular signs of LS, followed by genetic testing to confirm the diagnosis. Little is known about patient perspectives on tumor screening for LS, such as importance of knowing and communication about results; this understanding will guide successful implementation of screening programs. We performed semi-structured phone interviews among individuals newly diagnosed with CRC at two integrated health care systems—one with a screening program and one without: Kaiser Permanente Northwest (KPNW) and Kaiser Permanente Colorado (KPCO). Twenty-one patients (10 KPCO/11 KPNW, 52% female, 90% White) were interviewed up to 7 months from date of CRC diagnosis (mean age 63 years, median cancer Stage 2). While most patients (20/21) had limited prior knowledge of LS or tumor screening, almost all (19/21) felt learning LS status was important to them and their family, as it could inform their future medical and lifestyle choices. One third of patients felt that tumor screening should be standard care protocol, and most (17/21) had no concerns with documentation of the results in the medical record. A minority of participants expressed concerns about LS tumor screening which included: how documentation of results could affect future insurance coverage (6/21); privacy and data security (3/21); lack of consent for screening if automatic (2/21); and potential anxiety while awaiting results (2/21). Many (14/21) felt that screening results should be returned at an in-person visit, preferably by a familiar provider (13/21). Overall, most individuals interviewed felt positively about tumor screening for LS and had few concerns about the screening or documentation of results in their medical record. Patients felt they and their families would benefit from tumor screening and knowledge of their LS status. Importantly, 62% (13/21) of participants also had a blood relative seen by the same health care system, highlighting a possible opportunity for LS testing of blood relatives by health care systems.

## PgmNr 632: No woman left behind: Is universal *BRCA1/2* testing possible for women with high grade serous ovarian cancer?

### Authors:

L. Lynch <sup>1</sup>; K. Bell <sup>1,2</sup>; S. Lopiccolo <sup>3</sup>; B. Loiseau <sup>4</sup>; K. Zbuk <sup>1,2</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Juravinski Cancer Centre- Hamilton Health Sciences, Hamilton, Ontario, Canada; 2) Department of Oncology, McMaster University, Hamilton, Ontario, Canada; 3) Michael G DeGroote School of Medicine, McMaster University, Hamilton, Ontario, Canada; 4) Department of Health Research Methods, Evidence and Impact, McMaster University, Hamilton, Ontario, Canada

---

**Background:** The Society of Gynecologic Oncology of Canada has created the “No Woman Left Behind” campaign, seeking to ensure that every woman with high grade serous ovarian cancer (HGSOC) is informed of her *BRCA* mutation status. Women with *BRCA1/2* mutations may benefit from targeted therapies and their blood relatives may benefit from predictive genetic testing and risk reducing measures. We previously published that 62% of patients with HGSOC at our centre were referred for genetic counselling/testing.

**Objective:** To document the care pathway for women referred to the Juravinski Cancer Center (JCC) in Hamilton, Ontario, Canada with: (i) a diagnosis of ovarian cancer (OC), fallopian tube cancer (FTC), or primary peritoneal cancer (PPC) (ii) a suspicious pelvic mass or (iii) clinical symptoms suggestive of OC to determine if there is a common touch point that would allow for 100% of this patient population to access *BRCA1/2* testing.

**Methods:** A retrospective chart review was conducted on 284 new patient referrals to the gynecologic oncology service at the JCC from January 2016-December 2017. Data related to the patient’s diagnostic assessment, surgery and/or treatment was extracted to construct patient care pathways. These pathways were analyzed to identify the area of greatest convergence.

**Results:** Outpatient blood work was obtained for 94.7% (269/284) of patients by their first appointment at the JCC. Eleven patients had bloodwork at their second or subsequent appointment. Beyond the first appointment, there was significant divergence in care pathways. There were four individuals who did not have blood work due to poor health/functional status.

**Conclusions:** Blood samples for germline *BRCA1/2* testing could be obtained at the first appointment as bloodwork is a standard component of the order set for all women with (i) a confirmed diagnosis of OC, FTC, or PPC (ii) a suspicious pelvic mass or (iii) clinical symptoms suggestive of OC. This would allow the majority of these patients to have the opportunity to provide a DNA sample which can be used for *BRCA1/2* testing upon patient/family consent and/or confirmation of the diagnosis. While our study shows it was not possible to obtain a blood sample from 100% of women in our patient population, our proposed suggestion of obtaining blood at the patient’s first appointment would be a 32.7% improvement on the previously reported low referral rates for *BRCA1/2* testing.

## PgmNr 633: Exploring healthcare providers perspective on the clinical utility of cfDNA testing.

### Authors:

M. Clausen<sup>1</sup>; L. Oldfield<sup>3</sup>; C. Mighton<sup>1,2</sup>; A. Sebastian<sup>1,2</sup>; S. Shickh<sup>1,2</sup>; S. Manjrekar<sup>1</sup>; J. Ho<sup>1</sup>; A. Pollett<sup>2,5,6</sup>; R. Kim<sup>3,4,5</sup>; T. Pugh<sup>2,3,7</sup>; Y. Bombard<sup>1,2</sup>

---

### Background

Individuals with an inherited cancer syndrome undergo costly and invasive serial screenings that are ineffective at detecting all associated malignancies. Detecting cancer early is critical to improving patient outcomes and research has shown that cell-free DNA (cfDNA) analysis can be utilized as a minimally invasive and effective cancer screening modality. While implementation of cfDNA testing into the clinic for early cancer detection is promising, no studies to date have consulted with healthcare providers and researchers on the realities surrounding the utility and implementation of cfDNA screening.

### Aim

Understand healthcare providers and researchers perceptions of the clinical utility of cfDNA testing for early cancer detection and identify the factors impacting clinical uptake.

### Methods

We are conducting 25-30 semi-structured interviews with researchers and healthcare practitioners, including oncologists, medical geneticists, genetics counsellors, and primary care providers. Interviews will be transcribed and analyzed thematically. Data collection and analysis will be completed by August of 2019.

### Results

Interviews with 10 practitioners and researchers have been completed. Preliminary analyses reveal that the utility of cfDNA screening depends on whether there exist effective screening modalities for particular cancer types. For example, for patients with BRCA1/2 mutations cfDNA could serve as a screening modality for ovarian cancer since no effective screening strategy exists, and as an adjunct test for breast cancer to help decipher benign breast lumps from malignancies. However, participant's perceived limited utility for screening colorectal cancers in Lynch syndrome carriers, given the effectiveness of colonoscopies at decreasing cancer risk. When discussing barriers and facilitators to uptake, participants expressed that a cfDNA screening test would need to have a low false positive rate, strong scientific evidence base and be accompanied by end-user education and practice guidelines. Cost and the inability of non-specialists to interpret results were seen as potential barriers.

## Discussion

Our preliminary analyses provide insights into how practitioners may use cfDNA in care and how the value of the test is largely dependent on whether effective screening strategies are available for a hereditary cancer syndrome. This study provides valuable information that will enable the optimal adoption of cfDNA into clinical care.

## PgmNr 634: Informed consent for genomic sequencing in diverse populations: Does diversity impact consent time?

### Authors:

L. Desrosiers<sup>1,2</sup>; S. Scollon<sup>1,2</sup>; A. Recinos<sup>1,2</sup>; R. Raesz-Martinez<sup>1,2</sup>; T. Wang<sup>3</sup>; J. Robinson<sup>4</sup>; M. Jibaja-Weiss<sup>3</sup>; D.W. Parsons<sup>1,2</sup>; A. McGuire<sup>4</sup>; S. Plon<sup>1,2</sup>

### Affiliations:

1) Department of Pediatrics, Baylor College of Medicine, Houston, TX.; 2) Texas Children's Cancer Center, Texas Children's Hospital, Houston, TX; 3) Dan L. Duncan Cancer Center, Baylor College of Medicine, Houston, TX; 4) Center for Medical Ethics and Health Policy, Baylor College of Medicine, Houston, TX

**Background:** Most studies of the informed consent (IC) process for genomic sequencing (in both research and clinical settings) have been conducted in institutions with limited racial/ethnic patient diversity. Findings demonstrated large variability in the estimated length of time to provide IC that differed by factors including experience, provider and population. The Texas KidsCanSeq (KCS) Study, an NIH funded Clinical Sequencing Evidence-Generating Research consortium project is studying implementation of genomic sequencing for pediatric cancer patients (germline for all subjects and tumor included for high risk patients) across the diverse population of Texas. Analysis of the time and effort required to obtain consent provides an opportunity to explore the IC process among ethnically diverse participants.

**Methods:** Study staff trained in IC offered KCS enrollment to patients treated in the Texas Children's Hospital (TCH) Cancer Center. The IC process was performed in the family's preferred language, with a native Spanish-speaker consenting in Spanish. All study materials (including consent forms and videos) were available in English and Spanish. Data analyzed of the IC process includes language, number of times parents discussed the study with staff (IC attempt), and total time spent in direct patient contact until enrollment. Participant-reported ethnicity was used to compare consent characteristics of enrolled patients in 3 groups (Non-Hispanic consented in English, Hispanic consented in English and Hispanic consented in Spanish) via Kruskal-Wallis Test.

**Results:** Enrollment opened in June 2018. To date, 129 families have consented and are included in the analysis. Overall, the median was 1 attempt and the maximum was 7 with 12% enrolled with more than 3 attempts. Time required to enroll participants ranged from 25 to 165 minutes with a median of 60 minutes. Among this cohort, 57 (44%) are Hispanic including 23 (18%) consented in Spanish. Among the 3 groups, the majority of participants were enrolled with 1 attempt (52.9%-56.5%) and average consent times were 62-73 minutes. There was no difference in IC attempts or time between the 3 groups ( $p=0.99$  and  $p=0.16$ , respectively).

**Conclusion:** In a setting with provision of study materials in English and Spanish and native speakers describing the study, there was no significant difference in the staffing requirements and parental time commitment to complete enrollment into a complex cancer genomic study.

## PgmNr 635: Sharing exome sequencing results with family members: Experiences of participants in a clinical sequencing study of hereditary colorectal cancer and polyposis.

### Authors:

---

**Background:** Family sharing of genetic test results improves the clinical and economic value of genetic testing for cancer risk. However, relatively little is understood about the impact of result type on sharing motivations and behavior. To learn more about these features of familial communication we interviewed colorectal cancer and polyposis (CRCP) patients with positive, negative, or uncertain results who reported either no sharing, or extensive sharing, with relatives. **Methods:** Patients referred for genetic testing were enrolled in the New EXome Technology in Medicine (NEXT Medicine) Study, a Clinical Sequencing Exploratory Research (CSER) consortium Randomized Controlled Trial (RCT) that compared exome sequencing versus usual care for genetic evaluation for CRCP. We interviewed 15 participants one month post-disclosure: 8 who reported no immediate sharing (2 with negative results, 2 positive, 4 VUS) and 7 who reported sharing with 4 or more relatives (2 negative, 2 positive, 3 VUS). Interviews were designed to elicit attitudes toward results received, familial sharing behavior, and relatives' responses to result sharing. Interviews were audio-recorded, transcribed, and subjected to a directed content analysis. **Results:** Interviewees described a variety of family communication practices in response to receiving CRCP results. Those who regarded the information received as useful, either because it explained personal or family history of disease or because it suggested a lower than anticipated risk, appeared more willing and able to share results with their relatives than those who remembered their results as inconclusive or unimportant. Close relatives were informed more often than distant ones due to barriers such as infrequent contact, estrangement, or ambiguity regarding responsibility for sharing results. Interviewees described relatives responding differently to the genetic risk information received: some family members expressed worry and became proactive in passing on the information to other relatives, while other family members responded with skepticism or dismissed the information. **Conclusions:** Familial communication of CRCP-related exome sequencing results was complex and dependent on individual factors and relationships within families. In this study, the perceived utility of the test result was an important determinant of how widely and in how much detail the result was shared with family members.

## PgmNr 636: Development and testing of a pre-test genetic counseling educational tool for inherited cancer.

### Authors:

D. Cragun <sup>1</sup>; A. Tezak <sup>2</sup>; A. Weidner <sup>2</sup>; G. Wiesner <sup>2</sup>; B. Zuniga <sup>2</sup>; T. Pal <sup>2</sup>

### Affiliations:

1) Public Health, Univ South Florida, Tampa, Florida.; 2) Ingram Cancer Center, Vanderbilt, Nashville, TN

**Introduction:** National organizations recommend genetic counseling (GC) prior to testing for hereditary cancer. Yet lack of trained genetic specialists limits the ability to meet the increasing demand due to expanded test indications. GC could be streamlined with automated and scalable tools to meet this demand. We sought to develop and test a web-based educational tool to cover pre-test GC elements.

**Methods:** A 12-minute web-based educational tool ("GeneCounsel") was iteratively developed to cover the standard pre-test GC elements and tested among patients without prior counseling scheduled for a new patient appointment in the Vanderbilt Hereditary Cancer Clinic. Participants consented and completed pre- and post-tool surveys online before and after viewing the tool. The surveys assessed knowledge, attitudinal values about genetic testing, informed/empowered decision-making, and health literacy. Participants were randomly assigned to two groups, of which only Group A completed knowledge questions on the pre-tool survey to evaluate for a priming effect. Pre- and post-tool scores were compared, and group comparisons were made based on randomization and literacy level.

**Results:** 122 patients were approached for the study to achieve a sample size of 100 participants (50 per group). Participants included 77% female, 56% with a cancer diagnosis, and a mean age of 49. Group A completed the 14 knowledge questions on both the pre- and post-tool surveys, with a median number correct of 7 at baseline which significantly increased to 12 after viewing the tool ( $p < 0.001$ ). The median correct for Group B was 11 on the post-tool survey, which was not significantly different from Group A ( $p = 0.675$ ). Pre- and post-tool surveys indicated: 1) Proportions who felt informed and empowered were 32% and 77% respectively ( $p < 0.001$ ); and 2) Attitudinal values did not change significantly ( $p = 0.607$ ). Median pre-tool knowledge scores among low and high literacy groups were 4 and 8, respectively ( $p = 0.016$ ); this gap narrowed to 11 and 12 after viewing GeneCounsel ( $p = 0.214$ ).

**Conclusion:** Viewing GeneCounsel resulted in significant gains in knowledge across all literacy levels and the majority of individuals felt informed and empowered to make decisions about testing, based on accurate knowledge and would be congruent with patients' values. These findings support the potential to automate components of pre-test GC to streamline the delivery of GC and testing services for inherited cancers.

## PgmNr 637: Large scale group genetic counselling: A novel model for genetic counselling and genetic testing for hereditary cancer.

### Authors:

### Affiliations:

1) Hereditary Cancer, BC Cancer, Vancouver, BC, Canada; 2) Canada's Michael Smith Genome Sciences Centre, BC Cancer, Vancouver, BC, Canada; 3) Department of Interdisciplinary Oncology, The University of British Columbia, Vancouver, BC, Canada; 4) Department of Molecular Oncology, The University of British Columbia, Vancouver, BC, Canada; 5) Department of Medical Genetics, The University of British Columbia, Vancouver, BC, Canada; 6) Division of Medical Oncology, The University of British Columbia, Vancouver, BC, Canada

**Introduction:** Meeting the demand for hereditary cancer genetic services is increasingly challenging which has led to the development of novel service delivery models. To shorten the wait time for non-urgent patients, we piloted a large scale group genetic counselling (GC) model that offered genetic testing to unaffected individuals within a publicly funded population-based healthcare system.

**Materials and Methods:** All patients were recruited from the Hereditary Cancer Program in British Columbia, Canada and were eligible to participate if they met provincial criteria for hereditary cancer risk assessment, had no personal history of cancer, had no prior genetic testing performed in the family, and had no living testable family member residing in BC or the Yukon. Pre-test group GC (up to 50 patients per group) was compared to traditional one-on-one GC. Patients who pursued testing underwent a post-test one-on-one GC results session. Patient reported outcome measures included the Genetic Counselling Outcome Scale (T1: immediately prior to pre-test GC and T2: 4 weeks after post-test GC), a satisfaction survey (immediately after pre-test GC) and the Multidimensional Impact of Cancer Risk Assessment (4 weeks after post-test GC) for those undergoing testing.

**Results:** To date, 392 patients have been seen (190 in the group arm and 202 in the traditional one-on-one arm). Eight group sessions have been held (median group size: 26 patients). Patients in both arms showed high satisfaction with the majority of patients reporting that the appointment was helpful (98% group arm, 99% traditional arm), that they understood the information presented (99% group arm, 99% traditional arm), and that their questions were answered (82% group arm, 99% traditional arm). Of the 299 patients who have completed testing, 5.5% (N=16) had a pathogenic or likely pathogenic variant identified including: *BRCA1* (2), *BRCA2* (2), monoallelic *MUTYH* (2), *MLH1* (1), *MSH2* (1), *MSH6* (1), *PALB2* (1), *MITF* (1), *FH* (2), *BRIP1* (1), *NBN* (1), and *TSC1* (1). A small portion of patients (7%) declined participation in the group session because they preferred one-on-one GC.

**Conclusions:** Large scale group genetic counselling is feasible and acceptable to patients, and represents a new streamlined model for cancer genetic counselling.

## PgmNr 638: Is there a lack of personal and family history information in genetics referrals for evaluation of hereditary cancer risk?

### Authors:

K. Muessig<sup>1</sup>; J. Zepp<sup>1</sup>; M. Gilmore<sup>1</sup>; J. Hunter<sup>1</sup>; S. Knerr<sup>2</sup>; E. Shuster<sup>1</sup>; H. Feigelson<sup>3</sup>; K. Goddard<sup>1</sup>

1) Center for Health Research, Kaiser Permanente, Portland, OR; 2) Department of Health Services, University of Washington, Seattle, WA; 3) Institute for Health Research Kaiser Permanente Colorado, Denver, CO

---

Genetics providers are facing increasing numbers of referrals for evaluation of hereditary cancer risk. Providing detailed information about the indicators of hereditary risk, such as personal and family cancer history, can facilitate timely patient triaging for appointments. We evaluated referrals to the Kaiser Permanente Northwest (KPNW) genetics department containing diagnosis codes associated with hereditary cancer risk made between June-December 2017. Referrals were excluded if the patient was pregnant at the time of the referral or age  $\leq 17$ , or the referral did not contain personal or family history diagnosis codes for cancers associated with hereditary risk. A genetic counselor evaluated content in the medical chart, including age, notes, and diagnosis codes, to characterize referrals based on two criteria. First, the genetic counselor coded the referrals on whether they contained enough information to determine the patient's eligibility for hereditary cancer evaluation. If there was enough information, the ACMG/NSGC practice guidelines were used to determine if patients met criteria for genetic testing. Demographic and clinical characteristics were also abstracted. A total of 1047 eligible referrals were included in the analysis for 927 unique patients. The majority of patients who received a referral were female (93%), White (88%), and less than 50 years of age (50%) at the time of the referral. Thirty-nine percent had a personal history of cancer. Of those, 26% had hereditary breast or ovarian related cancer, 7% were associated with Lynch syndrome, and 6% reported other cancer types. Referred patients had been KPNW members for an average of 14 years (variance 13 years). Of eligible referrals, 68% contained enough information to determine whether or not to offer genetic evaluation; of those, 63% referrals also met ACMG/NSGC criteria for genetic counseling. Referring clinic location (metropolitan area versus outlying areas) did not affect the amount of information provided. Referring provider specialty was associated with the amount of information provided, with Oncology (68%) having the highest proportion of referrals with enough information to assess whether to offer genetic counseling. Most patient referrals to KPNW genetics for evaluation of hereditary cancer risk include enough information to determine eligibility for further evaluation, however more than a third of referring providers would benefit from additional training or support.

## PgmNr 639: A comprehensive cancer center's experiences utilizing alternative service delivery models for cancer genetic testing.

---

Genetic medicine is an integral part of cancer care. The number of individuals who qualify for genetic testing is increasing and the traditional model of pre- and post-test counseling provided by a genetic counselor (GC) or geneticist in a dedicated cancer genetics clinic is struggling to meet growing demands. Here we describe one institution's experiences implementing non-traditional models of cancer genetic service delivery.

Between 3/1/18 – 5/31/19, genetics services were integrated into 3 specialty clinics within the University of Michigan Rogel Cancer Center as follows: (1) a nurse coordinator ordered genetic testing on select patients in a multidisciplinary pancreatic (MDP) cancer clinic; (2) a GC staffed a multidisciplinary colorectal (MDCRC) cancer clinic; and (3) a GC was embedded as part of the care team in an endocrine oncology (EndoOnc) clinic. We queried the number of patients who received a genetic evaluation in each setting and evaluated factors contributing to successful genetic service delivery.

269 patients underwent genetic evaluation, including 40 in the MDP, 81 in MDCRC, and 126 in EndoOnc. The EndoOnc model was the most successful in identifying patients for genetic evaluation and in acceptance of a genetic counselor into the clinical team, in large part due to strong physician support within the clinic. Barriers to service delivery were encountered when non-genetic providers struggled to appropriately identify high risk individuals, particularly in cases where an individual's history might not meet traditional insurance guidelines but an evaluation was still indicated. This occurred most commonly in the MDP clinic, where genetic evaluation criteria are complex and multifaceted, and differences exist between guidelines for a genetic evaluation vs. insurance guidelines for genetic testing.

In conclusion, integrating genetic services into multidisciplinary cancer care clinics can help meet high demands for genetic services. Appointments can be more streamlined and eliminate the need for extra clinic space, allowing a greater number of individuals to undergo a genetic evaluation than would be possible utilizing only the traditional model of referring patients to cancer genetics. Non-traditional service delivery models are more likely to be successful when there is physician-support, the criteria for what constitutes high risk is clear, and when a genetic counselor is incorporated as an established part of the multidisciplinary care team.

## PgmNr 640: Genetic counseling experience of a large scale web-based return of *BRCA2* research results in Iceland.

### Authors:

E. Thorolfsson<sup>1</sup>; V. Stefansdottir<sup>1</sup>; H.B. Hognason<sup>1</sup>; B.B. Gunnarsdottir<sup>1</sup>; T. Jonsdottir<sup>1</sup>; A. Ulfarsdottir<sup>1</sup>; J.J. Jonsson<sup>1,2</sup>; H.T. Bjornsson<sup>1,2</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Landspítali National University Hospital, Reykjavik, Iceland; 2) Faculty of Medicine, University of Iceland

---

**Background.** Increasingly, genetic results from research are being returned to participants. deCODE Genetics, a genetic research company based in Iceland, has genotypic data from almost half of the Icelandic population (160.000 Icelanders). Almost 1% of Icelanders carry a known pathogenic *BRCA2* founder variant, NM\_000059.3:c.767\_771delCAAAT. In an effort to report an important actionable result back to the population, deCODE genetics recently (May 2018) opened the website arfgerd.is to enable Icelanders to find out their *BRCA2* founder mutation status.

**Methods.** Positive individuals were advised to contact the genetic counseling unit (GCU) at Landspítali-National University Hospital for confirmatory testing and counseling. Here we have quantified some observations from this experience. We report a one year clinical experience of the GCU from the opening of the webpage up until the end of May 2019. At the time, 46.000 individuals had signed onto the website.

**Results and discussion.** A total of 352 (average age 44 years), had received a positive result by the end of the period. Based on information from local support groups, we estimate that at least 40 of the 352 had received their results and genetic counseling prior to signing up. A total of 195 (63%) of the remaining 312 had contacted the GCU by the end of May 2019. A total of 117 (37%) had not, without there being a clear reason for their absence. Some may yet come, and others may seek information and/or surveillance in other venues (through family, online or outside Iceland). In addition, 129 relatives contacted the GCU directly after receiving news of the pathogenic variant within the family. Of the *BRCA2* positive (n=195), 74 (38%) knew about the pathogenic variant in the family prior to signing up to the website, while 121 (62%) did not. The majority were grateful for being able to access this information. A subset reported being surprised to learn the results (46, 24%), while others were expecting them (61, 31%). Some expressed their concerns with the positive results (45, 23%), while others (24, 12%) communicated that they were not concerned. The increased need for counseling and surveillance was significant, especially given the small size of the units involved at Landspítali-National University Hospital. However, given the frequency of this founder variant in Iceland, it offers a unique opportunity to study how to best deliver actionable genetic results to a large subset of a single nation.

## PgmNr 641: Patient empowerment following genetic counselling: A Patient Reported Outcome Measure (PROM) study.

---

**Background:** Measurement of patient-derived benefits from cancer genetics services (CGS) is lacking but is essential to guide service evaluation and quality improvements. We measured improvement in patient empowerment, if any, following genetic counselling in Singapore using a culturally-adapted version of the Genetic Counselling Outcome Scale (GCOS-24); with the secondary intention to identify and understand the factors associated with change in empowerment.

**Methods:** The GCOS-24 was administered to 155 patients, who attended the CGS at the National Cancer Centre Singapore (NCCS) (May 2016 - May 2017), at pre- and post-counselling or testing stages. There were 106 patients who underwent genetic testing. Individual pre- and post-counselling or testing responses were subjected to Rasch analysis; the scale was subsequently split into Cognitive Control (CC) and Emotional Control (EC) domains. Associations of baseline characteristics with changes in CC and EC scores were assessed using multiple regression analysis.

**Results:** Both CC and EC scores showed significant improvement following genetic counselling and testing. While all items in the CC domain showed increases at follow-up, aspects of EC related to alleviating feelings of being upset ( $p = 0.88$ ) and hopelessness ( $p = 0.2$ ) did not demonstrate significant improvement. Having a family history of cancer was associated with less improvement in CC ( $p = 0.035$ ) while genetic testing uptake was associated with greater improvement in CC ( $p = 0.001$ ).

**Conclusions:** We found significant improvements in empowerment following genetic counselling and testing, demonstrating the value of cancer genetic services. Interventions addressing hope and negative emotions associated with genetic conditions and testing may be warranted.

## PgmNr 642: Uptake and predictors of genetic testing in unselected pancreatic ductal adenocarcinoma.

### Authors:

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Hereditary Cancer Program, BC Cancer, Vancouver, BC, Canada; 2) BC Cancer, Division of Medical Oncology, Vancouver, BC, Canada; 3) Pancreas Centre BC, Vancouver, BC, Canada; 4) Department of Pathology & Laboratory Medicine Vancouver General Hospital, Vancouver, BC, Canada

**Objectives:** Recent guidelines recommend consideration of genetic testing (GT) for all patients with pancreatic ductal adenocarcinoma (PDAC). We implemented a familial pancreatic cancer program to offer expedited appointments (within 90 days of referral if non-urgent), flexible service models (in-person, telephone and group counselling) and research-funded genetic testing using the 30 gene Color panel for any referred PDAC patient. The aim of this study was to assess uptake of GT, identify potential barriers and suggest areas for more efficient test coordination.

**Methodology:** Retrospective chart review was approved by the BC Cancer Research Ethics Board and undertaken for all PDAC patients referred to the FPCP from June 1, 2016 to January 31, 2019. Demographics, medical/family history, disease-specific data, mode of service delivery and testing uptake were compared across the cohort to determine predictors of GT uptake. Main motivations for attending the appointment were solicited by survey. Reasons for decline of testing were reviewed.

**Results:** A total of 311 patients were referred over the 2.5 year study period (55% female, 52% European ancestry, mean age at diagnosis was 64 years (SD=11). Referrals came from oncologists (71.7%), surgeons (7.7%), GP (7.1%), other (6.8%) and patient self-referral (6.4%). Disease stage was metastatic in 42.8%. Median time from cancer diagnosis to genetics referral was 47 days (2-5809) and from referral to appointment was 55.4 days (0-244). 79% (n=247) attended a genetic counselling appointment and 63% (n=196) completed GT. Patients with earlier stage disease stage were more likely to attend an appointment (p-value <0.05). Common reasons for not having an appointment booked were deteriorating health status or death (n=31; DNA banked in 40%); patient declined (n=27) and patient could not be reached (n=6). For patients who did not complete GT, 22 passively declined by not providing a sample; 12 patients died within one month of their appointment and did not complete GT; and 17 patients actively declined testing. Factors significantly associated with GT uptake (p-value <0.05) were age at diagnosis, smoking history, geographic location and mode of service delivery.

**Conclusions:** Given the sub-optimal uptake of genetic counselling/testing in PDAC, up front DNA banking for PDAC patients at initial oncologic visit may be the most effective approach to facilitate future hereditary cancer assessment for at-risk relatives.

## PgmNr 643: *TP53* variant discordance between and within families enrolled in the NCI's Li Fraumeni syndrome study.

**Authors:**

---

**Introduction:** The use of ACMG-AMP guidelines and semiquantitative approach to clinical variant curation improved concordance and accuracy of variant classification. However, discordant variant classification persists and poses a significant challenge for medical management. We evaluated discordant variant interpretations resulting from clinical genetic testing for germline *TP53* variants in families enrolled in the NCI's Li Fraumeni Syndrome (LFS) Study.

**Methods:** *TP53* test results were obtained from >300 individuals enrolled in the NCI IRB-approved LFS study between Sept 2011 and Feb 2019. A discordant test result was defined as a report of pathogenicity that differed between two clinical testing laboratories, between a testing laboratory and the ClinVar database, or between the lab or ClinVar database and the final variant classification provided by our study after review.

**Results:** 86 unique variants were identified in 143 LFS families. 54/143 (38%) were discordant by at least one interpretation (i.e., Pathogenic/Likely Pathogenic (P/LP), or LP/Variant of Uncertain Significance (VUS), or P/VUS). 14 variants in 16 families (11%) had discordant interpretations that would lead to a difference in medical management (P or LP vs. VUS). Interfamilial discordance - i.e., unrelated families sharing the same variant but given discrepant variant classifications, was observed in 4 families (2 different variants). Intra-familial discordance was observed in 6 families, with family members carrying the same variant but receiving discordant interpretations.

**Conclusions:** Discordant variant interpretations are frequent and may lead to differences in medical management. Inter- and intra-familial *TP53* variant discordance results in a significant ethical medical challenge for clinicians of how to follow individuals with an identical variant receiving discordant variant interpretations and thus different recommendations for medical management. In the case of a *TP53* P/LP variant vs. VUS; there is a substantial difference between getting comprehensive cancer screening and potential prophylactic surgeries vs. no clinical follow-up. The scope of this problem may not be fully appreciated by providers who use only one or two genetic testing laboratories or who are unaware of discordant calls for a given variant. Centralized data sharing of genetic variants and creation of variant curation consensus guidelines are crucial for unified variant interpretation and optimal patient care.

## PgmNr 644: Cancer risk management among women with mutations in *BRCA* genes compared to other inherited breast cancer genes.

### Authors:

T. Pal; A. Weidner; A. Tezak; K. Clouse; D. Cragun

[View Session](#) [Add to Schedule](#)

---

Authors: Tuya Pal, Anne Weidner, Ann Tezak, Kate Clouse, Deborah Cragun

**Introduction:** Identification of inherited breast cancer risk through genetic testing may guide medical care. Given the expanding numbers of women identified with a pathogenic/likely pathogenic (P/LP) variant in genes other than *BRCA1* and *BRCA2* (*BRCA*), we sought to compare cancer risk management(CRM) practices between these carriers.

**Methods:** Female participants with a P/LP variant in *BRCA*, *PALB2*, *CHEK2*, or *ATM* were surveyed about CRM practices. Frequencies of CRM based on screening (i.e., mammograms and/or breast MRI, among those with at-risk breast tissue) and risk-reducing surgery (i.e., risk-reducing mastectomy (RRM) and risk-reducing salpingo-oophorectomy (RRSO)) were compiled and compared. Descriptive statistics, bivariate analyses, and non-parametric tests were performed to assess for associations.

**Results:** The 238 participants with P/LP variants were as follows: 186 *BRCA*, 28 *PALB2*, 15 *CHEK2*, and 9 *ATM*. Median age of participants was 54 and most were non-Hispanic white (89%) with a prior cancer diagnosis (59%). Rates of RRM (defined as at least one breast removed prophylactically regardless of a prior breast cancer diagnosis) was 65.1% among *BRCA* carriers, with lower rates among *PALB2*, *CHEK2*, and *ATM* carriers (32.1%, 33.3%, and 33.3%, respectively). Rates of RRSO were appropriately higher among *BRCA* carriers (89.8%), but were also relatively common among *PALB2*, *CHEK2*, and *ATM* carriers (32.1%, 33.3%, and 66.7%). Among those with at-risk breast tissue, most had screening for breast cancer through mammogram and/or MRI. No significant differences were found between *BRCA* carriers vs. others in terms of insurance, employment, income, house size, education, race/ethnicity, cancer status, and/or involvement of a genetic healthcare provider (all  $p>0.05$ ).

**Conclusion:** Our results suggest that adherence to CRM for *BRCA* carriers is appropriately high. However, RRM among those with *PALB2*, *CHEK2*, and *ATM* P/LP variants are also frequently observed, despite the lack of practice guidelines to recommend RRM. Even more concerning are the appreciable RRSO rates in the absence of practice guidelines or data to confirm high ovarian cancer risk. Our data suggests that many patients with P/LP variants in genes other than *BRCA* receive surgeries for which guidelines are lacking. These efforts highlight the tremendous need to promote risk appropriate care and reduce over-treatment among these individuals.

---

**Background:** Genomic sequencing (GS) can inform diagnosis and management of hereditary conditions, such as hereditary cancer syndromes, and can also identify genetic predisposition for additional diseases (secondary findings or incidental results, IR). There is substantial uncertainty about when or if diseases associated with IR will occur, as well as if and how IR should be sought, reported, and managed. Patients may therefore experience uncertainty when making decisions about learning IR.

**Aim:** To explore how adults with cancer perceive, appraise and manage uncertainty when deciding whether or not to learn IR.

**Methods:** This was a qualitative, interpretive description study among adults receiving GS through an ongoing RCT. Participants selected IR from five categories: 1) medically actionable diseases, 2) common disease SNPs, 3) rare Mendelian diseases, 4) early-onset neurological diseases, and 5) carrier status. Semi-structured interviews were conducted with participants after selecting but before receiving IR. Transcripts were analyzed thematically using constant comparison.

**Results:** Fifteen participants were interviewed (12/15 women, on average 56 years old). All participants chose multiple categories of IR; 9/15 chose all IR. Participants' uncertainty related to their cancer (e.g. uncertainty about why they had cancer, their prognosis, family members' risks) was pervasive, "a grey cloud hanging over my head." Experiences with cancer uncertainty helped participants accept uncertainty related to IR (e.g. that results are "not 100%" or "nebulous"), despite generally disliking uncertainty. Participants viewed IR as valuable information, even though the information could be uncertain. Cancer experiences heightened the perceived value of learning IR, as IR may allow them to prepare for or prevent other diseases. Participants were fairly confident in their

ability to “deal with” IR-related uncertainty, in part because of their experiences managing cancer-related uncertainty. Participants anticipated managing IR-related uncertainty in a variety of ways, such as through information seeking, support from healthcare providers, or trying not to focus on uncertainty.

**Conclusions:** Cancer experiences fostered participants’ tolerance of uncertainty related to IR, and heightened the perceived value of IR. Genetic counseling for IR could involve exploration of patients’ attitudes toward uncertainty, and consideration of how illness experience may shape expectations for IR.

## PgmNr 646: The policy implications of the cancer genomics in Japan.

### Authors:

---

The purpose of this paper is to review the impact of the current policy change on cancer genomics in Japan. In 2017, the Ministry of Health, Labour and Welfare (MHLW) convened a Roundtable Consortium on the Promotion of Cancer Genomic Medicine. In addition to providing Japanese citizens with early access to the world's leading-edge cancer genomic medicines under the national health insurance system, the consortium clarified ownership of the constructed framework as an asset of Japanese citizens and set directions for the functions and roles of medical institutions providing cancer genomic medicine, and institutions that aggregate, manage and promote the use of cancer genomic medicine (Report, June 27, 2017). In February 2018, the Japanese government designated 11 hospitals throughout Japan to serve as core hospitals for cancer genomic medicine. The government also appointed 156 facilities as liaison hospitals to work with the core hospitals. The MHLW approved the marketing of two cancer genome profiling systems in December 2018 - OncoGuide™ developed by the National Cancer Center of Japan and health instrument-maker Sysmex Corp., and FoundationOne® CDx sold by Chugai Pharmaceutical Co. The MHLW decided that these tests would be covered by the public health insurance system after June 2019. While the fee for these products would be ¥560,000 (USD 5,100), patients will have to pay 10 to 30 percent of the total fees. The MHLW will also ask the hospitals to submit the anonymized data of the genomic profiling to the Cancer Genome Information Repository, after obtaining patients' consent. The accumulated information is expected to be utilized for the development of new treatments. Insurance coverage will be applied to patients with solid tumor who have not responded to conventional therapy, which is expected that up to 26,000 people will use annually. The secondary findings of hereditary cancers will be disclosed to patients who gave consent to know. However, we have no law to regulate genetic discrimination. The Life Insurance Association has been considering the guidelines about notification when making an insurance contract. Furthermore, we have no roundtable to discuss employment issues. It is an urgent issue to respond toward concerns about genetic discrimination.

## PgmNr 647: Pre-emptive hereditary cancer genetic testing in primary care: Leveraging early program data for process improvement.

---

Primary care physicians (PCPs) are in a unique position to present pre-emptive genetic testing to patients, yet little is known about the service delivery and outcomes in this setting. To assess interest, system feasibility, and patient outcomes, as part of a learning health care system initiative, complimentary hereditary cancer genetic testing (30-gene next generation sequencing-based panel) was offered through 4 primary care sites during a patient's annual exam. Of the patients who read the test offer message in their healthcare portal prior to their appointment, 39% agreed to undergo testing through their PCP. A total of 1006 patients had testing in November and December of 2018. Systematic chart review and descriptive data analysis revealed that patients who had testing were primarily non-Hispanic (95.5%), Caucasian (64.5%), and female (67.2%), with ages ranging from 18-78 (median age 49). Ninety-two pathogenic variants were identified in 90 (9.1%) patients, in 16 genes: *MUTYH*, *CHEK2*, *APC*, *BRCA2*, *BRCA1*, *ATM*, *BARD1*, *MITF*, *BRIP1*, *NBN*, *PALB2*, *PMS2*, *RAD51C*, *MSH6*, *CDH1*, and *CDKN2A*. Of the 90 positive patients, 38 (42%) received 41 referrals to specialty clinics; 21 (51%) completed their referrals as of May 2019. Eighteen (20%) had 1 or more cancer screening tests recommended (32 tests), and 14 (78%) completed at least one screening test. One case of occult disease was detected on mammogram in a *BRCA1* positive patient. To elicit patient feedback, a focus group was conducted. This subset of patients reported satisfaction with the cancer genetic testing through their PCP, benefits from learning both positive and negative results, practice workflow issues, and a need for more pre- and -post test education. The study data has informed service delivery improvements in a subsequent larger pre-emptive genetic testing program in primary care: a coordinated care center has been initiated to assist in patient follow through with medical referrals and recommendations; additional multi-modal educational resources are provided to patients and PCPs at various points throughout the testing process; a PCP advisory group was developed to provide programmatic input; and mechanisms were created to provide continual clinical and operational feedback to providers. Our findings highlight the importance of early systematic appraisal and opportunity for changes throughout the pre-emptive genetic testing process to improve service delivery and patient care.

## PgmNr 648: What factors influence completing cancer genetic testing in a population screening study using a medical model? Preliminary data from the BRCA Founder Outreach (BFOR) study.

**Background:** In order to develop and evaluate a feasible approach to population-based genetic screening, the BRCA Founder Outreach (BFOR) study offers online education, study enrollment, and consent to *BRCA1/2* founder mutation testing to individuals of Ashkenazi Jewish descent in 4 US cities. Participants then visit a local lab facility to have blood drawn for no-cost *BRCA1/2* testing, with results review and management by their primary care providers or genetics specialists. To better understand testing barriers, we sought to determine what characteristics distinguish those individuals enrolling in the study who ultimately complete genetic testing from those who do not.

**Method:** During online study enrollment (Bforstudy.com), participants answered survey items about demographic (gender, age, location, parental status), medical (has a primary care provider, personal cancer history, family cancer history, known familial *BRCA1/2* mutation, personal genetic testing experience), and psychological (perceived cancer risk, cancer-specific distress, general anxiety, knowledge about *BRCA1/2* testing) characteristics. Data were collected on whether each participant did or did not obtain *BRCA1/2* testing by up to 6 months after enrollment. We conducted univariate analyses followed by multivariable logistic regression to evaluate which characteristics were associated with *BRCA1/2* test completion.

**Results:** From March 2018 through November 2018, 2363 participants enrolled in the BFOR study (79% female; 6.7% <30 years old, 40.6% 30-50 years, 52.6% >50 years; 12.2% personal cancer history). Of these, 2085 (88.2%) had blood drawn and completed *BRCA1/2* testing, while 278 (11.8%) did not obtain testing within 6 months of enrollment. In multivariable regression, factors associated with greater odds of test completion included having a personal cancer history (OR=2.73, 95%CI=1.57-4.74) and having children (OR=1.42, 95%CI=1.09-1.87). No other demographic, medical, or psychological factors were significantly associated with test completion.

**Conclusion:** A minority of those enrolling in a population screening study ultimately decide against *BRCA1/2* genetic testing. Limited demographic and medical variables are associated with completing genetic testing in this context. Novel strategies may be needed to better engage individuals without

the motivators of a personal cancer history or potentially at-risk children. Ongoing data collection and a second study phase will address these issues.

## PgmNr 649: Achieving equity in genomic services for hereditary cancer syndromes.

---

**Background:** Lynch syndrome (LS) and hereditary breast and ovarian cancer (HBOC) are the two most common hereditary cancer syndromes. While more patients are accessing genetic testing than ever before, rates of testing for and diagnosis of LS and HBOC remain low, and patients who are racial/ethnic minorities and/or low-SES (hereafter referred to as underserved) are even less likely to have access to this testing. The Cancer Health Assessments Reaching Many (CHARM) study, part of the Clinical Sequencing Evidence-generating Research (CSER) consortium funded by NHGRI, is studying methods to increase access to genetic testing for hereditary cancer syndromes in primary care for underserved patients.

**Methods:** English and Spanish speaking patients at Kaiser Permanente Northwest, an integrated delivery system in Portland, OR, and Denver Health, an integrated federally qualified health system in Denver, CO, are contacted via email, text message, postcard, and/or phone calls to complete an online cancer family history risk assessment. Those that screen at higher risk or have limited family history knowledge are offered clinical exome sequencing for 39 genes related to hereditary cancer risk and 92 genes related to medically actionable or carrier findings. Participants receive post-test genetic counseling.

**Results:** To date, we have invited ~6500 patients (56% underserved) to complete the risk assessment; 12% of underserved and 9% of non-underserved completed it. Among patients who completed the risk assessment, 82% underserved and 74% non-underserved were eligible. A similar percentage of underserved and non-underserved joined the study (80% vs. 79%). In total, 67% of 402 participants are underserved - 31% racial or ethnic minority, 40% low-SES, and 29% meet both of those criteria. Of the first 220 results reported, 16% had a positive cancer finding, 1% had a positive non-cancer medically actionable secondary finding and 16% had a carrier status finding.

**Conclusion:** At every step in the process, we have been successful at recruiting and enrolling underserved patients. The implementation of an online family history tool in the primary care setting

may be an effective and scalable approach to increase access to genetic testing for underserved populations.

## PgmNr 650: Development and early implementation of a hereditary cancer risk assessment program in a diverse patient population.

---

**Introduction:** Lynch syndrome and hereditary breast and ovarian cancer are the most common hereditary cancer syndromes (HCS); each confers increased risk of multiple types of cancer. Selective screening to identify patients at risk for HCS prior to cancer onset requires in-depth family health history, which is often not collected, contains insufficient detail, or is not acted on by providers – these barriers disproportionately affect underserved populations. To address this care gap, we created a low-literacy, patient-facing HCS risk assessment tool.

**Methods:** We adapted two validated risk assessment algorithms - the Breast Cancer Genetics Referral Screening Tool (B-RST™ 3.0) and Prediction Model for gene Mutations (PREMM<sub>5</sub>), and developed a unique family knowledge screening module. Working iteratively with experts and patient stakeholders, we combined these three assessments into a low-literacy interactive electronic application. We recruited patients of two large health care systems to complete the tool; interactions with the tool were tracked and evaluated.

**Results:** We made two major modifications to the PREMM<sub>5</sub>: asking patients to complete family history, rather than to select an affected side, and reducing complex terms and computation (e.g. “*first degree* relatives”). B-RST™ 3.0 was adapted to present questions individually rather than in a table, to reduce graphicacy and numeracy demands. The entire tool includes pop-up literacy aids such as infographics and definitions.

A total of 688 individuals began the tool; 55% met study criteria for underserved populations (racial/ethnic minority and/or low SES). Only 6% of individuals (26% underserved) who began the tool did not complete it. Most (86%) incomplete interactions lasted under 5 minutes. Most people completed the tool without assistance (93%) spending a mean of 4.2 minutes (range: 0.4-53) doing so. Time spent was similar between underserved individuals (mean: 4.0 min, range: 0.4-24.1) and those who were not underserved (mean: 4.4 min; range: 0.4-53). Completion times for PREMM<sub>5</sub>, B-RST™, and the limited history assessment modules were 2.4 minutes (range: 0.3-49), 1.7 minutes (range: 0.4-39), and 1.5 minutes (range: 0.4-8.6), respectively.

**Conclusions:** Most patients quickly self-completed this risk assessment for HCS. Using a patient-facing

tool ensures standardized assessment and provides clear 'results' (high/low risk), which may facilitate appropriate referrals for genetics services.

---

Genetic testing through multi-gene cancer panels is widely available and has become an integral part of the genetic counselling and oncologic practice that is used to inform clinical management options. *RAD51C* and *RAD51D* are included on most cancer panels due the reported associations of predicted pathogenic variants (PPVs) in these genes with ovarian cancer. However, the available ovarian cancer relative risk (RR) estimates vary widely, are imprecise and the associations of *RAD51C/D* PPVs with breast cancer risk remain uncertain.

We used pooled data on 154 families with PPVs in *RAD51C* and 65 families with PPVs in *RAD51D*, ascertained through gene sequencing in 29 population- and family-based studies. Complex segregation analysis was used to estimate age-specific RRs and absolute risks of ovarian and breast cancer. We fitted genetic models to the cancer inheritance patterns in families, while adjusting for the mode of ascertainment for each family. The models allowed for the residual familial aggregation of both ovarian and breast cancer.

PPVs in both *RAD51C* and *RAD51D* were associated with ovarian cancer (*RAD51C* RR=8.29, 95% CI: 6.17-11.14,  $p=1.2\times 10^{-44}$ ; *RAD51D* RR=8.17, 95% CI: 6.00-11.12,  $p=1.2\times 10^{-40}$ ) and breast cancer (*RAD51C* RR=1.99, 95% CI: 1.39-2.85,  $p=1.9\times 10^{-4}$ ; *RAD51D* RR=1.93, 95% CI: 1.30-2.86,  $p=1.0\times 10^{-3}$ ). There was evidence that the ovarian cancer RRs were higher at ages 50 years or older for both *RAD51C* (RR=10.69, 95% CI: 7.55-15.14 for ages 50 or over versus RR=5.10, 95% CI: 2.83-9.20 for ages under 50) and *RAD51D* carriers (RR=11.52, 95% CI: 8.11-16.36 for ages 50 or over versus RR=3.45, 95% CI: 1.47-8.11 for ages under 50). There was a suggestion for higher breast cancer RRs at younger ages for both *RAD51C* and *RAD51D* PPV carriers, but these models did not fit significantly better than models with a constant RR. There was significant evidence that both ovarian and breast cancer risks for *RAD51C/D* PPV carriers vary by family history of the diseases. The estimated absolute risks of developing ovarian cancer by 80, based on the age-specific RR models, were 15% (95% CI: 11-21%) for *RAD51C* and 16% (95%CI: 12-22%) for *RAD51D* PPV carriers. The corresponding breast cancer risk was 21% (95% CI: 15-29%) for *RAD51C* and 20% (95%CI: 14-29%) for *RAD51D* PPV carriers.

These estimates will facilitate the genetic counselling of *RAD51C* and *RAD51D* PPV carriers and will inform the incorporation of *RAD51C* and *RAD51D* into cancer risk prediction models.

## PgmNr 652: Clinical implementation of Face2Gene facial photograph analysis in an adult, non-syndromic, cardiovascular genetic disease population.

### Authors:

E. Jordan; A. Morales; C. Hausfeld; R. Hershberger

[View Session](#) [Add to Schedule](#)

**Affiliation:** 0339 Biomedical Research Tower, 460 West 12th Avenue, Columbus, OH 43210, 0339 Biomedical Research Tower, 460 West 12th Avenue, Columbus, OH 43210, Columbus, Ohio.

---

Face2Gene (F2G) is a phenotyping application that uses facial analysis and a deep-learning network to identify patterns across hundreds of conditions to aid in diagnosis of genetic disease. From data extrapolated from facial photograph measurements and clinical features, F2G suggests differential genetic diagnoses. F2G has demonstrated most significant utility in syndromic, often pediatric, conditions with known or suspected dysmorphic gestalts. To our knowledge, F2G use in adult, primarily non-syndromic cardiovascular (CV) disease has not been published. The Ohio State University (OSU) CV genetics program has implemented F2G into clinical care in two outpatient clinics staffed by genetic counselors (GCs) and cardiologists. Of 331 patients seen over 17 months, 208 (63%) provided consent. Nine probands also had family members participate (N=13), therefore 94% of participants are unrelated. Photographs were obtained and securely stored in the F2G iPad app as a part of clinical workflow. Age, height, weight, ancestry and phenotypic features were collected by GCs and uploaded to F2G by a student assistant including: cardiomyopathy (CM) (40%), arrhythmia (13%), dyslipidemia (13%), aortopathies (8%), valve and vascular disease (5%), muscular and/or skeletal abnormalities (4%), other CV disease (12%), and other various features (5%). Of those with CM (N=153), 39% have hypertrophic CM, 33% have dilated CM, 9% have other CMs, and 19% have CM-related features. Due to limited sample size, statistical comparisons of gestalts for individual phenotypes were uninformative. CV genetic testing panels ordered often include some genes with syndromic associations. When variants are identified in syndromic genes, F2G is consulted. In addition, F2G suggested additional diagnoses in some cases that supported referral to additional genetics clinics. Based on 63% of patients opting to consent for the use of F2G, our experience supports the feasibility of F2G implementation in a largely adult, non-syndromic, CV genetic clinic setting. Further, associating genotype data with CV phenotypes and F2G photograph analysis has the potential to define previously undescribed gestalts, identify subclinical phenotypes, and serve as an interpretation tool in assessment of genetic variants. As the F2G system matures and additional CV phenotypes are collected within the F2G database, opportunities to conduct additional research and broaden the scope of F2G in new disease categories will present.

## PgmNr 653: *TNNI3* gene mutation as a cause of cardiomyopathy among Iranian patients.

---

**Introduction:** Cardiomyopathy is common cause of cardiac death that is categorized to different types including HCM, DCM, LVNC and RCM. Over 20 genes detected to cause HCM; most of them are responsible to code sarcomeric proteins. More than 40 genes encoding cytoskeletal sarcomeric proteins, Z-disc have been described to cause familial DCM. The genetics of RCM is similar to HCM and sometimes this overlapping cause mixed HCM/DCM phenotype. Here, we study *TNNI3* mutations among Iranian patients with cardiomyopathy.

**Materials and Methods:** Total number of 30 patients affected with HCM, DCM and RCM were recruited in this study. Clinical data and EKG information were documented. All exons and introns of *TNNI3* gene were amplified and sequenced. Insilico analyses were applied for detection of novel variants.

**Results:** From the total number of 30, 13 patients were selected with dilated cardiomyopathy, 13 hypertrophic cardiomyopathies and 4 restrictive cardiomyopathies. After insilico analysis, two pathogenic variants were observed. Both were categorized as disease causing in Mutation taster (Free web-based application) and CADD score were calculated 38 and 12.60(CADD mutation version 1.4).

**Discussion:** *TNNI3* gene has been examined for the first time in a group of Iranian population in this study. Based on the Obtained information, *TNNI3* probably plays an important role in the incidence of cardiomyopathy. Few patients were recruited in this study; therefore, it is suggested that this study may be carry out on large populations.

---

**Objective:** Health technology assessment calls for careful consideration of patient and societal values. In the context of genetic testing, existing research has demonstrated that personal and societal values influence how individuals and families orient and respond to tests on offer. Data that reflect on these values in the context of whole genome sequencing (WGS) and secondary variants (SVs) are only beginning to emerge. The objective of this study is to understand how personal, familial, and societal factors influence parents' decision to pursue WGS for their child.

**Methods:** Embedded in the Ted Rogers' Cardiac Genome Clinic (CGC) at the Hospital for Sick Children (Toronto, ON), parents of children with congenital heart disease who are offered WGS were eligible to participate. Prior to the receipt of WGS results, telephone-based semi-structured interviews explored personal, familial, and societal factors that influenced parents' decisions regarding WGS and the receipt of secondary variants. Interviews are audio-recorded and transcribed verbatim. Guided by the PEN-3 model that orients to the concept of culture in a multi-dimensional way, deductive and inductive coding identified core themes.

**Results:** We conducted 20 interviews with parents who were predominately healthy, English-speaking mothers of children with congenital heart defects or cardiomyopathies. During decision-making, parents value control and see primary and secondary variants as means to achieve control over their family's health and psychosocial aspects of their child's cardiac status. Parents' interest in WGS variants appears to be driven by their sense of responsibility to their child and their family. They express a moral obligation to seek out this information, no matter the emotional burden. For some, decisions to receive medically actionable secondary variants were value-laden and deliberated, while for others, decisions appeared to be value-neutral and somewhat automatic.

**Conclusion:** Findings from this study shed light on the acceptability of the technology from parents' perspectives and may inform education and counseling strategies.

## PgmNr 655: Genetic testing for stroke: Implications for sustainable interventions towards stroke prevention in West Africa.

### Authors:

---

**Background:** It is crucial to assess stroke literacy as well as practices related to genetic testing for stroke among Africans in preparation for the ethical, legal and societal implications of the genetic revolution which has begun in Africa.

**Objective:** To assess the knowledge and practices of West Africans about stroke and genetic testing.

**Methods:** A comparative cross-sectional study was conducted among stroke patients and stroke-free controls recruited across 15 sites in Ghana and Nigeria under the SIREN study. Participants' knowledge of heritability of stroke, willingness to undergo genetic testing and methods of disclosing genetic test results were assessed using interviewer-administered questionnaire. Descriptive, frequency distribution and multiple regression analyses were performed.

**Results:** Only 49% of 2,029 stroke patients and 57% of 2,603 stroke-free individuals knew that stroke was a heritable disorder. Among those who knew, 90% were willing to undergo genetic testing. Knowledge of stroke heritability was associated with having at least post-secondary education (OR 1.51, 1.25-1.81) and a family history of stroke (OR 1.20, 1.03-1.39) while Islamic religion (OR=0.82, CI: 0.72-0.94), being currently unmarried (OR = 0.81, CI: 0.70-0.92), and alcohol use (OR = 0.78, CI: 0.67-0.91) were associated with lower odds of awareness of stroke as a heritable disorder. Willingness to undergo genetic testing for stroke was greater among respondents aged >45 years (78%) and married (73%) and was associated with having a family history of stroke (OR 1.34, 1.03-1.74) but inversely associated with a medical history of high blood pressure (OR = 0.79, 0.65-0.96). Only (40%, 17% & 14%) of stroke patients and (60%, 12% & 2.4%) of stroke-free individuals prefer to have their genetic test results disclosed to them in person, through telephone call and in the presence or through a family member respectively. Disclosure of genetic test results was significant (Fishers test<0.001) with age, educational and marital status of respondents.

**Conclusion:** Findings from the study shows that knowledge of stroke as a heritable disorder is sub-optimal. To further improve stroke knowledge, willingness to embrace genetic testing for and

prevention of stroke, there is need to target not just individuals with less formal education, history of high blood pressure, no family history of stroke but the wider population with contextually-driven, culturally-sensitive interventions.

## PgmNr 656: Newborn genomic screening for hypertrophic cardiomyopathy: Penetrance estimates from the PreEMPT model.

### Authors:

K.D. Christensen <sup>1,2</sup>; M. Gooch <sup>3</sup>; P.M. McMahon <sup>3</sup>; N.K. Stout <sup>2,3</sup>; J.M. Yeh <sup>2,4</sup>; A.C. Wu <sup>2,3</sup>

---

### Purpose

Genomic screening can identify genetic risk factors in asymptomatic individuals, but few studies have projected whether the health benefits justify the financial costs and harms. We developed a simulation model to project the impact of genomic screening for conditions such as hypertrophic cardiomyopathy (HCM), where identification of disease-causing variants may inform screening and lifestyle recommendations and reduce sudden cardiac deaths. Here, we summarize preliminary model estimates of the number of newborns that would be identified with HCM variants and the associated penetrance through age 20.

### Methods

The Precision Medicine Policy and Treatment (PreEMPT) Model is a simulation model of population-based newborn genomic screening. The model integrates data from various sources to inform model inputs, including disease incidence, pathologic variant frequencies, and the proportion of affected individuals with pathogenic variants. Outputs include cumulative disease incidence and penetrance. We targeted genes associated with HCM based on gene-disease associations classified as definitive by a ClinGen Gene Curation Expert Panel. Variants were included if they were classified as likely pathogenic or pathogenic in ClinVar with a 2-star rating.

### Results

In a simulated cohort of 4 million newborns representative of an annual US birth cohort, we estimated that screening would identify 6,787 (95%UI: 6,197-7,296) newborns with genetic risk factors for HCM, and that 93 (95%UI: 56-164) of them would develop HCM by age 20 (estimated penetrance=1.4%, 95%UI: 0.9%-2.2%). Ongoing work incorporates benefits and risks that include early detection of disease, use of implantable cardioverter defibrillators, and reductions in sudden cardiac death. Sensitivity analyses will consider the impact of different reporting criteria and the likelihood that future applications may incorporate a greater number of genes and variants.

### Conclusion

The PreEMPT Model provides an innovative example of a model that simulates the impact of newborn genomic sequencing. Challenges in developing the model included deciding which genes and variants to target, estimating penetrance, and deciding what benefits and harms to include. Future results from the PreEMPT Model will provide insight about the cost-effectiveness of newborn genomic

screening not only for HCM alone, but in combination with newborn genomic screening for pediatric cancers, long QT syndrome, and other childhood-onset conditions.

## PgmNr 657: A 5-year retrospective study of individuals with phenylketonuria (PKU) treated at two specialized U.S. clinics.

HMI-100-001 is a retrospective chart review of patients with a diagnosis of PKU due to Phenylalanine hydroxylase (PAH) deficiency using records spanning a 5-year period ending in November 2017 to capture real-world data associated with managing PKU under current standard of care.

PAH deficiency is an inborn error of metabolism due to mutations in the *PAH* gene, resulting in phenylketonuria (PKU). The mutations lead to absent or deficient *PAH* enzyme which converts Phe to tyrosine (Tyr), a precursor to multiple biologically important downstream neurotransmitters. Phenotypes range from mild HPA (Phe 120-360  $\mu\text{mol/L}$ ) to classical PKU (Phe over 1200  $\mu\text{mol/L}$ ). With the advent of newborn screening in 1963, managing the disease by low Phe diet in infants before clinical symptoms appear became the standard of care. Untreated PKU in children results in progressive irreversible neurological impairment. Current treatments do not address the underlying genetic defect.

The study was conducted at two U.S. clinics, a total of 152 patients (10-40 years old) were enrolled (65.8% with classical PKU). Data were collected from electronic medical records from baseline to -5 years (+/- 3 months) and characterized demographics, medical history, treatments and blood Phe. The number of patients with consecutive lab values decreased as the Phe threshold was lowered (Phe below 600, 360, 120 and 30  $\mu\text{mol/L}$ ). The data demonstrated decreased Phe control with age; mean Phe  $\pm$  standard error for patients 10-18 and over 18-40 was  $456.8 \pm 27.0$  and  $694.7 \pm 36.7$   $\mu\text{mol/L}$  respectively. 62.5% of patients were reported as having a history of at least one neuropsychiatric comorbidity, and adults were more likely than adolescents (69.5% vs. 54.3%). 90 of 98 *PAH* genotypes collected were distinct mutations; the 6 null-null genotypes were associated with classical PKU. Despite use of protein restriction, Phe concentrations over 360  $\mu\text{mol/L}$  were observed, particularly in classical PKU patients. Overall the demographics and clinical data were consistent across both sites.

These real-world data show that Phe levels were elevated, even when patients were on a Phe-restricted diet, and mostly above 360  $\mu\text{mol/L}$  (considered well-controlled based on current U.S. treatment guidelines). There remains an unmet need for therapies to control Phe concentrations without a Phe-restricted diet. As an autosomal recessive, monogenic defect, PKU due to PAH deficiency is a suitable condition for potential AAV-based gene therapy.

## PgmNr 658: A familial investigation of recurrent Osteogenesis Imperfecta (OI) over three decades.

OI is a spectrum of bone genetic condition with variable severity. Before the advances of genomic, diagnostic was made via imaging and clinical examination. Then, biochemical analyses allowed further characterisation of physiopathology using protein electrophoresis. Today, OI is known to be genetically heterogeneous and is diagnosed by molecular sequencing. Although its inheritance is mainly autosomal dominant *de novo*, some autosomal recessive inheritance has been described, and recurrent diagnoses of autosomal dominant OI has been reported as well *via* the mechanism of germline mosaicism.

We present a case of recurrence of a lethal form of OI in siblings where 3 successive pregnancies were affected between 1977 and 1982. The first affected pregnancy was misdiagnosed as phocomelia, and low recurrence risk was given. The second pregnancy was properly diagnosed as affected with OI thanks to radiography imaging. The third affected pregnancy displayed abnormal skeletal ultrasonographic findings and the couple took the decision to have termination of the pregnancy. Autosomal recessive inheritance was mentioned to the couple, with a 25% recurrence risk. In 2017, a non-affected daughter of this couple is seen in Prenatal Genetics for her first pregnancy for which she would like be reassured regarding the risk of OI. In the medical chart of her mother, we discovered a result of biochemical analysis from 1986 using parental fibroblast and a sample from amniocentesis performed on the last affected pregnancy, leaning toward an autosomal dominant form of the condition from the electrophoresis pattern obtained. Surprisingly, a sample of DNA from the last affected pregnancy was stored since 1982. We wanted to be able to identify the causal mutation of recurrence of OI in this family, in order to offer proper genetic counselling to our patient. The foetal sample from 1982, sent for a molecular panel of genes associated to OI, revealed the heterozygous pathogenic novel mutation **COL1A1 (c.2336G>A)**.

This result confirmed the diagnostic of OI in its dominant form, and validated the explanation of germline mosaicism as the more likely to cause the familial recurrence. Thanks to the rise of genomic technologies, and the storage of biological material for more than 30 years, we resolved the uncertainty of a mother with a delicate reproductive past while reassuring her daughter, whom the recurrence risk of OI for all her pregnancies would be similar to general population.

## PgmNr 659: Role of genomic literacy in reducing the burden of common genetic diseases in Africa.

**Authors:**

G. Mboowa; I. Sserwadda

[View Session](#) [Add to Schedule](#)

**Affiliation:** Immunology and Molecular Biology, Makerere University, Kampala, Uganda

---

**Background:** In Africa, health practitioners and the public's current knowledge of genetics and genomics is still very low and yet this has potential to reduce the burden of common genetic diseases. Many initiatives have promoted genomic research, infrastructure, and capacity building in Africa. Now building on the critical mass of genomics achievements and collaborative projects already furnished on the continent through the H3Africa Initiative, African scientists are poised to move these initiatives to the next level while ensuring long-term sustainability by lobbying for funds from their governments and beyond. What remains to be done is to improve genomics literacy among populations and communities while utilizing an array of strategies. Genomic literacy and awareness are key in the formulating genomics related policies, genomics research and more importantly in the management of genetic diseases which includes diagnosis, prevention of complications and therapy. Africa is characterized by great cultural and language diversity thereby requiring a multidisciplinary approach to improving public and community genomic literacy and engagement. However, this is further complicated by having the fact that sub-Saharan Africa is comprised of countries with the lowest literacy rates in the world.

**Methods:** We applied the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines to review genomic literacy in Africa using PubMed database.

**Results:** We found very limited evidence of genomic literacy for genetic diseases in Africa.

**Conclusion:** We propose a number of approaches that if embraced will significantly increase the genomic literacy and reduce the burden of genetic diseases in Africa namely; genomic counselling, revision of medical curricula, introduce genetics & genomics new graduate programs, genomics workshops & fellowships for healthcare workers, and community outreach programs delivered through a wide range of platforms.

## **PgmNr 660: Genetic analysis of children and adolescents living in Korean orphanage with behavior problems or developmental delay using chromosomal microarray and clinical exome sequencing.**

### **Authors:**

J. Kim; J. Cho; H. Kim

[View Session](#)
[Add to Schedule](#)

**Affiliation:** Department of Genetic Counseling Clinic, Konyang University Hospital, Daejeon, Korea

### **Purpose**

The aim of this study is to investigate genetic cause of developmental delay or behavior problems of residents of orphanage.

### **Methods**

Total 12 patients were referred to genetic counseling department of Konyang University Hospital from Korean orphanage facilities due to unexplained developmental delay or behavior problem (autism spectrum disorder (ASD) or violence) at between July 2017 and May 2019.

### **Results**

Mean age was  $13.8 \pm 5.7$  yrs (3-24 aged). Six patients were males. Six patients were females. All patients underwent chromosomal microarray (CMA). Seven patients had no abnormality in CMA. Seven variants from five patients were detected. Five variants were classified as benign CNV. Two pathogenic variants from two patients were 19p13.3 duplication and 16p14.11 duplication. Five of twelve patients were undertaken clinical exome sequencing (CES). Five variants from four patients were detected. One patient has no abnormality. Two variants were likely pathogenic variants. Three variants were variants of unknown significance (VUS). We could not co-segregation analysis because parents were not available for testing. Considering patients phenotype, we concluded that following gene variants were possible cause of their problems. Gene variant that founded are as follows: NPHP4, CD96 gene mutation (Nephronophthisis type 4, Opitz-Trigonocephaly syndrome), DNMT1 gene mutation (Autosomal dominant cerebellar ataxia, deafness, and narcolepsy), SRCAP gene mutation (Floating-harbor syndrome), RANBP gene mutation (Infection-induced encephalopathy 3).

Six patients among twelve patients were non-diagnostic.

### **Conclusion**

Total twelve patients with developmental delay and behavior problem including ASD were referred from the orphanage and was investigated for further diagnosis with CMA and CES. Diagnostic yield rate was 50% (six of total twelve patients). Genetic counseling was provided to caregivers for the understanding of biologic cause of their abnormal behaviors. Accurate genetic diagnosis enabled us to provide genetic counseling to caregivers of orphanage for better understanding of their problems and better care and management of them.

## PgmNr 661: Wolf-Hirschhorn syndrome: Natural history into adulthood, a preliminary study of 27 individuals.

### Authors:

J.C.. Carey <sup>1</sup>; A. Lortz <sup>2</sup>; A. Battaglia <sup>3</sup>

---

Information on long-term outcome in Wolf-Hirschhorn syndrome (WHS) is very limited. Only five adult WHS are described in the medical literature, with age range between 24 and 37 years. We recruited 30 WHS individuals (22 females; 8 males), aged between 27ys and 54ys. 18 were personally observed at the Stella Maris Clinical Research Institute by A.B., and followed up between 5 and 20 years; and 12 were recruited from the 4p- Support Group-USA (9/12 had enough medical information to be included in the study); thus we are reporting on these 27. All are described as being happy, friendly, outgoing adults, liking to be around family and friends.

17/27 are close to requiring total care with assisted needs in feeding, diapering, bathing, dressing/undressing, and when walking needing assistance on uneven ground or transitioning from carpet to tile. 9/27 are partly self-independent, being able to feed and dress themselves, but needing supervision and some assistance with personal hygiene, and, at times, with walking on uneven ground. 1/27 is fully independent. All had variable degrees of developmental disabilities with a moderate-severe cognitive deficit. 18/27 enjoy good health, whereas 1/27 has diabetes type II, diagnosed at age 13; 1/27 has Raynaud disease, diagnosed at age 18; 1/27 had esophagitis at age 19; and 6/27 were diagnosed with hepatic neoplasms. All but one are seizures free. All are enrolled in a personalized rehabilitation program. Additionally we are collaborating with the CoRDS Registry at Sanford Research, South Dakota who have created a patient-reported database of information on individuals with rare diseases; the 4p- Support group has recruited many participants, including 18 persons > 18 years. Analysis of these persons with WHS is ongoing. Knowledge of the medical and developmental aspects of adults with WHS will inform health supervision.

## PgmNr 662: Biochemical genetics education: Legos for inborn errors of metabolism.

### Authors:

H.J. Lin <sup>1,2</sup>; P. Prasad <sup>3</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Medical Genetics, Harbor-UCLA Medical Center, Torrance, CA; 2) Department of Pediatrics, David Geffen School of Medicine at UCLA, Los Angeles, CA; 3) NICHD/Perinatology Research Branch, Wayne State University School of Medicine, Detroit, MI

---

Earlier we showed how Lego bricks can be used to build atomically correct models of compounds relevant to medical biochemistry (Lin HJ, Lehoang J, Kwan I, Baghaee A, Prasad P, Ha-Chen SJ, Moss T, Woods JD. Lego bricks and the octet rule: molecular models for biochemical pathways with plastic, interlocking toy bricks. *Biochem Mol Biol Educ* 2018; 46:54-7. PMID 29105928). The models use “2 x 4” Lego bricks, in which the 8 studs represent the outer shell (or octet) of electrons around carbon, nitrogen, and oxygen atoms. Thus, Lego bricks model the chemical bonds in many small biological molecules, e.g., most amino acids, fatty acids, glucose (even the ring form), and intermediate metabolites. Joining 2 bricks with 2 studs indicates a single bond. Similarly, 4 studs model a double bond, and 6 studs form a triple bond.

Physicians in training are mostly unenthusiastic about reviewing metabolic pathways through names or chemical structures of compounds. But they quickly build Lego molecules. So we developed Lego teaching sessions to explain: fatty acid oxidation disorders; propionic and methylmalonic acidemias; and urea cycle defects. The sessions emphasize biochemical understanding to better grasp pathogenesis and treatment.

Our Lego sessions begin with fatty acid beta-oxidation to “acetate,” from which trainees build ketones -- acetoacetate, beta-hydroxybutyrate, and acetone. Later, they use Legos to see how propionate (e.g., from beta-oxidation of odd chain length fatty acids) normally converts to methylmalonate and then succinate. Legos show how propionate can disrupt the Krebs cycle and impede acetate catabolism -- causing ketone body accumulation and ketoacidosis. Next, trainees build the entire urea cycle with Legos -- including synthesis of *N*-acetylglutamate from “acetate” and glutamate. The models point out the causes of high ammonia in fatty acid oxidation disorders (less acetate available to form *N*-acetylglutamate) and in propionic acidemia (blocking of *N*-acetylglutamate synthase by propionate).

Trainees express satisfaction (even enjoyment) with reviewing biochemistry with Legos. They will easily go over the material with Legos almost daily, during a 2- or 4-week rotation in medical genetics. Our sessions have involved individual trainees, small groups (~10 people), and a group of nearly 30 people (with giant Legos for demonstration). Using Legos can be an engaging, chemically correct, simple, and fun way to teach on inborn errors of metabolism.

## PgmNr 663: Questionnaire survey for newborn screening including lysosome storage diseases.

### Authors:

M. Ozawa <sup>1</sup>; O. Migita <sup>1,2</sup>; Y. Abe <sup>2</sup>; N. Shimizu <sup>1</sup>

2)Department of Clinical Genetics, St. Marianna University, School of Medicine, Kawasaki, Kanagawa, Japan

---

Among congenital diseases, there are some diseases which can prevent severe symptoms by early intervention. For those treatable disease, the longtime delay to diagnosis interferes early intervention, and it leads to treatment failure. Newborn screening is one of an effective and most important approaches to detect serious diseases on early or presymptomatic stage and lead to maximize efficacies of therapies.

Lysosomal storage diseases (LSDs) have promising therapeutic options, such as enzyme replacement therapies or pharmacological chaperones. But implementation of newborn screening (NBS) for LSDs is still debatable and some concerning points are existing. Some patients who have later-onset forms or attenuated forms of LSDs may not need to start treatment in their early life. It is still controversial issue, that NBS for LSDs creates unnecessary emotional and financial burden on the family. There are still few countries, which already provide nation-wide or region-wide neonatal screening program includes lysosomal storage diseases. Japan is one of the countries which are not including the lysosome diseases in nation-wide newborn screening. However, pilot screening studies have been started with expense of parents in some medical institutions. Before starting the new NBS tests including LSDs, families need to have knowledges of targeting diseases, and consensus of financial burden.

To address these issues, we have conducted questionnaires for assessing opinions of parents with their young children. Our aim of this questionnaire what type information and benefits expected for NBS before consent, what and when is the appropriate way to inform them, and how much financial burden is acceptable for families. We conducted a questionnaire survey on parents who visited our hospital for their newborn infant checkup. In our ongoing survey, 70% of the parents replied that they did not have any knowledge of LSDs, and 23% replied that they have been a little heard about LSD before. But after reading leaflet, 86% of parents replied that they would like to request the NBS for LSDs to their child, if they had known the LSD before NBS. They also commented that acceptable cost probably be around or below 10,000 Japanese yen. In order to avoid a delay in diagnosis, it is important to provide appropriate information of screening tests for LSDs.

---

**Background:** Acute Intermittent Porphyria (AIP) is a rare inborn error of heme biosynthesis characterized clinically by life-threatening acute neurovisceral attacks. Few studies have assessed quality of life (QoL) in AIP patients and those that have had small sample sizes, and used QoL tools which may not have captured important domains. In this study, the NIH PROMIS scales were assessed in AIP patients to determine their sensitivity to disease severity, and assess their psychometric properties. These analyses measured whether the PROMIS scales are appropriate patient-reported outcomes (PROs) for this population and can be used as endpoints in future studies.

**Methods:** Baseline data from the US Porphyrias Consortium's Longitudinal Study were obtained for 259 AIP patients. These included detailed disease and medical history as well as PROMIS data. The following PROMIS scales were used: anxiety, depression, pain interference, fatigue, sleep disturbance, physical function, and satisfaction with social roles. The relationships between PROMIS domain scores and key clinical and biochemical features of AIP were assessed, and exploratory and confirmatory factor analyses (EFA and CFA) were conducted.

**Results:** PROMIS domain scores among AIP patients were significantly worse than the general population across all domains except depression. Each PROMIS domain discriminated well between asymptomatic and symptomatic patients with symptomatic patients demonstrating worse scores. Many important clinical variables were significantly associated with domain scores in univariable analyses, showing good response for the PROMIS scales, specifically pain interference and fatigue scales. Internal consistency was high for all the PROMIS scales. EFA revealed a five-factor model as the most appropriate, each factor consisting of a separate domain: pain interference, anxiety, depression, sleep disturbance, and fatigue. CFA of this five-factor model showed good fit.

**Conclusion:** Pain interference and fatigue were the most responsive scales in measuring QoL in this cohort. The five-factor model fit the data well, which is different from the model observed in the general population. These findings provide initial evidence that the PROMIS scales were valid and

reliable measures for clinical outcomes in AIP. Thus, the PROMIS scales provide an optimal assessment of PROs.

## PgmNr 665: Two decades follow-up of 123 patients with Williams-Beuren syndrome.

### Authors:

R.S. Honjo <sup>1</sup>; V.F. Monteleone <sup>1</sup>; E.A. Furusawa <sup>2</sup>; K.T. Faria <sup>3</sup>; A.M. Santos <sup>3</sup>; M.C.T.V. Teixeira <sup>3</sup>; D.R. Bertola <sup>1</sup>; C.A. Kim <sup>1</sup>

---

**Objective:** The objective of this study was to analyse the natural history of Williams-Beuren syndrome based on the clinical findings of 123 patients. **Methods:** comprehensive retrospective review of the medical records of patients with molecular diagnosis of Williams-Beuren syndrome followed in our genetics outpatient clinic in a period of 20 years. **Results:** All cases were sporadic except one case of monozygotic twins and one case of first-degree cousins. All of the patients had the typical facial characteristics of the syndrome. Most patients presented with cardiovascular abnormalities and 75.6% have some form of congenital heart disease (CHD), being supravalvar aortic stenosis the main one (found in 47.3% of patients with CHD). Among them, 21.5% needed heart surgery and/or cardiac catheterization, and one patient needed a heart transplant. Hypertension was present in 40% of patients and 19.2% of those had renal artery stenosis. Other vascular stenoses were also reported. Additional prevalent findings were vertebral spine abnormalities (71.5%), urinary tract abnormalities (73.2%) and hernias (45%). Additional findings included hypothyroidism, ocular findings, radio-ulnar synostosis, precocious puberty, constipation, feeding difficulties, hypercalcemia, and some rare atypical findings. Most presented developmental delays and some level of intellectual disability, however 3 patients had a borderline IQ and 2 had a low average IQ. Almost half (49.6%) of our patients are adults, with ages ranging from 18y to 38y (mean 18.1y; median 17y). None of the adults was reported as employed. **Conclusions:** Our cohort behaved predominantly according to published literature, however there were some atypical findings. To our knowledge this is one the largest Brazilian cohorts of Williams-Beuren syndrome patients, including adult patients, making it possible to describe the natural history of Williams syndrome. In the context of the implementation of a national policy for rare diseases it is increasingly important to better characterize this population in Brazil and to emphasize the importance of long-term follow-up with a multidisciplinary team.

## PgmNr 666: 22q11.2 deletion syndrome and coexisting conditions: An important prognostic, management, and genetic counseling consideration.

### Authors:

---

**Background:** 22q11.2 Deletion Syndrome (22q11.2DS) is the most frequent copy number variant (CNV), affecting ~1/1000 fetuses and ~1/2000-4000 children, resulting in recognizable but variable findings across multiple organ systems. Patients with atypical features should prompt consideration of coexisting diagnoses due to the possibility of additional genome-wide mutations/CNVs which may be inherited, as well as, mutations/CNVs on the remaining intact chromosome 22q11.2 allele unmasking an autosomal recessive condition. Both occurrences compound symptoms impacting management and genetic counseling. **Methods:** Records on 1422 patients with a laboratory confirmed 22q11.2 deletion followed at the Children's Hospital of Philadelphia (CHOP) were reviewed to identify a dual diagnosis, including a subset of patients with atypical features, e.g. craniosynostosis, imperforate anus, limb differences, and sudden death, whose samples underwent next generation sequencing of the intact chromosome 22q11.2 allele as part of an ongoing IRB approved collaborative research protocol in Philadelphia, Leuven, and Warsaw. **Results:** 24 patients with 22q11.2DS were found to have a coexisting diagnosis representing 1.7% of our overall cohort. These included 8 patients with conditions unrelated to 22q11.2DS (Severe Combined Immunodeficiency, Trisomy 8 mosaicism, CHARGE syndrome due to a *CHD7* mutation, cystic fibrosis, a maternally inherited 17q12 deletion, G6PD deficiency, von Willebrand disease, and a 1q21.1 deletion) and 16 patients with a 22q11.2 deletion and a CNV/mutation on the remaining allele resulting in a previously undiagnosed autosomal recessive condition. The latter group included mutations or CNVs in *GP1BB*, *CDC45* (4), *LZTR1* (2), *SNAP29* (4), and *TANGO2* (5) which explained patient's atypical features in association with known conditions such as Bernard-Soulier, autosomal recessive Noonan syndrome, and CEDNIK syndrome, as well as, what we believe to be a new condition associated with a *CDC45* mutation, and *TANGO2* Related Disease unfortunately explaining the sudden death of a 5-year-old child. **Conclusions:** These findings support considering additional laboratory testing in all patients with 22q11.2DS, to ensure appropriate personalized care, as formulating medical management decisions hinges on establishing the correct diagnoses in their entirety, especially given that these findings are medically actionable, potentially altering long-term outcome and recurrence risk counseling.

## PgmNr 667: Clinical exome sequencing workflow for cerebellar ataxias: Increased diagnostic yield and identification of novel candidate.

### Clinical exome sequencing workflow for Cerebellar ataxias: increased diagnostic yield and identification of novel candidate

Priyanka Vishwakarma, Sarita Agarwal\*

Department of Medical Genetics, SGPGIMS, Lucknow

**Introduction:** Spinocerebellar ataxia (SCA) is a rare, genetically heterogeneous, adult onset, neurodegenerative disorder. It has 40 subtypes reported. Majority of SCA subtypes are caused by dominant CAG expansion mutations. Clinical features present by SCA patients are gait disturbance, movement problem, Nystagmus etc. Genetic studies of late onset sporadic ataxias are not routinely mentioned however, for unresolved cases NGS or clinical exome sequencing (CES) are available for a definitive diagnosis. **Materials and method:** In this study we recruited 50 SCA suspected patients for the routine genetic diagnosis of SCA (subtypes 1,2,3,6 and 7) by multiplex and TP-PCR method and we got 12 positive cases of SCA subtypes like 4 were positive for SCA1, 6 positive for SCA2 and 2 positive for SCA3 subtype. After this we found 38 patients who were uncharacterized for SCA in spite of this, they were presented with cerebellar ataxia features. Then we selected 10 patients from 38 uncharacterized cases of SCAs with autosomal dominant cerebellar ataxia for CES, because it was necessary to unravel the reason of problematic feature of patients. Additionally, we already excluded the presence of mutations in the genes causing FRDA by STR analysis in previous research projects. **Results:** we identified 3 cases of spastic paraplegia, all were male patients with a usual facial phenotype and they developed ataxia at early age of life with no significant family history and in initial clinical approach that ruled out common etiologies. Clinical exome sequencing was performed when the patients were 24, 24 and 21 years of age respectively. The results identified heterozygous pathogenic variant c.2014G-A (p. Gly672Arg), encode (SPG7 gene), and homozygous pathogenic variants c.869+1 G-T (5'Splice site), (SPG11 gene) and c.1A-G (p.met1?) (FA2H gene) in all 3 subjects respectively. Sanger sequencing in our laboratory confirmed all 3 variants. **Conclusion:** Our findings suggested that patients with progressive cerebellar ataxia would benefit diagnostically from CES irrespective of a positive family history or early age at onset. CES findings generally offer valuable information which can be used for clinical decision making and in defining new clinical & bioethical action like counseling.

## PgmNr 668: Systematic review and meta-analysis: Application of diagnostic sequencing in epilepsy, autism, and intellectual disability.

---

Understanding the underlying molecular pathology in neuropsychiatric disorders can affect patient management, predict recurrence risk, and enable clinical trial enrollment for novel precision medicine drugs. A comprehensive assessment of the field of clinical diagnostic sequencing across neuropsychiatric disorders is lacking. Here, we conducted a systematic literature analysis of clinical sequencing studies and found 8,396 articles. After additional filtering, we identified most studies for epilepsy (n=48), involving 15,277 patients. We also found 16 studies for intellectual disability, involving 2,317 patients, and 12 studies for autism, involving 1,578 patients. The diagnostic yield for autism was 0.26 (95% confidence interval [CI]: 0.19–0.33), for intellectual disability the yield was 0.25 (95% CI: 0.19–0.32), and for epilepsy, 0.23 (95% CI: 0.20–0.26). Uncorrected for pre-screening, the diagnostic yield for studies applying whole exome sequencing (WES) was 0.24 (95% confidence interval [CI]: 0.21–0.28), for gene panel sequencing the yield was 0.21 (95% CI: 0.18–0.23), and for whole genome sequencing (WGS), 0.19 (95% CI: 0.07–0.42). In the subset of epilepsy studies, the yield for combined generalized and focal epilepsies was 0.23 (95% confidence interval [CI]: 0.20–0.27), for generalized epilepsies the yield was 0.21 (95% CI: 0.15–0.29), and for focal epilepsies, 0.15 (95% CI: 0.08–0.25). We observed increasing numbers of clinical sequencing studies annually, particularly in research studies from Asia. In the combined list of 76 identified clinical sequencing studies, we did not find any publications from Africa, India, or Latin America. In contrast to earlier publications, more recent studies apply guidelines for variant interpretation and are more likely to report variants of uncertain significance. No study reported benign classified variants. In summary, clinical genetic testing represents a fast evolving, and increasingly useful approach in identifying the etiology of neuropsychiatric disorders. It is likely that the diagnostic yield will further increase with the broader application of more comprehensive testing (e.g., WES) and advanced variant interpretation methodologies. This systematic review provides a comprehensive overview of clinical sequencing studies of neuropsychiatric disorders, can guide policymaking, and help steer decision-making in patient management.

## PgmNr 669: Alexander disease: A rare case.

### Authors:

D. La Delfa

[View Session](#) [Add to Schedule](#)

**Affiliation:** American University of Antigua College of Medicine, Department of Internal Medicine, Kingsbrook Jewish Medical Center, Brooklyn, New York

---

Alexander disease is a rare autosomal dominant genetic disorder of the nervous system, classified as a leukodystrophy. The cause of Alexander disease is the destruction of myelin, a lipid layer which insulates the nerve fiber. This destruction decreases the rate of transmission of nerve impulses and leads to the overall functional impairment of the nervous system seen in clinical cases.

The true prevalence of Alexander disease is currently unknown, however, only approximately 500 cases have been reported since 1949. There are two subtypes of Alexander disease; Type I and Type II. Type I, infantile form, is typically diagnosed prior to age four while Type II, juvenile form, is diagnosed after age four. We present a case report of a 27-year-old African American female who was diagnosed with Infantile Alexander disease. She has required lifelong respiratory ventilation, nutritional supplementation via gastrostomy tube and prophylactic seizure medication. MRI of the brain showed persistent moderate leukoencephalopathy with abnormal patchy parenchymal enhancement involving the frontal lobe, pons, cerebellum, and basal ganglia bilaterally. This patient has doubled the estimated survival rate which makes this case even more rare.

Currently there is no treatment for patients with Alexander Disease. Supportive management should include nutritional therapy, antibiotic therapy for intercurrent infections, and antiepileptic therapy. It is crucial for affected patients to undergo preventative measures to avoid secondary complications. An MRI can assist in the confirmation of Alexander Disease. Specific findings can guide the diagnosis however physicians must keep in mind that other diseases can present similarly. Increased levels of  $\alpha\beta$ -crystallin, heat shock protein 27, and glial fibrillary acidic proteins were seen in all confirmed cases of Alexander Disease, making this the most specific test for establishing the diagnosis.

Although most cases present in early years of life, it is just as important for physicians practicing adult medicine to be familiar with the signs and symptoms of Alexander disease as it may mimic other neuromuscular diseases, such as Multiple Sclerosis.

*Key words: Alexander disease, leukodystrophy, glial fibrillary acidic protein, Multiple Sclerosis*

## PgmNr 670: A patient-centered perspective in genetic studies: Successful autism discoveries.

**Authors:**

Z. Talebizadeh; A. Shah

[View Session](#) [Add to Schedule](#)

**Affiliation:** Pediatrics, Children's Mercy Hosp, Kansas City, Missouri.

---

Concerns over the need to improve translational aspects of genetics studies and engage community members in the research process have been noted in the literature and raised by patient advocates. To address this gap, we have launched an initiative called Autism Genetics Outcomes (AutGO). The overall goal was to establish partnership with a wide range of stakeholders and develop a new integrated concept called GO (i.e., research approaches that utilize data and principles of both genetics and outcomes research). To date, we have accomplished the following: identified inclusion criteria for GO hypotheses, developed a semi-structured literature review protocol to collect stakeholders' perspectives for developing such hypotheses, and identified 10 different topics related to autism that may lead to a GO hypothesis. We have also developed a GO hypothesis for a topic prioritized by our AutGO members (i.e., depression in autism). While there is a consensus among different stakeholders on the need to make a bridge between outcomes and genetics research, there is a paucity of a practical and meaningful framework to implement this much needed synergy.

By applying lessons learned from AutGO, we assessed autism genetic findings from a patient-centered perspective. To do so, we evaluated a few successful/replicated discoveries (related to PTEN, MET, and Fragile X genes) from the standpoint of both scientific impact and patient-centeredness. The following elements were distilled: (1) if/how patient and/or parent concerns contributed to the study inception/development process, and (2) if/how they contributed to developing treatments and improving patient health outcomes, and (3) highlight elements included in hypothesis generation, research design, and data evaluation that were key factors in making these discoveries successful.

Such a unique retrospective assessment of the genetic findings will facilitate developing a practical set of recommendations (conceptual framework) for the policy makers, funding agencies, and the research community to further promote designing research protocols that have a higher likelihood of contributing to translational research. Gathering and sharing such dual perspectives could facilitate igniting interest on the topic of making a bridge between outcomes and genetics research in autism, and promote building synergistic frameworks among relevant, but currently disconnected, initiatives that are aiming to increase patient-centeredness.

---

Recent major advances in psychiatric genetics have been driven by both major technological advances and the establishment of international consortia. Several results can already be translated from bench to the bedside. For example, according to the statement of the International Society of Psychiatric Genetics (<https://ispg.net/genetic-testing-statement/>), psychiatric genetic testing (psyGT) and identification of pathogenic copy number variations may help psychiatric patients to better understand and accept their diagnoses and could improve the psychiatric genetic counselling (psyGC) for familial recurrence risk. PsyGC is also efficient for alleviating emotional distress and guilt and in improving self-efficacy and empowerment of patients and their family. However, integrating this evidence into clinical practice requires a substantial research effort to overcome major clinical, ethical and practical challenges.

In 2018, the European Union funded a COST Action to build a research network called EnGagE: “Enhancing Psychiatric Genetic Counselling, Testing, and Training in Europe” (<https://www.cost.eu/actions/CA17130/>). EnGagE is a knowledge-sharing and expertise-enhancing

network. The objectives are to develop a framework to facilitate the implementation of PsyGC and PsyGT into routine clinical care. EnGagE aims to develop standardized practice recommendations and research protocols, share scientific knowledge and data, and provide standardized training in PsyGC and PsyGT. The EnGagE network now includes preclinical and clinical researchers from the fields of neuroscience, psychiatric genetics, psychosocial research, and ethics; clinicians from the fields of psychiatry, psychology, and medical genetics; genetic counsellors, and scientists from diagnostic genetic testing laboratories. Furthermore, patient and family advocacy groups are actively involved in EnGagE. Currently, the EnGagE network comprises 30 European countries and has recruited active participants in Australia, Canada, Russia, and the USA.

We will present the structure of the EnGagE network (especially its different taskforces), the achievements that have been made in its first year, as well as the timeline of future commitments. The specificities and the challenges of PsyGC and PsyGT will be discussed, both from a practical and ethical point-of-view. We will discuss the difficulties encountered in transferring scientific knowledge of psychiatric genetics into routine clinical practice in Europe.

## PgmNr 672: The experience of parenting a son with X-linked retinoschisis.

### Authors:

R. Nolen <sup>1</sup>; C. D'Amanda <sup>1,5</sup>; B. Biesecker <sup>2</sup>; C. Cukras <sup>3</sup>; P. Sieving <sup>4</sup>; A. Turriff <sup>1</sup>

---

**Introduction:** Parenting a child with a genetic condition has been associated with significant stress, grief and loss, and concern for the future. Prior studies of carriers of X-linked conditions have found that guilt is prominent. X-linked retinoschisis (XLRS), a childhood-onset retinal dystrophy, differs from previously studied conditions in terms of disease prognosis, caregiver burden, and lack of established carrier phenotype. This study explored the experiences and characteristics of parents of sons with XLRS.

**Methods:** Parents of sons with XLRS who were evaluated at the National Eye Institute (clinicaltrials.gov: NCT00055029) between December 2017 and January 2019 were eligible for this cross-sectional, mixed methods study. Semi-structured interviews were conducted by two researchers either in person or by phone. Interviews were transcribed, coded, and analyzed thematically. Participants also completed a survey composed of demographic questions and validated scales to assess dispositional optimism, anxiety, and personality traits.

**Results:** 11 mothers and 8 fathers participated in this study. Recruitment occurred until no new concepts emerged from the interviews. Reported optimism, anxiety, and personality traits were consistent with published normative data. Parents described a process of continuous adaptation. The initial diagnosis was characterized by grief, shock and devastation for most parents, which was exacerbated by reportedly unfavorable interactions with providers who lacked familiarity with XLRS. Maternal guilt was common, but usually improved with time. As parents adjusted to life post-diagnosis, they attempted to maintain a sense of normalcy while balancing the desire to protect their sons. Significant stressors included decisions around sports participation, driving, and school accommodations. Among all parents, the fear of retinal detachment was an ongoing source of concern. Most parents identified perceived benefits from their experiences, such as increased compassion or family cohesion.

**Conclusions:** Most parents viewed XLRS as a significant challenge in their sons' lives, but one which could be overcome with the right guidance. Clinical encounters may be enhanced for families with XLRS by providing quality information, preparing families for potential challenges, and by assessing and acknowledging the psychosocial impact of living with XLRS.

## PgmNr 673: Evaluation of depression in patients with inherited forms of vision loss: Results from a clinical practice improvement pilot project using the PHQ-9 questionnaire.

### Authors:

D. Blain <sup>1</sup>; A. Turriff <sup>1</sup>; D. Claus <sup>1</sup>; A. Bamji <sup>1</sup>; C. D'Amanda <sup>2</sup>; B. Brooks <sup>1</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) OGVFB, Bldg 10, Rm 10N109, National Eye Institute, Bethesda, MD.; 2) Division of Genetics, Department of Medicine University of Rochester Medical Center 601 Elmwood Avenue, Box 641 Rochester, NY.

---

**Purpose:** Studies have documented the negative psychosocial impact of vision loss related to inherited eye conditions. In this context, a pilot practice improvement project was set up to evaluate whether a rapid assessment for depression during a clinical visit may facilitate identifying and appropriately referring at-risk patients. This project also allowed for a view into the depressive profiles of patients seen in clinic.

**Methods:** Nurse coordinators administered the Patient Health Questionnaire depression scale (PHQ-9) to 50 consecutive adult patients at the Ophthalmic Genetics and Visual Function Branch (OGVFB) clinic of the National Eye Institute (NEI) between January and March 2019. Patients scoring  $\geq 10$  on the scale were assessed by a genetic counselor that day, who followed up three months later by phone. Patient demographics and clinical findings were obtained from the NEI electronic medical record and correlated with the PHQ-9 scores for further characterization of the cohort.

**Results:** Data from 47 patients were included in the analysis. Median onset of visual symptoms was 24 years (range: birth to 60 years). On average, patients had lived 20 years with their symptoms. A majority (57%) did not have a family history of the condition. Most (96%) had a progressive or possibly worsening form of visual loss. Median Best Corrected Visual Acuity (BCVA) was 20/40 (range: 20/12.5 to Light Perception). PHQ-9 scores ranged from 0 to 17, with 41 patients (87%) falling into the Minimal or Mild depressive symptoms category (score  $\leq 4$ ). The average score was 3.6 (median: 2). No correlation was detected between scores and other variables such as BCVA, residual visual fields, age of onset, age at visit, length of diagnosis, sex and family history. Six participants (13%) had scores in the Moderate or Moderate to Severe category and were assessed by a genetic counselor. All had a history of depression and either had been or were under medical care for the diagnosis. Follow-up is ongoing.

**Conclusions:** The existing clinic infrastructure and brevity of the PHQ-9 questionnaire allowed for a rapid evaluation of patients for depressive symptoms. In this cohort, 13% were found to be at-risk, which is consistent with rates published for patients with chronic medical conditions, but lower than those reported in the literature for vision loss. The fact that all at-risk patients had a history of depression suggests that long-term follow-up may be needed for these patients.

## PgmNr 674: Greater than the sum: Thought experiment fusing HUGO Gene Nomenclature Committee assigned gene numbers into International Classification of Diseases for the coding of genetic variants.

### Authors:

H. Schlecht

[View Session](#)
[Add to Schedule](#)

**Affiliation:** Medicine, Baystate Health, Springfield, Massachusetts.

---

With the growing use of gene panels and next generation sequencing in the evaluation of human disease, gene-level description of illness is being realized on a more widespread basis. Despite this growing understanding, genetic variants and their attendant diseases remain difficult to study particularly due to a lack of pragmatic classification of genetic variants within medical nomenclature, *e.g.* International Classification of Diseases.

The internationally recognized HUGO Nomenclature Committee (HGNC) approves labelling of human loci to enable unambiguous scientific communication, including assignment of a unique HGNC ID number, *e.g.* *SYNGAP1* has been assigned the ID HGNC #11497. Even should the name or symbol of a gene change, the assigned HGNC ID remains stable. As a unique, durable identifier of a gene, it is an ideal label of pathogenic genetic variation. To code genetic variants in ICD-10, appending the HGNC ID to an ICD-10 prefix could be performed in the Q9 section (Chromosomal abnormalities, not elsewhere classified) of the Q chapter (Congenital malformations, deformations and chromosomal abnormalities), or to an unused U code chapter (U9 Germline Genetic Variants), *i.e.* Q91.1497 or U91.1497 for “*SYNGAP1* Pathogenic Variant Present, Germline or Postzygotic,” respectively. This methodology preserves the architecture of ICD-10 while utilizing an additional international system to remain consistent with the conventions of biomedical classification with numerous consequent benefits. Use of HGNC ID numbers within the Extension Codes of ICD-11 will then allow ongoing coding of pathogenic variants.

As such codes are entered into electronic medical records and billing databases, high-quality epidemiologic research and retrospective studies are possible. Moreover, in syndromes with multiple individual genetic causes, *e.g.* frontotemporal dementia or autism, gene-specific labelling can facilitate more detailed genotypic:phenotypic correlation or selective recruitment for clinical studies—a particularly important benefit with the rapid emergence of gene-specific therapies. Furthermore, this method can be adapted to add much-needed somatic mutation codes to ICD-10 as oncologic care increasingly considers personalized tumor genomics, *e.g.* U code chapter (U7 Somatic Genetic Variants), U79.047 “*PLAGL2* Pathogenic Variant Present, Somatic.” Use of the HGNC ID within ICD can begin a pragmatic and enduring method of incorporating genetic variation into medical coding.

## PgmNr 675: Phenotype-karyotype relationships in pediatric Turner syndrome.

Lurie Children's Hospital, Chicago, IL, USA; 3) Department of Pediatrics, Feinberg School of Medicine, Northwestern University, Chicago, IL, USA; 4) Division of Clinical Genetics, Northwestern University, Chicago, IL, USA; 5) Department of Obstetrics and Gynecology, Feinberg School of Medicine, Northwestern University, Chicago, IL, USA; 6) School of Public Health, University of Illinois at Chicago, Chicago, IL, USA; 7) Division of Genetics, Birth Defects, and Metabolism, Ann & Robert H. Lurie Children's Hospital, Chicago, IL, USA

---

**Background:** Turner syndrome (TS) is associated with both phenotypic and karyotypic variability. Previous studies looking at relationships between karyotype and phenotype have been discordant. The aims of this study were to understand karyotype-phenotype relationships using data from a large pediatric TS cohort, stratify risk of TS-related morbidities across the different karyotype variations and enrich the evidence-base for TS pediatric management recommendations in order to improve prognostic genetic counseling post diagnosis.

**Methods:** Retrospective chart review was performed on 187 TS patients managed by a multidisciplinary clinic at Lurie Children's Hospital of Chicago. Inclusion criteria were a confirmed TS karyotype and at least two endocrinology visits. Karyotypes were categorized into five groups: 45,X; 45,X/46,XX mosaicism; karyotypes with Y chromosome material identified; structural X variants; and mosaicism with Triple X. All clinical data were dichotomized into normal and abnormal for comparative analyses.

**Results:** Statistically significant differences among the karyotype groups were observed in ten of thirty of the clinical variables including: age of diagnosis, congenital cardiac defects, abnormal EKG scores, beta-blocker use, abnormal low-density lipoprotein (LDL), diagnoses of autoimmune thyroiditis, deficient Vitamin D levels, estrogen use, spontaneous menarche, and spontaneous thelarche. Novel findings in this study included an increased risk for electrocardiographic abnormalities, beta-blocker use, and abnormal LDL levels in the 45,X group; and increased risk of Vitamin D deficiency in the mosaic 45,X with Triple X karyotype.

**Conclusions:** In this cohort, 45,X was typically the most severely affected and structural X karyotypes showed an increased risk of autoimmune thyroiditis and pubertal delay. Some of the novel findings in this study corroborate the previous assertion that 45,X karyotypes are the most morbid, particularly regarding cardiac findings. Mosaic Turner syndrome with 46,XX, Y chromosome material, and Triple X karyotypes have some more mitigated features, particularly regarding puberty measures, although evaluation for all Turner syndrome associated comorbidities is still warranted. While Turner syndrome remains variable in presentation of both phenotype and karyotype, there is evidence of relationships between the two, which may add value to counseling regarding prognosis for patients and families at the time of diagnosis.

---

The ClinGen Actionability Working Group (AWG) has developed a standardized, evidence-based framework to assess the clinical actionability of genes and associated disorders in the clinical context of returning secondary findings of genome-scale sequencing. This framework includes the generation of summary reports of clinical actionability based on available evidence for clinical outcomes and interventions that could improve future health outcomes in these conditions. A semi-quantitative metric is then applied to generate consensus scores for four domains of clinical actionability for specific outcome and intervention pairs: 1) severity of the outcome; 2) likelihood of the outcome to occur; 3) effectiveness of the intervention to prevent or minimize the outcome; and 4) nature of the intervention, akin to risk and burden of the intervention to the individual. These publicly available materials provide evidence-based resources to guide development and implementation of recommendations and policies regarding the return of secondary findings. Most recently, the AWG has begun to expand this framework by developing methods to generate AWG assertions on the clinical actionability of genomic variation as secondary findings. To inform this effort, a survey was developed to collect AWG member perspectives on the degree of actionability of 15 topics previously assessed by the AWG. For each topic, the relevant summary report and consensus scores were provided with a

0 to 100 sliding scale to capture the scorer's perspective of clinical actionability, where 0 indicated "not at all actionable," 100 indicated "very actionable," and 50 indicated an "actionability threshold." To date, 15 AWG members have completed this survey. The median score for all 15 topics was above the "actionability threshold." Two of the 15 topics are on the ACMG SF 2.0 list and scored relatively high on this scale compared with other topics. Interestingly, actionability scores were variable within each topic, with the inter-rater coefficient of variation ranging from 13.4 to 53.7 across topics. This variability highlights the complexities and challenges of making assertions of clinical actionability. Next steps to modify the methods to provide AWG actionability assertions will be discussed. Overall, actionability assessments of the ClinGen AWG provide a significant resource to aid stakeholders and decision makers as they determine best practices regarding return of secondary findings.

## PgmNr 677: Development of an educational tool: Approach to addressing the direct to consumer genetic testing trend.

### Authors:

[View Session](#) [Add to Schedule](#)

**Affiliation:** McKusick-Nathans Institute of Genetic Medicine and Department of Pediatrics. Johns Hopkins University, Baltimore, MD.

---

Direct to consumer (DTC) genetic testing (GT) for health conditions has become easily accessible to the general public via several models. The US FDA has cleared at least one company to test for specific pathogenic variants. The company asks that consumers consult with their doctors to discuss concerns related to the results. Consumers can also utilize 3rd party analysis for interpretation of their raw genetic data. Of the variants reported by this additional analysis, ~40% may be false positives, thus highlighting the importance of confirming the results through clinical GT. Many health-care professionals are not familiar with handling GT results, and there is no consensus information about methods to communicate and manage DTC GT. Medical literature regarding the approach to DTC GT includes case-based scenarios for individuals presenting to primary-care with DTC GT variants in BRCA1/2 genes, Alzheimer disease and polycystic kidney disease. To our knowledge, education about DTC GT in ambulatory undergraduate medical education has not occurred. Practical strategies in a more comprehensive framework to help health-care professionals, both PCPs and specialists to navigate these results are needed as evidence evolves. We describe an approach piloted in the ambulatory clerkship at Johns Hopkins SOM to address the DTC GT trend. We have begun to offer a 90-minute Genetics in Ambulatory Care education session that focuses on DTC GT as an optional part of our medical student and postgraduate trainee elective. Five learners have thus far participated in the module. Post session survey showed that all participants agreed that the session was relevant to their future careers and recommended offering the session to future learners. Based on their input, we identified gaps in the knowledge of this target group and created a preliminary educational tool/algorithm to approaching DTC GT results. 15 genetics professionals and trainees also contributed to the algorithm. Next steps for presentation: An electronic survey will be distributed to a larger group of genetics professionals and trainees to further analyze the tool. A group of non-genetics health professionals and patients will be later invited to pilot the tool. We plan to suggest strategies to aid health-professionals and patients navigate DTC GT results.

## PgmNr 678: Tangibles for genetics learning experiences.

Genetics has evolved from a niche discipline to standing as one of the five core recognized conceptual areas for biology students. One could argue that basic genetics literacy is instrumental for all students, with genetics analyses starting to become routine in health care across the United States and beyond. Moreover, consumer testing is becoming more popular, with many college level students and/or close relatives having used consumer-testing services. Toward reaching students from different backgrounds, learning styles, and with varying level of expertise, it is important to offer different ways to convey content that go beyond classical lectures. At the same time, while “flipped classrooms” have recently met some advocacy, they are very difficult to realize effectively and apply to large classrooms; and thus, consequently are often not appreciated by students. To address these challenges, we developed instrumented physical artifacts (or “tangibles”) to enhance the genetics learning experience. Starting with the NIH 3D Print Exchange, we are developing 3D printed objects for molecular genetics toward use in the classroom for exploration and explanation. We also encourage students (often as part of group projects) to print their own 3D models to broaden their learning experiences, enable students to learn new skills, and use the resulting tangibles as both passive and active elements of their presentations. (Our institution has makerspaces with student access.) Finally, we have also begun integrating sensing, display, and actuation electronics and software into 3D printed objects, toward further increasing the functional, representational, cognitive, and communicative potential of such practice.

## PgmNr 679: Genomics educational priorities, knowledge and needs among healthcare providers: Preliminary survey results.

### Authors:

D. Messersmith <sup>1</sup>; G.E. Fotso Chekam <sup>1</sup>; C. Daulton <sup>1</sup>; C. Easter <sup>1</sup>; J. Jenkins <sup>2</sup>; K. Calzone <sup>3</sup>

---

**Background:** The implementation of genetics and genomics into clinical care has important implications for all healthcare providers, yet opportunities to upskill practitioners are limited.

**Aim:** To better understand the priorities, knowledge, and needs of healthcare providers for genomics educational resources.

**Methods:** We developed a survey incorporating both new and existing questions from validated instruments. Through collaborations with professional associations, the survey was distributed from July to September 2018 to healthcare providers.

**Results:** Data was analyzed from physicians (N=46), nurses (N=31), physician assistants (N=22), and pharmacists (N=48). Most respondents (78%; 115/147) thought it was very important for healthcare providers to become more educated about genetics and genomics of common disease. Almost all (97%; 142/146) thought that a potential advantage of integrating genetics of common disease into practice would lead to better treatment decisions and 91% (132/145) thought another advantage would be improved services to patients. A potential disadvantage noted by 78% (113/144) was that genetics/genomics may not be reimbursable/too costly. Another potential disadvantage noted by 67% (97/145) was an increase in insurance discrimination. When asked to rank the importance of incorporating genetics and genomics into their practice, 10% (15/145) reported low priority, 36% (52/145) moderate priority, and 54% (78/145) high priority. Regarding their genetics/genomics knowledge, 21% (31/146) rated knowledge as excellent, 53% (77/146) as good, and 26% (38/146) as poor. When asked "where do you go for genetics and genomics training and resources", the majority selected professional organizations, the internet, and peer-reviewed literature.

**Limitations:** Limitations of the data were a lack of diversity among respondents, low response rate, and a need for additional questions.

**Conclusions:** These results provide preliminary information on genomics priorities, knowledge and needs among healthcare providers. Because the majority indicated they go to their professional organizations for information about genetic and genomic training and resources, collaborating with these organizations is a potential educational and dissemination opportunity for the National Human Genome Research Institute.

**Next Steps:** We plan to distribute a revised, expanded survey to increase the overall response rate, the diversity of respondents, and to further explore our findings.

## PgmNr 680: Assessment of the knowledge and attitude regarding biobanking among undergraduate medical students in a Nigerian university.

### Authors:

---

With the recent advances in genetic and biomedical technologies, there has been a dramatic increase in the value of stored biospecimens. Researchers are now developing protocols to examine such tissues. With the paradigm shift in healthcare towards personalized medicine, biobanks are becoming primary means of delivering personalized diagnostics and treatment. All these require interactions between many stakeholders, including healthcare staff. In Africa, genomic methods are gradually being adopted in biomedical research, though the status of genetics and genomic medicine is far from meeting the needs of the population. Even with the curricular reforms in medical education, little is known about physicians/medical students' knowledge and attitudes concerning medical genetics and genomics in Africa. Several studies have described the role of the public and patients in tissue banking issues and other related matters, but very few have also actually studied the role of healthcare staff and medical students. We assessed the knowledge of Nigerian medical students about biobanks and their willingness to donate their biospecimens for research. Using self-administered questionnaires, a cross-sectional study of the consenting respondents among 143 eligible senior medical students in a Nigerian University was conducted in May 2019. Data analysis was done with SPSS version 22. The sample included 79 males and 35 females, and the mean age was 23.7 years. Only 28.1% knew the difference between genetics and genomics, and only 14% were confident of their knowledge of genetics and genomics. The majority (73%) were either not aware or not sure of the term 'biobank', though 55.3% were willing to donate specimens for research; with the chief reason for willingness being altruism. The main reason for unwillingness to donate was fear/uncertainty about the intentions of the researchers. A majority (64%) had never participated in health research. Blood, sputum, urine and stool specimens were the specimens the respondents were most willing to donate. Only 7% of the respondents were willing to donate specimens from dead relations. Fifty-five (48.3%) students were unwilling to donate any organ for the medical care of needy patients. There is a low level of knowledge about genetics/genomics and biobanking among the students. Their attitude to donation of specimens for research is guarded. There is a need to improve biomedical research education and medical genetics/genomics teaching among medical students.

## **PgmNr 681: Genetics education pipeline for elementary, middle, high school (K-12) and undergraduates to enhance diversity in sciences, technology, engineering, and mathematics (STEM) careers at the Louisiana State University Health Sciences Center (LSUHSC).**

### **Authors:**

F. Tsien <sup>1</sup>; J. Peñas <sup>1</sup>; A. Umrigar <sup>1</sup>; M. Cuccia <sup>2</sup>; A. Augustus-Wallace <sup>3</sup>

---

The Louisiana State University Health Sciences Center in New Orleans (LSUHSC) created a genetics educational pipeline through the Science Youth Initiative (SYI) and the Research Experiences for Undergraduates (REU) programs. The long term goals are to increase diversity in STEM fields especially in genetics. Underrepresented groups as defined by the NIH and NSF include African American/Blacks, Hispanic/Latinos, Native American/American Indians, Pacific Islanders, Alaska Natives, women, persons with disabilities, first generation college students, students residing in rural areas, non-traditional students, and veterans. SYI instruction includes hands-on experiments, workshops, and educational videos which are coordinated with elementary, middle, and high school (K-12) teachers to maximize learning and complement their curriculum. The goals of the SYI are to improve academic achievements, introduce diverse role models, increase awareness of genetics and science careers, and provide LSUHSC trainees instruction in communication skills to the lay public. Topics range from strawberry DNA isolation (elementary schools), to forensics and HeLa cells (high schools). Since 2009, the SYI has reached > 2900 K-12 students, of which 72% belong to underrepresented groups. Diverse LSUHSC trainees from the LSUHSC Schools of Medicine, Graduate Studies, and Public Health help educate K-12 students. The REU program provides undergraduates scientific problem solving skills, state-of-the-art laboratory techniques, scientific communication skills, and resume writing instruction for competitive graduate school preparation. Since 2014, the NSF-funded REU program provided internships to more than 50 undergraduates. General topics include population genetics, molecular and cellular biology, chromatin instability, mutation analysis, translational research, and bioinformatics. Following the REU program, students co-author scientific publications and conference presentations, obtain laboratory employment, and are accepted to STEM programs. Participating schools include rural, urban, public, private, and historically black colleges and universities (HBCUs). Assessments are by qualitative and quantitative surveys and NSF-REU common assessment tools. Students are tracked via on-line reporting systems. The SYI and REU programs have been successful in providing opportunities in STEM especially in the field of genetics, to K-12 and undergraduate students to help them achieve career goals.

## PgmNr 682: Genomics2020: An overview of the ongoing NHGRI strategic planning process.

**Authors:**

A. Wise; National Human Genome Research Institute

[View Session](#) [Add to Schedule](#)

**Affiliation:** Division of Genomic Medicine, National Human Genome Research Institute, Bethesda, Maryland.

---

The National Human Genome Research Institute (NHGRI) has a rich tradition of strategic planning that dates back to the Human Genome Project. The significant advances in genomics since the publication of NHGRI's last strategic plan in 2011 illustrate the need for an updated vision about the future of genomics for 2020 and beyond. In February 2018, NHGRI launched a new round of strategic planning, one that will yield publication of a new strategic plan in Fall 2020. The new plan will detail the most compelling areas of genomics research and their application to human health and disease; it will also inform NHGRI's scientific priorities and shape its research portfolio, ensuring that the Institute continues to be a driving force at the *Forefront of Genomics*. To formulate relevant and forward-reaching goals, NHGRI is fostering partnerships with research, healthcare, education, and policy communities, as well as the public. Starting in 2018, NHGRI has engaged a wide variety of stakeholders through workshops, town halls, advisory meetings, meeting sessions, and webinars. Over the next year, NHGRI plans to use the received input to develop draft tenets for the emerging plan as well as collect additional input through more focused activities. We continue to encourage the genomics community to participate in the process via [genome.gov/genomics2020](http://genome.gov/genomics2020), [genomics2020@nih.gov](mailto:genomics2020@nih.gov), and [#genomics2020](https://twitter.com/genomics2020). This poster, presented by NHGRI staff, provides an overview of the ongoing NHGRI strategic planning process to date.

## PgmNr 683: Integrating modern genetics, genomics, and bioethics into high school curricula: The *Teaching the Genome Generation* program.

### Authors:

C. Wray <sup>1</sup>; S. Wojiski <sup>2</sup>; M. McKernan <sup>1</sup>; D. Waring <sup>3</sup>; K. Bass <sup>4</sup>; A. Kieffer <sup>1</sup>

---

Teaching the Genome Generation (TtGG) is a high school teacher professional development program (PD) and curricular and laboratory resource effort that supports classroom instruction across three broad topics: molecular genetics, bioinformatics, and bioethics. The three instructional themes are aligned with Next Generation Science Standards. Modular lesson plans, laboratory protocols and instrument and reagent support are provided to teachers who participate. TtGG is unique because it uses voluntary, anonymous sampling and isolation of high school student genomic DNA for use in subsequent genotyping demonstrations. Bioinformatics exercises are designed to reinforce content presented in the laboratory exercises and highlight the deep levels of DNA sequence variation that exists in the human genome. Bioethics lessons, from the Personal Genetics Education Project (pgEd), align with and support the molecular genetics arm of the program and model how to introduce and facilitate discussion on controversial and sometimes difficult subjects with high school students. To date, 163 teachers have taught over 10,000 high school students content provided by the TtGG program. Lessons and laboratories are flexible and are taught across a range of high school courses; 40% of students are exposed to the curriculum in their introductory biology course, while 22% and 19% of students participate in the curriculum in honors or AP biology, respectively. The remainder of students experience the curricular elements in a biotechnology or other science course. Participating teachers from New England implement lessons and labs at a high rate; however, incorporation of bioinformatics lessons in high school classes lags behind laboratory and bioethics classroom integrations. In 2018, new case-based and narrative bioinformatics lessons were introduced in order to increase integration of bioinformatics into high school classes. Evaluation data collected over several years indicate that TtGG has increased teachers' abilities to integrate complex concepts of genetics and genomics into their high school classes. Self-efficacy items show increased teacher confidence when tested before the professional development (PD) and at the time of the school implementation, sometimes months later. For example, respondents from the 2017 PD cohort (n=27) are 17% more confident on tasks related to use of bioinformatics tools at the time of implementation than before the PD.

## PgmNr 684: An opportunity to restore scientific justice? Willingness to participate in genetic research in two rural Puerto Rican communities.

### Authors:

T. Dye <sup>1</sup>; C. Vélez-Vega <sup>2</sup>; J. Pérez-Ramos <sup>1</sup>; N. Cardona-Cordero <sup>1</sup>; D. Vega-Ocasio <sup>1</sup>; S. McIntosh <sup>3</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Obstetrics and Gynecology, University of Rochester, Rochester, NEW YORK.; 2) School of Public Health, University of Puerto Rico, San Juan, PUERTO RICO; 3) Public Health Sciences, University of Rochester, Rochester, NEW YORK.

---

**Background:** Historic bioethical abuses in the conduct of science and medical intervention in Puerto Rico has led to an atmosphere of scientific distrust and subdued interest in being included in research. As new, large research initiatives have created Puerto Rican-centered infrastructures, researchers are increasingly interested in engaging communities - equitably - in genetic research. Such engagement could help accomplish distributive justice in that communities may ultimately benefit from the research where they participate. We ascertained attitudes and intent to participate in genetic research in two rural communities of Puerto Rico where new tissue-based genetic research was being initiated.

**Methods:** This study used an in-person cross-sectional design to ascertain community members' attitudes toward genetic research and likelihood of participating in genetic research studies in two rural community health centers in the northern Karst region of Puerto Rico. We ascertained the relationship between willingness to participate in genetic research and psychometric, attitudinal, demographic, and general health indices.

**Results.** Overall, 44.8% indicated they were very/likely to participate in genetic research. Attitudes toward genetic research were strongly associated with likelihood of participating in such research: the Composite Attitudes Score was approximately 30% higher for participants very/likely to participate in genetic research versus others ( $p < .001$ ). Respondents indicating they were very/likely to participate in genetic research were significantly more likely to trust researchers ( $p < .001$ ); indeed, respondents indicating they trusted researchers were more than six times more likely to participate in genetic research than were respondents not indicating trust (84.6% v. 12.5%). Additionally, respondents perceiving that research could benefit them/ their family ( $p < .005$ ) were more likely to indicate they would participate in genetic research.

**Discussion.** Likelihood of participating in genetic research varied sharply by demographics, attitudes toward genetic research, and by psychosocial classifications in this sample of rural Puerto Ricans. Ensuring an informed understanding of what genetic research entails and overcoming "lack of trust" in researchers (*No confío en los investigadores*) - one of the strongest determinants of participation in research identified in this study - are critical in successfully partnering with communities.

## PgmNr 685: Scoping review of participant-centric initiatives in medical research.

### Authors:

N. Hamakawa <sup>1</sup>; R. Nakano <sup>2</sup>; A. Kogetsu <sup>1</sup>; J. Kaye <sup>3</sup>; B. Yamamoto <sup>2</sup>; K. Kato <sup>1</sup>

[View Session](#) [Add to Schedule](#)

---

The importance of patient and public involvement in medical research is increasingly recognized. There is a discernable movement away from a paternalistic model of medical research to one in which patients are actively involved in the research process to better reflect their experiences and needs. Participant-centric Initiatives (PCIs) are defined as “tools, programs, and projects that empower participants to engage in the research process” using digital technologies. Studies point to the effectiveness of using information and communication technology (ICT) for medical research via PCI platforms. Not only do they allow more patients to participate in research, but interactions between research participants and researchers are facilitated. However, there were no reports on the development of PCIs since 2012, and existing reports were limited in scope. Furthermore, previous studies had not sufficiently clarified how patient involvement is facilitated by PCIs.

The objective of this study was to clarify the status of PCIs and the key features of participant involvement using ICTs. In previous studies, patient involvement was broadly defined across a spectrum of distinct levels of involvement activity. Therefore, we focused on the question of what kinds of patient/participant involvement are facilitated by PCIs, aiming at clarifying the characteristics of different levels of participant involvement activity.

By applying a scoping review methodology, a literature search was conducted in 2017. After screening 6,568 documents and websites, 152 documents were found relevant to PCIs. By examining the abstracts of those documents, we extracted activities related to PCIs and analyzed their characteristics and key features. We found that they can be classified into two distinct groups in terms of the levels of participant involvement. Group 1: Patients are actively involved in the research as partners, by making decision or leading research activities. Group 2: Patients participate in the research by providing feedback or input, or to gain knowledge about research and ask questions to researchers. The preliminary results revealed that terminology usage and definitions of involvement are varied and inconsistent. By comparing these groups, we illustrate that the active involvement facilitated by PCIs can be achieved by continuous dialogue between participants and researchers, and priority setting by participants.

## **PgmNr 686: Regulating preimplantation genetic diagnosis across the world: A comparison of trends and international policy perspectives.**

### **Authors:**

R. Isasi; M. Ginoza

[View Session](#) [Add to Schedule](#)

**Affiliation:** Human Genetics, University of Miami Miller School of Medicine, Miami, Florida.

---

Preimplantation genetic diagnosis (PGD) is a reproductive technology which, in the course of in vitro fertilization (IVF), allows prospective parents to select their future offspring based on genetic characteristics. During the last decade, the regulation of PGD has followed mostly a linear path, with incremental changes driven by scientific advances or by court driven alterations to legal practice. But also, shift has been prompted by greater societal uptake. No longer considered an experimental practice, stakeholders (e.g. scientists, patients, etc.) across the world have challenged the status quo, recognizing that both technological and policy developments do not take place in a moral vacuum. They have done so under the flag of reproductive freedom, equitable access and welfare considerations, amongst other ethical concerns. Despite the passage of time, the ubiquitous presence of eugenics seems to constantly cast a shadow over technologies that open the door for selecting the genetic characteristics of a human offspring. For this reason, we can predict that despite greater societal acceptance, widening the permissibility criteria for PGD will remain contested and a matter of continue social and policy debate.

In this presentation, we examine – from a comparative perspective - variations in policy approaches to the regulation of PGD. We draw on a representative sample of 19 countries (Australia, Austria, Belgium, Brazil, Canada, China, France, Germany, India, Israel, Italy, Japan, Mexico, Netherlands, Singapore, South Korea, Switzerland, United Kingdom, and the United States) to provide a global landscape of the spectrum of policy and legislative approaches (e.g. restrictive to permissive, public vs. private models). We also explore central socio-ethical and policy issues and contentious applications as for instance, permissibility criteria (e.g. medical necessity), non-medical sex selection and reproductive tourism. Finally, we further outline genetic counseling requirements across policy approaches.

## **PgmNr 687: GenEtiquette: Developing guidelines for the conduct of genomic research in collaboration with Aboriginal and/or Torres Strait Islander peoples of Queensland, Australia.**

### **Authors:**

G. Pratt; M. Vidgen; S. Kaladharan; D. Whiteman; C. Brown; J. Pearson; N. Waddell

[View Session](#) [Add to Schedule](#)

**Affiliation:** QIMR Berghofer Medical Research Institute, Brisbane, Queensland, Australia

---

Precision medicine serves to benefit detection, diagnosis and personalising of the health care experience. It is widely recognised that there is significant bias in genomics databases towards people of European ancestry. Aboriginal and/or Torres Strait Islander residents of Queensland, Australia experience significantly higher mortality and morbidity and lower life expectancy compared with non-indigenous Queenslanders. With a growing emphasis on genomics in healthcare, there is a risk that advances in genomics will not benefit Indigenous Australians. In 2018, QIMR Berghofer undertook to develop guidelines to support genomic researchers to partner with Indigenous Queenslanders. Development of the guidelines was informed by community engagement across the health service, research and ethics sector. Led by an Aboriginal man, the project was developed and delivered by a team with complementary skills in stakeholder engagement, epidemiology, medicine, genomics, ethics and biotechnology. Governance of the project was overseen by a project steering committee comprising noted Indigenous experts from the university, health service, research, policy and ethic sectors of Queensland. Community and stakeholder forums availed an opportunity to provide input, feedback and advice about the topics of genomics, genetics and precision medicine and to directly inform the development of the guidelines. The guidelines provide practical suggestions for genomic researchers to evidence a commitment to Indigenous research and to respect the right to self-determination and empowerment of Aboriginal and/or Torres Strait Islander leadership and voice. Consultation and engagement are essential to the uptake and translation of key learnings, ensuring that consumers, families, communities, service providers, policy personnel, researchers and clinicians are informed about, respected and empowered to make decisions and influence health action. The Aboriginal and/or Torres Strait Islander community of Queensland, Australia showed overwhelming support for our engagement and the opportunity to learn more about genomics and precision medicine. The guidelines serve as a launch pad to support relationships, conversation and partnership in the area of Indigenous genomics in Queensland, Australia. Key learnings serve to benefit the international community about the value of deliberate and empowering strategies to encourage public discourse about genomics and precision medicine.

## **PgmNr 688: Regulation of international direct-to-participant genomic research: Results of a 32-country study.**

### Regulation of International Direct-to-Participant (DTP) Genomic Research: Results of a 32-Country Study

Mark A Rothstein, Ma'n H Zawati, Bartha Maria Knoppers

The online recruitment of participants is helping to facilitate genomic research on rare disorders. With the development of cooperative arrangements between researchers and disease-specific patient organizations, interested patients and caregivers can be easily recruited, without relying on traditional recruitment models that depend on physicians and hospitals. Internet recruitment has the further advantage of allowing prospective participants in remote locations to take part in research. Such participants may supply samples for genome sequencing and provide access to electronic health records. International direct-to-participant (DTP) research promises to greatly increase the number and diversity of participants for research on rare disorders, but participant recruitment across international borders is often thwarted by prohibitions on research without ethics review in each participating country. The process of obtaining ethics review in multiple jurisdictions, while an essential part of traditional research, can quickly become burdensome and infeasible. Researchers may be hesitant to undertake such effort only to enroll a few participants in each studied country. Thus, although global recruitment is a promising strategy, much work remains in devising methods that are legally compliant and ethically acceptable for this novel research. There is an urgent need to understand the international regulatory landscape in order to foster greater potential for a global DTP genomic research model. In this presentation, we will outline the results of an NIH-funded study in 32 countries on six continents. Drawing on the reports of our local expert collaborators, we will describe the state of the law and genomic research practices, and discuss the measures needed to ensure the successful implementation of international DTP genomic research.

## **PgmNr 689: The latent class analysis to clarify the factors associated with the structure of the public attitude toward the genome research at the survey in 2016 in Japan.**

### **Authors:**

---

[Aim] The aim of this study was to clarify the structure of the public attitude toward the genome research by the latent class analysis.

[Methods] The nationwide surveys about the attitude toward the genome research were conducted in 2016 in Japan. The participants were comprised of 2,000 people (age, 20-69), selected from the Japanese general population by using the two-step stratified random sampling method.

[Results] Five clusters were assumed as an explanation model of six variables related to the knowledge of genome and attitudes toward genomic research promotion about three themes; basic genome research, genome research related to agriculture and medicine at the survey in 2016. They were able to be named "Group of aggressive promotion" (41.5%), "Group of passive support" (20.8%), "Group not making judgment" (19.2%), "Group making prudent judgment" (18.5%), and "Group not interested in genome". The results in 2008 and 2009 were almost the same as that in 2005. It is possible to forecast to which cluster to belong according to respondent's attribute, and we can forecast the reaction to other questions by using a cluster oppositely. For examples, "Group of aggressive promotion" is the layer of a high academic background, and is positive to donate their blood for the genome research, "Group making prudent judgment" is high academic background persons as same as "Group of aggressive promotion", and is interesting in the science and technology, but is negative to the blood donation for the research.

## **PgmNr 690: “Additional findings”: Expected and unexpected benefits of All of Us for federally qualified health centers (FQHCs) and community-based organizations (CBOs).**

### **Authors:**

### **Affiliations:**

1) University of Washington School of Medicine, Box 356320 1959 NE Pacific St HSB RR307, Seattle, WA 98195; 2) Association of Asian Pacific Community Health Organizations, 101 Callan Avenue, Suite 400, San Leandro, CA 94577; 3) Institute for Public Health Genetics, University of Washington, 1959 NE Pacific St HSB, Seattle, WA 98195; 4) Sage Bionetworks, 2901 3rd Ave #330, Seattle, WA 98121; 5) Treuman Katz Center for Pediatric Bioethics, Seattle Children’s Research Institute, 1900 Ninth Ave, M/S JMB-6, Seattle, WA 98101

---

The All of Us Research Program has the potential to enable precision medicine for all people in the U.S. Likely, this vision will be realized over the course of decades and depends on the engagement of FQHCs and CBOs to recruit and retain a diverse cohort, and to strengthen newly formed institutional partnerships. These institutions are not only critical linchpins for equitable inclusion but are key stakeholders who anticipate and experience benefits and risks of All of Us participation in the here-and-now. Building on findings from interviews with FQHC medical directors and CBO executive directors prior to All of Us, we conducted two related qualitative research projects that inform our understanding of organizational and community benefits of the All of Us Research Program. Interview and focus group participants (n=10) from All of Us-funded and non-funded FQHC members of the Association of Asian Pacific Community Health Organizations suggest that experienced and expected benefits include resources for building IT and EHR infrastructure, improving patient portal access and use, activating patients on their health conditions, and increasing opportunities for conducting community-based research through partnering with local investigators. Interviews (n=16) with leaders of minority health CBOs, citizen scientists, and patient-led researchers, suggest that supporting communities to engage in big data research may be a welcomed ancillary benefit with impacts beyond precision medicine. These potential impacts include more authentic relationships with researchers and tangible benefits from community-led research that support advocacy and agency as patients and communities. We conclude that while participants recognized the value of equitable precision medicine based on the availability of more inclusive data, more proximal and practical benefits appear to drive both interest and commitment to All of Us. Understanding and articulating the full range of expected and unexpected proximal benefits and even risks of All of Us to FQHCs and CBOs may support organizational commitments by clarifying its value, improve community engagement including subsequent participant recruitment and retention, and demonstrate a commitment to enduring partnership.

## PgmNr 691: Clinical exome and chromosomal microarray reanalysis: Balancing the burden on laboratories, clinicians, and families.

---

In a recent policy statement on re-contact after revision of genomic results, the ACMG states that responsibility for re-contact is shared between ordering clinicians, clinical laboratories, and patients, and indicates that although there is an ethical obligation to attempt to re-contact patients with new medically actionable results, the patient has the right to decline such re-contact. As our understanding of the molecular basis of genetic disease increases, so does the likelihood of finding a diagnosis through case-level reanalysis of previously non-diagnostic genomic tests. Studies estimate that at least 60-70% of clinical exomes are inconclusive or negative after initial testing, and subsequent reanalysis identifies a diagnosis in ~10-15% of cases. Thus, many clinical laboratories are performing clinician-requested and/or laboratory-initiated case-level reanalysis on previously completed non-diagnostic cases. Clinician-requested reanalysis (CRR) is often ordered at a follow up visit, allowing the patient/family to affirm their interest in reanalysis and their understanding of potential outcomes. In contrast, laboratory-initiated reanalysis (LIR) is usually instigated unbeknownst to patients and clinicians as part of laboratory quality improvement efforts or routine reanalysis. Although this method may be more streamlined and fruitful than CRR, it can be challenging due to the resource requirements for variant analysis and results reporting. In addition, LIR can increase the burden on clinicians to provide results, particularly if they are no longer in contact with the family, and on families who may have to deal with complex emotional ramifications. The family may no longer be seeking a diagnosis or may be facing medical/emotional struggles that outweigh the desire for new information. Thus, while an increased diagnostic rate leads to improved medical management and a shortened diagnostic odyssey, reanalysis can have disadvantages. Through surveys and/or interviews with laboratory personnel and frequent orderers of genomic testing at CHOP, our qualitative study explores laboratories' and clinicians' experiences with identifying, receiving and sharing results from reanalysis. Our goal is to understand the impacts and identify potential enhancements in processes and communication between the three groups. It is essential to balance the improvements in diagnosis and medical care with the potential repercussions for clinicians, families, and laboratories.

## PgmNr 692: An analysis of the factors affecting family adaptation for families of people with rare diseases.

**Authors:**

I.H. Choi; H.W. Yoo

[View Session](#) [Add to Schedule](#)

**Affiliation:** Medical Genetics Center, Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea.

---

Family burden, family resilience, and patient support group activities affect the adaptation for the patients with rare genetic diseases and their family members.

In the current study, the relationships were assessed between variables that may affect family adaptation for patients with rare diseases and their families and the mediating effects of family resilience, and the moderating effects of patient support group activities between family burden and family adaptation.

A survey of 245 patients with rare diseases and their families was conducted.

The results of the study can be summarized as follows:

First, regarding the links between family burden, family resilience, patient support group activities, and family adaptation, a significant negative correlation was found between family burden, family resilience, and family adjustment. A significant positive correlation was found between family resilience, patient support group satisfaction, and family adaptation.

Second, regarding the comparison between rare disease groups, the group with neuromuscular disorders and those having problems with treatment, prognosis, and management had a heavier family burden and lower levels of family resilience and family adaptation. They also showed higher levels of patient support group participation and satisfaction.

Third, the lower the level of family burden, the higher the level of family resilience and family adaptation for patients and their families, while the higher the level of family resilience, the higher the level of family adaptation for patients with rare diseases and their families.

These results can be utilized as basic data for defining guidelines and future perspectives regarding support and the provision of higher-quality care at school, hospital, and national level. They will also be helpful in improving family adaptation in the case of patients with rare diseases and their families, as well as in developing educational programs to facilitate family adaptation.

## PgmNr 693: A novel approach to supporting employee benefits programs for genetic wellness.

### Authors:

C.A. Fine; B.J. Swope; E.S. Gordon; L. Meyers; S.M. Weissman; J. Bailey; A. Fan; E. Jordan; B. LeLuyer; A.F. Rope; H. Shabazz; S.B. Bleyl

---

Vying for top talent in a tight labor market is difficult for employers as the economy grows and competition increases. Thus, employee packages have started incorporating benefits called “genetic wellness” as a result of an explosion of affordable genetic tests offering medically actionable insights. Employers offering these benefits typically do not partner with genetic clinicians, but rather with a single genetic laboratory offering a specific test. We describe an employee benefit program offering medical genetics services through Genome Medical, a nationwide genomics medical practice, and a proactive genetic screen for cardiac, cancer and other conditions. This program was offered during a three-month timeframe with a registration cap of 200 employees. It included mandatory viewing of an educational webinar of material typically discussed in a genetic counseling session. Employees were required to complete a medical and family history questionnaire which was assessed by a certified genetic counselor (CGC), and had the option of a pre- and/or post-test virtual one-on-one CGC session. Genetic results were interpreted by a CGC in the context of each employee’s reported histories, and a results-based clinical action plan was provided to each participant. 200 employees registered for the program. 189 (95%) individuals watched the webinar. 181 (91%) completed the required questionnaire. Only 25% requested a pre-test CGC session. 170 individuals pursued proactive screening with some of the following motivations: understand a condition in family (42%), help family members (14%), and/or take medical action (12%). 15/75 (20%) individuals were found to have medically actionable genetic variant(s) for hemochromatosis, familial hypertrophic cardiomyopathy, a hereditary cancer syndrome, and/or malignant hyperthermia. 74/170 (44%) individuals were found to be a carrier for at least one condition. Only 20% of participants requested a post-test CGC session. Satisfaction data indicated >80% of responding participants did not prefer an in-person pre-test CGC session; 92% did not prefer an in-person post-test CGC session, program expectations were met in 92% of respondents and 91% found the program to be valuable. Almost 100% of respondents would recommend this program to a coworker. Assisting employers in helping their employees obtain personalized actionable genetic insights can be done in a responsible, scalable and efficient manner, with a high rate of satisfaction.

## PgmNr 694: Clinical characteristics of pregnant women who chose not to have prenatal genetic testing after careful genetic counseling for advanced maternal ages: From an experience in a single institute.

### Authors:

E. Kise <sup>1</sup>; M. Ishikawa <sup>1</sup>; T. Kojima <sup>2</sup>; N. Kikuchi <sup>3</sup>; Y. Fukushima <sup>4</sup>; T. Kosho <sup>1,2</sup>

---

**Background:** In Shinshu University Hospital, three-staged careful genetic counseling (GC) is provided on pregnant women for the decision whether or not to have amniocentesis for advanced maternal ages (AMA): (1) pre-counseling session by certified genetic counselors (CGC) by phone or after prenatal checkups; (2) GC by CGC, collecting detailed clinical and psychosocial information through listening to their narratives; followed by GC by clinical geneticists with CGC, providing comprehensive medical and social information and making free discussion about what is the value and true meaning of the testing for the women and their husbands; (3) post-counseling session by CGC by phone or after prenatal checkups. The purpose of this study is to demonstrate the prevalence of having amniocentesis after such GC and factors influencing the decision whether or not to have amniocentesis.

**Materials and methods:** Pregnant women receiving GC for AMA in our institute from April 2013 to March 2019 were recruited. Detailed information mainly focusing on decision-making process was collected through their medical records and thoroughly reviewed.

**Results:** In total, 230 pregnant women received GC: 102 (44%) had prenatal testing and/or screening (amniocentesis, n=85; maternal serum screening, n=13; NIPT, n=3; and maternal serum screening and amniocentesis, n=1) and the remaining 128(56%) did not. Among 85 pregnant women having amniocentesis, one miscarried, and two had fetuses diagnosed with trisomy 21. In those who had testing and those who did not, the median ages were both 39 years old, the median numbers of previous pregnancies were both 1, and the median numbers of previous miscarriages were both 0. In those who had testing, 24 (23.5%) had histories of infertility treatment, whereas, in those who did not, 51 (39.8%) had these histories. Reasons for not choosing prenatal testing were described as “refusal to terminate their fetuses” and “information that any pregnant women could be mothers of babies with congenital disorders or handicaps and that there is sufficient medical and social support system in Japan”.

**Discussion:** Sincere discussion based on comprehensive information through careful GC provided by CGC and clinical geneticists in our institute might have been related to the low prevalence (44%) of prenatal testing mainly consisting of amniocentesis, though experiences of infertility treatment might have had some effects on the choices.

## PgmNr 695: The Genome Empowerment Scale (GEmS): An assessment of parental empowerment in families with undiagnosed disease.

---

While genomic sequencing (exome and genome- ES and GS) has the potential to diagnose children with difficult to diagnose phenotypes, it demands a high level of parental involvement in understanding and emotionally managing information, and engaging with healthcare providers. Thus, objective measures to assess parental perspectives of sequencing are essential to optimize the process and psychosocial outcomes. We present the preliminary validity and reliability of the Genome Empowerment Scale (GEmS), developed using a theoretical model of healthcare empowerment. To evaluate its psychometric properties, we enrolled 158 parents of 117 children with an undiagnosed condition undergoing ES and/or GS. Parents completed the GEmS, measures for criterion validity and for depression and anxiety. Using Principal Components Analysis with Varimax rotation, resulted in a four factor solution: 1) Meaning of a diagnosis; 2) Emotional management of the process; 3) Seeking information and support and 4) Implications and planning. Reliability and validity analyses demonstrate that the GEmS has good psychometric properties. The Cronbach Alpha estimates ranged from 0.83-0.67. We found reasonable standard error of measurements, temporal stability, and the GEmS aligns with our targeted criterion measures providing preliminary evidence for convergent validity. The inter-relationships among the four factors revealed a profile, which has the potential to identify parents who may be at risk for a poorer outcome as well as areas that may benefit from targeted genetic counseling interventions. As an objective measure of parental healthcare empowerment for genomic sequencing, the GEmS can be utilized for future research and translational applications.

## PgmNr 696: An integrated end-to-end platform for engaged population-scale research.

**Authors:**

C. Neben; S. Topper; A. Zhou

[View Session](#) [Add to Schedule](#)

**Affiliation:** Color, Burlingame, California.

---

Human subjects research is a partnership. It cannot begin without the generosity and trust of participants, and it will not be successful without researchers' attention focused on their scientific and clinical questions.

Participants expect to be acknowledged as interested parties as the project progresses. That interest can extend to study results, their personal data, clinically relevant incidental findings in that data, and derivative sample usage. Researchers recognize a duty to consider these expectations, but considerable logistical and ethical concerns exist. These include ensuring the analytic and clinical validity of data reported to individuals, supporting communication, education, data sharing and clinical routing, capturing and honoring informed consent, and constraining costs.

Recent projects such as the *All of Us* Research Program have made great contributions to the current thinking around human subjects research and genomic return of results. Here, we describe the essential components of an integrated end-to-end platform for engaged population-scale research. We describe our process to drive recruitment and participant engagement, the logistics and laboratory infrastructure, and clinical validation and return of results for several studies, including two StandUpToCancer Dream Teams: MAGENTA and GENERATE.

The Color web-platform provides customizable study-specific landing pages, supports consent and data gathering workflows, and scheduled interactions to engage the participants over the course of the study. Integrated logistics support distributed sample collection and tracking. Our state-of-the-art CLIA/CAP next-generation sequencing laboratory provides efficient and affordable data assets, including clinical, deep whole genome sequencing (WGS), research-grade low-coverage WGS, and customized analytics. Finally, the clinical infrastructure ensures that incidental findings are confirmed, clinically interpreted using best practices, and returned to participants and their healthcare provider using clear language, and supported by Color's Genetic Counseling service.

Taken together, Color's research platform powers responsible and efficient large-scale research studies by fully supporting a clinically valid return of results component. Our unique capabilities to provide software innovations and educational opportunities ensures the success of studies in the eyes of the researchers and coordinators as well as those of the studies' participants.

## PgmNr 697: Pseudo-dominance in inherited retinal dystrophies: The need to consider common pathogenic variants in recessive disease genes as causative of multi-generational retinal dystrophy.

### Authors:

E. Place; N. Wagner; K. Bujakowska; R. Huckfeldt; J. Comander; E. Pierce

[View Session](#) [Add to Schedule](#)

**Affiliation:** Ocular Genomics Institute, Department of Ophthalmology, Massachusetts Eye & Ear Infirmary, Boston, Massachusetts.

---

**Background:** Inherited retinal dystrophies (IRDs) are genetically heterogeneous, with over 250 genes identified to cause autosomal dominant (AD), autosomal recessive (AR) and x-linked (XL) disease. For families with multi-generational retinal dystrophy, AD or XL inheritance is initially considered. When initial analysis does not identify a likely causative variant in an AD or XL gene, other genetic explanations are considered including new disease gene or a non-coding mutation in a known IRD gene. Before considering these possibilities, AR inheritance in all affected generations should be considered as multiple pathogenic alleles of the same gene may be involved. To determine the prevalence of AR mutations as causative of pseudo-dominant IRD, a cohort of patients with a known family history of retinal disease was genetically analyzed. **Methods:** Next-generation sequencing (NGS) of over 250 known IRD genes was performed for > 1000 IRD probands. Clinical diagnosis was based on a complete ophthalmic evaluation. In probands with a reported multi-generational family history of retinal disease and no pathogenic or likely pathogenic variants in known AD or XL disease genes, an AR explanation of disease was considered. Targeted NGS was performed on available family members, which included copy number analysis.

**Results:** We identified 8 pseudo-dominant families with multiple generations of AR disease. In 5 families with macular degeneration the disease was due to mutations in *ABCA4*. In multiple families, the common pathogenic mutation p.(Gly1961Glu) was identified, which has an allele frequency of 0.0046% in gnomAD (10 homozygote reported). In one family, where disease was due to mutations in *BBS1*, the common mutation p.(Met390Arg) was involved, which has a gnomAD allele frequency of 0.0016%. Finally, we identified two families in which the family history was suggestive of XL disease or AD disease with reduced penetrance, and yet causal mutations in *C2orf71* and *ABCA4* were identified. **Conclusions:** Mutations in AR genes are an important cause of IRD in families with multi-generational disease. Certain AR pathogenic mutations can be relatively frequent in the general population, thus contributing significantly to pseudo-dominant inheritance. Given the high carrier frequency of some disease-causing IRD alleles, the re-occurrence of AR may be higher than initially estimated, which needs to be considered during genetic counseling of probands with AR disease.

## PgmNr 698: Reporting of variants in genes with limited, disputed, or no evidence for a Mendelian condition among GenomeConnect participants.

---

The rapid evolution of DNA sequencing technologies has escalated the detection of genomic variants. However, a variant or gene's relationship to disease may still be unclear, making variants of uncertain significance (VUS) commonplace. VUS results can be challenging for genetic counselors and patients alike. One aim of the NIH-funded Clinical Genome Resource (ClinGen) is to establish the clinical validity of gene-disease relationships for use in genomic medicine and genetic counseling. Per ACMG/AMP sequence interpretation guidelines, an established gene-disease relationship is necessary to determine a variant's pathogenicity, and without such, a variant should only be classified as a VUS. To date, 743 gene-disease pairs have been curated by ClinGen; a gene can be curated for more than one disease. Here, we report on clinically reported variants in gene-disease pairs with limited, disputed, refuted, or no reported evidence that were shared by participants in GenomeConnect, the ClinGen patient registry, to characterize how variants in such genes have been reported.

Of 969 variants evaluated, 1.5% (n=15) were in a gene-disease pair that ClinGen curated as limited, disputed, refuted, or no reported evidence. Of these variants, the majority were reported as a VUS (n=14) and one was reported as pathogenic. These variants were reported via disease specific panels (n=10), familial cascade testing (n=1), or exome sequencing (n=4). Variants reported via disease specific panels or familial testing were likely assumed to have a clearer disease association by the laboratory given the testing type. From exome, none of the variants detected were described as being in genes of uncertain significance, meaning the laboratory likely thought there was a disease relationship. Overall, the way these variants were reported suggests that they were classified based on the data available regarding the variant alone, and not due to the gene-disease relationship. This indicates that variants in genes curated by ClinGen as having little or no evidence may be reported as though they are disease causing. Pairing a gene's relationship to disease and the strength of that relationship impacts genomic medicine by informing multiple parts of the genetic counseling process including test selection, counseling for a variant's significance, and familial cascade testing. An understanding of how genes with limited or no evidence are being reported can inform genomic medicine moving forward.

## PgmNr 699: Delivering high-quality, scalable genetic counseling in international settings: Case studies from Trinidad and Tobago and the United Arab Emirates.

### Authors:

1) Color Genomics, Burlingame, CA.; 2) Yale New Haven Hospital, New Haven, CT

---

**Background:** Genetic counseling (GC) is an important component to help individuals understand genetic testing results and their implications for their medical care. GC is often provided through in-office consultation. However, as genetic testing continues to become more affordable and accessible, the field must re-evaluate how to deliver high-quality, scalable GC across diverse populations. Color has provided telephone-based GC to over 15,000 individuals, including 1048 individuals from 51 countries outside the US. Here, we present two case studies on GC in two very different international settings: United Arab Emirates (UAE), a well-resourced, digitally savvy, country with a total GDP of \$432.612B, and Trinidad and Tobago (T&T), a less well-resourced country with a total GDP of \$22.438B.

**Methods:** The T&T cohort received genetic testing with a 30-gene NGS panel for hereditary cancer that was offered through a high-risk study. The UEA cohort received genetic testing for hereditary cancer risk as well as a 30-gene NGS panel for hereditary cardiovascular disease that was offered as an employee benefit. In both cohorts, GC was conducted by telephone, with translation services available. Color GCs also met with healthcare providers (HCPs) from T&T and UAE to better understand their healthcare systems to ensure cultural competency.

**Results:** In the T&T cohort, 141 individuals received GC, 16% had a positive result. 99% were female, and the majority were age 35-64 years. Many individuals did not have consistent access to email or a computer, and as such, consults were scheduled by telephone. Results and notes from GCs were emailed or sent via post. In the UAE cohort, 52 individuals received GC, 85% had a positive result. 42% were female, and the majority were age 25-44 years. In contrast to the T&T cohort, all individuals in the UAE cohort had access to email or a computer and were able to schedule consults and view results online. In both cases, all GC was delivered successfully.

**Conclusions:** Providing GC in an international setting requires consideration of the unique needs of each country including time zone and language, as well as cultural competency. Leveraging technology can help enable access to high-quality genetic counseling in countries with disparate levels of healthcare. Finally, building partnerships with local HCPs is crucial to ensure a warm handoff for individuals, particularly those with a positive result to receive appropriate follow-up care.

## PgmNr 700: Uptake of services among patients referred for hereditary cancer genetic counseling.

### Authors:

E.S. Gordon; C.A. Fine; B. Swope; L. Myers; S.M. Weissman; J. Bailey; A. Fan; E. Jordan; B. LeLuyer; A.F. Rope; H. Shabazz; S.B. Bleyl

---

Recent studies have found that despite clear guidelines, patients are under referred for genetic counseling for hereditary cancer risks (Childers et al 2017). However the impact of low referral is further compounded by low uptake of genetic counseling among those who are referred. Published data suggests that in the majority of studies uptake of referrals for hereditary cancer counseling is less than 50% (7.3% to 44%) (Niendorf et al 2016, Kne et al 2017, Rahm et al 2007). Here we describe our approach to referrals, data on patient follow through and proposed opportunities for improvement. Genome Medical, a nationwide telegenetic service, contracted with a large health system to provide cancer genetic counseling services. To date, we received 407 referrals in an 11 week period. All patients were referred to genetics within the health system previously, but due to staffing shortages did not see a genetics provider. Some referrals were up to 12 months old. All patients referred to Genome Medical were contacted within one week of receiving the referral to attempt to schedule. Two different approaches were taken to this outreach. For the first six weeks patients received a phone call, followed by two emails, all 24 hours apart with 49% of referred patients scheduling. In order to try to increase follow through, the outreach approach was adapted for the following five weeks, with patient's receiving two emails followed by a phone call over a one week period. In total, 207/407 (51%) of patients referred chose to schedule an appointment and 93% of scheduled patients completed their appointment. No statistically significant difference in the uptake of appointments was observed with the change of approach. Additional work is needed to evaluate barriers and to drive further uptake of referrals. Barriers under investigation include: time since original referral for genetic services; understanding of the reason for referral or perceived utility; concerns regarding cost; completion of a genetic counseling visit elsewhere, and discomfort with telemedicine. Potential interventions to improve uptake include: decreased time between initial referral and first point of outreach; additional education about the cost of the appointment and utility of genetic counseling; and improved ease of use.

---

**Background:** Despite the rapid increase in genomic sequencing, there are few practical recommendations to guide healthcare systems (HCS) when returning unsolicited or unanticipated genomic results. One aim of the 3<sup>rd</sup> phase of the electronic Medical Record and Genomics Network (eMERGE3) is to understand the implementation of genomic medicine by sequencing over 100 genes in 25,000 participants and returning the results of actionable variants to consenting participants and their health care providers (HCP). We sought to compare the return of results (RoR) protocols at the eMERGE3 sites with the goal of developing recommended RoR guidelines for HCS.

**Methods:** Each of the 10 eMERGE3 sites independently developed processes for RoR and discussed the plans as part of the eMERGE3 RoR Workgroup. The Consolidated Framework for Implementation Research (CFIR) was used to characterize the planned RoR processes at each site and to compare these plans across three essential domains: disclosure to the participant, notification of the health care provider, and integration of results into the electronic health record (EHR).

**Results:** A high degree of variability in RoR protocols was found across the 10 institutions. 8 sites enrolled adults and 2 sites enrolled pediatric participants, and most planned on returning the pathogenic or likely pathogenic results from the genes on the eMERGE platform. Three main RoR pathways were identified, with half of sites (n=5) planning to disclose to the participant, followed by HCP notification and uploading to the EHR. Three sites planned to disclose to the participant, followed by EHR uploading and then notifying the HCP, and 2 sites uploaded to the EHR, then notified the participant and the HCP. Modifications were made in all three pathways during the initial stages of eMERGE3 to accommodate unusual or unforeseen events, including participant death, loss of contact, sample integrity, gender mismatch and variant mosaicism.

**Conclusion:** The RoR processes in the eMERGE3 network are heterogeneous and reflect the “real world” of genomic medicine in which RoR procedures are shaped by the needs of the patients and institutional environment. This study provides early empirical evidence about the structure and framework of the RoR process that can be used by HCS considering genomic medicine programs and for future studies examining the implementation of genomic data in healthcare.

# PgmNr 702: Perspective of Nigerian health care providers, researchers, and bioethicists on germline editing technology.

## Authors:

O. Obak <sup>1</sup>; E. Obak <sup>1</sup>; C. Ugorji <sup>2</sup>

## Introduction

Gene editing technology is one of the new technologies useful for genomics research and therapy. Despite the ethical and safety concerns that needs to be addressed, its rapid wide spread by scientists, drug companies and the general public enthuse overs its potential benefits. In this study, we evaluate the perspective of Nigerian health care providers, bioethicists and researchers on the use of germline editing technology.

## Methodology

We utilized the consensus opinion summarized by Professor Charis Thomson of the proceedings at the International Summit on Human Gene Editing to develop questionnaire on attitude to genome editing. After a brief introduction to the technology, we asked Nigerian scientists, health care providers, bioethicists and researchers how much they agreed with the consensus opinions using Likert scale. The questionnaires were distributed both directly and electronically (SurveyMonkey, Twitter and Facebook) to respondents. We analyzed our responses using Stata®.

## Findings

There were 85 respondents, mean age (SD) of 34.4 (8.6) years and almost half were doctors (49.4%) while others were researchers, nurses, medical laboratory scientists and others. Some 57.0% (49 of 85) had no previous knowledge of gene editing technology. Most 85.9% agreed or strongly agreed that gene editing can be used to eliminate serious genetic conditions if it is likely to be safe and effective. 59.5% of the respondents support or strongly support placing a moratorium on gene editing technology while the technical issues are resolved, 21.4% disagreed or strongly disagreed. Some 63.1% support or strongly support placing a moratorium on gene editing technology for ethical reasons while 19.1% disagreed or strongly disagreed. Some 41.2% disagreed or strongly disagreed with trusting scientists to take decisions on when to use gene editing technology while 25.9% were neutral and 32.9% were willing to trust scientists.

## Conclusion

Majority of the Nigerian health care providers, scientists and bioethicist had no awareness of gene editing technology but accepted its use after a brief education and under different circumstances. Most of them wanted a moratorium on its use until technical and ethical issues are resolved. Minority were willing to trust scientists alone to take decisions on the use gene editing technologies.

## PgmNr 703: A case of mosaic Turner syndrome - a value of examination different germ layers and combination of karyotyping and FISH.

### Authors:

### Affiliations:

1) Department of Medical Genetics University Hospital and Palacky University Olomouc, Czech Republic; 2) Department of Pediatrics University Hospital and Palacky University Olomouc, Czech Republic

We present a case of a prenatal detection Turner's syndrome in pregnancy with increased risk of trisomy 21 (1: 20, NT 6.9mm, maternal age 35 years). Amniocentesis was performed, fetal karyotype was 45,X [28]/46,XX [22] (56% of monosomy X). The mother decided to continue her pregnancy.

The child was born at 33 + 5 wg for pathological CTG, was hypoxic postnatally, and required 48 hours oxygen therapy. Small coarctation of aorta was detected during newborn screening, conservative approach was recommended by cardiologist. No other congenital malformations were found, further postpartum adaptations were uncomplicated.

Postnatally following investigations were performed on cells from three germ layers utilizing G banded karyotype on 50 metaphases from peripheral lymphocytes. FISH cells obtained from three different germ layers: uncultivated lymphocytes from peripheral blood (mesoderm), buccal smear (ectoderm) and smear from the root of the tongue (endoderm). FISH examination of 250 nuclei with centromeric probes (Cytocell).

### Results:

Karyotype: 45,X [2]/46,XX [48] (4% of monosomy X)

FISH native peripheral blood (mesoderm): ish (DXZ1x1)[34]/(DXZ1x2)[216] (13.6% of monosomy X)

FISH buccal smear (ectoderm): ish (DXZ1x1)[60]/(DXZ1x2)[190] (24% of monosomy X)

FISH root of the tongue (endoderm): ish (DXZ1x1)[23]/(DXZ1x2)[227] (9.2% of monosomy X)

The karyotype still represents gold standard for determination of numerical chromosomal aberrations. In case of mosaic finding the proportion of abnormal cells may differ according to the method used and to the tissue examined. In case of monosomy X the proportion of monosomic cells may appear non significant (less than 5%) but expanded testing as demonstrated above may reveal much larger proportion of monosomic cells with an outcome for genetic counselling and further management.

Early diagnosis of Turner syndrome enables timely multi-disciplinary follow-up, which includes an endocrinologist (growth and puberty monitoring, growth hormone therapy), cardiologist, psychologist and pregnancy planning.

**Supported by MH CZ - DRO (FNOI, 00098892)**

## PgmNr 704: Daytime napping is an addictive behavior lowering general health rating for middle-aged and old adults: A pan-phenotype mendelian randomization study based on UK Biobank.

### Authors:

L. Chen <sup>1</sup>; P. Chen <sup>2,3,5</sup>; M. Zhang <sup>3</sup>; Y. Wu <sup>4</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) College of Clinical Medicine, Jilin University, Changchun, Jilin Province, China; 2) The Key Laboratory of Pathobiology, Ministry of Education, College of Basic Medical Sciences, Jilin University, Changchun, Jilin Province, China; 3) Department of Genetics, College of Basic Medical Sciences, Jilin University, Changchun, Jilin Province, China; 4) University Archives, Jilin University, Changchun, Jilin Province, China; 5) Department of Pathology, College of Basic Medical Sciences, Jilin University, Changchun, Jilin Province, China

**Purpose:** As a common practice, daytime napping has been taken worldwide. However, it is still controversial as to whether daytime napping is beneficial for our health since some studies unveil its function in improving memory and cognitive abilities while others demonstrate its deleterious effects on metabolism. Thus, We have performed a pan-phenotype mendelian randomization analysis to detect all the potential phenotypes that are in a causal relationship with daytime napping and finally reveal the important role daytime napping play in health.

**Methods:** Mendelian randomization, a randomized trial based on Mendel's law of inheritance, was utilized to grope for the potential causal links. The data source came from UK Biobank repository, whose participants aged from 40~69 years old. A high throughput method was developed to deal with it. In addition, a false discovery rate was employed to add power to our multiple statistical tests.

**Results:** Our findings have unveiled the causal relationship between daytime napping and other five categories of phenotypes including metabolism, psychiatry/pain, anthropometry, lifestyle and blood count among adults. The daytime napping can raise the both systolic ( $\beta=0.207$ ,  $Se=0.053$ , IVW P value= $9.98 \times 10^{-5}$ ,  $FDR=2.89 \times 10^{-2}$ ) and diastolic ( $\beta=0.226$ ,  $Se=0.056$ , IVW P value= $4.67 \times 10^{-5}$ ,  $FDR=1.95 \times 10^{-2}$ ) blood pressure, along with elevating the body fat percentage ( $\beta=0.234$ ,  $Se=0.054$ , IVW P value= $1.37 \times 10^{-5}$ ,  $FDR=1.11 \times 10^{-2}$ ) including arms, legs and trunk. In addition, increased daytime napping frequency can make people feel more tired and lethargic ( $\beta=0.266$ ,  $Se=0.047$ , IVW P value= $1.32 \times 10^{-8}$ ,  $FDR=2.99 \times 10^{-5}$ ) as well as decrease the daily activity, for example lowering usually walking pace ( $\beta=-0.157$ ,  $Se=0.027$ , IVW P value= $4.22 \times 10^{-9}$ ,  $FDR=1.19 \times 10^{-5}$ ). Moreover, there exists direct evidence that increased daytime napping frequency can lower overall health rating ( $\beta=0.156$ ,  $Se=0.041$ , IVW P value= $1.21 \times 10^{-4}$ ,  $FDR=3.13 \times 10^{-2}$ ), a phenotype in UK Biobank.

**Conclusion:** Generally, daytime napping can be denoted as a kind of addictive behavior for adults since it can trap nappers into a vicious circle, where an increased daytime napping frequency can cause increased tiredness and lethargy, resulting in more daytime napping in turn. Moreover, such addictive behavior has a detriment effect on metabolism, potentially leading to cardiovascular diseases.

## PgmNr 705: Establishing molecular medicine laboratories and generating population specific DNA sequence data in the developing country.

---

The first human genome sequence was established at the beginning of the third millennium. Since then advanced life sciences has been shaping economy, societies, bodies and mind. Globally, biodiversity is concentrated around the equator, but the scientific institutions generating DNA sequence data tend to be clustered in developed countries. A lack of funding and insufficient scientific knowledge of the governments, the financial, technical and logistical difficulties are major hurdles to establish medical laboratories and producing DNA sequence data in the developing countries.

Here, we introduce our case for North Cyprus in illustrating the problems of adjusting to the 'new molecular bioscience', since it is an example of a developing country that is striving to progress from an agrarian to an educational and research technology development society.

Cyprus, which is the third largest island in the Mediterranean Sea, has been at the crossroads of multiple civilizations throughout human history. Today, Turkish Cypriots are located in the *de facto* state that comprises the northeastern portion of the island of Cyprus. North Cyprus is recognized only by Turkey. Due to its lack of recognition, ~350.000 population of Northern Cyprus is heavily dependent on Turkey for economic, political and military support.

Despite being unrecognized, Near East University greatly contributes the economy and its recognition by placing thousand of international students in North Cyprus. Recently, the university have been concentrating on research and development. Since 2015, molecular medicine laboratories have been established as well as molecular medicine postgraduate program to generate scientists which having many international students in the program. Currently, basic molecular techniques are quite well established.

In the laboratory, novel disease-causing mutations were identified and many cases were unsolved. Lack of genetic databases in the region, the laboratory set up the capacity to produce DNA sequence data expands the number of contributors to DNA sequence databases, which is beneficial for science generally and may be helpful for any number of bioinformatic analyses.

Our data is not only helping us to contribute population specific allele frequencies of variants, it also

strengthens scientific institutions in the country. In conclusion, our establishment and success raise awareness of the North Cyprus government and address the importance of education and research.

## PgmNr 706: Scalable IRB framework for returning genetic/genomic test results to research patients in community healthcare settings.

---

**Introduction/Background:** In the era of transparency, big data, and expansion of genetics/genomics (G/G) technologies into learning healthcare systems—communication of individual findings to patients who donate biospecimens for clinical research is an emerging area of health policy focus.

**Problem Statement:** Non-CLIA laboratory results, tests with uncertain value, tests lacking sufficient analytic and clinical validity, clinical utility, and regulatory compliance represent multiple competing stakeholder priorities for Institutional Review Boards (IRBs) when assessing plans for the return of G/G research test information to patients. Recent initiatives such as the NIH Precision Medicine Initiative *All of Us* and the NHGRI's electronic Medical Records and Genomics (eMERGE) Network provide exemplars of delivering individual G/G results to patients within the context of Institutional Review Board (IRB) oversight and funding mechanisms affiliated with major tertiary care facilities. However ethical, legal social and policy (ELSI) implications are presented when expanding similar efforts into community health care hospitals and systems which lack comparable institutional infrastructure capable of supporting complex laboratory, regulatory, clinical research, data management, and governance oversight requirements.

**Methods:** A focused review of the literature concerning the return of individual G/G research results was conducted. Available IRB translation resources and interventions for community hospital network settings were identified. A simplified evaluation and implementation framework specific to the level of IRB policy, IRB protocol review, and return of individual G/G research results was conceptualized.

**Conclusion:** Critical logistical elements of IRB oversight for genomic medicine research protocols that involve individual return of G/G research tests in community hospital and network settings need to be simplified to be compatible with available resources.

**Recommendation:** As Precision Medicine translation initiatives grow beyond academic medical centers and diffuse into more limited-resource community health care settings, efforts should be made to develop scalable IRB implementation frameworks for smaller hospitals and health care systems that are not excessively burdensome.

## PgmNr 707: Population-based genetic screening: Does diagnostic information enter into the medical record?

---

Population-based genetic screening can be a valuable screening tool for relatively common genetic risk conditions such as hereditary breast and ovarian cancer (HBOC). However, underlying the assumption that screening the general population is effective is the premise that the vast majority of screened individuals will take consistent and persistent recommended actions regarding positive findings, starting with reporting such findings to their healthcare providers.

We report here our early findings on the follow-up of genetic carrier status into the medical records of population-based genetic screening participants. As part of the Healthy Nevada Project (HNP) in Northern Nevada (Renown Health, Reno), 23,713 unselected participants underwent independent clinical exome sequencing from March 15 to Sept 30, 2018 (135 HBOC, 46 Lynch syndrome (LS), and 117 familial hypercholesterolemia (FH) carriers). Overall, 243 of the carriers had populated medical records with Renown and for 177 (78 HBOC, 33 LS, 66 FH) of carriers, genetic findings were delivered by qualified Renown physicians or outside genetic counselors. Medical record diagnoses were retrieved at a minimum period of three months after delivery of findings. Twenty-one of HBOC carriers had an appropriate diagnosis code (ICD9/10) documenting the genetic finding in their medical record and for 13 (18.6%), HNP testing was the precipitator of the documentation. Five of LS carriers had an appropriate ICD code, two (6.7%) of which were contributed due to HNP testing. Twelve of the FH patients had an appropriate ICD code, 10 of which were in response to HNP testing (15.6%).

Our results underscore the potential of population-based genetic screening for broader identifications of individuals at risk and likely under-represent the rate of provider notification by participants. However, the setting of the HNP in northern Nevada is unique, with Renown being the dominant primary care provider. Therefore, the low rate of diagnostic documentation in Renown's medical records may have implications regarding the effectiveness of voluntary, independent population-based genetic screening, even for life threatening conditions. We plan to review these findings on a periodic basis and survey HNP participants for the actual rate and reasons for non-reporting of genetic findings. Such feedback is essential to maximize the value of independent population-based genetic screening as a preventive tool.

## PgmNr 708: The potential economic burden of genetics on healthcare.

---

Everyone carries genetic variants that influence disease risk, but it is unknown how these variants influence healthcare costs at a population level. To address this, we conducted a genome-wide association study (GWAS) on healthcare utilization with further focus on common and rare variants that influence human traits. Because actual healthcare costs may differ by who is paying, what is actually recovered, and can vary dramatically by service and institution, we calculated a Medicare Risk Adjustment Model (MRAM) score as a proxy. MRAM is a standardized model developed by Centers for Medicare & Medicaid Services designed to predict future costs and is used to set premiums for Medicare insureds. MRAM scores were calculated for nearly 20,000 Medicare eligible individuals across eight separate healthcare systems that participated in the eMERGE Network. Input variables for MRAM scores include International Classifications of Disease Codes, age, and sex.

Using a linear mixed model from GCTA, approximately 3.8% of the predicted variance for MRAM scores was explained by thousands of common variants known to be associated with human traits according to the GWAS Catalog. This is compared to 14.3% of the predicted variance explained by the genome. No single common variant reached genome-wide significance. Conversely, multiple statistically significant associations passed a conservative experiment wise Bonferroni correction when focusing on known trait specific variants. For example, when evaluating 263 rare non-monomorphic variants associated with predominantly Mendelian disorders, a genotype consistent with alpha-1 antitrypsin deficiency (AATD) was associated with healthcare utilization ( $P=1.89e-4$ ). Those diagnosed with AATD often had costly liver and lung ailments (e.g., liver transplants) based on manual review of medical records. Moreover, when generating weighted polygenic risk scores (PRS) for 735 common traits, education status ( $P=1.76e-5$ ) was significantly associated with MRAM scores. Several other phenotypes approached statistical significance including type II diabetes ( $P=9.58e-5$ ) and obesity ( $P=1.31e-4$ ).

In conclusion, these results emphasize that both common and rare variants contribute to healthcare utilization at the population level. Importantly, these results also underscore the importance of maintaining and strengthening legislation, such as the Genetic Information Nondiscrimination Act, to protect all since everyone carries disease risk alleles.

## PgmNr 709: Impact of non-clinical genetic trait insights on clinical engagement in participants after clinical genetic testing.

### Authors:

J. Van Den Akker; A. Boateng-Kuffour; L. Servais; L.E. Jones; C.L. Neben; L. Ryan; A.Y. Zhou

[View Session](#) [Add to Schedule](#)

**Affiliation:** Color Genomics, Burlingame, California.

---

**Background:** Patient recall, or a patient's ability to recollect pertinent medical information, is key to an effective patient-provider communication and adherence to prevention and treatment plans. However, multiple studies report that up to 40-80% of patients are unable to recollect information from their medical encounters. To improve patient engagement with their genetic results, Color offers 'Discovery', a platform that engages clients and provides them with non-clinical genetic insights such as ancestry, bitter taste perception, lactose intolerance, and alcohol flush response. In this study, we sought to assess the impact of Discovery on engagement with clinical results after genetic testing.

**Methods:** We analyzed de-identified data from a consecutive cohort of 12,410 Color clients who consented to participate in research. Clients received a clinical report from Color for genetic risk associated with hereditary cancer, hereditary cardiovascular disease, or medication response. Engagement metrics included the following actions: viewing a clinical report for the first time, re-reviewing an existing clinical report, downloading a clinical report(s), and sharing a clinical report(s) with their healthcare provider.

**Results:** 25.3% of clients in the cohort opted to participate in Discovery. Of these, 91.8% viewed at least one and 70.3% viewed at least six non-clinical genetic trait insights. Within 30 minutes of viewing their trait insights, 28% of Discovery participants re-reviewed at least one clinical report for hereditary cancer, hereditary cardiovascular disease, or medication response. 98.0% of Discovery participants viewed their clinical report(s) within 30 days after their release, as compared to 93.6% of non-Discovery participants. Discovery participants were also more likely to re-review their clinical report(s) after their initial view (70.6 vs 47.9%), share their clinical report(s) with their healthcare provider (8.9% vs 5.0%), and download their clinical report(s) (21.1 vs 16.2%).

**Conclusion:** Color Discovery is an effective engagement tool that prompts participants to take clinical actions such as reviewing, downloading, and sharing their clinical reports with their healthcare provider. Overall, Discovery participants took more clinical actions than non-Discovery participants. Our results demonstrate that this engagement platform may be an effective way to engage clients to drive better medical information recall and ultimately, adherence.

## PgmNr 710: Willingness to pay for whole genome sequencing after testing.

### Authors:

N. Aggarwal <sup>1</sup>; K. Christensen <sup>2</sup>; J. Robinson <sup>3</sup>; C. Blout <sup>2,4</sup>; R. Green <sup>2,5</sup>; A. McGuire <sup>3</sup>

1) Medical College of Georgia, Augusta, GA; 2) Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 3) Baylor College of Medicine, Houston, TX; 4) Massachusetts General Hospital, Boston, MA; 5) Partners Center for Personalized Genetic Medicine, Broad Institute of MIT & Harvard, Boston, MA

---

**Background:** With increasing availability of whole genome sequencing (WGS), it is crucial to examine its economic impact in ways that consider the personal utility it may provide. Willingness to pay (WTP) is a common approach to measure personal utility, but its use to assess genomic testing raises concerns about whether valid data can be collected from people who are unfamiliar with the technology. To address this, we collected WTP data from patients who did or did not receive WGS in randomized trial.

**Methods:** The MedSeq Project was a randomized clinical trial of WGS. Adults from primary care clinics (mean age 54, 58% female) and from cardiology clinics with cardiomyopathy diagnoses (mean age 55, 43% female) were randomized to review family histories alone or with WGS. Prior to and 6 months after receiving reports, participants stated the maximum amount they are willing to pay for WGS, as well as their likelihood to pursue WGS via insurance- or self-payment on 4-point scales. Analyses determined WTP changes over time and variation by experience.

**Results:** At 6 months, the mean likelihood to pursue WGS if insurance covered payment was 3.5 on a 4-point scale, and ratings did not differ between participants who did and did not receive WGS ( $p=0.72$ ) or change from baseline ( $p=0.41$ ). The mean likelihood to pursue WGS through self-payment was 2.3 on a 4-point scale, lower than the likelihood if insurance paid ( $p<0.001$ ). Ratings for self-pay did not differ between participants who did and did not receive WGS ( $p=0.73$ ) or change from baseline ( $p=0.26$ ). Six months after receiving care, WTP decreased an average of \$532 from baseline ( $p<0.001$ ). Changes in WTP did not vary between those who did and did not receive WGS ( $p=0.41$ ). Analyses restricted to participants who received WGS showed no associations between identification of monogenic disease risks or polygenic risk predictions and changes in WTP or likelihood of pursuing testing.

**Conclusions:** Participants were willing to pay less for WGS after participating in the MedSeq Project, although changes did not appear to be affected by the experience of WGS. Participants rated their likelihood to pursue WGS the same at the end of the study as at enrollment, even if they had to self-pay for testing. Findings suggest that researchers can collect valid assessments of WTP even if individuals do not receive WGS. Future work will explore reasons why WTP for WGS decreased.

## PgmNr 711: Parental perspectives on return of secondary findings from a research biobank.

### Authors:

J.J. Connolly <sup>1</sup>; H.S. Hain <sup>1</sup>; M.H. Harr <sup>1</sup>; H. Hakonarson <sup>1,2</sup>; Electronic Medical Records and Genomics (eMERGE) Consortium

This study examined parental perspectives across several dimensions and how they may differ by sociodemographic factors in a targeted genetic testing, research setting. The aim of the study was to determine differences and associations in perspectives in a baseline survey, prior to return of results from a targeted sequencing panel, enriched for genes on the American College of Medical Genetics incidental findings panel. These results are intended to be used to promote health utilization for genetic testing and other healthcare services centered on the child and their family.

Participants completed an online self-reported survey focused on challenges faced in and the impact on participants of return of results, specifically attitudes to testing, family sharing, decision conflict, feelings about genomic results, information seeking, privacy, as well as a range of health/psychosocial outcomes. Sociodemographic parameters were collected as well for comparison purposes.

Ancestry affected responses for attitudes toward genetic testing, family sharing and information seeking. The health status of participants and/or their children affected responses for attitudes toward genetic testing, information seeking, privacy concerns and literacy. Information seeking was different in groups based on sex and religion as well. Attitudes toward genetic testing were more favorable in participants with a lower education level. Learning written medical information differed by religiosity, income, education, self-reported health and insurance. Confidence about filling out medical forms varied by income level and presence of a genetic disorder in participants or their children.

Overall, participant attitudes were favorable towards research genetic testing. Sociodemographic differences observed in literacy, privacy, and information seeking survey questions could guide educational materials and practices used to personalize genetic counseling sessions.

## PgmNr 712: Exploring women's experiences of non-invasive prenatal testing in a private health care setting in the Western Cape, South Africa.

---

Non-invasive prenatal testing (NIPT) is the most accurate prenatal screening test that is used to screen for common chromosomal anomalies including Down syndrome (DS). NIPT can be done from 8-10 weeks gestation with a simple blood test which makes use of cell free DNA in maternal plasma. It is recommended that all women undergoing NIPT receive adequate pre-test counselling. Currently in South Africa, NIPT is only available in the private health care setting. Very little qualitative research has been performed to understand the experience and psychological impact of NIPT. This study aims to explore the experiences of women who have undergone NIPT in a private health care setting in Cape Town, South Africa.

This study used a qualitative exploratory design, which allowed for investigation of the topic. The sample population included women who had NIPT in a private health care setting in Cape Town. Participants were recruited through private practice genetic counsellors (GCs). Semi-structured interviews were conducted to collect the research data. Interviews were recorded and transcribed verbatim and the data was analysed using thematic analysis.

A total of 10 participants were interviewed, all received low risk NIPT results. Five themes were identified in the data namely, 'It's not just a DS test', 'Emotional rollercoaster', 'Making the choice', 'Support' and 'Genetic counselling'. There are medical and emotional consequences of NIPT which may be more complicated than traditional prenatal screening. Women were anxious to learn of their 'increased risk' for chromosomal abnormalities, particularly those other than DS. The early timing of NIPT and information it could provide were factors valued by all women in decision-making. Participants' initial anxiety was followed by reassurance. Women equated this reassurance with the reliability of diagnostic testing and often extended it to the overall health of the fetus. Sex chromosome testing was poorly understood. Most women did not initially disclose their increased risk with family and friends due to the tentative nature of the pregnancy. Women all had some external support but also relied on their own resilience. As mothers, they felt responsible for the health of the fetus. Genetic counselling helped contextualise risk, disseminate information and provided emotional support.

This data provides healthcare professionals with some insight into how they can implement a better NIPT service.

## PgmNr 713: Public involvement in global genomics research.

**Authors:**

J.S. Nunn <sup>1,2</sup>; S. Kent <sup>1</sup>; V. Sundararajan <sup>1</sup>; J. Tiller <sup>2</sup>; P. Peter Fransquet <sup>2</sup>; P. Lacaze <sup>2</sup>

---

Public involvement in research occurs when the public, patients, or research participants are actively contributing to the research process. Public involvement has been acknowledged as a key priority for prominent human genomics research initiatives in many different countries. However, to date, there has been no detailed analysis or review of the features, methods, and impacts of public involvement occurring in human genomics research projects worldwide. We reviewed the reported public involvement in 96 human genomics projects (initiatives), based on a database of initiatives hosted by the Global Alliance for Genomics and Health, according to information reported on public domain websites. To conduct the scoping review, we applied a structured categorization of criteria to all information extracted from the search.

We found that only a third of all initiatives reported public involvement in any capacity (32/96, 33%). In those reporting public involvement, we found considerable variation in both the methods and tasks of involvement. Some noteworthy initiatives reported diverse and comprehensive ways of involving the public, occurring through different stages of the research project cycle. Our findings suggest there would be intrinsic value in having more public involvement occur in human genomics research worldwide. We also suggest that more systematic ways of reporting and evaluating involvement would be highly beneficial, to help develop best practices.

We are now working to apply these findings to four prominent genomics research projects in Australia, to co-design their studies and explore people's views about involvement. These projects include a large cohort study of >15,000 healthy, elderly research participants, the Australian Indigenous Precision Medicine project, a group of patients and families affected by a rare immunological disorder, and an extended family of donor-siblings who share the same sperm-donor father. We have assessed the impacts of involving people at various stages of each project, from study design, to recruitment to ethical oversight and governance. We have created a standardised reporting framework to evaluate impacts across these studies.

## **PgmNr 714: Preparation for a child with a genetic condition: What is gained from prenatal diagnosis when parents choose not to terminate?**

### **Authors:**

Some critics of prenatal genetic testing have argued it is primarily used to enable elective terminations. Yet many women and families say they choose prenatal testing for a very different reason: “preparation.” Although literature on prenatal testing often cites preparation as a reason genetic tests are offered or accepted, this concept is not well researched, and no clear definitions or recommendations exist for prenatal preparation. Here we compare “preparation” as it is used in clinical literature with a qualitative study of parental experiences after prenatal diagnosis of aneuploidy. Semi-structured phone interviews explored the experiences of 29 participants who received a prenatal diagnosis of trisomy 18 (n=14) or trisomy 21 (n=15) three or fewer years ago, recruited via national patient advocacy groups. Data were analyzed using an approach based on grounded theory and constant comparative analysis. Our extensive literature review found that preparation has been used to refer to at least 3 overlapping ways in which prenatal information may change parents’ approach to the rest of the pregnancy: (1) clinical activities during or immediately following pregnancy; (2) social and informational support, including interactions with support groups; and (3) psychological adjustment to a revised vision for the future child and family. In interviews, parents discussed many of the same themes, but characterized and prioritized them somewhat differently. Practical activities reported during pregnancy did include clinical decision-making, but also included modifying pregnancy and delivery plans to accommodate personal and family needs, especially when fetal or newborn death was likely. Connecting with other parents with similar experiences took priority for most interviewees, and a lack of timely referral to such connections was one of the most frequent disappointments the interviewees voiced about their clinical providers. Finally, psychological preparation included not only individual re-visioning of the future, but also carefully planned communication strategies with friends, extended family, and other children. In assessing clinical providers, parents prioritized support for values-based decisions throughout pregnancy over clinical knowledge. These findings provide insight into the experiences of families, suggest actions providers can take to improve patient care, and inform ethical conversations about the translation and scope of prenatal genetic tests.

## PgmNr 715: Implementation of exome sequencing in a diverse pediatric population: Experiences from UCSF.

### Authors:

---

The Program in Prenatal and Pediatric Genomic Sequencing (P3EGS) at UCSF is one of six sites in the NIH-funded Clinical Sequencing Evidence-Generating Research (CSER) Consortium studying the utility of integrating genomic sequencing into the clinical care of diverse and medically underserved (MU) patients. The pediatric arm of P3EGS is currently enrolling patients presenting with intellectual disability, metabolic disease, epilepsy, or multiple congenital anomalies.

Since recruitment began in October 2017, we have enrolled 217 children and their biological parents from three hospitals in San Francisco and Oakland, California, that serve diverse and MU communities. 87% of participants have MediCal (CA's Medicaid program) and about one third live in a zip code classified as a MU area. 53% of parents self-identify as Hispanic/Latino(a); 13% as white; 12% as Asian; 8% as Middle Eastern or North African; 5% as Black or African American; 2% as other groups; and 7% as more than one race/ethnicity category. The preferred language of almost half (47%) of enrolled families was a language other than English. Informed consent and results have been communicated via medical interpreters in Spanish, Farsi/Dari, Arabic, Punjabi, Mam and others. Exome results have been returned to 134 families with 37 definitive/probable positive results (28%). 176/217 (81%) of families requested return of secondary findings and 3/176 (1.7%) received positive secondary findings.

During the implementation of P3EGS we addressed several challenges that arose in the process of conducting research with diverse and MU populations. One eligibility criterion is a non-diagnostic microarray, which may not be covered by insurance (especially MediCal), and can require multiple clinic visits. We established a process to obtain pre-authorization for microarrays in order to minimize visits and reduce burden on families. We also adapted our consent form to accommodate lower literacy and non-English speaking populations with a focus on concise, simple language around complex data sharing policies. Lastly, we incorporated flexible survey administration procedures that offer families a choice of completing surveys in-person, through mail or e-mail, thereby minimizing the burden on participants. While offering exome sequencing to MU populations presents unique challenges, our preliminary results show that P3EGS is effectively enrolling and addressing the needs of a wide range of patients and their families.

## PgmNr 716: Methods for identifying health care attributable to unexpected genomic findings.

---

Existing recommendations for clinical genomic sequencing include screening for secondary findings that may be unrelated to test indications, and many advocates envision a future where results are used routinely not only to screen for genetic risk factors, but also to improve medication choices, inform reproductive decisions, etc. The variety of health-relevant information generated by genomic sequencing creates challenges to tracking health care utilization and assessing the full range of clinical benefits that genomic sequencing can provide. In the BabySeq Project, a multi-site randomized clinical trial, we implemented six different approaches to identify health care services that were motivated by newborn genomic sequencing findings over a 10-month period, including (1) reviews of medical records based on recommendations from a genetics specialist during disclosure sessions; (2) reviews of medical records based on risks identified on disclosure reports; interviews of (3) parents and (4) providers; surveys of (5) parents and (6) providers. Preliminary results show that parent interviews were most comprehensive for capturing common services, including 13 of 15 specialty visits (87%) and 21 of 21 cardiac screening tests (100%) for the newborn. Parent interviews were less effective than other approaches for identifying infrequent services such as follow-up genetic tests and lab tests of newborns and other family members. Findings highlight the challenges of assessing downstream medical services that result from unexpected genomic findings. They also demonstrate the benefits of using multiple approaches to assess follow-up care that was received not only by the patient, but by other family members. We discuss these benefits against the conceptual strengths and limitations of each approach, including their feasibility to implement, their ability to track follow-up care that occurs outside of study sites, the ability to account for loss to follow-up and incomplete or biased recall. We also discuss the ability of each approach to capture services that may have been 'avoided' by enhancing prevention.

## PgmNr 717: Effective recruitment and retention of diverse populations in NYCKidSeq.

### Affiliations:

1) Charles Bronfman Institute for Personalized Medicine, Icahn School of Medicine at Mount Sinai, New York, NY.; 2) Center for Genomic Health, Icahn School of Medicine at Mount Sinai, New York, NY.; 3) The Center for Statistical Genetics, Icahn School of Medicine at Mount Sinai, New York, NY.; 4) The Icahn Institute of Genomics and Multiscale Biology, Icahn School of Medicine at Mount Sinai, New York, NY.; 5) Montefiore Medical Center/Albert Einstein College of Medicine, Bronx, NY.; 6) Center for Health Equity and Community Engaged Research, Icahn School of Medicine at Mount Sinai, New York, NY.; 7) Department of Genetics and Genomic Sciences, Icahn School of Medicine, New York, NY.; 8) Mindich Child Health and Development Institute, Icahn School of Medicine at Mount Sinai, New York, NY.; 9) Bethel Gospel Assembly, New York, NY.

Genomic research heavily skews toward participants of European descent, and there is a gap in understanding the impact of genetic testing in underrepresented and diverse populations. Here, we outline effective recruitment and retention strategies of diverse populations into NYCKidSeq, a clinical trial offering whole genome sequencing (WGS) to 1,100 children and young adults with undiagnosed neurologic, cardiovascular disorders or primary immunodeficiencies. The goal is to compare WGS to standard targeted gene panels for diagnosis, and to test participants' understanding of genetic test results using a bi-lingual health app. The patient population is from predominantly low-income and minority communities from Harlem and the Bronx. As these families are particularly vulnerable, recruiting them warrants the design of culturally sensitive, ethically sound recruitment strategies.

Researchers worked with patients, advocates and clinicians as part of a genomic stakeholder board to develop approaches to recruitment and retention and they reviewed all study materials. All study coordinators are bilingual, and a committee of individuals from diverse Latin nations translated study materials into Spanish, including recruitment and educational materials and study surveys. We also continuously engage providers and clinical staff. Our team put in place flexible solutions to accommodate the needs of families who live far from the hospital, are unavailable during work hours, or in which parents are separated. We also use continuous engagement and retention strategies such as mailing customized holiday and birthday cards, and making regular phone-calls throughout the duration of the trial.

To date, we have recruited 63 patients, and their families at 11 clinics throughout Manhattan and the Bronx: 17% Black and 60% are Hispanic/Latinx (half of whom completed the baseline survey in Spanish). Their median household income range was \$25K to \$50K, and less than 60% of parents completed a bachelor's degree. Common reasons among 10 parents who refused to participate were lack of time, concerns with life insurance, or belief that the test is unnecessary.

We have developed, are implementing, and will test the impact of strategies developed in partnership with patients, advocates and clinicians, to enhance recruitment of underrepresented, minority populations into genomics research. These strategies may help mitigate the risk of propagating health

disparities among the US population.

# PgmNr 718: Effect of genetics clinical decision support tools on healthcare providers' decision making: A systematic review.

## Authors:

A. Sebastian <sup>1,2</sup>; J. Carroll <sup>1,3</sup>; L. Oldfield <sup>4</sup>; E. Uleryk <sup>5</sup>; Y. Bombard <sup>1,2</sup>

[View Session](#) [Add to Schedule](#)

## Affiliations:

1) University of Toronto, Toronto, Ontario, Canada; 2) St. Michael's Hospital, Li Ka Shing Knowledge Institute, Toronto, Ontario, Canada; 3) Mount Sinai Hospital, Toronto, Ontario, Canada; 4) Princess Margaret Cancer Centre, University Health Network, Toronto, Ontario, Canada; 5) EU Consulting, Toronto, Ontario, Canada

**Background:** Deciding when to order genetic tests, refer to genetics specialists, or change treatment or surveillance based on genetic risk, is particularly challenging for non-genetics healthcare providers. Clinical decision support (CDS) tools have been suggested as a potential solution because they provide patient-specific risk assessment or management recommendations. This systematic review synthesized evidence on whether using CDS tools affected appropriate changes in genetics-related patient management by non-genetics healthcare providers, compared to standard clinical care without using CDS.

**Methods:** A comprehensive search in Medline, Embase and CINAHL from the year of database inception to March 6 2019 yielded 2254 articles, plus an additional 11 articles from handsearching. Two independent reviewers screened abstracts and full texts for articles that quantitatively compared management outcomes when non-genetics clinicians (clinicians other than medical geneticists, laboratory geneticists or genetic counsellors) used a CDS tool in actual patient care. 9 articles (3 RCTs, 5 pre-post studies and 1 cohort study) were included in the final review. Effect sizes were calculated, and a narrative synthesis was performed for the 9 articles. Study-level bias was assessed using the Joanna-Briggs Institute Checklist appropriate for study design. High risk of bias did not lead to study exclusion.

**Results:** CDS tools focused mainly on pharmacogenetics or cancer, with two tools on thrombophilia and one on cystic fibrosis. CDS tools had a small positive effect on changes in management based on clinical guidelines or best practices that was statistically significant compared to pre-implementation but not significant compared to control groups. These findings are limited by low statistical power, sources of bias in the comparative data such as no controls or blinding, and significant heterogeneity of interventions. Certain predictors of CDS tool success, such as an active design and integration into the clinical workflow, were absent in almost all tools evaluating management outcomes.

**Conclusions and Significance:** This systematic review is the first to review quantitative evidence of CDS tools on genetics management decisions by non-genetics providers. CDS tools show promise because they show a small effect leading to changes in management, but more studies explicitly evaluating tools and bigger sample sizes are needed to establish effectiveness.

## **PgmNr 719: A study on data sharing policies among human gene/variation databases: Data accessibility, usability and disclaimers.**

### **Authors:**

C. Yamasaki; N. Ohashi; K. Kato

[View Session](#) [Add to Schedule](#)

**Affiliation:** Graduate School of Medicine, Osaka University, Osaka, Japan

---

The human gene and variation data are used by a large number of users on wide range of human-related researches from basic sciences to applied and clinical researches. The advances on human genome research, especially personal genome analysis and studies on personalized medicine made those databases essential infrastructure for modern biomedical research. There are several human gene and variation databases, and the numbers of such databases are still increasing year by year. However, the data sharing policies and guidelines for users are different in each database and decided by each database almost independently, which may be one of the causes for difficulties of international collaborations and data-sharing.

In this study, we investigated data-sharing policies of human gene and variation databases, specially focusing on the policies for their data accessibility, usability and disclaimers. We selected and referred to total of 20 human gene and variation databases, 9 from USA, 6 from Europe and 5 from Asia. Next, we extracted and compared the database policies in terms of descriptions of data accessibility, usability and disclaimers for non-profit and commercial users. Then, we examined and summarized the conditions and restrictions for non-profit and commercial users. Here, we report the summary of the current situation and the problems on the international collaboration and data-sharing for all users, and propose what kind of data-sharing policies are required for future researches.

## PgmNr 720: Challenges and prospects of genomic researches in developing countries: Insights from African researchers.

### Authors:

O. Adewole <sup>1</sup>; T. Adewole <sup>2</sup>; S. Ottaru <sup>3</sup>; J. Edem-Hotah <sup>4</sup>; D. Kemevor-Asema <sup>5</sup>; J. Jumbo <sup>6</sup>

---

**Introduction:** Africa unlike other parts of the world is lagging behind in the adoption of genomics. The implication of this, if not addressed is that global health inequities gap may continue to widen. In order to mitigate against this, it is important to understand the challenges and perception of African researchers about genomic studies.

**Aims/Objectives:** This study seeks to unravel the challenges being faced by African researchers in conducting genomic studies and their perceptions of the role genomics in healthcare.

**Methods:** We conducted a qualitative study, involving in depth interviews of 40 mid career and established researchers/physicians across three African Countries (Nigeria, Tanzania and Ghana). The locations were purposively selected. Snowball sampling technique was employed to select the respondents. The data was imported into ATLAS.ti computer software for analysis. Data were analyzed using inductive coding and results were presented thematically using network diagrams.

**Results:** The findings revealed that majority of the respondents are interested in conducting genomic studies, but have never been opportuned. Lack of facilities , non availability of funding , ignorance of the importance of genomics and lack of mentors were some of the reasons identified as being responsible. There are no curriculum for genetics in majority of the respondents medical schools. Most commonly conducted genomics studies were related to infectious disease and were mostly conducted outside their home institutions. The researchers believed that genomics can greatly impact national health care development and disease outcome. They also believed that developed countries are not doing enough to honestly encourage genomic studies by African researchers.

**Conclusion:** The study concluded that if genomics medicine will positively influence healthcare in Africa, there is a need to ensure that African researchers can conduct genomic studies in their native countries as well.

## **PgmNr 721: Description of an active educational system supporting the implementation of a personalized medicine program, in a large multi-site rural hospital.**

### **Authors:**

---

Precision medicine has become more prevalent in healthcare over the last decade. Pharmacogenetics (PGx), an emerging field of precision medicine, has become an important tool that enables clinicians to better predict the efficacy and toxicity of specific medications. The objective of this poster is to describe our unique and robust educational program created to support the implementation of our PGx program in a large rural setting.

As a large health care institution consisting of 44 hospitals and 289 clinics in nine states, Sanford Health serves a predominantly rural population with 1,400 physicians providing care for more than 2 million patients. Imagenetics (our personalized medicine program) began offering PGx testing in 2015. Education is an essential part of PGx implementation. Our education initiatives aim to address a large audience, including patients, providers, pharmacists, laboratory personnel, nurses, and other healthcare professionals.

To maximize patient education, we developed a comprehensive series of educational material, including patient pamphlets and flyers, a public website, and various lectures to the community and various patient groups. Our public website contains storyboard-type videos and explanations that are clear and easy for patients to understand. We have found that patient education and awareness facilitated the acceptance and adoption of this new type of testing by helping to introduce, and explain the benefits of a guided treatment plan tailored to each patient's unique genetic makeup. Our employee educational program uses various tools and platforms to deploy customized educational material in order to reach a diverse audience of healthcare professionals. Our training material includes mandatory webinars, live lectures, and clinic in-services supplemented by informational handouts. We developed a centralized informational resources website that contains videos and downloadable educational materials.

The Sanford PGx educational program thus contains a wide spectrum of components to address patient and healthcare professional educational needs. We developed tools for our institution to improve the awareness about the use and interpretation of PGx testing among our healthcare professionals and the public community. This poster aims to share our experience. We also hope to provide guidance for other institutions seeking to develop an educational process and materials for a PGx program in their clinical practice.

## PgmNr 722: The triad approach: Stimulating learning in the undergraduate genetics classroom.

**Authors:**

M. Eslinger; J. Torre

[View Session](#) [Add to Schedule](#)

**Affiliation:** Department of Chemistry & Life Science, US Military Academy, West Point, New York

---

National education efforts emphasize the need to practice the process skills of science rather than strictly focus on discipline-specific content. Developing these vital skills early within undergraduate education promotes cognitive progression and conceptual application; however, they require deliberate cultivation, particularly with early-stage scientists. We developed the “Triad Approach” for use in the genetics classroom as a departure from traditional lecture to encourage translational skills. The Triad leverages active-learning through iterative cycling of lectures, journal clubs, and case studies on specific genetics course related themes. Thus, students observe, analyze, and apply content three times from unique perspectives, resonating with multiple learning styles. Following Triad iterations, students were also assessed with comprehensive problem sets, requiring interpretation of data, analysis of case studies, and mining primary sources for genomic-related information. Through a systematic comparison of data from direct and indirect mechanisms (self-assessments, grades, and surveys) we show marked improvements in learning and scientific literacy. Pre- and post-course self-assessments show a 0.55 average normalized gain in quantitative knowledge (modeling); 0.33 gain in critical thinking; 0.40 gain in quantitative reasoning (math); and a 0.63 gain in analytical genetic skills (-omics). Importantly, student report a 0.70 average gain in their ability to lead scientific discussions on genomics and bioethics. Similarly, we compare cumulative pre-course GPA to genetics course performance to identify students who “over” or “under” perform through this approach and relate this to preferences for traditional learning or active learning strategies. Finally, we see higher reported means for critical thinking and learning indicators in the genetics cohort compared to students across the university. Moreover, the departure from memorization of foundational knowledge enhances their ability to apply knowledge in new ways. Together, we present this effective teaching style as a mechanism for faculty to stimulate independent student learning while leveraging contemporary tools for data acquisition and analysis, all important skills desirable to improve retention and conceptual application.

## PgmNr 723: Student genomics: Integrating DNA sequencing into a middle school classroom.

---

**Background:** While many partnerships exist between research institutions and secondary schools, few opportunities exist for young learners to become involved in established research projects. New technologies such as 3rd generation DNA sequencing are often perceived to be out of reach of new faculty, or postdocs and predoctoral trainees who cannot write their own grants. With slight modifications, projects can be adapted as learning opportunities for learners at all stages of development. In this classroom pilot, we adapted ongoing DNA sequencing projects at Baylor College of Medicine to meet learning objectives for a flexible 7th grade science elective. So, **how well would DNA libraries prepared in the classroom by 7th graders compare to those of a “proficient user?”**

**Methods:** Meeting every other day for 55-minute periods (4 periods total over 2 weeks), students were taught about DNA, biological information content, and the manual dexterity required to process Biosafety Level 1 DNA pellets from cultured *Lactobacillus reuteri* for downstream multiplexed sequencing on the MinION Mk1B device (Oxford Nanopore Technologies, Oxford, UK). Students were also taught the technology behind this sequencer, and spaced retrieval was used to reinforce concepts. The libraries produced in the classroom were compared to the libraries produced in a typical laboratory by a trained professional.

**Results:** Students completed a majority (53%) of procedures needed to create the libraries, and the quality of these libraries exceeded the quality of libraries from a proficient user. Data from this sequencing run has contributed to multiple manuscripts.

#### 7th Grade Classroom Libraries

1.) 4 bacterial pellets (bar02-05) (“Student Genomics”; in prep)

#### Control “proficient user” Libraries

2.) Transgenic mouse genomic DNA (bar01, 12) (in prep)

3.) Single plasmid (bar 10, 11) (Gener, 2019. BioRxiv. <https://doi.org/10.1101/611848>)

#### 4.) Multiple plasmids (bar06-09) (“Physical Multiplexing”; in prep)

**Conclusions:** To our knowledge, this pilot is the first time students at this level were able to contribute to ongoing DNA sequencing projects, serving as a proof-of-concept for future collaborations between research institutions and secondary schools. While self-contained, similar work may be completed within the current bandwidth of most sequencing centers, demonstrating that real data may be recovered from educational activities.

## PgmNr 724: Challenges and prospects of genetic education in primary and secondary science education in Japan by international comparative study.

### Authors:

R. Kawaguchi <sup>1</sup>; F. Takada <sup>1,2</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Department of Genetics, Kitasato University Hospital, Sagamihara, Kanagawa, Japan; 2) Department of Medical Genetics and Genomics, Kitasato University Graduate School of Medical Sciences, Sagamihara, Kanagawa, Japan

---

**Purpose** Recently, genetic tests which look at human genes or chromosomes have become close to Japanese citizens. That makes them more interested in Genetics. On the other hand, it is pointed out that the contents of science education aren't enough for citizens to understand Genetics (Ikeuchi, 2012, 2015). In this study, we focused on science education in primary and secondary education which played an important role as an education of the public. Purposes of this study were understanding the present situation, extracting problems, and considering improvement plans of genetic education in Japan.

**Method** In this study, we classified "Genetics" as "Heredity" and "Variation". We selected items about heredity and variation using science curriculums in primary and secondary education which were published from the education ministry of Japan, USA (California, Massachusetts), UK (England), Australia, Canada (Ontario), Singapore, Philippine and International Baccalaureate Organization (IBO). And then, we investigated differences of genetic education among Japan, foreign countries and IBO.

**Results** Problems of current curriculums include only discussing the law of segregation in middle school, and not using the term of "mutation" in secondary education. Despite this, there is enough information taught that students can understand the link between genetics and diversity. We confirmed that genetic education in Japan is shorter than other countries and other countries deal with diversity in primary education. Genetic diseases are taught in some countries. Therefore, it is a global problem that most curriculums do not include information on various genetic diseases.

**Discussion** To improve the genetic literacy of citizens, it is important to do genetic education to all the people common in primary and secondary education. We think that it is necessary to do gradually genetic education from primary education over the multi-year and include contents which students can understand the basis of genetics link to human genetics.

**Conclusion** In this study, we understood the present situation and considered improvement plans of genetic education in Japan. It is difficult to state that genetic education in Japan is enough. We think that Japan should consider improvement of educational curriculum refer to global genetic education.

## PgmNr 725: SoapyCilantro<sup>(R)</sup> AFLP assay: A facile genomics education tool for students, STEM educators, and health care professionals.

---

**Background:** Genomics is the foundation of precision medicine, the future of human health care. Since 2003, voluminous information on structure and function of human genome has been gathered. However, translation of this technical knowledge into routine health care applications has progressed at a relatively slower pace. Lack of trained health care professionals is deemed a major barrier. Experts recommend inclusion of genomics in pharmacy, nursing, medical and allied health care education. Moreover, genomic analysis of students' own DNA has been shown to improve learning outcomes and student interest in precision medicine. Despite these pedagogical benefits, this approach has an inherent ethical limitation. These methods use gene-phenotype pairs with health implications for participants, necessitating genetic counselling. Lack of access to genetic counselling precludes many institutions from offering genomic education and training. We have developed a facile DNA genotyping assay to alleviate this ethical concern further enhancing the educational value of the experience.

**Methods and Results:** We employed the 'soapy cilantro' phenotype for genetic variations rs72921001 and rs78503206, as a tool to teach effects of single nucleotide polymorphism (SNPs) on human traits. Specific PCR primer sets were designed to amplify genomic DNA containing these SNPs associated with the 'soapy' cilantro taste. Variations in DNA sequence were detected by amplicon fragment length polymorphism (AFLP) using specific restriction enzymes.

Primer sets we designed successfully amplified DNA regions containing rs72921001 and rs78503206. Agarose gel electrophoresis of amplicons before and after restriction digestion agreed with *in silico* predicted results and confirmed the presence of specific genetic variation. Using this method, we detected 'soapy' genotype in 12 out of 118 DNA samples from adult human volunteers. Our method shows a 100% concordance for the 'soapy' genotype with the taste-test phenotype. These results, along with advantages and limitations of our protocol are discussed.

**Implications:** Our method is a safe, facile AFLP genotyping assay for a human phenotype. It alleviates ethical limitations about sharing participants' genomic information. It is being used for genomic education of students from middle school to professional school, as well as for continuing education of STEM teachers, health care professionals and community members alike.

## PgmNr 726: Influence of genetic education in the practices of health-care workers in University College Hospital, Ibadan, Nigeria.

### Authors:

---

Geneticist and genetic counsellors are scarce in developing nations. Providing access to genetic information and appropriate use of genetic technologies becomes prerogative duties of available health care practitioners in the health centers. Thus, this study assessed health-care workers' knowledge of genetic education and the influence it had on their practices of genetic services in a foremost tertiary hospital in Nigeria.

A descriptive cross-sectional design was employed. Sample size was calculated using Cochran formula. Multistage sampling technique was used to select 320 health workers (Nurses, Physicians, Pharmacists and Laboratory scientist). A 29-item questionnaire was used for data collection. It had three sections. Section A explored the socio-demographic details of the respondents, section B assessed their level of knowledge of genetic education and past training curricula while section C determined their current practices of genetic services. Ethical approval was obtained before data collection. Data was analyzed using SPSS version 21.0. Results were presented in descriptive and inferential statistics (chi square) used to test for hypothesis at p-value of 0.05.

Result revealed that more than half (56.6%) of the respondents were below 40 years of age, with majority having first degree in their field (77.2%) and married (71.6%). Less than half (48.2%) had more than ten years of work experience, while (55.6%) were Nurses and had worked in the field of clinical genetics (57.8%). Few (15.9%) of the respondents had poor knowledge of genetic education, and 42.5% had good knowledge. Among the items assessed and the percentage of correct responses were, unit of inheritance (60.3%), mutation definition (72.2%) and list of diseases with genetic components (75.3%). More than half (57.8%) of the respondents reported good practice while 42.2% had poor practice of genetic services. Educational level, profession and years of experience had significant association ( $p < 0.05$ ) with knowledge of genetic education. Also, educational level, profession, availability of medical genetic unit and experience in clinical genetics were significantly associated ( $P < 0.05$ ) with practice of genetic services.

This study concluded that provision of facilities for the practice of genetics in various department is needed to improve practitioners' knowledge and practice of genetics services.

## PgmNr 727: Integrating an alternative genetic services delivery model using an online platform.

---

The Department of Molecular and Human Genetics at Baylor College of Medicine has created and implemented a hybrid genetic service delivery model called Consultagene™ (www.Consultagene.org). Consultagene™ is a secure multimedia platform that offers a variety of educational videos, genetic counseling, and peer-to-peer genetic services. The videos enhance traditional face-to-face encounters, and the platform provides a venue for tele-genetic counseling services. For the past two years, a Whole Exome Sequencing (WES) video was integrated into the clinic workflow to assist with consenting patients for WES. Pre- and post-video surveys demonstrate improved patient knowledge, understanding, and comfort level with explaining WES to others after viewing the video (i.e. patient comfort explaining WES improved from 1.82 (N=243) on a Likert scale of 1 to 5 to 3.42 (N=196) after viewing the WES video.

As a result of this favorable patient feedback, we have now implemented an expanded array of videos and educational “journeys”, which are guided client experiences customized to the referral indication, in additional settings including cancer. Here we present our ongoing experience with our hybrid service delivery model. The videos, including: Basics of Genetics, BRCA1 & BRCA2 Sequencing, and Multigene Panel Testing, are assigned for viewing based on patients’ indications prior to their appointments. Survey data is collected on their experiences with videos as well as experiences with the tele-genetic counseling process for those who received tele-genetic counseling. Survey respondents who viewed the Basics of Genetics video (N=33) rated the informativeness of the video as 4.05 on a scale of 5. Comfort level explaining genetic testing for BRCA1 and BRCA2 variants to others improved from 2.38 (N=24) to 3.5 (N=22) out of 5 after viewing the video, and improved from 2.2 (N=10) to 3.78 (N=9) after viewing the multigene panel video.

This preliminary data suggests that the videos effectively supplement genetic counseling by improving patient knowledge and understanding of relevant genetics concepts. In addition, we have accumulating evidence that patients have more focused questions as a result of having viewed the videos in advance, therefore, improving clinical efficiency. Given the improvement in patient understanding of genetics concepts via video education, we plan to generate additional data from newly developed prenatal and preconception educational journeys.

## PgmNr 728: Exploring genetics through genetic disorders: Developing and testing an NGSS-aligned high school curriculum unit.

### Authors:

L. Stark <sup>1,2</sup>; M. Malone <sup>2</sup>; S. Homburger <sup>2</sup>; K. Fenker <sup>2</sup>; D. Dritz-Esser <sup>2</sup>; M. Kelly <sup>2</sup>; R. Perkins <sup>2</sup>; K. Breitenbach <sup>2</sup>; J. Peterson <sup>2</sup>; K. Pompei <sup>2</sup>

---

We have developed an NGSS-aligned high school genetics unit, *Exploring Genetics Through Genetic Disorders*. In this 3-week unit, students explore foundational genetic concepts on the Learn.Genetics website, then they apply those concepts to explore how a specific allele causes the symptoms of a genetic disorder. They emerge with a concrete understanding of how variations in genes—through effects on proteins, cells, tissues, and organs—lead to phenotypes. Resources include in-depth information on 5 alleles for each of 5 disorders: alpha-1 antitrypsin deficiency, cystic fibrosis, hemoglobin disorders, hemophilia, and Marfan syndrome. The unit addresses the 3 dimensions of the Next Generation Science Standards (NGSS): Disciplinary Core Ideas (HS-LS1 and LS3); Science Practices (Developing & Using Models, Analyzing & Interpreting Data); and Crosscutting Concepts (Cause & Effect, Structure & Function).

Our iterative process for developing and refining the unit involved an alpha test with two biology teachers, followed by revisions, and a pilot test with two others the following year. During the pilot phase, we collected data through: (1) a pre/post student knowledge gain assessment with 27 multiple choice and 2 open-response items, developed and validated using our published methods (Bass, Dritz-Esser & Stark, 2016); (2) a teacher end-of-implementation survey, designed to understand teachers' experiences with the unit, perceived student learning and engagement, and feedback for making revisions; and (3) classroom observations.

The 80 students who completed both the pretest and the posttest showed statistically significant learning gains,  $t(79) = 7.44$ ,  $p < .001$ , with a Cohen  $d$  effect size of .82. Surveys indicated that both teachers plan to teach the entire unit in sequence with the addition of other lessons; that students learned all the unit's intended learning outcomes either very well (genes code for proteins, most traits are influenced by both genes and the environment) or somewhat well (mutation is a natural process that generates variation in DNA sequences); and that the disease-causing allele investigation was effective for student engagement.

We will revise the unit then conduct an RCT in September 2019 with 6-8 teachers, comparing learning gains of students who experience the curriculum either with or without the disease-causing allele investigation. We will present preliminary RCT results along with pilot test results.

## PgmNr 729: ClinGen community curation: Crowdsourcing curation efforts from geneticists to citizen scientists.

### Authors:

---

With the current advancements in molecular diagnostics and precision medicine, new genes and genetic variants are discovered daily. Recent reports highlight that ~15,000 genes are associated with human disease. Genetic variants may number in the tens to thousands per gene, indicating the involvement of millions of variants with disease. Current variant numbers in ClinVar, a variant database, indicate half a million disease-causing variants, with numbers projected to rise in the coming years. Though automation of evidence curation by machine learning approaches has the potential to improve and accelerate curation, it will not replace the need for manual curation and interpretation of complex data in the foreseeable future. ClinGen has developed and implemented standards and infrastructure to support expert clinical annotation and interpretation of genes and variants; however, a significant crowdsourcing effort is needed to support the exponential increase in the number of genes and variants requiring interpretation. In order to establish a community of volunteer curators, from clinical geneticists to citizen scientists, ClinGen established the Community Curation Working Group (CCWG). Since forming in Fall 2018, CCWG outreach efforts have matched over 200 volunteer genetics professionals from 19 countries with their preferred ClinGen curation effort (gene, variant, dosage, somatic cancer, and actionability) and clinical disease area via an online survey on the ClinGen website. In addition, the CCWG is developing a web-based volunteer annotation program to engage citizen scientists who wish to contribute to the overarching genomic knowledge base of clinical evidence, such as human phenotyping and disease ontologies, variant identifiers, and tags corresponding to ACMG and AMP sequence variant pathogenicity criteria. Here, we will present an overview of the engagement process, curation results, and volunteer feedback. Global participation is the cornerstone of sustainable and widely utilized gene and variant curation and expert interpretation, and the growing awareness of ClinGen activities with the development of web-based curation interfaces is cultivating a grassroots interest in a “crowdsourcing” effort that will enable large-scale enhancement and acceleration of ClinGen’s mission to “curate the clinical genome.”

## **PgmNr 730: Genetic education: Preparing Physician Assistants (PAs) for the genetic patient.**

### **Authors:**

L. Tribble; W. Patterson

[View Session](#) [Add to Schedule](#)

**Affiliation:** Greenwood Genetic Center, Greenwood, South Carolina.

---

### **Background:**

In today's practice of medicine, there is growing acceptance of the role that genetics and genomics play in providing effective patient care. Given the shortage of clinical geneticists and genetic counselors, there is a need to bring other health care providers into the care of genetic patients. The challenge is to provide the genetic education to enhance providers' knowledge, application and practice of genetics and genomics.

### **Objectives:**

To address this challenge and shortage, the Greenwood Genetic Center's (GGC) Division of Education designed and implemented a pilot program targeting physician assistant students. The objectives were to provide background on basic processes, genetic testing, family history, and when to consider referring to genetic professionals. With this information, it is anticipated that when in practice, these students will have a better understanding and knowledge of what to look for and how to better manage their patients.

### **Methods and Design:**

The pilot program was a series of five meetings with the PA students consisting of formal presentations on the major areas of cytogenetics, molecular and biochemical genetics, and dysmorphology, through the use of patient cases. Through grant support to expand PA education in biochemical genetics, students were also introduced to lysosomal storage diseases, a group of rare conditions that are thought to be under diagnosed, but for which many medical management options exist.

### **Results and Conclusion:**

Formal student evaluations and pre and post assessment scores indicated an improved understanding of the genetic content. This is a positive result but one on which to continue building. Genetics content should be more fully integrated throughout the training curriculum to reinforce the role and application of genetics and genomics in family medicine, oncology, cardiology, and other areas of practice. Genomic medicine is here and PAs must be prepared to be the first medical encounter for the patient and to provide professional, long-term care for the patient.

## **PgmNr 731: Genetically modified education: Exploring new paradigms for public engagement with genomics at community biology (DIYbio) labs.**

**Authors:**

E. Tuck

[View Session](#) [Add to Schedule](#)**Affiliation:** Genspace, Brooklyn, New York.

---

As genomic information and technologies become increasingly prevalent and integrated into our daily lives in sectors such as medicine, material design, agriculture, and environmental conservation, there is an increasing need for robust public engagement and community-focused dialogs about these myriad applications. With respect to human health specifically, many people express curiosity to learn more about their personal genomic information, as evidenced by the growing popularity of consumer genetic testing services, but they are often left with significant gaps in the ability to dive more deeply into this information with trusted experts, and there are very few places for dialog to explore what this information might mean for themselves, their families, and their communities. Community Biology Labs (sometimes referred to as DIYbio labs or biohackerspaces) have emerged over the last ten years as community-centered spaces where anyone, regardless of educational background or prior experience, can explore various aspects of emerging biotechnology in a hands-on, experiential, and personally relevant way. Popular media representations of these spaces implies they are full of reckless, radical self-experimentalists, but in reality this growing global movement provides a space for people to learn about new technologies and participate in the growing bioeconomy in a safe, environmentally responsible, and inclusive setting.

In this study, we investigate the role that Genspace, a community biology lab based in Brooklyn, NY and the first community lab world-wide, play in public engagement with genomics. Over the past 6 months, we have collected demographic information and conducted focus groups to discuss the types of information people are seeking to investigate about their genomes and their role in understanding their identity, their health risks, and the ethical, legal, and social implications of exploring this information in a Community Biology Lab setting. Emerging themes include a strong emphasis on data access and sharing, as well as a larger interest in developing the computational and data literacy skills needed to investigate genomic data themselves. Community Lab participants express strong views about the autonomy of personal genomic data, concerns over the role of industry in monetizing genomic data, and general optimism about the role genomic information can play in making healthcare and other personal decisions.

## PgmNr 732: Improving undergraduate medical genomics education with an elective intercession course.

### Authors:

2) Johns Hopkins University School of Medicine, Baltimore, MD

---

Next generation sequencing (NGS) technology is increasingly used as a diagnostic tool and for aiding in complex trait, genetic risk assessment and pharmacogenetic testing. However, physician education on how to use and interpret NGS technology, particularly whole exome sequencing (WES) lags behind. Undergraduate medical education needs to encompass NGS technology, data analysis, interpretation, counseling, and ethical consideration.

We developed an elective Topics in Interdisciplinary Medicine (TIME) course available to Johns Hopkins University (JHU) School of Medicine students as a pilot in 2017, then as an integrated course in the Genes to Society curriculum in 2018. The course objectives were: 1) Understand differences, applications and consequences of single gene, disease gene panels, and WES/WGS in the clinic; 2) Understand laboratory/analysis techniques used to generate NGS data; 3) Identify key databases and programs to evaluate sequence data and interpret variants; 4) Understand variant classification criteria, causality, variants of unknown significance, incidental findings, and how these results are reported; and, 5) Appreciate the necessity for pre-/post-genetic counseling for sequence-based tests, especially for WES/WGS, including review of consent, test reports, and related ethical issues. The 3 day course included lectures and small group sessions with literature discussion, role-playing of patient consenting, and identifying pathogenic variants with PhenoDB (Sobreira et al, Hum Mut, 2015), an online, problem-based teaching tool developed by as part of the Baylor-Hopkins Center for Mendelian Genomics. A student survey was used to evaluate perception of course quality/effectiveness and identify areas of improvement.

The course was positively received by the majority of students. 61.5% of students rated the quality of the course as Very Good or Excellent. 84% Agree/Strongly Agree that they received clear learning objectives for the course. 84% Agree/Strongly Agree that the course content reflected those learning objectives. And, 80.5% of students Agree/Strongly Agree that they feel confident in their ability to share information on genetic conditions and other supportive resources with patients and families. The course will be offered annually for third year medical students at JHU School of Medicine, with the long-term goal of increasing future physicians' familiarity with genetic testing and comprehension of clinical WES/WGS.

## **PgmNr 733: “Genetics for Clinicians,” an online-only graduate course: Design, methods, and experience.**

### **Authors:**

R.S. Wildin <sup>1</sup>; C.A. Giummo <sup>1</sup>; T.F. Williams <sup>2</sup>

[View Session](#) [Add to Schedule](#)

### **Affiliations:**

1) Pathology and Laboratory Medicine, University of Vermont Health Network, Burlington, Vermont.; 2) Equitas Life Sciences, Essex, Vermont.

---

Genetics education in graduate nursing programs is essential to prepare nurses and other health providers for advanced clinical practice. A 3-credit, 14-week course in healthcare genetics has been offered annually at the University of Vermont since 2014 as part of the Ph.D. Nursing and Masters-level Medical Laboratory Science programs. Most students work in healthcare settings across a rural state with limited availability to attend on-site classes. The course is designed with modular content including video lectures, reading assignments, quizzes, and facilitated discussions. Cross-functional Genetics professionals have expanded and updated the clinical and case-based content, and created or modified modules. An online teaching platform is used with robust capabilities for multimodal teaching and grading, and for facilitating interactions via asynchronous discussion boards. Despite the limitations of online learning, ratings from the over 100 students completing the course are consistently high. Mentored clinical experiences are replaced by reflections placing their learning in their own clinical context by retelling real-life nursing or personal experiences on a guided discussion board.

Advantages of online teaching of genetics include reusability of modules, automated module release, integration with grade management platforms, accessibility for geographically distributed students and those with diverse work schedules, and instructor-facilitated discussions involving >30 students. Asynchronous teaching alleviates scheduling conflicts with patient care responsibilities for the instructors as well. Incorporating simulated clinical encounters and other web-based tools enriches the learning experience. Lack of face-to-face interaction with instructors, and the associated barriers to mutual insight and respect, is a potential disadvantage. Overall, the utilization of multiple interactive learning modalities, schedule and teaching flexibility, and integration into technology platforms has empowered a highly successful learning experience. Expansion to other clinician learners is contemplated.

## PgmNr 734: An analysis of genetics-related discussions on social media over the last decade.

**Authors:**

N.M. Ferraro; A. Lavertu; R.B. Altman; S.B. Montgomery

[View Session](#) [Add to Schedule](#)

**Affiliation:** Stanford University, Stanford, California.

---

Increased accessibility of genetic testing is shaping public discussions around the impact of genetics. The coinciding rise in social media usage provides an opportunity to assess how genetics is discussed on these platforms. We focus on the social media site Reddit, the 5th most trafficked site in the US. Reddit is organized into topic-specific communities that indicate at a high-level the focus of that set of users' interactions and comments.

To identify a set of relevant terms, we created a word embedding model and conducted a beam-search within the embedded space starting with the term "genetic". This resulted in a set of 8,580 genetics-related terms and hundreds of millions of comments containing those terms across 318,105 topic-specific boards.

The main variation in this set of terms in the embedded space occurs on an axis of formal usage more typical of academic fields like biology or geography to informal usage, with references to racial identifiers, stereotypes, and relationships. Clustering terms reveals 7 primary topic spheres, including discussions of (1) racial/ethnic identity, (2) sociodemographics, (3) geography and history, (4) populations and communities, (5) ancestry and population genetics, (6) molecular biology, and (7) trait associations.

We track comments containing terms in each cluster from 2008-2018. The only cluster to increase in proportional frequency relative to 2008 is (1) racial/ethnic identity. Based on topic board usage, clusters 1 and 5 are the most dissimilar, indicating little overlap in discussions around genetics between these communities. Specifically, for a forum discussing DTC genetic testing, 23andme, we find that the predominant cluster switches in 2017 from discussions centered around (6) biology to (3) geography and (4) populations.

As an example, we highlight responses to high-profile coverage of genetics in the media, following presidential candidate Elizabeth Warren's release of genetic test results. Comments mentioning Warren in all clusters increased substantially in the month of the release, before returning to baseline in the next month. Cluster 4 increased most dramatically. This may indicate a short window of opportunity for researchers to inform public perception surrounding high-profile genetics work. Overall, we aim to inform genetics researchers of varied public interpretations of the field, and leverage these insights to understand how researchers could better communicate with the public.

## PgmNr 735: A mixed recruitment approach to enrolling participants in monogenic diabetes genetic research.

**Authors:**

J. Goehring; M. Snyder; K. Blessing; P. Gingrich; S. Thomas; Y. Hu; D. Carey

[View Session](#) [Add to Schedule](#)

**Affiliation:** Genomics, Geisinger Med Ctr, Danville, Pennsylvania.

---

Diagnosis of monogenic diabetes (MD) is complicated by phenotypic heterogeneity and lack of adequate screening methods. Via a multicenter study, Geisinger and 3 other sites sought to develop an approach to identify MD using varied recruitment, systematic screening, and genetic testing. Unlike the 3 urban recruitment sites, Geisinger is a rural healthcare system in central Pennsylvania and southern New Jersey. To identify the optimal recruitment method in a rural-based endocrinology population, we compared the success of various recruitment strategies used in this study.

Patients were screened for enrollment through an electronic health record (EHR) data pull and patient intake questionnaire (IQ), administered in one of three ways: regular mail, via a secure EHR patient portal (MyG), or in person during a routine endocrinology outpatient visit. The research team reviewed all IQs for study eligibility. Eligible participants were invited to complete a study visit, during which study data forms and venipuncture for laboratory testing were completed. The data were then used to select participants for genetic testing. Those who had genetic testing were notified of a positive or negative result. Cascade testing was offered to family members.

IQs were mailed to 2,240 individuals (1,970 adult, 270 pediatric); 67 (55 adult, 12 pediatric) enrolled in the study (3%). IQs were sent to 1,541 individuals (1,266 adult, 275 pediatric) via MyG; 50% of adults and 33% of guardians of pediatric patients read the recruitment message without responding; 34% of adults and 49% of guardians did not open the message; 14% of adults and 17% of guardians responded to the message; 26 enrolled in the study (2%). IQs were administered to 580 adult patients at the time of an outpatient endocrinology visit; 58 enrolled in the study (10% enrolled). These results suggest that in this rural health care system in-person encounters are more effective enrollment strategies than either mail or electronic approaches. Further research is needed to determine the factors that account for this difference.

## PgmNr 736: A pilot study integrating clinical genome sequencing into the US Air Force: Airmen's perceptions and attitudes after receiving results in the MilSeq Study.

---

Clinical integration of exome sequencing (ES) in active-duty military settings raises unique considerations, including how ES results may influence service members' careers.

The MilSeq Project is a pilot study that enrolled ostensibly healthy, active-duty Airmen in the United States Air Force (USAF) to undergo ES (n=75). Airmen completed surveys to assess their perceptions of ES prior to (pre) and 6 weeks after (post) receiving results (n=69). Airmen's ES results were incorporated into their medical records and included monogenic findings, carrier status variants, disease-associated risk alleles, and pharmacogenomic information.

The majority of Airmen who responded at post (66%) agreed that they trust the USAF with their genetic information. When asked whether ES should be used for duty assignments, 32% disagreed and 56% were neutral; when asked whether ES should be used for deployment decisions, 34% disagreed and 50% were neutral. Most (76%) did not support the USAF requiring Airmen to undergo ES.

Despite this, before undergoing ES, 87% of Airmen thought that their results were unlikely to influence their career in the Air Force, and at post, 96% reported that the ES results had in fact no impact on their career (regardless of results type(s) received). The majority of those respondents (99%) also did not think there would be an impact to their career in the future.

At post, 85% of Airmen agreed that ES has health benefits and 83% agreed that the benefits outweigh the risks. Airmen on average scored the future utility of ES at post an 8 ( $\pm 1.6$ ) out of 10 on a scale anchored by (1) not at all useful to (10) extremely useful. Participants concerns about future insurability and discrimination decreased significantly ( $p < 0.05$ ) at follow up (38% to 19% and 18% to 10%, respectively).

We found that Airmen perceived benefits to receiving ES results. At post, Airmen were less worried about discrimination than at pre, and did not think the information would impact their career. Yet,

they remained wary about the potential influence of ES in duty and deployment decisions. Our findings suggest an openness among participant Airmen to incorporation of ES in the Military Health System with some use limitations.

## PgmNr 737: Political slant, gaps, and misinformation in public discussions of DNA testing of migrant families at the US-Mexico border.

### Authors:

D. Madden <sup>1,3,4</sup>; J.K. Wagner <sup>1</sup>; V. Oray <sup>2</sup>; S.H. Katsanis <sup>2,3,4</sup>

---

The 2018 separation of migrant families at the US-Mexico border and subsequent use of DNA testing for family reunification sparked controversy in news and social media. Public debate continued into 2019, fueled by a rapid DNA program at the border by US Immigration and Customs Enforcement to perform kinship analysis to verify migrant family claims. We sought to evaluate how the use of DNA in a politically-charged, non-medical context was covered by news and social media. We conducted systematic searches of newspaper databases and the social media platform Twitter for coverage of DNA testing and migrants for the 2-month period of June and July 2018. After refining for relevance, we identified 183 articles and 153 Tweets. Of the articles, only 70 contained discussion of DNA testing beyond reporting that it was being used, and only 27 had substantive DNA testing-related content. For comparison, our search parameters were repeated in May 2019 to capture articles and Tweets about the rapid DNA program. Using qualitative approaches, we evaluated the data for biases: (1) political, (2) immigration (i.e., "zero-tolerance") policy, and (3) DNA testing (i.e., for/against testing). We then coded content to identify coverage of the science, process of DNA testing, and major ethical considerations. We identified trends, including common topics and miscommunications, as well as significant gaps in coverage of DNA testing and ELSI topics. In both news articles and Tweets, we found that a politically conservative or pro-zero tolerance policy slant strongly corresponded to a pro-DNA testing stance, while a liberal or anti-zero tolerance policy slant corresponded diversely to pro-, anti-, and neutral DNA testing stances. Public discussion of recent events at the US-Mexico border demonstrates both the complexity of the arena in which DNA testing for immigration is considered as well as key communication issues facing the genetics community. These issues include: (a) lack of transparency on the use of genetic information (causing speculation); (b) ineffective inclusion of genetics experts in public conversations (causing misinformation to spread); and (c) ill-preparedness of the genetics community to react to public confusion and outcry (causing scientific misunderstandings to go uncorrected). Genetic experts' contributions to such discussions shape public opinion and are an opportunity to accurately communicate the risks and benefits of DNA testing in non-medical contexts.

## **PgmNr 738: The ethical considerations of using ancestry DNA testing in statelessness and tribal citizenship cases to determine heritage and attribute nationality.**

### **Authors:**

V. Oray <sup>1</sup>; A. Porter <sup>1</sup>; S. Katsanis <sup>1, 2, 3</sup>

---

As national security interests lead to the strengthening of borders, there are heightened efforts to detect fraud in nationality claims. One tool to evaluate these claims is through ancestry DNA testing. However, results from commercial DNA testing for ancestral origins can be erroneously confounded with nationality. While DNA can reveal clues regarding ancestral geographic migration patterns, it cannot determine countries in which past generations might have resided or held citizenship. Nevertheless, such DNA tools might be informative, or even the only recourse to provide evidence of ancestral heritage, such as in the case of statelessness or tribal membership. The UNHCR estimates that 10 million people are stateless, that is lacking documentation of citizenship to any country. Stateless people might not be permitted to travel, marry, and/or work either in their country of origin or their destination country. Similarly, other sovereign states, such as indigenous tribes in the United States and Canada, have begun using DNA testing for citizenship. The ability to provide scientific evidence of native ancestry and receive an authentic tribal membership can allow one to have access to material goods and emotional support. These two examples provide an opportunity to examine how ancestry DNA results are used as scientific evidence of nationality and group membership. As part of our research into the applications of genetic information in immigration, we evaluated examples of contexts where DNA testing was applied to determine ancestral origin as a proxy for nationality, considering the personal, sociopolitical, and cultural risks and benefits. In one of these contexts, an ancestral DNA test was allegedly used to screen for claims of nationality for a stateless person to support a refugee claim. We also examined the use of ancestry DNA results to support claims to American indigenous tribal citizenship. We compared these examples to identify overlapping themes with regard to autonomy, identity, human right to migration, documentation of statehood, informed consent and risk of stigmatization. Our result is an examination of the ethical considerations for use of ancestry DNA testing, alternatively, to screen out nationalities, versus as an individual tool for documentation of nationality. Ultimately, the use of ancestry DNA testing as a proxy for nationality leads to the potential conflation of biological origins with political borders and cultural narratives.

## PgmNr 739: Can forensic genetic genealogy and SNP typing be used to investigate missing migrants' cases? Should it?

### Authors:

---

The reported successes of forensic genetic genealogy (FGG) in criminal cases and the ensuing debates regarding the privacy implications of this investigative approach prompted us to question whether SNP typing could be useful-or should be considered-to investigate missing migrants' cases. Over the last decade, thousands of human remains have been found along the southern US border. Due to a lack of DNA data-sharing, deceased migrants remain unidentified for years. Similar to the cold cases comprising most of the criminal FGG cases to date, missing migrants' cases have few options for resolution. But the privacy implications of law enforcement investigations resulting from genetic leads to biological relatives are unresolved, and not yet considered for missing migrants' cases. The data in public databases (GEDmatch) are thought to not be diverse enough to provide any identity by descent (IBD) similarities useful for non-European origin cases. Yet, if a database were diverse enough to benefit Latinx cases, what would be the ethical and privacy implications of such an approach? We sought to test the feasibility of using SNP typing to develop leads via FGG and phenotypic markers to inform unidentified migrants' cases. We typed DNA specimens from three sets of unidentified migrant remains for genome-wide SNPs. SNP data with greater than 60% coverage were compared to both public and private genealogical databases to determine IBD overlap that could generate leads. We also estimated biological origin of human remains through analysis of ancestry informative markers (AIMs). These data were used as leads for nationality, which is useful for verifying post-mortem data, such as ID cards. We chronicled the successes and failures of (a) gaining leads to biological relatives of deceased migrants and (b) predicting country of origin for the remains. We documented ethical considerations as each case was investigated, outlining concerns related to (a) data privacy, (b) personal privacy of living relatives, (c) the effect of stringent border policies on investigations, and (d) the representation of Latinx genomic data in SNP databases. Examining the ethical challenges in these cases can inform broader policy options for use of FGG in criminal cases. With this study, we highlighted the key considerations of FGG and SNP typing in missing migrants' cases with an aim to ensure that the rights of those involved in this process (biological relatives, the deceased) are respected.

## PgmNr 740: Cancer patients' preferences for incidental genomic sequencing results.

---

**Background:** Genomic sequencing (GS) has the potential to identify a large volume of secondary or incidental results (IR), which can be associated with various types of diseases and levels of clinical actionability. Guidelines recommend that patients undergoing GS have the option to receive medically actionable IR. However, the literature suggests that patients are interested in learning results beyond those classified as medically actionable. Most studies evaluating patient preferences use a limited range of IR; there are few studies assessing patients' preferences for the broad range of possible results that can be revealed by GS.

**Aim:** We aimed to describe patient preferences for receiving a broad range of IR.

**Methods:** We conducted an analysis of preference data generated within a randomized controlled trial of a decision aid (DA) ([www.GenomicsADvISER.com](http://www.GenomicsADvISER.com)) for the selection of IR from GS. Participants were adult cancer patients who had previously received an uninformative result from genetic testing related to their cancer. Participants enrolled in the trial used the DA or spoke with a genetic counselor to choose between five categories of IR: 1) medically actionable and pharmacogenomics results 2) common disease SNPs, 3) rare Mendelian disorders, 4) early-onset neurological diseases and 5) carrier status.

**Results:** One hundred thirty-three patients participated in the trial. Participants were predominantly White/European (74%), female (90%), and  $\geq 50$  years old (60%). The majority of participants chose to receive incidental results. About 97% of participants (129/133) elected to receive medically actionable and pharmacogenomics results. Despite the lack of medical actionability of the other categories, participants were overall very interested in receiving them; 74% selected common disease SNPs, 75% chose carrier results, while 53% chose to receive results associated with rare Mendelian diseases and 59% early-onset neurological disorders.

**Conclusions:** Our results suggest that patients are interested in receiving a broad range of incidental results, including those without evidence of medical actionability such as early-onset neurological diseases. This is in contrast to current guidelines that recommend only the return of medically actionable results. In addition to consideration of the clinical evidence, future guidelines should take patient preferences into account.

## PgmNr 741: Balance of requests for molecular studies between different medical specialties in 2018.

### Authors:

I. Bernal <sup>1,2</sup>; Y. Gomez <sup>1</sup>; A. Muñoz <sup>1,2</sup>; S. Maradei <sup>1,2</sup>

[View Session](#)[Add to Schedule](#)

### Affiliations:

1) Genetics, BIOTECGEN S.A, Bogota, Colombia; 2) National University of Colombia

---

### Introduction

In recent years, there has been a marked increase in the technical capacity for detecting variants in DNA that allow a diagnostic approach to multiple pathologies that previously could not be determined by aetiology.

With the advent of these new technologies and knowledge about the human genome there has been a dramatic increase in the request for molecular studies by multiple medical specialties, but without increasing knowledge in the relevance of request for it or its proper analysis.

The studies that present greater difficulties for its adequate interpretation are the complete exomas and the genomes.

This makes it necessary to evaluate the capacity of the different medical specialties for the interpretation and classification of all the findings observed in molecular tests and their impact on the patient.

### Objectives

To determine which are the specialties that most requested molecular studies in 2018 and the pertinence of requesting the same.

### Methodology

A review of the BIOTECGEN S.A. molecular studies databases corresponding to the year 2018 is carried out, grouping them by applicant speciality, type of study and result.

### Results

During 2018, a total of 1450 orders of molecular studies were received from 18 different medical specialties, with a total of 363 positive results (25.03%) and 209 variants of uncertain significance (14.41%). The specialties that most requested molecular studies were clinical genetics and oncohematology. Breast surgery presented a percentage equal to clinical genetics (30%) while positive results and 44.4% of the requesting specialties obtained only negative results or variants of uncertain significance.

### Discussion

It is important to analyze the clinical context of each patient together with management guidelines aimed at the molecular study of each pathology, seeking of pertinent molecular tests, taking into account that only 30% of all requested studies are positive in the best of cases.

Given the percentage of studies with variants of uncertain significance, it is necessary to instruct the different medical specialties in order to be more assertive

It is striking to note that approximately half of the specialties requesting molecular tests do not obtain any positive results, which translates into misdiagnosis

It should be assessed whether all medical professionals should be allowed to request molecular studies or whether this activity should be restricted to a select group of specialties with the appropriate training

## PgmNr 742: Models of shared decision making for counseling of genetic tests.

**Authors:**

S. Lin

[View Session](#) [Add to Schedule](#)**Affiliation:** Genetic Counseling Center, Chi Mei Hospital, Tainan, Taiwan, Taiwan

---

Model of shared decision making (SDM) offers a structured way to help patients to reach evidence-informed and value-based decisions. The SDM process is relevant in genetic counseling especially for conditions which need a close discussion and trade-off between harms and benefits. But there is a lack of examples about how to accomplish the approach using SDM in genetic counseling. Our aim here is to share our experience of how to do SDM in genetic testing. We developed two models of SDM, one focus on non-invasive prenatal testing and another on breast cancer gene testing. In our project, we constructed tools to facilitate SDM communication and measurement of the effectiveness of the process. For the convenience of genetic counselors and genetic health educators, in addition to SDM patient aid tools, we also develop visual aid APP with local language to assist communication in related genetic concepts and knowledge. The SDM models were conducted in prenatal care clinic and familial cancer prevention program in a genetic counseling center located in southern Taiwan. Participants included pregnant women who ask for prenatal genetic test and family members of breast cancers who came for cancer preventive screening. An overall rating of satisfaction from participants was 95% agree that good and above. Comparison of pre- and post-test for the genetic knowledge content after the SDM process showed that genetic knowledge score increased and most significantly in the concept of risk and detection rate of gene tests. In summary, we presented facilitating strategies, patient decision aids and measurement tools for conducting and evaluation of SDM in genetic counseling. The SDM models provide structured communication, increase patient engagement and autonomy, and facilitate patient-centered decision-making.

## PgmNr 743: Alabama Genomic Health Initiative: Outcomes from the first two years.

---

The Alabama Genomic Health Initiative (AGHI) is one of the first statewide, state-funded efforts to provide genomic testing on a broad basis. AGHI engages two distinct cohorts who enroll into a research protocol that provides access to genetic testing and offers biobank participation. The 'affected' cohort consists of children and adults with undiagnosed disease who receive whole genome sequencing (WGS) to identify primary and secondary findings. The 'population cohort' consists of interested adults who receive a genotyping assay to identify risk factors in medically-actionable genes. In the first two years of AGHI, 191 affected and 4527 population participants have been enrolled. Consent and result disclosure in the affected cohort is facilitated by staff at clinical research sites. Among 142 affected individuals analyzed to date, 60 (42%) have received a primary finding (15 pathogenic, 13 likely pathogenic, 32 variants of uncertain significance); seven individuals (2.8%) have received a secondary finding. Among 4357 analyzed population participants, 66 pathogenic or likely pathogenic variants have been returned to 65 participants (1.5%). Genetic counselors disclose positive results via phone, and written result reports are mailed to all participants. An online survey of population participants assessed their motivation, satisfaction, and outcomes. Of 3874 participants that received a result and agreed to be re-contacted, 858 participants completed the survey (22% overall response rate), including 21 individuals with a medically-actionable result (40% positive result response rate). The largest motivators for participating were concern for future health (29%), contribution to genetic research (23%), and general curiosity (18%). Twelve incorrectly recalled receiving a medically-actionable result and 45 reported they were unsure of their result type. Seven percent of respondents have or plan to talk with a medical provider, 2% had a test/procedure, and 12% made a health or wellness change because of their AGHI result. The majority of respondents (78%) shared results with family and 4% reported that a family member took an action based on this information. Most respondents (89%) were very or extremely satisfied with their decision to participate in AGHI. Results from this study elucidate the impact of genomic screening for AGHI participants, as well as inform changes to improve communication with participants and increase understanding

## **PgmNr 744: Parent interpretations of their child's genomic test results: Informing development of a return of results communications tool for NYCKidSeq.**

---

### Background

Returning the results of genetic and genomic testing to families is a complex process that combines education about the testing itself, interpretation of often ambiguous results, and sensitivity to the emotional roller coaster families experience.

### Objective

The NYCKidSeq Study is developing a novel web-based tool to improve return of results from whole genome sequencing in a racially and ethnically diverse population. To guide tool development, we conducted formative research to understand how parents interpret their child's genomic test result.

### Methods

We recruited and screened parents from physicians' patient lists at two NYC hospitals where their children had undergone whole exome sequencing, target gene panel or microarray within the previous 12 months. We conducted in-depth interviews with 22 parents of diverse children (5 Black; 10 Latinx, 5 white; 2 multi-racial) who had received results classified as 'negative' (N=10), 'uncertain' (N=7), or 'positive' (N=5). Analysis was conducted using grounded theory's constant comparative method across data points, cases and themes.

### Results

Parents described the diagnostic odyssey they undertook to identify and treat their child's illness and symptoms, with genomic testing being only one of many diagnostic experiences. Parents' understanding of 'negative' test results was variable: minimal, but un concerning because results were negative; simple, that "everything was normal"; or self-censored, that further inquiry was unwarranted. 'Positive' results were clearer, potentially overwhelming but also satisfying to "know the name" of the disease and a path to treatment. 'Uncertain' results left parents concerned and confused, with their diagnostic odyssey unresolved. Regardless of classification, parents conflated

test results with the presence of their child's illness, causing misunderstandings about the actionable meaning of test results. Parents generally accepted not understanding results because they assigned responsibility for that understanding to trusted providers.

### Conclusion

Parents struggled with the meaning of genomic test results delivered as being 'negative' or 'uncertain' but understood 'positive' results clearly. Clinicians should be mindful that patients usually don't understand results and may not ask questions, trusting their providers to manage results for them. For parents, the treatment implications of test results rather than complete understanding of genetic findings is the priority.

## PgmNr 745: The NHGRI Genome Sequencing Program: Products & deliverables.

**Authors:**

T. Stephan; NHGRI Genome Sequencing Program

[View Session](#) [Add to Schedule](#)

**Affiliation:** National Human Genome Research Institute, Bethesda, Maryland.

---

The Genome Sequencing Program, funded by the National Human Genome Research Institute, uses genome sequencing to identify genes and genomic variants involved in human disease. The program supports gene and variant discovery in rare, inherited (Mendelian) cases as well as common, genetically complex diseases. The program also supports analysis and tool development.

The Centers for Mendelian Genomics (CMG) use exome sequencing and complementary genomic approaches to discover as many genes and variants underlying the full spectrum of Mendelian inheritance patterns. The four centers coordinate with sample providers, clinicians, clinical sequencing laboratories, patients, and model organism researchers to disseminate knowledge and discoveries. To date, the CMGs have sequenced over 61K individuals and made over 1,700 novel disease associations - a significant contribution to the 65% of Mendelian phenotypes with a known underlying gene (OMIN).

The Centers for Common Disease Genomics (CCDG) have sequenced over 80K WGS and 81K WES across three main disease areas: neuropsychiatric (Alzheimer's, autism, and epilepsy), immune-mediated (asthma, inflammatory bowel disease, T1D), and cardiovascular (early onset coronary disease, atrial fibrillation, and hemorrhagic stroke). In their quest to identify rare risk and protective variants in common disease, the centers aim further the understanding of genomic architecture; design effective rare variant association studies (RVAS); develop new sequencing technologies and pipelines; and informatics tools.

The GSP Analysis Centers (GSPAC) undertake novel analyses on CMG and CCDG data, develop new methods and tools, and collaborate with researchers within and outside the GSP. The GSP Coordinating Center (GSPCC) provides scientific leadership and expertise for GSP-wide initiatives and coordinates administrative and outreach activities.

In the final year of the program, the GSP will: build an imputation server; map genome variation; develop a standard for sharing RVAS summary statistics; create a common controls resource; train new investigators; collaborate with biobanks and model organism communities; build an annotation server; calculate and validate polygenic risk scores; and develop ethnicity-specific linkage disequilibrium and recombination maps.

GSP data, analyses, methods, tools, and the functional equivalence WGS pipeline are or will be available via: dbGaP, AnVIL, ClinVar, Matchmaker Exchange Network, gnomAD, BRAVO, and GitHub.

## **PgmNr 746: Systematic review of online media coverage of GWAS publications from 2005 to 2018: Insights on trends in media coverage, readability of websites, and mentions to key social issues using text mining.**

### **Authors:**

J.J. Morosoli <sup>1,2</sup>; L. Colodro-Conde <sup>1</sup>; F.K. Barlow <sup>2</sup>; S.E. Medland <sup>1,2</sup>

[View Session](#) [Add to Schedule](#)

### **Affiliations:**

2) School of Psychology, University of Queensland, Brisbane, Queensland, Australia

---

We present a systematic review of online media coverage of GWAS since its inception, using statistical and text mining techniques. GWAS publications were identified via the NHGRI-EBI GWAS Catalogue and classified into phenotype categories using the ICD-10. Blog and news articles about these studies were identified using the Altmetric database. As of 19/09/18, there were 3557 GWAS studies on 1945 different traits. We were able to retrieve 5349 different English language websites that mentioned these publications. Only 41.4% of those websites offered original content (not identical to another website). The most researched areas in the GWAS literature have been non-disease traits (e.g., body mass index, educational attainment; N=1197), neoplasms (N=462), and behavioral disorders (N=371). Only 20.1%, 21.4%, and 15.9% of the works in these areas were mentioned in two or more websites, respectively. Both publications and online mentions have increased every year. Partial correlation between year and number of online mentions (given GWAS publications per year) was  $r = 0.80$ . A regression analysis on number of online mentions including year of publication, number of hits, impact factor, and sample size showed that all predictors were positively and significantly associated with the outcome. However, residuals were not constant across phenotype categories, suggesting different patterns in public interest. In particular, GWAS on non-disease traits, and behavioral and nervous system disorders, generated 1.5 times more attention than predicted. We conducted a topic modeling analysis of the websites' content, and identified to which topic each website most probably belonged. Then we searched for key terms associated with public understanding of genetics. The five most frequent topics were Alzheimer's, depression, breast and prostate cancer, intelligence, and asthma. We found that only a low percentage of websites mentioned 'insurance' (0.9%), 'ethic' (2.2%), 'discrimination' (0.9%), or 'eugenic' (1.0%). However, 'environment' was frequently mentioned (28.6%). These keywords were most frequently found in articles about intelligence, and about 23andMe. Finally, we estimated the complexity of the language used in the websites using traditional readability formulas. More than 95% of all online articles would require at least university level reading skills to understand them. Implications for science communication and genetic literacy campaigns will be discussed.

## PgmNr 747: Physician attitudes, confidence, and perceived utility following experience with newborn genomic sequencing in the BabySeq Project.

### Authors:

H. Smith<sup>1</sup>; S. Pereira<sup>1</sup>; J. Robinson<sup>1</sup>; L. Frankel<sup>2</sup>; K. Christensen<sup>3,4</sup>; R. Parad<sup>3,4,5</sup>; P. Agrawal<sup>3,5</sup>; T. Yu<sup>3,5</sup>; I. Holm<sup>3,5</sup>; A. Beggs<sup>3,5</sup>; R. Green<sup>3,4,6</sup>; A. McGuire<sup>1</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Baylor College of Medicine, Houston, TX; 2) University of Houston, Houston, TX; 3) Harvard Medical School, Boston, MA; 4) Brigham and Women's Hospital, Boston, MA; 5) Boston Children's Hospital, Boston, MA; 6) The Broad Institute of MIT and Harvard, Cambridge, MA

Physicians' perceived utility and confidence in managing results of newborn genomic sequencing (nGS) compared to conventional newborn screening (NBS) are unknown. We studied physician perceptions as part of the BabySeq Project, a trial in which newborn participants were randomly assigned to receive either NBS and a family history report alone (control arm) or with a nGS report (sequencing arm). We enrolled physician participants from the same hospital units as newborns, some of whom had patients who were BabySeq participants. At the end of the study, we surveyed physicians (n=95; 27% response rate) to study whether receipt of nGS report (n=31) was associated with differences in perceived utility.

Physicians perceived NBS to currently be more useful than nGS to identify patients' conditions (mean 9.0 vs. 6.6 on a 1-10 scale;  $p<0.001$ ) and manage care (7.9 vs. 5.9;  $p<0.001$ ) but similarly useful to predict future risk of disease (6.3 vs. 6.1;  $p=0.51$ ). Physicians' perceived nGS utility did not differ by exposure to BabySeq nGS reports (all  $p>0.11$ ). However, respondents expected the utility of nGS to increase for each purpose over the next decade (all  $p<0.001$ ). Respondents predicted that 10 years in the future the utility of NBS and nGS will be similar to identify conditions (8.7 vs. 8.7;  $p=0.75$ ) and manage care (8.2 vs. 8.1;  $p=0.84$ ), while NBS is anticipated to be less useful than nGS to predict future disease risk (7.4 vs. 8.5;  $p<0.001$ ).

Only 27% of physicians reported being somewhat or very confident in their ability to make recommendations based on a positive genomic sequencing result, which was in contrast to 92% ( $p<0.001$ ) for NBS and not associated with receipt of a nGS report ( $p=0.22$ ). While all respondents agreed that every newborn should receive NBS, only 12% agreed that every newborn should receive nGS ( $p<0.001$ ), although a majority (59%) of physicians agreed there are health benefits associated with nGS.

Among physicians studied as part of the BabySeq project, experience with an nGS report is not associated with differences in perceived nGS utility at the end of the study. Physicians perceive NBS to have higher utility than nGS and are more confident in their ability to interpret and make recommendations based on results from NBS than nGS. Physicians expect the utility of nGS to increase in the next 10 years and feel that there are potential health benefits of nGS, attitudes which did not differ based on nGS report receipt.

## **PgmNr 748: The use of public genealogy databases in scientific research: A proposed approach to terms of use (TOU) authorization.**

### **Authors:**

J. Contreras <sup>1,2</sup>; C. Teerlink <sup>2</sup>; L. Cannon-Albright <sup>2</sup>

[View Session](#) [Add to Schedule](#)

### **Affiliations:**

1) College of Law, University of Utah, Salt Lake City, UT.; 2) University of Utah, School of Medicine, Salt Lake City, UT

---

In the wake of the recent Golden State Killer case, substantial public attention has focused on the use of public genealogy databases (PGD) such as GEDMatch by law enforcement authorities. In this paper, we address a different, but even more prevalent, use of PGD: scientific research. In recent years, PGDs have been used in dozens of epidemiological and genetic studies. But despite the success of these studies, it is not clear that the contractual Terms of Use (TOUs) associated with the PGDs from which data was obtained permit the conduct of this research.

We analyzed the TOUs associated with 38 major PGDs and assessed the degree to which they permit or prohibit the use of publicly-accessible data for scientific research. We found that many TOUs contain prohibitions on use, ranging from broad blanket prohibitions on all uses other than personal (non-commercial) genealogy research to more narrow prohibitions on commercial marketing, insurance underwriting and law enforcement uses. Moreover, no TOU that we examined expressly permits the use of available data for scientific research, making its use questionable under applicable data privacy laws. In all cases, the use of PDG data for non-permitted purposes could expose researchers to both civil and criminal penalties. And while we are not aware of any such legal action, rising public awareness of issues associated with PGDs increases the likelihood that such liability may arise in the future.

Accordingly, we propose a solution to enable scientific research using publicly-available PGD data without the threat of legal liability. It involves the development of a standardized rider that could be added to the TOU for all PGDs (PGD Rider). This approach is modeled after the SPARC Author Addendum developed by the Scholarly Publishing and Academic Resources Coalition to allow self-archiving of scientific journal articles. The proposed PGD Rider would expressly authorize scientific research using PGD data without addressing the more controversial issues associated with law enforcement and commercial uses. In addition, it would require researchers to observe data privacy and security measures with respect to personal data obtained from PGD sources.

We believe that the broad adoption of a PGD Rider would contribute to the continued use of these valuable data resources in scientific research without attempting to resolve the more challenging questions arising from law enforcement and commercial uses of this data.

1) San Francisco VA Healthcare System, San Francisco, California.; 2) Departments of Pediatrics and Medicine, University of California, San Francisco; 3) VA Greater Los Angeles Healthcare System; 4) VA Salt Lake City Healthcare System; 5) VA Boston Healthcare System; 6) David Geffen School of Medicine at UCLA

**Objective:** As part of a larger initiative to examine coordination of genetic healthcare in the Department of Veterans Affairs (VA), we examined completion of genetic consults for VA patients.

**Methods:** We identified all genetic consults from 2010-17. Data extracted: consult status, patient characteristics, referral reasons, submitting and receiving sites, and attempts to schedule. Multiple logistic regression evaluated associations of variables with consult status.

**Results:** We identified 24,956 patients with genetic consults. Mean age was 50.6 (SD,14.9), 51% were female, and 63% white. Cancer was the most common (53%) referral reason. Most consults (58%) were received by the national VA program that provides telehealth consults; 28% were received by other VAs; and 14% were referred to the community (non-VA). Consults to VA were twice as likely to be completed than non-VA (national: OR=1.78;1.48-2.14; other: OR=1.90;1.54-2.33), with longer time to complete (mean days 162.3[154.8] vs 64.7[77.1],  $p<0.001$ ) and fewer scheduling attempts (mean attempts 1.11[0.39] vs 1.49[0.91],  $p<0.001$ ) in non-VA vs VA. Compared to non-VA, women and African Americans referred to the national VA program were less likely to complete consults (OR=0.73;0.61-0.87 and OR=0.69;0.57-0.83, respectively); this was not seen with other VAs. We did not find differences in completing consults for common referral reasons (cancer vs cardiovascular/connective tissue, gastrointestinal/polyps, or neuro-psychiatric). In contrast, less common referral reasons (e.g., immunology, endocrine, nephrology, reproductive) were 19% less likely to be completed (OR=0.81;0.70-0.95) compared to cancer. However, consults for less common referral reasons were more likely completed in the VA than non-VA (national: OR=1.70;1.41-2.06, other: OR=1.51;1.23-1.86).

**Conclusions:** Veterans are more likely to complete genetic consults if referred to the VA than the community. Completing a consult for less common referral reasons was greater in the VA, suggesting better access to a breadth of genetics expertise in the VA. Gender and race/ethnicity differences in completing consults with the national VA program might be due to patient preferences regarding telehealth. Future studies should address disparities that may increase with the growing number of women Veterans and community referrals. Implementation strategies should leverage the genetics expertise within the VA to improve care coordination and reduce disparities.

## **PgmNr 750: Clustering and classification analysis of Korean government-funded R&D projects and PubMed literature using machine learning techniques to support R&D investment decision making on biomedical fields.**

### **Authors:**

G. Yoo; H. Kim

**Affiliation:** Korea Institute of Science & Technology Evaluation and Planning, 60 Mabang-ro, Seocho-gu, Seoul, Korea, Republic of

---

South Korean government's budget for R&D on biomedical technology exceeds 1 trillion won (850 million dollars), and deeper analysis of R&D investment is needed more than ever to support investment decision making on advanced biotechnology. However, the current practice of R&D investment portfolio management cannot reflect the rapidly changing biomedical technology trends as the analysis of R&D investment is merely based on simple statistics that utilizes fixed classification hierarchies. To solve this problem, we implemented a context search engine, a clustering analytic tool, and an automatic classifier for Korean national R&D projects and worldwide literature from PubMed using machine learning techniques. The purpose of this system is to provide more flexible and rapid tools for analyzing the status of national R&D investment and the global R&D trend (PubMed literature), and ultimately to help policy makers in investment decision making. First, all abstracts of the national R&D projects and the PubMed literature were embedded into 300-dimensional vectors through the doc2vec algorithm. Using the context search and the clustering analysis, which operate based on cosine similarities of the embedded vectors, a user can grasp the R&D investment status and knowledge structure of the desired technology field. We applied the system to the research projects and PubMed literature in the field of genetics between 2013 and 2017, and the results were consistent with common sense. For example, the amount of literature on whole-genome sequencing has been reduced, and clusters of literature such as genome-phenotype association studies and CRISPR gene editing expanded. Secondly, we implemented an automatic classifier for the national R&D projects using machine learning algorithms such as gradient boosting machine, multilayer perception, and support vector machine. This tool provides two most likely predictions according to the classification model trained with existing classified data. As a result, we achieved high accuracy rates (>80%) of classifying the R&D projects on drug development by the stage of development, the target disease, and the type of drug. We are planning to launch a Web service based on this system in the future for R&D policy makers.

## PgmNr 751: The yield of full *BRCA1/2* genotyping in Israeli Arab high-risk breast /ovarian cancer patients.

---

**Purpose:** While the spectrum of germline mutations in *BRCA1/2* genes in the Israeli Jewish population has been extensively studied, there is a paucity of data pertaining to Israeli Arab high-risk cases.

**Methods:** Consecutive Israeli Arab breast cancer (BC) or ovarian cancer (OC) patients were recruited using an ethically approved protocol from January 2012 to February 2019. All OC cases were referred for *BRCA* genotyping. BC patients were offered *BRCA* sequencing and deletion/duplication analysis after genetic counseling, if the calculated risk for carrying a *BRCA* mutation by risk prediction algorithms was  $\geq 10\%$ .

**Results:** Overall, 188 patients participated; 150 BC cases (median age at diagnosis: 40 years, range: 22-67) and 38 had OC (median age at diagnosis: 52.5 years, range: 26-79). Of genotyped cases, 18 (10%) carried one of 12 pathogenic or likely pathogenic variants, 12 in *BRCA1*, 6 in *BRCA2*. Only one was a rearrangement. Three variants recurred in more than one case; one was detected in five seemingly unrelated families. The detection rate for all BC cases was 4%, 5% in bilateral BC cases and 3% if BC was diagnosed < 40 years. Of patients with OC, 12/38 (32%) were carriers; the detection rate reached 75% (3/4) among patients diagnosed with both BC and OC.

**Conclusions:** The overall yield of comprehensive *BRCA1/2* testing in high-risk Israeli Arab individuals is low in BC patients, and much higher in OC patients. These results may guide optimal cancer susceptibility testing strategy in the Arab Israeli population.

## PgmNr 752: Hemochromatosis genotype does not increase colorectal cancer risk or age of onset.

---

**Objective:** Homozygotes for the higher penetrance hemochromatosis risk allele, HFE C282Y (rs1800562), have been reported to be at a 2-3 fold increased risk for colorectal cancer (CRC; see PMIDS 26893171 and 23281741). These results have been reported in generally small sample sizes with no information about age of onset for such cancer. We evaluated a larger sample to assess HFE genotype effects on CRC risk and age of onset.

**Methods:** Using data from the Colorectal Cancer Translational Study and Genetics and Epidemiology of Colorectal Cancer Consortium, we evaluated distribution of CRC cases and age of onset in people of European ancestry with the HFE C282Y/C282Y genotype vs. those with zero C282Y or H63D alleles. These data included 52,151 CRC cases and 62,484 controls. We used logistic regression to estimate odds ratios (ORs) adjusted for age, sex, genotyping platform, and 3 principle components. As hemochromatosis penetrance is higher in males, analyses were repeated stratified by sex. Similar analyses were undertaken in 8606 self-reported CRC cases and 984,723 controls in the 23andMe cohort of consented research participants.

**Results:** The frequency of the HFE C282Y/C282Y genotype was 0.46% in CRC cases (240 of 52,151) and 0.54% in controls (340 of 62,484). The OR for CRC risk was 1.08 (95% CI: 0.91-1.29; p=0.39). Stratified analyses by sex identified no increased risk in males (OR: 0.94; p=0.64) or females (OR: 1.22; p=0.12). Age of CRC onset also did not differ by genotype; 64.2 years for the 199 C282Y/C282Y genotype individuals and 64.7 years for 34,832 non-carriers (p=0.6). Secondary analyses considering N=2,307 C282Y/H63D compound heterozygotes (967 CRC cases and 1340 controls) both separately or combined with the C282Y homozygotes vs. controls also detected no association with CRC risk or CRC onset age. Preliminary results in the 23andMe cohort suggest no increased CRC risk in C282Y homozygotes. Ongoing analyses considering hemochromatosis diagnosis suggest that penetrant disease has a modest increased CRC risk and no change in age of onset.

**Conclusion:** These are the largest analyses of the relationship between CRC and HFE risk and the only analyses of age of onset to date. We find no increased risk with genotype, but increased CRC risk with no age of onset change for those with penetrant disease. These results should be reassuring for those with HFE risk and suggest that these persons can follow population screening recommendations for CRC.

## PgmNr 753: Frequency of pathogenic variation in germline cancer susceptibility genes in rhabdomyosarcoma.

**Introduction.** Rhabdomyosarcoma (RMS) is the most common childhood soft-tissue sarcoma. Genetic disorders associated with an increased risk of RMS include Li-Fraumeni, *DICER1*, NF1, Costello, Beckwith-Wiedemann, and Noonan syndromes. We investigated the frequency of pathogenic germline variation in discovery and secondary cohorts of individuals with RMS.

**Methods.** Patient blood-derived DNA samples were collected by Children's Oncology Group clinical trials and other institutional cohorts. Genome sequencing was conducted at The Hospital for Sick Children (discovery; n=273); exome sequencing was conducted at the National Cancer Institute (secondary; n=121). Variant pathogenicity in 310 candidate (syndrome, pathway, RMS-somatic, RMS-GWAS) genes was determined using ClinVar "badged labs," HGMD DM manual review and InterVar. The frequency of pathogenic/likely pathogenic (P/LP) variation was compared with non-TCGA gnomAD controls (n=118,479) using the Fisher exact test; multiple testing correction was applied using false discovery rate.

**Results.** In the discovery cohort, 8% harbored a statistically significant excess of P/LP variants compared with 0.5% in non-TCGA gnomAD controls in 11 genes (n=21): *CTC1*(3), *TRIM37*(2), *MSH2*(1), *L2HGDH*(2), *NF1*(4), *DICER1*(1), *TP53*(4), *SMARCA4*(1), *PTCH1*(1), *MLLT1*(1), *MYCN*(1). P/LP variants in *TP53*, *NF1*, *L2HGDH*, *MYCN* were significant after correction for multiple testing (q<0.05). In the secondary cohort, 10% harbored a statistically significant excess of P/LP variants compared with 0.3% in non-TCGA gnomAD controls in 11 genes (n=12): *RET*(1), *JAK3*(2), *TP53*(1), *L2HGDH*(1), *NHP2*(1), *MSH6*(1), *DIS3L2*(1), *TSC2*(1), *DICER1*(1), *IL1RN*(1), *BCOR*(1); none were significant after

correction for multiple testing. Excess P/LP variants in *TP53*, *DICER1*, *L2HGDH* were observed in both cohorts. Homozygous and compound heterozygous *L2HGDH* P/LP variation is associated with an excess of L-2-hydroxyglutarate, an epigenetic modifier and putative oncometabolite. Notably, there was an excess of P/LP variants in Lynch syndrome (*MSH2*, *MSH6*) and telomere biology genes (*CTC1*, *NHP2*) in both cohorts.

**Conclusion.** In the largest RMS exome/genome dataset to date, we observed in two independent cohorts an excess (8-10%) of P/LP variants, most commonly in known RMS-associated disorders (*NF1*, *TP53* and *DICER1*). Our findings suggest that Lynch and telomere biology genes are contributors to RMS germline risk. Risk associated with *L2HGDH* variation merits follow-up.

## PgmNr 754: Presymptomatic knowledge of BRCA carrier status: Impact on subsequent breast cancer stage, therapy and survival.

### Affiliations:

1) Medical Genetics Institute, Shaare Zedek Medical Center, Jerusalem, Israel.; 2) Faculty of Medicine, Hebrew University Medical School, Jerusalem, Israel.; 3) Breast Surgery Unit, Department of General Surgery, Shaare Zedek Medical Center, Jerusalem, Israel.; 4) Institute of Oncology, Shaare Zedek Medical Center, Jerusalem, Israel.; 5) Department of Pathology, Shaare Zedek Medical Center, Jerusalem, Israel.; 6) Department of Radiation Oncology; University of Colorado Comprehensive Cancer Center, Denver CO, USA

**Background:** Screening healthy Ashkenazi Jews for germline BRCA1/BRCA2 mutations is not standard policy, despite high (2.5%) carrier rates. Most carriers are identified only after diagnosis of a BRCA-associated cancer.

**Aim:** To determine if pre-symptomatic knowledge of carrier status affects breast cancer stage, management and survival.

**Methods:** We reviewed medical records of BRCA1/BRCA2 carriers diagnosed with breast cancer between 1/2005-4/2016 at a single institution. We compared outcomes between women identified as BRCA carriers prior to their breast cancer diagnosis (Pre-Dx carriers) vs. those identified only after breast cancer diagnosis (Post-Dx carriers).

**Results:** Of 105 BRCA carriers with breast cancer, 42 (40%) were Pre-Dx and 63 (60%) were Post-Dx. None had had risk-reduction mastectomies. Mean age at diagnosis (50.4y) and BRCA1:BRCA2 distribution (64%:36%) were similar in both groups. Pre-Dx carriers were significantly more likely to have suggestive family history (93% vs. 63%). Pre-Dx carriers had lower clinical and pathological stage at diagnosis ( $p < 0.001$ ), with no differences in tumor grade, hormonal receptor or Her2 status. In Pre-Dx carriers, 38% of tumors were DCIS vs. 3.2% in Post-Dx carriers ( $< 0.001$ ). Pre-Dx carriers were less likely to receive chemotherapy (34% vs. 94%), and more likely to elect bilateral mastectomies (66% vs. 17%) than Post-Dx carriers ( $p \leq .001$ , all comparisons). In multivariate analysis, identification of carrier status prior to breast cancer diagnosis was the only significant predictor of early stage (0-I) breast cancer diagnosis (OR 10.6,  $p < 0.001$ ; age, calendar year of diagnosis, family history, and gene were all NS). 5-year overall survival in Pre-Dx carriers and Post-Dx carriers was 94% and 78%, respectively (HR=0.2,  $p = 0.04$ ).

**Conclusions:** Presymptomatic identification of BRCA carrier status is associated with significantly earlier stage at breast cancer diagnosis, less extensive treatment, and possible improvement in overall survival. These results support routine BRCA testing in the Ashkenazi Jewish population.

## PgmNr 755: Genetic determinants of recurrence in *BRCA1/2* germline mutation-associated breast and ovarian cancers.

---

*BRCA1/2* mutation-associated breast and ovarian tumors are sensitive to platinum-based chemotherapies and poly (ADP-ribose) polymerase inhibitors (PARPi). However, these tumors frequently return as therapy-resistant recurrences. To identify mechanisms of therapeutic resistance, we are evaluating genetic, transcriptomic, and immune features between matched primary and recurrent *BRCA1/2* tumors. We have compared whole exome sequencing from five pairs of *BRCA1* breast and nine pairs of *BRCA1/2* ovarian tumors, which is the largest such sample set collected to date. We analyzed multiple recurrences for five patients in this group. Ten patients received platinum-based chemotherapy, four patients received PARPi, and all patients received other forms of chemotherapy. We first compared homologous recombination deficiency (HRD) scores in matched tumors, finding that recurrences had significantly fewer large-scale state transitions (LSTs) compared to matched primary tumors ( $p=0.026$ ). We also identified a *BRCA1* reversion mutation, which was absent in the patient's first recurrence (after platinum treatment) but present in the second recurrence (after PARPi). Next, we assessed chromosomal copy number changes in matched tumors, after normalizing for cellularity and ploidy. We identified segments of chromosomal losses ( $CN=1$ ), gains ( $CN=4-5$ ), and amplifications ( $CN\geq 6$ ) that were present exclusively in recurrences. Recurrence-exclusive chromosomal copy number profiles showed low concordance between multiple recurrences from the same patient, but many large ( $>30\text{Mb}$ ) chromosomal losses were shared across several patients' recurrences, irrespective of cancer type or treatment. We also identified heterozygous, recurrence-exclusive losses in *MAD2L2* and *TP53BP1*. We found that shared gains and amplifications encompassed genes that could be pro-tumorigenic in the metastatic setting. Specifically, we noted gains and amplifications in lineage-related genes in  $\geq 4/14$  patients (*PAX1*, *PAX4*, *PAX6*, *EZH1*, *ELF5*, and two *KRT* gene clusters). We also found gains and amplifications in genes for tumor microenvironment factors (*FGFR2*, *ITGB4*, *CD44*), TNF $\alpha$  signaling (*TRAF6*, *MADD*), and DNA repair (*PARP1*, *PARP2*, *CHD2*, *EMSY*) in  $\geq 5/14$  patients. Next, we will use RNA-sequencing and immunohistochemistry to compare transcriptomes and immune milieus of matched *BRCA1/2* tumors. Ultimately, we seek to identify drivers of therapeutic resistance in *BRCA1/2* cancers, thereby informing novel treatment strategies.

## PgmNr 756: The genomic landscape of *de novo* mutations in first-generation carriers of TP53 germline mutations.

Germline mutations are the driving force behind genome evolution and etiology of diseases. It has been well established that the number of *de novo* germline mutations is positively correlated with the age of the father and that of the mother. However, it remains largely unknown what factors other than perhaps parental ages would affect the initiation and accumulation of germline mutations. This question is particularly important for Li-Fraumeni syndrome (LFS), a cancer predisposition syndrome mostly caused by germline *TP53* mutations, in which there is an unusually high prevalence of *de novo* mutations (7-35%). To investigate this issue, we generated whole-genome sequencing data (at a 30x read depth) from five quartets of LFS probands who carry DNMs in *TP53*, healthy siblings and their parents, and compared the whole genomes of the probands with the siblings. Our cohort includes over ~8,600,000 single-nucleotide variants (SNVs) of which 702 are *de novo* mutations. We estimate a mutation rate of  $\sim 1.26 \times 10^{-8}$  SNVs per site per generation for *de novo TP53* mutation carriers and  $\sim 1.07 \times 10^{-8}$  SNVs per site per generation for the healthy siblings. Comparing probands and siblings we found a statistically significant increase in *de novo* SNV counts ( $p = 0.01$ , paired t-test). With the exception of *TP53*, probands do not carry more gene-disruptive mutations than their siblings, have a similar *de novo* mutation spectrum and were matched by age (within 4 years). Our findings suggest *de novo TP53* mutation carriers have an increase in the quantity but not quality of mutations in probands and differences in *de novo* mutation acquisition are unrelated to parental ages. Our study will advise on how disease causing and rare germline mutations are acquired and established in the genome.

## PgmNr 757: The contribution of MITF to melanoma and renal cancer.

---

**Background:** A single missense variant (c.952G>A, p.Glu318Lys) in microphthalmia-associated transcription factor (*MITF*) has been implicated in melanoma and renal cancer. Studies suggest that up to 2.8% of patients with melanoma and up to 3.0% of those with renal cancer harbor the *MITF* Glu318Lys variant. The aim of this work was to evaluate the yield of *MITF* Glu318Lys in individuals undergoing multi-gene hereditary cancer panel testing, paying particular attention to those with cutaneous melanoma and renal cancer.

**Methods:** We performed a retrospective review of all individuals undergoing panel testing of up to 64 genes, including *MITF* Glu318Lys. The personal histories of Glu318Lys carriers were reviewed.

**Results:** In total, 9,431 individuals underwent panel testing that included *MITF* Glu318Lys testing and of those, 43 (0.5%) were found to have *MITF* Glu318Lys. Seven of 544 probands (1.3%) with cutaneous melanoma were found to carry *MITF* Glu318Lys, with a mean age of diagnosis of 60 (51-71). Over half of those individuals also reported a family history of melanoma and one individual reported multiple primary melanomas. Those positive for *MITF* Glu318Lys did not carry another pathogenic variant in another melanoma-associated gene, including *CDKN2A* and *CDK4*. One thousand twenty-eight probands with a renal tumor underwent panel testing including *MITF* Glu318Lys and 5 (0.5%) were found to carry the pathogenic variant. Reported renal pathologies included clear cell, papillary type 1, and oncocytoma. Aside from melanoma and renal tumors, other frequent findings in the 36 affected individuals included breast cancer (n=15) and colon polyps (n=6). Breast cancer was observed in 15/33 (45%) female carriers with only one of these individuals carrying a pathogenic variant in another gene that may explain this diagnosis.

**Conclusions:** *MITF* Glu318Lys was observed in 1.3% of patients with melanoma and 0.5% of patients with a renal tumor in our cohort. Though our yields are lower than published cohorts, literature reports included either smaller cohorts or those enriched for probands with previously negative genetic testing for known melanoma/renal cancer susceptibility genes. Our findings suggest that there may be additional phenotypes associated with *MITF* Glu318Lys, but further evidence is needed before definitive conclusions can be drawn.

## PgmNr 758: Assessment of the clinical phenotype of *BAP1* germline whole gene and large deletions.

### Authors:

M.H. Abdel-Rahman <sup>1,2</sup>; R. Pilarski <sup>2</sup>; J.B. Massengill <sup>1</sup>; F.H. Davidorf <sup>1</sup>; C.M. Cebulla <sup>1</sup>

### Affiliations:

1) Department of Ophthalmology and Visual Science, The Ohio State University, Columbus, Ohio.; 2) Division of Human Genetics, The Ohio State University, Columbus, Ohio

---

**Purpose:** Germline pathogenic mutations in *BAP1* are associated with a hereditary cancer predisposition syndrome with four main cancers: uveal melanoma, cutaneous melanoma, mesothelioma and renal cell carcinoma. Most of the reported cases were for patients with single nucleotide polymorphisms or < 3 base pair alterations. The aim of this study was to assess the clinical phenotype of germline whole gene and large deletions of the *BAP1* gene.

**Methods:** Whole gene deletions were diagnosed in clinical laboratories or in our laboratory using multiplex ligation probe amplification (MLPA) or Sanger sequencing. Segregation in family members was carried out by quantitative PCR using at least 2 different probes or by sequencing.

**Results:** We identified three probands and one relative with germline whole gene deletions and one proband and a relative with multi-exon deletion of *BAP1*. Five of them were female and one male. Average age was 39 years (range 16-62 years). Two subjects presented with uveal melanoma (ages 16 and 30 years), one with a uveal nevus (age (29 years), two with *BAP1*-inactivated melanocytic nevus/melanocytoma (ages 39 and 42 years) and one with two primary cancers: colon (54 years) and basal cell (60 years). None of the cases with whole gene deletion were identified by Sanger sequencing.

**Conclusion:** Whole gene deletion is an important mechanism for germline alteration in *BAP1*. Assessment for large deletions should be included in clinical testing. The clinical phenotype of patients with germline large deletion in *BAP1* is similar to the range of phenotypes in patients with other pathogenic *BAP1* mutations. Further assessments of the phenotype in additional subjects, as well as, study of environmental and genetic modifier of the phenotype are warranted.

## PgmNr 759: Mutation spectrum and genotype-phenotype analyses of pheochromocytomas/paragangliomas in Korea.

### Authors:

---

Pheochromocytomas (PHEOs) and paragangliomas (PGLs) are rare neuroendocrine tumors that produce sporadic catecholamine. More than 30% of these tumors were found to have inherited origin due to germ-line mutations in at least 10 genes including *RET*, *VHL*, *SDHB*, *SDHD*. New reports of phenotype-genotype correlation are emerging within PHEOs and PGLs depending on the gene and mutation location. We aimed to characterize the mutation spectrum and characteristics in Korean PHEOs/PGLs patients through analyzing causative genes. In this study, we included 171 patients with clinically confirmed PHEOs/PGLs who were treated between March 2009 and January 2019 at the Seoul National University Hospital in Korea. Targeted next-generation sequencing of 10 genes *MAX*, *NF1*, *RET*, *SDHA*, *SDHAF2*, *SDHB*, *SDHC*, *SDHD*, *TMEM127*, *VHL* were performed on 56 (32.8%) patients. 107 patients were tested only some of these 10 genes using Sanger sequencing and gene dosage analyses using multiplex ligation-dependent probe amplification. This study revealed that 20.5% of all cases (35 patients) harbored causative mutations in one of the PHEOs/PGLs genes: *RET* (34.3%, 12 patients), *VHL* (25.7%, 9 patients), *SDHB* (20%, 7 patients), *SDHD* (14.3%, 5 patients), *NF1* (2.9%, 1 patient), *NF2* (2.9%, 1 patient). *SDHB* mutations were usually found in high-risk PHEOs/PGLs. *SDHD* mutations were associated with extra-adrenal paragangliomas. *RET* D631Y variants were frequently observed compared with previous reports. This study indicated that the 4 genes including *RET*, *VHL*, *SDHB*, *SDHD* is the most important causative genes among Koreans, and four genes showed a specific spectrum of mutations in Korea.

## PgmNr 760: Parotid gland desmoid tumor as clinical presentation of familial adenomatous polyposis.

### Authors:

### Introduction:

Familial adenomatous polyposis (FAP [MIM 175100]) is an autosomal dominant hereditary cancer syndrome characterized by the development of multiple adenomatous colorectal polyps in the second or third decade of life and variably extracolonic manifestations such as hepatoblastoma, congenital hypertrophy of the retinal pigment epithelium, desmoid tumors, soft tissue tumors, dental anomalies, osteomas, odontomas, epidermoid cysts, duodenal adenomas and associated cancer. It is caused by mutations in the *APC* gene which almost always cause premature truncation of the protein.

### Case report:

We present the case of a 20-year-old woman with a desmoid tumor in the left parotid gland diagnosed at 15 years of age with recurrence at 17 and 19 years of age. A total left parotidectomy was performed with preservation of the facial nerve, with pathology reporting fibromatosis of desmoid type. Five years after the parotid tumor diagnosis, her father was diagnosed with colonic polyposis at 55 years old, and at that time FAP was suspected. The genetic study revealed a heterozygous frameshift mutation c.1977\_1978insTTTCT (p.Asn660Phefs\*12) in the *APC* gene, inherited from her father, confirming the diagnosis. Gastroscopy and colonoscopy were performed, showing numerous colonic polyps. Total prophylactic colectomy will be performed, and both the patient and family members are under multidisciplinary clinical follow-up. It is of note, that this patient also has a kidney malformation and history of epilepsy, ataxia and coagulation disorder in study. However, until now no other molecular studies have been carried out.

### Discussion:

It is well known the association of desmoid tumors with FAP, but these are usually found within the abdomen or in the abdominal wall. There are few reported cases of parotid tumors in this syndrome, and, to the best of our knowledge, just one case of a fibromatous parotid tumor. We consider important to highlight different forms of clinical presentations of FAP, as the parotid gland desmoid tumor in our patient, in order to make a timely diagnosis, since it is essential to provide an early management to prevent colorectal cancer that occurs inevitably in untreated FAP patients.

## PgmNr 761: A spontaneous rhesus macaque model of heritable colorectal cancer associated with mutations in DNA Mismatch Repair (MMR) genes: An improved animal model of Lynch syndrome in humans.

---

Colorectal cancer (CRC) is the third most common cancer in the US. Most CRC cases arise on a sporadic background, but Lynch Syndrome (LS) is the most common hereditary condition predisposing to CRC. LS is secondary to germline mutations in one of four DNA mismatch repair (MMR) genes: *MLH1*, *MSH2*, *MSH6* or *PMS2*. Heterozygous carriers have high lifetime risk to develop cancers commonly located in the proximal colon or ileocecal valve, as well as extracolonic tumors (endometrium, ovaries, stomach, small intestine and others). Since 2001, 65 cases of spontaneous CRC have been diagnosed among rhesus macaques (*Macaca mulatta*) at the Keeling Center for Comparative Medicine and Research (KCCMR). Rhesus CRC commonly presents as anemia, weight loss, diarrhea and a palpable abdominal mass. Mean age at death due to CRC is 18.3 years, roughly equivalent to mid-60's in humans. Histopathology of these tumors closely resembles human Lynch Syndrome. We previously reported two potential causative germline mutations identified by whole genome sequencing (WGS) of 20 of the 65 total CRC cases: a premature stop codon in *MLH1* and a missense mutation in *MSH6*, predicted to be highly deleterious (Combined Annotation-Dependent Depletion score of 22.8). Subsequent genotyping of all adults in the KCCMR rhesus colony (n = 595) revealed allele frequencies for the *MLH1* premature stop codon and *MSH6* missense variants of 0.04 and 0.06 respectively, with *MLH1* and *MSH6* heterozygotes highly overrepresented in CRC cases ( $\chi^2$  test  $p < 0.01$ ). Human LS exhibits microsatellite instability (MSI), an increase in somatic indels in microsatellite repeats. Initial studies in rhesus CRC cases indicate high MSI in some but not all cases. Additional analyses of MSI are in progress. We draw three conclusions from these data: a) approximately half of KCCMR rhesus CRC cases can be described as LS based on the damaging mutations in *MLH1* or *MSH6* and clinicopathologic presentation; b) further analyses are needed to determine if other molecular changes (e.g. disruption of *MLH1* promoter methylation) may underlie CRC in cases not attributable to *MLH1* or *MSH6* variants; c) because attempts to model Lynch Syndrome in rodents by disrupting MMR genes do not generate pathology that parallels human LS, this spontaneous rhesus macaque model, due to natural mutations in MMR genes and displaying nearly identical pathology, will be uniquely valuable in efforts to develop improved immune therapies and prevention strategies.

## PgmNr 762: Whole exome sequencing identifies homozygous *MSH6* variants in patient presenting with multiple malignancies.

---

**Introduction:** Here we describe our experience using research whole exome sequencing (WES) in a pediatric patient with multiple malignancies admitted at the Columbia University Irving Medical Center/New York Presbyterian Pediatric Intensive Care Unit (PICU).

**Case description:** A 13-year-old male of Middle Eastern descent presented to the PICU with multiple brain masses and an abnormal brain MRI showing cortical tubers, as well as seizures and café-au-lait macules. A diagnosis of Tuberous Sclerosis Complex (TSC) was initially suspected. Research WES resulted in an unexpected diagnosis of Constitutional Mismatch Repair Deficiency Syndrome (CMMRD). CMMRD is a rare autosomal recessive condition caused by homozygous variants in the mismatch repair genes (*MLH1*, *MSH2*, *MSH6*, and *PMS2*), and is characterized by brain tumors, colon cancer, hematologic cancer, and café-au-lait macules. Interestingly, microsatellite instability (MSI) testing ordered on a glioma sample from the patient was MSI negative, a phenomenon only observed in 5% of tumors caused by pathogenic variants in a mismatch repair gene. Immunohistochemistry (IHC) testing following the WES results confirmed the lack of expression of the MSH6 protein. Major clinical implications following the diagnosis of CMMRD included a change in the patient's chemotherapy treatment, as well as the identification of an additional signet cell peritoneal/intestinal tumor in the patient's stomach. Social implications included the diagnosis of the patient's mother with Lynch Syndrome, as well as increased risk of Lynch Syndrome and CMMRD to the patient's father and two siblings respectively.

**Conclusion:** Although a rare condition, CMMRD should be considered in patients with multiple brain masses and other malignancies given the potential for targeted treatment as well as future screening for the patient and family members. Targeted molecular testing for TSC and IHC testing alone would have missed this diagnosis. Whole exome sequencing is a useful tool in identifying the etiology of multiple malignancies in the pediatric setting.

## **PgmNr 763: In-depth dissection of *APC* pathogenic variants: Spectrum of more than 400 pathogenic variants, challenges of variant interpretation, and new observations in a large clinical laboratory testing cohort.**

*APC* as a classic tumor suppressor gene is involved in the initial tumorigenesis of colorectal cancer, and is responsible for inherited polyposis syndromes, familial adenomatous polyposis (FAP), attenuated FAP, and gastric adenocarcinoma and proximal polyposis of the stomach (GAPPS). Since *APC* was first discovered about three decades ago, numerous studies have reported germline *APC* variants and associated clinical findings in the literature. With recent technological advances in genomic sequencing, *APC* genetic testing is routinely included as part of hereditary cancer panel testing and easily performed in clinical laboratories. While *APC* has been extensively studied, we continue to encounter novel variants given the large number of individuals tested in our clinical laboratory.

Here we report an in-depth dissection of *APC* variants among over 208,000 individuals tested clinically, which includes analysis of over 400 unique pathogenic variants. *APC* comprises 16 exons, with a large last exon 16 encoding ~80% of the *APC* protein. *APC* also has well-characterized regulatory regions, promoter 1A and promoter 1B. Germline variants in promoter 1B that disrupt transcription factor binding have been reported as disease causing. Among the pathogenic variants, 88% of all variants were truncating variants, 4% were missense, silent and intronic variants affecting splicing, 6% were subgenic copy-number variants (CNVs), ~1% were regulatory variants in promoter 1B, and ~1% were exonic retrotransposon (Alu and LINE-1) insertions. Due to the high penetrance of disease, variant interpretation of novel variants is less complicated. However, there are some challenges: 1) interpretation of novel truncating variants escaping nonsense-mediated decay (NMD) in the large exon 16 requires additional evidence; 2) interpretation of variants affecting regulatory regions requires more rigorous evidence to prove pathogenicity; 3) interpretation of subgenic duplications that are assumed in-tandem is accounted for by clinical information and penetrance. Nonetheless, experience over the years has helped us to resolve some of these challenges, which we will cover in this study. Lastly, we report new observations from our clinical testing: 1) pathogenic germline variants affecting the YY1 motif of promoter 1B in GAPPS and FAP families; and 2) subgenic duplications of the 5' end of the gene involving promoter 1A and/or exon 2, but excluding promoter 1B, that are likely disease-causing variants.

## PgmNr 764: Novel presentation of jaw odontogenic cyst in *SUFU*-associated Gorlin syndrome.

Gorlin syndrome (GS), also known as nevoid basal cell carcinoma syndrome, is an autosomal dominant benign and malignant tumor predisposition. GS is characterized by jaw keratocysts, ectopic calcification of the falx, skeletal anomalies, plantar/palmar pitting, cardiac and ovarian fibromas, and in some individuals, distinctive facial features. Tumor risk includes medulloblastoma (particularly desmoplastic type) and multiple basal cell carcinomas. Germline mutations in components of the Sonic hedgehog pathway, *Patched1* (*PTCH1*) and *Suppressor of fused* (*SUFU*) are responsible for GS. Jaw keratocysts are well described among *PTCH1* carriers but not described in *SUFU* mutation carriers. Given the morbidity associated with untreated cysts, digital surveillance of the jaw is recommended.

Historically, GS surveillance has been indifferent to genotype (*PTCH1* vs. *SUFU*). Foulkes et al. published the first protocol suggesting surveillance by genotype. This included elimination of odontogenic cyst screening in patients with *SUFU* mutations. Following this, Evans et al. reported genotype/phenotype data of 182 individuals meeting clinical GS diagnostic criteria, in which 9 individuals had *SUFU* mutations. None of the *SUFU* mutation carriers were reported to have jaw cysts.

To the best of our knowledge, we document the first case of a jaw keratocyst in an individual with *SUFU*-related GS. Our patient is a 33-year-old Hispanic male who presented at age four with medulloblastoma. He underwent subtotal resection, craniospinal radiation and chemotherapy. At age 18, an osteochondroma of the lumbar vertebrae was identified and resected. At age 20, he was found to have an infundibulocystic basal cell carcinoma of the left periapical scalp and seizures. At 23, his physical exam was significant for palmar pits and an odontogenic cyst that was excised. His history also includes bilateral cataracts, subsequent basal cell carcinomas, meningioma at age 30 and a transient ischemic attack, likely radiation-induced. Germline testing of *PTCH1* and *SUFU* revealed a novel heterozygous likely pathogenic *SUFU* mutation, c.595C>T, (p.Gln199\*).

Previous series of *SUFU*-related GS have limited numbers of patients given the rarity of the condition. Therefore, the finding of a jaw keratocyst in our patient is notable and suggests that jaw cysts may also be associated with germline *SUFU* mutations; potentially warranting digital jaw surveillance.

## PgmNr 765: A germline susceptibility variant in *VHL* in a patient with Maffucci syndrome.

---

*VHL* downregulates HIF1A, the main regulator of adaptation to hypoxia, by targeting HIF1A for degradation. Loss-of-function variants in *VHL* are known to cause von-Hippel Lindau syndrome, an autosomal dominant familial cancer syndrome, and autosomal recessive familial erythrocytosis. *VHL* is also associated with other tumors, such as cerebellar hemangioblastoma, pheochromocytoma, and renal cell carcinoma. Maffucci syndrome (MS) is a rare disorder characterized by multiple enchondromas and vascular anomalies. Patients with MS are also at increased risk for cancer - mainly, chondrosarcomas and vascular malignancies. Here we describe a patient with MS and additional features not described before, such as a region of epidermal and dermal atrophy on the left chest, a lymphoepithelioma of the nasopharynx with parapharyngeal involvement, an exostosis in the left wrist, developmental delay and intellectual disability. We performed WES on multiple samples, including blood, an enchondroma and an exostosis. A germline *VHL* variant (c.C505T; p.R169W) was identified by WES. RNA-seq confirmed that the *VHL* variant is present at heterozygous levels (45-70%) in RNA from all tissues tested: an enchondroma, an exostosis, a vascular anomaly biopsy, and an unaffected skin biopsy. Western Blot showed that *VHL* in the patient's unaffected skin biopsy and vascular anomaly biopsy is within the range of the controls. WES also identified a somatic mosaic variant in *PDGFRB* (c.C1998A; p.N666K), known to be pathogenic and causative of somatic infantile myofibromatosis. This variant was identified in the enchondroma but not in the exostosis and in the blood. We performed digital droplet PCR and confirmed that the *PDGFRB*-p.N666K variant was not present in the blood, but was present in all 4 patient's enchondromas tested (21.8%, 27.5%, 50.5%, and 49.8%), in his in his exostosis (0.64%), in his unaffected skin biopsy (22%) and vascular anomaly biopsy (0.88%). Based on these findings we suggest that the *VHL*-p.R169W is likely pathogenic, and that, similarly to the *VHL*-R200W and the *VHL*-H191D variants that result in polycythemia, it causes overproduction of the HIF-targets by attenuating formation of the E3 ubiquitin ligase and attenuating binding to HIF1. We also suggest that this patient has a tumor predisposition syndrome characterized by the germline susceptibility *VHL*-p.R169W variant and additional tumor variants, such as the *PDGFRB*-p.N666, leading to tumor formation.

## PgmNr 766: Germline variants in predisposition genes in children with Down syndrome and acute lymphoblastic leukemia.

### Authors:

A.J. de Smith <sup>1</sup>; P. Winer <sup>1</sup>; I.S. Muskens <sup>1</sup>; K.M. Walsh <sup>2</sup>; A. Vora <sup>3</sup>; J.L. Wiemels <sup>1</sup>; A.V. Moorman <sup>4</sup>; I. Roberts <sup>5</sup>; A. Roy <sup>5</sup>

### Affiliations:

1) Center for Genetic Epidemiology, Department of Preventive Medicine, University of Southern California, Los Angeles, California, USA; 2) Department of Neurosurgery, Duke University, Durham, North Carolina, USA; 3) Great Ormond Street Hospital for Children NHS trust, London, UK; 4) Wolfson Childhood Cancer Research Centre, Northern Institute for Cancer Research, Newcastle University, Newcastle-upon-Tyne, UK; 5) Department of Paediatrics and MRC Molecular Haematology Unit, Weatherall Institute of Molecular Medicine, Oxford University and BRC Blood Theme, NIHR Oxford Biomedical Centre, Oxford, UK

**Background:** Despite advances in treatment, acute lymphoblastic leukemia (ALL) remains a leading cause of childhood mortality. Children with Down syndrome (DS), caused by constitutive trisomy 21, have a 20-fold increased risk of ALL (DS-ALL) and significantly lower event-free survival than non-DS patients with ALL. There is a critical need to understand the increased risk of ALL in children with DS. We determined the frequency of rare predisposing germline variants in 77 DS-ALL patients in the International Study of Down Syndrome Acute Leukemia.

**Methods:** We identified 59 DS-ALL patients in the Bloodwise Childhood Leukemia Cell Bank (UK) and 18 patients in the New York State Department of Health Newborn Screening program, with available germline material. Whole exome sequencing of extracted DNA was performed at 60X coverage. FASTQ files were aligned to human reference genome hg38 using BWA, and variant calling performed following GATK “best practices” guidelines. For quality control, we used Variant Quality Score Recalibration for non-chromosome 21 variants, and hard filtering for chromosome 21 variants. After annotating variants using ANNOVAR, we retained those with allele frequency <0.01% in the Genome Aggregation Database, and limited to loss-of-function variants (nonsense, frameshift, splicing), and/or those classed as “Pathogenic” or “Likely pathogenic” in the ClinVar database.

**Results:** At least 5/77 (6.5%) DS-ALL patients harbored rare and predicted pathogenic germline variants; a similar frequency was reported in non-DS ALL. Three variants were previously described: a deleterious missense variant in *IKZF1*, associated with immunodeficiency and childhood ALL; a pathogenic frameshift mutation in the Nijmegen breakage syndrome gene *NBN*; and a missense variant in *RTEL1*, reported previously in patients with dyskeratosis congenita. Two additional variants were identified in genes without a known role in leukemia predisposition: a loss-of-function frameshift mutation in the B-cell transcription factor gene *FOXP1*, and a mutation in the leukemia fusion gene *MLLT1* listed as likely pathogenic in ClinVar in a patient with congenital abnormalities. No putative pathogenic mutations were found on the trisomic chromosome 21.

**Conclusions:** Children with DS-ALL may harbor pathogenic germline variants in predisposition genes, likely contributing to their leukemia development, which may inform future risk stratification and genetic counseling in this vulnerable population.

# PgmNr 767: Copy number burden characterization and prediction across human cancers.

**Authors:**

B. Lasseigne <sup>1</sup>; R. Darji <sup>2</sup>; J. Fisher <sup>3</sup>

[View Session](#) [Add to Schedule](#)

---

**Introduction**

Chromosomal instability, or altered chromosome number and structure, is an enabling characteristic of the hallmarks of cancer and is associated with disease etiology, patient prognosis, and drug efficacy. However, copy number burden has been calculated by many different metrics and the relationship between them, or which are most biologically relevant with respect to context or biological question, is unknown.

**Methods**

Using The Cancer Genome Atlas cancer cohort (n=22,158 patients, 33 cancers), we calculated, compared, and characterized copy number burden by metrics including total aneuploidy index, copy number aberration count, the percent of bases with copy number variation, and the total number of breakpoints.

**Results**

We demonstrate these metrics are not equivalent, occur at different frequencies within and across cancer types, and likely represent distinct biological properties like homologous repair defects and selective pressure for copy number regions with driver genes. We also identified molecular features including DNA methylation, transcription factor occupancy profile overlap, gene ontology term enrichment, and proximity to tissue-specific eQTLs associated with each chromosomal instability metric both within and across cancer types, as well as clinical factors (e.g., patient age, tumor stage) and drug responses associated with each metric. Additionally, because chromosomal instability is linked to widespread DNA hypomethylation and characteristic gene expression changes even across species, we hypothesized measures of chromosomal instability can be inferred from these and other data types. Therefore, we predicted chromosomal instability metrics from each TCGA data type using machine learning approaches, consistently building models with favorable performance characteristics.

**Discussion**

The models we generated are being implemented as an R package useful for inferring different chromosomal instability metrics from genomics data sets where copy number variation data may not

be available, enabling more information to be extracted from available molecular profiles. This study improves chromosomal instability signature interpretation by providing insight into the role of chromosomal instability in human cancer etiology, progression, and potential treatment strategies, while providing models for predicting it in other data types like gene expression and DNA methylation.

## PgmNr 768: LD score regression analysis of lung cancer using multi-traits from UK Biobank.

Identifying genetic correlations between complex traits and diseases can provide valuable insights into epidemiological and etiological studies. The major challenge for estimating genetic correlation from genome-wide association study (GWAS) data is the lack of availability of individual-level genotype data and sample overlap among meta-analyses. Linkage disequilibrium (LD) score regression using GWAS summary statistics quantifies the genetic correlation and SNP heritability, which is proportion of phenotypic variance explained by all SNPs between pairs of traits. This technique could provide insights into the genetic contributions of different phenotypes potentially associated with lung cancer risk.

We harmonized 824 publicly-available GWAS summary-level datasets from 36 consortia including 82 diseases, 154 complex traits, 181 metabolites, and 12 immune-related disorders from the UK Biobank and OncoArray lung consortium. We calculated pairwise genetic correlation between lung cancer including histologic subtypes and other phenotypes.

Results demonstrated that smoking and socio-economic status related traits are the strongest factors associated with an increased risk of lung cancer. The correlation between smoking and overall lung cancer was 0.42 ( $P=1.70E-84$ ,  $h^2=0.10$ ) and a negative correlation was observed between lung cancer and education years, -0.34 ( $P=5.10E-63$ ,  $h^2=0.15$ ). Additionally, primary biliary cirrhosis (PBC), ulcerative colitis (UC), and multiple sclerosis (MS) all showed positive correlation with lung adenocarcinoma. To correct for the contribution of smoking to these associations, chromosomal regions previously associated with cigarettes per day, smoking cessation and age at initiation were excluded (500kb regions centered on SNPs identified by Liu et al. (Nature Genetics, 2019)). After removing these regions, the greatest genetic correlation across all lung cancer subtypes was a paternal history of lung cancer ( $r^2 = 0.77$ ,  $P= 3.63E-34$ ,  $h^2=0.01$ ), followed by PBC ( $r^2 =0.58$ ,  $P= 9.44E-31$ ,  $h^2=0.74$ ), UC ( $r^2=0.39$ ,  $P=2.56E-24$ ,  $h^2=0.34$ ) and MS ( $r^2=0.45$ ,  $P=1.39E-18$ ,  $h^2=0.18$ ). These results are consistent with previous research and expand prior findings by identifying novel phenotype correlations with several autoimmune diseases. Mendelian randomization analyses will help clarify the potentially causal relationship between autoimmune diseases and lung cancer risk.

## PgmNr 769: An integrative multi-omics network-based approach identifies key regulators for breast cancer.

### Authors:

---

Breast cancer is one of the most common diagnosed cancers and leading causes of cancer-related death in females. Several GWASs have identified over 600 breast cancer susceptibility SNPs, but most SNPs are located within non-coding genomic regions and their functions need to be interpreted. We developed a framework named integrative genomics network-based approach (IGNA) to identify potential regulatory genes based on disease-related biological processes and the network topology. This approach was applied to identify key genes in regulatory networks for breast cancer by integrating interactions and functional data from multiple biological scales, including GWASs, eQTLs, epigenomic elements, transcriptome, protein interactome and chromatin long-range interactions from disease relevant tissues. We collected 1,077,575 SNP-gene mapping pairs by integrating GWASs results with SNPs functional information. To identified biological related gene sets of breast cancer, we collected knowledge-driven pathway and co-expression modules to investigate the genetical perturbations on the regulatory networks. Across 5 breast cancer gene expression profiles, we identified co-expression 357 modules. We gathered 1077 canonical pathways from public databases. Among the total 1,434 gene sets, 12, 31 and 108 gene sets in African, East Asian, European population significantly enriched in disease-associated SNPs with P-value < 0.05. We found 185 overlap of genes across 3 populations and performed pathway enrichment analysis to find the contribution of identified gene sets to biological mechanisms. The top ranked pathways were cancer-related pathways and the shared genes showed the enrichment in several important signaling pathways, cellular processes and viral infection pathways. Moreover, we uncovered key genes for each regulatory network based on GWAS signals and the topology of networks. The top 20 ranked-order genes are *MYC*, *CCND1*, *CDKN1A*, *SMAD3*, *DUSP1*, *RB1*, *STAT1*, *EGFR*, *TGFB1*, *IGF1R*, *TP53*, *STAT3*, *CFLAR*, *MDM2*, *NFKBIA*, *RHOB*, *VEGFA*, *SMAD2*, *GADD45B* and *JUND*. Moreover, we found that abnormal expression levels of the top 20 ranked-order genes were significantly related with poor survival outcomes (P=0.025). Our integrative network-based approach provided a genetic-driven framework to unveil tissue-specific interactions from multiple biological scales and to reveal potential risk genes to complex diseases.

## PgmNr 770: Multiple pathogenic genetic variants in a Puerto Rican (Hispanic) patient with ovarian cancer: Unreported variants and the implications of *de novo* haploinsufficiency in cancer development.

---

Forty-seven years old female patient with history of ovarian carcinoma and a pathogenic variant in *BRCA2* gene, c.3922G>T (p.Glu1308\*) was referred to Genetics for evaluation and counseling. Family history was significant for thyroid, lung and ovarian cancer in three generations. A multi-gene cancer panel was requested and the pathogenic variant in *BRCA2* was confirmed. This variant is associated with autosomal dominant hereditary breast and ovarian cancer syndrome, where this sequence change creates a premature translational stop signal, resulting in an absent or disrupted protein product. In addition, a pathogenic variant, c.1187G>A (p.Gly396Asp), was identified in *MUTYH*, which is associated with autosomal recessive *MUTYH*-associated polyposis. Because *MUTYH*-related conditions are autosomal recessive, one pathogenic variant alone may not explain individual's reported condition. However, there is evidence that this monoallelic pathogenic *MUTYH* variant is associated with colon cancer. Also, two variants of uncertain significance were reported, c.4532A>T (p.Asp1511Val) in *ATM* and c.2083G>A (p.Val695Ile) in *BARD1*. The *ATM* gene is associated with an increased risk for autosomal dominant breast, pancreatic and prostate cancers. This variant is not present in population databases but algorithms developed to predict effect of variations suggest that this variant is likely disruptive. The *BARD1* gene is associated with an increased risk for autosomal dominant breast and ovarian cancer in individuals who carry a single pathogenic variant. Further studies of these variants may prove to be an important step toward the clinical and molecular characterization of cancer in our population. Of particular interest is the effect of the loss of heterozygosity (haploinsufficiency) effect as a potentiator of the cancer development process. While targeted gene panels are indicated for analyzing specific mutations, multi-gene panel was an excellent approach in this case due to the clinical manifestations.

## PgmNr 771: Identification of novel potential genetic predictors of urothelial bladder carcinoma susceptibility in Pakistani population.

---

Urothelial bladder carcinoma (UBC) is the most common among urinary bladder neoplasms. We carried out a preliminary study to determine the genetic etiology of UBC in Pakistani population. For this purpose, 25 sequence variants from 17 candidate genes were studied in 400 individuals by using polymerase chain reaction-based techniques. Multivariate logistic regression analysis was performed for association analysis of the overall data as well as the data stratified by smoking status, tumor grade and tumor stage. Variants of *GSTM1*, *IGFBP3*, *LEPR* and *ACE* were found to be associated with altered UBC risk in the overall comparison. *CYP1B1* and *CDKN1A* variants displayed a risk modulation among smokers; *IGFBP3* and *LEPR* variants among nonsmokers while *GSTM1* polymorphism exhibited association with both. *GSTM1* and *LEPR* variants conferred an altered susceptibility to low grade UBC; *GSTT1*, *IGFBP3* and *PPARG* variants to high grade UBC while *ACE* polymorphism to both grades. *GSTM1* and *LEPR* variants exhibited risk modulation for non-muscle-invasive bladder cancer (NMIBC); *GSTT1* and *PPARG* variants for muscle-invasive bladder cancer (MIBC), and *ACE* variant for NMIBC as well as MIBC. In general, the susceptibility markers were common for low grade and NMIBC; and distinct from those for high grade and MIBC indicating the distinct pathologies of both groups. In brief, our results conform to reports of previously associated variants in addition to identifying novel potential genetic predictors of UBC susceptibility.

## PgmNr 772: Identification of differential expressed genes in HBV-related hepatocellular carcinoma.

---

Hepatocellular carcinoma (HCC) is the third leading cause of deaths from cancer worldwide. Hepatitis B virus (HBV) infection and hepatitis C virus (HCV) infection are the leading risk factors for developing HCC, particularly in East Asia. There is lack of effective treatment and early detection methods for HCC. Genomic and transcriptomic profiles in HCC tumors are critical in understanding the mechanism of HCC development and providing guidance for novel therapeutic and biomarker development. There are limited transcriptomic studies in HBV-related HCC, most of which underpowered, do not differentiate between HBV- or HCV-associated HCC, and lack validation across studies. We performed a meta-analysis to assess changes in gene expression patterns in HBV-HCC by integrating HBV-HCC samples from TCGA (The Cancer Genome Atlas) and four GEO (Gene Expression Omnibus) datasets. Each of the five datasets had 1000-7000 differentially expressed genes (DEGs) from the tumor/normal tissue comparison (threshold >1.5-fold change, FDR p-value <0.05). In the HBV-HCC TCGA dataset, there were 6603 DEGs. There were 512 DEGs (328 over-expressed, 184 under-expressed) shared across all five datasets in the same direction, indicating 7.8% of DEGs from TCGA HBV-HCC can be replicated. Among top DEGs, several are known to be involved in HCC, e.g. the over-expression of *GPC3* and *PTTG1*, and the under-expression of *CYP1A2* and *CLEC4G*, while most others' role in HBV-HCC have not been defined, including *LYVE-1* involved in tumor metastasis, and *KCNN2*, an ion transporter. Pathway analysis based on overlapping genes revealed that toxin and fatty acid degradation pathways were highly under-expressed (including cytochrome P450 family enzymes that metabolize and degrade toxins, drugs and lipids, e.g. *CYP2A6*) while cell cycle replication and retinoid X receptor (RXR) inhibition pathways are over-expressed (including *Cyclins*, *SLC10A1*, *ALDH8A1*). These identified pathways and genes may have utility in the development of targeted therapies and prevention of HCC. (Funded by the National Cancer Institute, under contract HHSN26120080001E).

## PgmNr 773: Decreased expression of *ZEB1* and *SOX2* in glioma in comparison with meningioma.

### Affiliations:

1) Medical Genetics Department, School of Medicine, Tehran University of Medical Sciences, Tehran, Iran; 2) Department of Neurosurgery, Shariati Hospital, Tehran University of Medical Sciences, Tehran, Iran; 3) Department of Epidemiology and Biostatistics, School of Public Health, Tehran University of Medical Sciences, Tehran, Iran

Gliomas are the most common primary malignant brain tumors in adults. Their aggressiveness results from their high invasive ability which makes their total surgical resection impossible and renders high grade glioma the capability to relapse. Epithelial-to-Mesenchymal Transition (EMT) has been considered as one of the major mechanisms helping glioma aggressiveness. EMT is a complex process modulated by multitude of transcription factors and signaling pathways. This process is known to be implicated not only in malignancy progression, but also in cancer therapy resistance.

Meningioma, the tumor arising from the meninges, is a benign tumor that is efficiently treated by surgical resection with invasiveness occurring in only 15-20 % of cases.

*p21* is an anti-proliferative molecule which arrests the cell cycle. *SOX2* has been proven to interact with *p21* and plays an important role in cell cycle progression and carcinogenesis in addition to its implication in EMT and tumor metastasis. *ZEB1*, an EMT marker, has been proven to be implicated in cancer aggressiveness and metastasis. Therefore, a comparison of the expression of these molecular targets implicated in EMT can help elucidate the underlying mechanisms that contribute to glioma aggressiveness in comparison with the benign tumors of meningioma.

A comparison of the mRNA expression of the molecular targets *ZEB1*, *p21* and *SOX2*, has been carried out in this study using real-time PCR technique in 31 samples of glioma and 44 samples of meningioma. The clinicopathological features of these patients have also been studied.

Based on our Real-Time PCR results, *SOX2* and *ZEB1* expression were significantly lower in glioma in comparison with meningioma. The findings on *ZEB1* and *SOX2* were statistically significant and meaningful. The P value for the difference of *SOX2* and *ZEB1* expression were 0.016 and 0.017 respectively. *p21* expression level was higher in glioma compared to meningioma but the difference was not considered statistically significant.

The difference in the expression of *ZEB1* and *SOX2* between glioma and meningioma samples suggests the fact that there are potential roles for them as targets implicated in aggressive behavior, but the extent up to which these molecules can play their roles needs further elucidation.

\*Shiva Bayat, Mohammad Taghi Raouf and Negar Mousavi are the co-first authors of this article.

Human papillomavirus (HPV) infection is pivotal in cervical cancer development. However, only a small portion of HPV infected women progress to cervical cancer, suggesting the importance of host genetic makeup. Transporter associated with antigen processing (TAP) plays a central role in MHC I antigen presentation. Defects of these genes have been reported to be common in different types of cancer. This study aims to investigate whether variants of the *TAP1* and *TAP2* genes are associated with cervical cancer in Taiwanese women. The *TAP1* *rs1057141* A/G and *rs1135216* A/G, and *TAP2* *rs2228396* G/A, *rs241447* G/A, *rs4148876* G/A and *rs1800454* C/T polymorphisms were genotyped in 320 cervical squamous cell carcinoma (CSCC) patients and 320 age/sex matched healthy controls. The presence and genotypes of HPV in CSCC patients were also determined. We found no significant association between any polymorphisms or haplotypes examined and CSCC risk. Stratified by the positivity of HPV-16 infection also did not find marked association. Our findings provide no support for the hypothesis that specific polymorphisms of *TAP1* and *TAP2* genes are associated with CSCC risk in Taiwanese women.

## PgmNr 775: Discovering germline metastasis risk variants in colorectal carcinoma via case-case GWAS.

Colorectal carcinoma (CRC) is a leading cancer by incidence and mortality worldwide. Majority of death is attributable to distal organ metastasis. Hitherto, germline contribution to metastasis of sporadic CRC is unclear. We aimed to determine the contribution of germline risk variants to CRC metastasis via case-case genome-wide association study (GWAS) in about 3,000 Chinese sporadic CRC patients. Genome-wide genotyping was performed with Affymetrix SNP6 microarray. Metastasis-positive status is confirmed based on distal organ involvement attributable to primary CRC, either from histopathological report or computed tomography/positron emission tomography (CT/PET) scan regardless of the tumor staging at the time of operation. Metastasis-negative status is confirmed with at least 5 years of follow-up without distal organ involvement. The finalized dataset after quality assurance filtering (overall genotypic call rate of >0.9, minor allelic frequency of > 1%, and principal component analysis (PCA)) comprises approximately equal metastasis-positive (n=1282) and metastasis-negative (n=1395) cases. PCA plot with the Singapore Genome Variant Project (SGVP) and the HapMap subjects comprising various ethnicities indicates that there is no population substructure. The Q-Q plot indicates good genomic control ( $\lambda=1.0087$ ) without the need for any PC correction. Single nucleotide polymorphism (SNP) association testing using the additive model indicates several regions of interest (ROI) with the top SNP at  $-\log_{10}p=6.1$  and odds ratio of  $\sim 1.4$  at chromosome 20p12. Notably, sub-group analysis stratifying by tumor site, staging, distal organ metastasis and gender reveal higher  $-\log_{10}p$ -values (with SNPs in three ROIs exceeding genome-wide significance of 7.3) and effect sizes despite smaller sample sizes suggesting that the variants could be specific to the particular subgroup which is more homogeneous. Two ROIs for peritoneal- and bone-specific metastasis have rarer SNPs with high effect-sizes indicating probable population-specific risk variants. Top ranking SNPs from selected ROIs are currently being validated in an independent replication panel of another  $\sim 1,000$  cases.

## PgmNr 776: Variant characterization and effect size estimation of established colorectal cancer susceptibility genes from sequence-based case-control analysis.

Genes responsible for Hereditary Non-polyposis Colorectal Cancer (HNPCC) have been extensively evaluated in colorectal cancer pedigrees. However, few studies have conducted detailed assessment of these genes in large case-control studies with complete gene sequencing. We conducted a high-throughput sequencing case-control study in 1810 colorectal cases and 5659 controls to further characterize the risks of known pathogenic variants and variants of uncertain significance (VUSs) in these genes. The two genes responsible for the largest proportion of HNPCC cases, *MLH1* and *MSH2*, both exhibited very large effect sizes, with ORs of 32.0 (95% CI:3.9-1462) for *MLH1* and 29.5 (CI:6.4-272.3) for *MSH2*. In contrast, pathogenic and truncating variants exhibited a more modest OR of 5.3 (CI:0.4-73.3) in *PMS2*, with no evidence of association in *MSH6* (OR = 1.2, CI:0.4-3.3). The estimated proportion of familial relative risk (pFRR) attributable to these variants was 1.8% for *MLH1*, 3.3% for *MSH2*, and 0.3% for *PMS2*. Although the associations were not statistically significant, we observed ORs greater than 1.0 for VUSs in the domain regions of each of these three genes, suggesting that a substantial proportion of pathogenic missense variants have yet to be identified. We also report effect size estimates for known pathogenic variants and VUSs in other established colorectal cancer susceptibility genes, including *APC* and *POLD1*. In total, VUSs in our study contributed a pFRR of 0.7%, for a total of 6.1% for all variant categories across all genes. Our results suggest that a substantial proportion of pFRR may be explained by VUSs in well-established high-risk genes while highlighting the need for larger sequence-based association studies to more accurately classify missense variants in established susceptibility genes and to evaluate the contribution of rare variants to cancer heritability.

**Introduction:** Harnessing the rich data resource of the cancer-enriched cohort of the Michigan Genomics Initiative (MGI, <https://precisionhealth.umich.edu/michigangenomics/>), a longitudinal biorepository effort at Michigan Medicine, we pursue an analytic discovery framework to integrate genetic risk information and electronic health records (EHR) to uncover novel association and/or relevant cross-phenotype associations.

**Methods:** Our current framework condenses summary statistics of published genome-wide association studies (GWAS) on cancer traits into polygenic risk scores (PRS) using linkage disequilibrium pruning and p-value thresholding (P&T) or genome-wide posterior mean effect size weighting (LDpred). For each PRS, we determine its predictive performance before performing association scans across the PheCode-based phenomes of MGI and the UK Biobank study.

**Results:** So far, we have mined various sources of available cancer GWAS data, e.g. the Neale Lab UK Biobank GWAS results or the NHGRI-EBI GWAS Catalog and constructed 36 PRS for 19 common cancer traits. Phenome-wide association studies (PheWAS) of these PRS across the MGI phenome of over 38,000 unrelated, European participants included over 1,600 phenotypes and, for some PRS, indicated strong association with their primary cancer trait as well as additional secondary traits. For GWAS-catalog-based PRS, we also validated our approach using the large, population-based UK Biobank study.

**Conclusions:** Since there is an urgent need to better communicate results from such big data exploration with a broad and multi-disciplinary audience, e.g. to inspire hypothesis development, we are developing PRSweb, an interactive webpage for intuitive result browsing. A current working draft already shows downloadable PRS constructions and PRS PheWAS results for all constructed PRS and is available at <http://csg.sph.umich.edu/larsf/PRSweb>. Future implementations will incorporate PRS for a broader set of complex traits beyond cancer and also include tools and tutorials for PRS research.

## **PgmNr 778: Discovery of rare and novel variants associated with breast cancer in Trinidadian families using whole exome sequencing.**

**Authors:**

R. Haraksingh

[View Session](#) [Add to Schedule](#)

**Affiliation:** Dept. of Life Sciences, The University of the West Indies, St. Augustine, Trinidad and Tobago

---

Breast Cancer is the most prevalent cancer that affects women both worldwide and in Trinidad & Tobago. According to the World Health Organization it accounts for 22.1% of all cancer mortality cases as of 2014. This study aims to determine whether there are novel genetic contributors to the development of Breast Cancer in Trinidadian individuals. Approximately 30 genes contributing to Breast Cancer susceptibility have been discovered largely through studies done on Caucasian populations. However, the extent to which these genetic contributors are relevant in Caribbean populations is unknown. 90 Breast Cancer patients in Trinidad have undergone genetic screening for common cancer-causing mutations using the most extensive Breast Cancer screening panel to date. This panel covers 30 genes and 78% of these patients were found to not carry any of these known mutations. As such, we believe that there may be novel genetic variants present in this population that are the potential cause of some hereditary Breast Cancer cases. We performed Whole Exome Sequencing of two members of such a family with evidence of hereditary Breast Cancer. Subsequent bioinformatics analysis revealed potential novel and understudied genetic variants associated with the Breast Cancer condition in this family. This study demonstrates the importance of inclusion of understudied populations in medical research and reveals novel molecular points of entry for developing new Breast Cancer diagnostics and therapeutics for this population.

## PgmNr 779: Early age of onset in lymphoid cancer families after controlling for ascertainment bias.

### Authors:

S. Jones <sup>1,2</sup>; J. Voong <sup>3</sup>; J. Graham <sup>3</sup>; A. Brooks-Wilson <sup>1,4</sup>

---

**Introduction:** Lymphoid cancers are the fourth most common cancer type in the United States. Familial aggregation and early onset of lymphoid cancers are suggestive of shared genetic risk factors. Genetic anticipation, the earlier onset of disease in successive generations, has been reported among lymphoid cancer families; however, the underlying molecular mechanism is unknown. Ascertainment bias and birth cohort effects can be misinterpreted as genetic anticipation.

**Methods:** We reviewed 200 multigenerational pedigrees with 2 or more lymphoid cancer cases including non-Hodgkin lymphoma (NHL), Hodgkin lymphoma (HL), chronic lymphocytic leukemia (CLL) and multiple myeloma (MM), for deviation from the expected population age of onset. SEER population data was used to control for reported sex, ethnicity, lymphoid cancer subtype and age of onset, allowing for the uniform comparison of individuals and cofactors that affect risk of lymphoid cancers. Ascertainment bias was controlled for by excluding probands and adjusting for birth cohort effect.

**Results:** The mean age of onset varied by type of lymphoid cancer ( $p < 0.0001$ ), and remained significant after controlling for sex, ethnicity, and subtype ( $p = 0.0023$ ). Median familial NHL ( $p < 0.0001$ ), HL ( $p = 0.0019$ ), CLL ( $p < 0.0001$ ) and MM ( $p = 0.0096$ ) ages of onset are substantially earlier than comparable population data. Anticipation for NHL ( $p < 0.0001$ ), HL ( $p = 0.0008$ ) and CLL ( $p = 0.0255$ ) (but not MM) was observed, and remained significant for NHL ( $p < 0.0001$ ) and HL ( $p = 0.0410$ ) after excluding probands. Anticipation for NHL ( $p = 0.0060$ ) and lymphoid cancers collectively ( $p < 0.0001$ ) was observed after excluding young birth cohorts.

**Conclusions:** The median age of onset in families was substantially younger than population cases when controlling for known cofactors that affect risk. Evidence for anticipation remained even after controlling for cofactors and excluding probands and young birth cohorts. These observations support the application of genomic methods to identify genes and genetic variants that underlie familial lymphoid cancers. Awareness of patterns such as anticipation in lymphoid cancer families may help predict risk in family members.

---

Multiple Myeloma (MM) accounts for almost 14% of all hematologic cancers and is essentially incurable. A clear racial disparity in incidence and mortality is observed in MM. The precursor state Monoclonal Gammopathy of Uncertain Significance (MGUS) shows a progression risk of 1% each year. Several low penetrant common variations near transcriptional regulators and tumor suppressors associated with risk of sporadic MM have been identified from genome-wide association studies. A few monogenic high penetrant pathogenic germline mutations were also identified in European American familial and sporadic cases. We have created the Multiple Myeloma Genetics Consortium (MMAGIC) to address genetic MM predisposition using germline whole exome sequence (WES) data. Using the approved resources of the Center for Inherited Disease Research sequencing facility, we conducted a pilot study of 155 WES from MSKCC and WCMC. We analyzed the QC/QA metrics derived from the Illumina NovaSeq 6000 100 bp paired-end sequenced samples on 155 individuals, with capture using the exome bait sets from Twist Biosciences. We compared these with HiSeq 4000 sequencing on a subset of individuals. The samples included in the pilot were a few families and otherwise early onset sporadic cases of MM. We then ran our automated variant curator PathoMAN on the resulting variant data. We observed one rare recurrent variant in *RAD51B* and a few other rare variants in other DNA repair pathway genes such as *BLM* and *RECQL*. Our preliminary analysis shows the presence of rare pathogenic DNA repair gene mutations in MM.

## PgmNr 781: Putative non-coding regulatory driver discovery using allele specific expression in unmatched tumor-healthy samples.

### Authors:

N.M.R Lykoskoufis; H. Ongen; E.T. Dermitzakis

[View Session](#) [Add to Schedule](#)

**Affiliation:** Department of Genetic Medicine and Development, University of Geneva, Geneva, Geneva, Switzerland

---

Cancer development is not fully understood, and evidence suggest that non-coding regulatory drivers play a key role in tumorigenesis. Protein-coding drivers being the sole forces of tumorigenesis increasingly appears as biologically implausible at least for some cancers. However, given the complexity of non-coding DNA, regulatory driver discovery requires new methods.

We had developed a method that uses allele specific expression (ASE) as a proxy to discovering genes with allelic dysregulation impacted by non-coding somatic mutations, that requires matched healthy-tumor samples (Ongen et al., 2014). However, matched cohorts are not easy to obtain. Thus, we developed a novel method following the same principles as previously, that can be used with reference unmatched samples, from RNA-seq datasets, from the same tissue of origin.

Regulatory somatic mutations are expected to be in heterozygosity, so they will affect ASE. Hence, under selection, we expect genes to show increased ASE in tumor compared to healthy samples and a directional change of expression levels. Thus, to detect regulatory drivers, we devised our method based on three key filtering steps.

We use colorectal cancer data from the SYSCOL project comprising of matched healthy-tumor samples and GTEx data from colon sigmoid and colon transverse. We perform three unmatched analyses that we compare with previous results from a SYSCOL matched design. At 5% FDR, we discover 360 genes when treating SYSCOL samples as unmatched, 360 genes combining tumor with colon sigmoid and 409 genes combining tumor with colon transverse. Of these, 287 genes overlap all three analyses. We compare them to the 105 genes discovered in the SYSCOL matched design and observe an overlap of 95 genes, indicating that our method efficiently detects regulatory drivers. Some identified genes are already implicated in cancer like *KRAS* and we observe an enrichment for colorectal cancer involved pathways like the APC and MAPK pathways.

We had showed that the impact of copy number alterations (CNA) is minimal. However, we are improving our analytical framework to account for it. We extend our analysis to prostate and other cancers and plan on using WGS to discover the actual non-coding somatic mutations that may be causing the observed ASE difference.

All in all, this method provides a great opportunity to learn more about regulatory drivers that can be broaden to multiple cancers and allow us to obtain the full picture of tumorigenesis.

## PgmNr 782: An integrative genetic epidemiologic approach identifies new low- and medium-penetrance susceptibility genes for breast cancer.

### Authors:

**Introduction:** A large fraction of common (peri- and post-menopausal) breast cancer cases in the general population may be due to segregation of genes with low and moderate risk [relative risk  $\leq 4$ ] for breast cancer; the majority of these genes remain unidentified due to methodological challenges presented by small effect sizes. We used a hypothesis-driven integrative genetic epidemiologic approach aimed at identifying low-penetrance breast cancer susceptibility genes.

**Methods:** We tested the association of common breast cancer with genes in a candidate biologic pathway by analyzing multiomics data including genome-wide association studies (GWAS), gene expression microarray, transcriptome, and proteome datasets. We restricted analysis to Caucasian cases with invasive ductal breast carcinoma diagnosed at  $\geq 50$  years of age and healthy controls. Raw data from four gene expression microarray datasets (98 cases, 163 controls) were used for pathway and meta-analysis. Raw data from four GWAS datasets (2961 cases, 4335 controls) were analyzed using logistic regression to calculate odds ratios (OR) and 95% confidence intervals (CI) adjusting for covariates. We also analyzed The Cancer Genome Atlas (TCGA) breast tumor data (522 cases) by comparing frequency of mutations in our candidate genes with all other genes and with known breast cancer susceptibility genes.

**Results:** Meta-analysis of gene expression microarray datasets identified significant upregulation of several of our candidate genes including *ERCC6* ( $p=7.95 \times 10^{-6}$ ) and *ERCC8* ( $p=4.67 \times 10^{-6}$ ). Candidate-gene analysis of GWAS data identified increased risk for variations in those genes in all datasets; for example, increase in risk associated with one *ERCC6* variation ranged from 35% (OR=1.35, 95%CI:1.01-1.80,  $p=0.04$ ) to 3-fold (OR=2.91, 95%CI:1.05-8.06,  $p=0.04$ ) in different datasets. Statistically-significant increased risk was also found with specific haplotypes in each gene and with joint *ERCC6-ERCC8* diplotypes (up to 5-fold,  $p \leq 0.034$ ). Analysis of TCGA data supported our findings; for example, *ERCC6* mutation frequency in breast tumors (1.80%) was comparable to known high- and medium-penetrance breast cancer susceptibility genes such as *BRCA1* (2.90%), *BRCA2* (2.90%), *BLM* (1.90%), and *CHEK2* (1.00%).

**Conclusions:** Using a hypothesis-driven integrative genetic epidemiologic approach to analysis of multiomics data, we have identified several previously unreported low- and medium-penetrance breast cancer susceptibility genes.

## PgmNr 783: Evaluating association of colon cancer SNPs with colonoscopy results and precancerous polyps.

---

Recent meta-GWAS of 125,478 colorectal cancer (CRC) cases and controls has increased the number of replicated SNPs associated with CRC to 212, resulting in a predictive CRC genetic risk score (GRS) comprised of 120 SNPs (Hyghe et al. Nature Genetics, 2018). The goal of our study was to evaluate associations between these CRC SNPs and longitudinal outcomes in a prospective CRC screening cohort followed for at least 10 years using the VA medical record. The VA Cooperative Studies Program (CSP) 380 study was initiated between 1994-1997 and enrolled 3,121 healthy veterans at average risk of CRC at baseline. This cohort includes an associated biorepository with DNA, serum, polyp and normal tissue. Genome-wide genotyping was performed on DNA from 612 individuals representing 1,220 colonoscopies over a 10-year period. The primary outcome of this study was the finding of advanced neoplasia (AN) at any colonoscopy, defined as any tubular adenoma  $\geq 10$  mm, villous histology, high-grade dysplasia or CRC. Each colonoscopy provided a phenotype for the presence or absence of AN. We identified 238,254 SNPs genotyped in the CSP 380 dataset representing SNPs +/- 2 mb from each CRC SNP in the literature. We performed a genetic association analysis in the subset of 500 European-Americans for cases versus those without AN using logistic regression with an additive genetic model, adjusting for age and two genetic principal components (PCs) as implemented in PLINK version 1.09. We also performed an analysis of AN at each colonoscopy using a linear mixed model as implemented in R glmmPQL. Fourteen SNPs in eight regions had p-values  $< 10^{-4}$ . Of particular interest are associations of AN with four CRC regions: 1) chromosome 6p21.32 with 4 CRC SNPs within 2 mb of rs12207382 (OR=1.76); 2) chromosome 17q25.3 with 2 CRC SNPs within 2 mb of rs9914652 (OR=1.77), rs62073391 (OR=2.20) and rs56975743 (OR=1.91); 3) chromosome 19p13.11 with 1 CRC SNP within 2 mb of rs2733762 (OR=1.78); and 4) chromosome 20q13.13 with 3 CRC SNPs within 2 mb of rs230013 (OR=1.78). These regions may represent genetic variants associated with early preneoplastic stages in the progression to CRC and may be particularly useful in early risk stratification at the time of colonoscopy. Next steps include evaluation of the utility of the CRC GRS in prediction of participants with AN and development of a suitably large mega-cohort of individuals with longitudinal colonoscopies.

## PgmNr 784: Germline genotyping association with tumor immune RNAseq signatures in NSCLC.

Improvements in the clinical efficacy of immunoncology have invigorated immunotherapeutic treatments of multiple forms of cancer. Tumor immune signatures as biomarkers have been utilized to investigate both the tumor immune landscape and microenvironment. Furthermore, the composition of the tumor immune infiltrate has increasingly demonstrated predictive capabilities for immunotherapeutic response in cancer patients.

Germline polymorphisms are known to influence drug efficacy and cancer susceptibility. Germline variation and somatic tumor DNA alterations interactions from The Cancer Genome Atlas (TCGA) have demonstrated the influence of inherited germline polymorphisms on the landscape of somatic mutation profiles in tissue and gene-specific manner. Additional TCGA studies reveal the germline SNP influence on the cancer-immune phenotype and therapeutic response.

Here, we explore associations of germline SNPs with tumor immune RNAseq signatures by leveraging pre-treatment tumor transcriptomic data and matched germline genotype data from clinical samples with non-small cell lung cancer (NSCLC). Twenty-three immune enrichment scores were calculated from processed RNAseq data for the following immune sets: tumor inflammation signature (TIS), the immunologic constant of rejection (ICR), exhaustion signature, and the Bindea immune cell signatures. Immune scores, genotypes, and study covariates for the clinical studies were analyzed in a linear association framework (n=385 total patients).

Genome-wide analysis revealed 2 statistically significant association regions ( $p < 5e-08$ ) to the central memory T cell (TCM) and natural killer cells with a lower surface density of CD56 antigen (NK.CD56dim) immune scores. To restrict multiple testing burden, germline SNPs were filtered to +/-50kb of 113 immunoncology-related genes and 2 additional significant associations with the B-cell and T effector memory cell (TEM) signatures were identified ( $p < 8e-07$ ). Interestingly, eQTL effects do not explain these associations as the implicated genes are not part of the signatures. Ongoing analyses of associated regions aim to uncover potential genetic mechanisms between SNPs, genes, and signatures.

Our results support a germline genetic influence on the tumor immune environment. These findings implicate germline SNPs as a potentially important factor for the tumor immune landscape and could aid efforts to stratify patients receiving immunotherapies.

## PgmNr 785: Functional characterization of non-coding regulatory drivers in chronic lymphocytic leukemia.

---

The role of coding mutations in cancer development has been widely studied. However, the identification of the non-coding regulatory drivers and the genes mediating their effects, remains poorly understood. In a previous study (BioRxiv 174219), we identified 19 local modules of coordinated non-coding regulatory elements of the genome (cis-regulatory domains or CRDs, FDR 5%) that accumulated an excess of somatic mutations in 150 patients with chronic lymphocytic leukemia (CLL), a cancer affecting B-cells. We hypothesize that the CRDs with an excess of somatic mutations (after controlling for mutational confounders) can have a driver role in CLL development and we aim to perform functional characterization of their effect on the 45 genes inferred to be regulated by these putative driver CRDs.

In this work, we present the development of an in vitro cancer-like model in which transformed lymphoblastoid cell lines (LCLs) are evaluated for their ability to reproduce cancer-like phenotypes such as increase in cell migration and proliferation and decrease of apoptosis. Among the 45 genes identified, 35 genes showed differential expression between CLL and LCLs. For 21 genes with increased expression due to hypermutated CRDs, we setup a multiplexing approach to knock-in several genes at once using a single lentiviral gene expression vector and evaluate the phenotypic changes. For 14 genes with observed decreased expression, we use a multiplex CRISPR-Cas9 approach based on a single lentiviral vector coding for the Cas9 protein together with multiple gRNA guides. The presence of a GFP tag will allow FACS-based screening for the selection of cells with high GFP expression and thus high multiplicity of infection.

Limitations of this approach are the difficulties to transfect LCLs, partially solved by the decision to use a lentiviral vector increasing the vector delivery, and the complexity to mimic a disease using an in vitro model.

The identification of changes in transformed B-cells towards a cancer-like phenotype will provide a functional characterization of non-coding mutations in CLL and it will potentially identify new genes driving tumorigenesis. This study could also provide a strong functional and experimental framework to explore and dissect the contribution of the non-coding cancer genome not only in CLL but also in other cancers, helping to understand the biological complexity of these effects. Experiments are in process and first results will be presented.

## PgmNr 786: Cancer spectrum in male *BRCA1/BRCA2* mutation carriers: Results from the Consortium of Investigators of Modifiers of *BRCA1/BRCA2* (CIMBA).

Men with *BRCA1/2* mutations represent a unique group in terms of clinical management. The paucity of data on cancers arising in male *BRCA1/2* mutation carriers has limited the development of clinical guidelines for men with *BRCA1/2* mutations. We characterized the cancer spectrum observed in male *BRCA1/2* mutation carriers collected within the Consortium of Investigators of Modifiers of *BRCA1/2* (CIMBA) and compared *BRCA1* with *BRCA2* mutation carriers in terms of number, site and age of cancer diagnoses.

This study encompassed data from 6902 men, 3651 (52.9%) with *BRCA1* and 3251 (47.1%) with *BRCA2* mutations. A total of 1376 men (19.9%) had at least one cancer diagnosis, the majority (922/1376, 67%) carrying a *BRCA2* mutation. Compared with men carrying *BRCA1* mutations, men carrying *BRCA2* mutations are more likely to be affected with cancer [Odds Ratio (OR) = 3.20, 95% Confidence Interval (CI) 2.79-3.67,  $p < 0.0001$ ] and to develop multiple tumors (OR for trend = 2.77, 95%CI 2.46-3.11,  $p < 0.0001$ ). A total of 1634 cancers were reported in the 1376 affected individuals. Breast and prostate cancers were significantly more frequent (OR for breast cancer = 5.49, 95%CI 4.03-7.48,  $p < 0.0001$ ; OR for prostate cancer = 1.42, 95%CI 1.11-1.82,  $p = 0.006$ ), whereas all cancers other than breast and prostate taken together were significantly less frequent (OR = 0.22, 95%CI 0.18-0.28,  $p < 0.0001$ ), in *BRCA2* compared with *BRCA1* mutation carriers. In analyses restricted to cancers other than breast and prostate, colorectal cancer was less frequent (OR = 0.47, 95%CI 0.29-0.77,  $p = 0.003$ ), whereas pancreatic cancer was more frequent (OR = 3.04, 95%CI 1.57-5.88,  $p = 0.001$ ) in *BRCA2* compared with *BRCA1* mutation carriers.

Mean ages at diagnosis of breast and prostate cancers were similar for *BRCA1* and *BRCA2* mutation carriers, while for other malignancies taken together, age at diagnosis was older in *BRCA1* (59 years) compared with *BRCA2* mutation carriers (55.6 years,  $t$ -test  $p$ -value=0.0036).

Our results highlight significant differences in male *BRCA2* mutation carriers compared with *BRCA1* mutation carriers, that may actually help refine existing recommendations in terms of specifying

distinct surveillance guidelines for men with either *BRCA1* or *BRCA2* mutations.

As under the present study design it was not possible to assess the hypothesis that *BRCA1/2* mutations are associated with elevated cancer risks for male carriers compared to non-carriers, future studies are planned to address these issues.

## PgmNr 787: Identification and functional characterization of germline variants predisposing patients to congenital anomalies and childhood cancer.

### Authors:

S. Sisoudiya<sup>1,2</sup>; H. Li<sup>3</sup>; J. Schraw<sup>4</sup>; A. Sabo<sup>3</sup>; P.J. Lupo<sup>2</sup>; S.E. Plon<sup>1,2,3</sup>

**Introduction:** Little is known about the role of non-chromosomal birth defects on cancer risk and the underlying genetic mechanism. In the **Genetic Overlap Between Anomalies and Cancer in Kids** (GOBACK) Study, we performed association analysis between birth defects (BD) and childhood cancers (CC) by leveraging birth defect and cancer registries from Texas, Michigan, Arkansas and North Carolina. We evaluated more than 10 million births which enabled us to identify specific BD-CC patterns (Lupo et al., JAMA Oncology, *in press*). Based on these associations, proband-parent trios from the GOBACK Study are being enrolled for a family-based whole-genome sequencing (WGS) study to evaluate the underlying genetic mechanisms.

**Method:** WGS (40X) was performed on DNA extracted from salivary samples of the enrolled families. Single nucleotide variants and short insertions/deletions were called using Platypus. Structural variants (SVs) were called using multiple callers, followed by merging and filtering via SURVIVOR. A consensus call was made by at least 2 callers.

**Results:** Our epidemiology study identified a novel association between choanal atresia and acute leukemia (HR=9.2, 95% CI: 3.8-22.1). SV analysis of the WGS data identified a ~5kb *de novo* heterozygous deletion in *USP9X* in a female proband with multiple anomalies including choanal atresia and acute leukemia (B-ALL). Furthermore, the patient's clinical phenotype was indicative of a CHARGE-like syndrome with negative *CHD7* analysis. *De novo* LOF mutations in *USP9X* were recently implicated in a female-specific CHARGE-like syndrome with overlapping features to our patient including two patients with childhood cancer (one each with B-ALL and osteosarcoma). *USP9X* is also recurrently somatically mutated in sporadic ALL. It encodes a highly conserved deubiquitinating enzyme. We have successfully used CRISPR/Cas9 to create the heterozygous deletion and a full knock-out of *USP9X* in B-cell derived lymphoblastoid cells. Clones of these edited cells will be assayed for alterations in proliferation and transformation characteristics as well as changes in stability of *USP9X* targets to understand the potential role of *USP9X* as a novel ALL susceptibility gene.

**Conclusion:** Our results suggest that *USP9X* represents a novel ALL susceptibility gene and also plays an important role in sporadic ALL. The experiments underway should provide insights into the molecular mechanisms of *USP9X*-mediated leukemogenesis.

## **PgmNr 788: Mutational signatures and mutagenic impacts associated with betel quid chewing in oral squamous cell carcinoma.**

---

Betel quid (BQ) chewing is a prevailing risk for oral squamous cell carcinoma (OSCC) in Central and Southeast Asia. Yet, the detailed mechanisms by which BQ chewing damages the genome and creates somatic alterations that ultimately cause OSCC are still not fully understood. Through performing exome sequencing of tumor-normal pairs from 196 OSCC patients, including 95 habitual BQ chewers and 101 non-BQ users, we conducted a quantitative survey of mutational signatures and genomic aberrations and explored their association with BQ chewing. Elevated mutation rate was seen in cancers of the tongue but not in overall OSCC with respect to the use of BQ. Additionally, we identified a specific mutational signature that is enriched in tumors from BQ users. Moreover, increased numbers of small insertions and deletions (INDELs) and breakpoints derived from structural variations (SV) were observed, whereas decreased extent of loss of heterozygosity was detected in the coding regions of BQ-related OSCC genomes. However, neither the number of base substitutions and microsatellite instability events nor the extent of copy-number alterations differed between BQ-related and -unrelated OSCC. In concordance with the proposition that BQ chewing increases OSCC risk as a mutagen, our results unveil a BQ-associated mutational pattern and indicate mutagenic impacts of BQ chewing on preferentially eliciting small INDELs and SV-related breakpoints in OSCC genomes.

## PgmNr 789: Rethinking models to study the metastatic and metastatic suppressive molecular pathways in skin and brain.

Studying the molecular mechanism of the least metastatic cancers could be as significant as studying highly metastatic cancers for molecular mechanistic targeting clues. We hypothesized that spectrum of cancers, based on metastatic and invasion features, could be a good *in vivo* model and the molecular mechanism of the least metastatic cancer to elucidate key regulatory molecules in EMT and stemness on the road to development of the most metastatic cancer in spectrum of cancers. This hypothesis was examined in two spectrums of cancers, from the least metastatic to the most metastatic cancer in skin cancers and brain tumors with both organ systems originating from the embryonic ectodermal layer.

Firstly, 443 samples of the spectrum of skin cancers, from basal cell carcinoma (BCC-the least metastatic cancer), to squamous cell carcinoma (SCC-often metastatic cancer) and to melanoma (most metastatic cancer) were collected to study the expression level of ten mRNA/lncRNA as EMT and stemness key regulatory molecules in skin cancers compared to related controls (*BMI1*, *TWIST1*, *SNAI2*, *SNAI1*, *EZH2*, *HIF1a*, *SOX9*, *p16*, *FAL1* and *ANRIL*). We demonstrated downregulation of *SNAI1* ( $p=0.005$ ), *EZH2* ( $p=0.022$ ), *HIF1a* ( $p=0.008$ ), *TWIST1* ( $p=0.017$ ), *BMI1* ( $p=0.000$ ), *ANRIL* ( $p=0.004$ ) and *FAL1* ( $p=0.935$ ) and also upregulation of *p16* ( $p=0.000$ ), *SOX9* ( $p=0.0128$ ) and *SNAI2* ( $p=0.000$ ) in non-metastatic BCCs. In SCCs, upregulation of *p16* ( $p=0.001$ ), *HIF1a* ( $p=0.001$ ), and *ANRIL* ( $p=0.002$ ) were seen. In melanomas, upregulation of *p16* ( $p=0.035$ ) and *ANRIL* ( $p=0.000$ ) were shown.

Subsequently, 75 samples of the spectrum of brain tumors (glioma and meningioma) alongside with the 27 BCCs and 12 controls were collected and the mRNA expression of *p21*, *ZEB1* and *SOX2* were analyzed. The expression of *SOX2* significantly decreased in BCCs, as the least metastatic cancer ( $p<0.001$ ), compared with controls. The expression of *SOX2* and *ZEB1* significantly increased in meningiomas, as the least aggressive tumor, compared to gliomas, as the aggressive tumor ( $p=0.016$ ,  $p=0.017$ , respectively).

These findings stress the importance of further studies on spectrum of cancers, based on

metastatic/invasion features, which could be a good *in vivo* model to shed some light on the molecular mechanism of metastasis/aggressiveness of cancers. Also, our findings emphasized that BCC could be a unique *in vivo* cancer model to comprehend the intrinsic metastatic attenuating regulatory mechanisms.

## PgmNr 790: Whole-exome sequencing analyses identify risk genomic loci for nasopharyngeal carcinomas.

R. China.; 6) Center for Precision Medicine, Sun Yat-sen University, Guangzhou 510080, P. R. China

### Background:

Nasopharyngeal carcinoma (NPC) featured a relatively high prevalence in southern China, southeast Asia and Northern Africa, yet our current understanding of its genetic etiology is confined to common variants which were identified through genome-wide association studies. It has been estimated that the genetic variation contributes 61.3% of the risk to develop NPC (narrow sense heritability), with only 16.9% of this genetic contribution attributable to the common variants, indicating an urgent need to study genetic effects from germline rare variants for this disease.

### Methods:

Exome-wide sequencing was conducted for blood samples of 2465 NPC patients and 2304 healthy controls recruited from south China and southeast Asia. This collection also includes 354 NPC patients with a family history. A SNP-set (Sequence) kernel association test (SKAT) was applied to localize aggregate genetic effects from germline rare variants in coding genes on NPC. A Generalized gene-set analysis was used to identify the combined genetic effect from both common and rare variants at pathway level on NPC.

### Results:

The gene-based SKAT analysis identified seven genes displaying consistently elevated frequency of rare mutations in NPC patients across samples as compared with healthy controls. A subset of these genes additionally showed a higher frequency of mutation in subgroups of patients with family history. The exon-based SKAT analysis combined with single variants association tests localized major contributing rare variants for the association observed at gene level. A proportion of these contributing rare variants showed distinguished minor allele frequency in Asia population as compared with European population. The generalized gene-set analysis identified functional pathways showing increased frequency of risk alleles from both common and rare variants in NPC patients.

### Conclusions:

This study identified important germline rare mutations, coding genes and molecular pathways contributing to the genetic etiology of NPC. We provided potential biomarkers for personalized NPC

genetic risk evaluation and potential explanations of the regional differences of NPC prevalence. Future studies of functional consequences of these molecular variation are required to elucidate the causal pathways connecting these germline mutations and NPC.

## PgmNr 791: Integrating multi-omics data identified novel susceptibility genes for colorectal cancer.

### Authors:

---

Colorectal cancer (CRC) is the third most common cancer and the fourth leading cause of cancer-related deaths worldwide. Recent studies of the genomics, transcriptomics, proteomics and metabolomics landscapes of human CRC have identified many alterations and molecular markers of the disease. However, the rapidly accumulating omics data have yet to bring novel biomarkers and drug targets to the clinic. To better understand the disease, we integrated multi-omics data of CRC to identify novel susceptibility genes. The data we used included the genome-wide association studies (GWAS) summary data of the malignant neoplasm of colorectum from UK Biobank in a total of 3,825 CRC patients and 448,439 controls and the summary-level GWAS data of blood metabolites involving 363 metabolites. The protein expression data of 90 tumor specimens and 30 normal tissues was derived from Clinical Proteomic Tumor Analysis Consortium (CPTAC), and the transcriptome data of CRC with 645 tumor specimens and 51 normal tissues was from The Cancer Genome Atlas (TCGA). We began an exploration of the causal associations between blood metabolites and CRC with two-sample Mendelian randomization (MR) method and identified that 31 blood metabolites had causal effect on CRC with a suggestive P value ( $P < 0.05$ ). Enrichment and pathway analyses showed that these metabolites were involved in 39 pathways and functional processes, such as glutathione metabolism, glycerophospholipid metabolism, urea cycle and energy metabolism, which referred 684 genes defined by Kyoto Encyclopedia of Genes and Genomes (KEGG). Moreover, the different expression analyses both in proteomic and transcriptomic landscapes indicated 128 CRC-associated genes. Therein, *ANPEP* and *GGCT*, the glutathione regulatory genes, were confirmed had an effect on patient survival and implicated novel targets for CRC. In summary, we performed integration analysis comprising genomics, transcriptomics, proteomics and metabolomics, and found that *ANPEP* and *GGCT* may be novel susceptibility genes for CRC.

**Background.** Neuroblastoma is a malignancy that arises during sympathetic nervous system development and causes 12% of pediatric cancer deaths. Neuroblastoma has a complex genetic basis: approximately 1-2% of cases result from rare mutations that are inherited in a Mendelian autosomal dominant fashion, but the vast majority arise sporadically without family history. Although genome-wide association studies have identified common variants that confer risk for sporadic neuroblastoma at over a dozen loci, the contribution of rare variants has not yet been well-characterized due to limited sample sizes.

**Methods.** To identify large, rare germline copy number variants (CNVs) associated with neuroblastoma, we analyzed two independent, multi-ethnic cohorts totaling 5,585 neuroblastoma patients and 23,505 cancer-free controls genotyped on matched single-nucleotide polymorphism (SNP) arrays. Large (>500 kb), rare (<1% in controls) CNVs were tested for association using Fisher's exact test with a Bonferroni-corrected significance threshold. Whole-genome sequencing (WGS) was used to validate candidate CNVs and assess heritability in a subset of patients.

**Results.** Out of 40 CNVs tested, the only CNV reaching genome-wide significance in the discovery cohort was a 550-kb deletion on chromosome 16p11.2 (0.36% of cases and 0.02% of controls;  $p=8.3 \times 10^{-76}$ ). Notably, this CNV corresponds to a known microdeletion syndrome that confers risk for diverse developmental phenotypes including autism spectrum disorder and other neurodevelopmental disorders. We validated this association in the independent replication cohort ( $p=3.0 \times 10^{-6}$ ). Meta-analysis yielded a combined p-value of  $3.3 \times 10^{-9}$  and odds ratio of 13.9 (95% confidence interval=5.8-33.4), suggesting a substantial impact on neuroblastoma risk. The association remained significant when we restricted our analysis to individuals of European ancestry to mitigate potential confounding by population stratification (0.42% of cases and 0.03% of controls;  $p=4.10 \times 10^{-8}$ ). We validated the deletion in paired germline and tumor DNA from twelve patients by

WGS. Finally, WGS of four patient-parent trios revealed that the deletion primarily arose *de novo* without maternal or paternal bias.

**Conclusion.** This finding constitutes the first association of 16p11.2 microdeletion with cancer and suggests that disruption of the 16p11.2 region may dysregulate neurodevelopmental pathways that influence both neurological phenotypes and neuroblastoma.

## **PgmNr 793: Are we ready to offer polygenic risk score tests in the clinic? Expanding the utility of prostate cancer polygenic risk score in multiple ethnicities and clinical best practices.**

Pathogenic variants explain only a small portion of prostate cancer (PCa), however the utility of disease risk measured by polygenic risk score, has been consistently demonstrated for many common diseases, including PCa. Polygenic tests are currently being developed, offered and used in the clinical space. In collaboration with experts in the field, we have developed a comprehensive clinical polygenic PCa test that looks at SNPs stratified by risk among different ethnicities, namely, East Asian, African American and Non-Hispanic White. The individuals are categorized as average, moderately-high or high risk for developing PCa. Medical management recommendations like earlier and more frequent screenings for PCa are included in the clinical report. These recommendations are based on the individuals' risk, and generally follow the risk-based PCa screening guidelines of the U.S. Preventive Service Task Force. Here we propose best practices for developing a clinical polygenic risk score test in multiple ethnicities as well as provide recommendations on counseling patients that have undergone such tests.

For test development, we used the odds ratio (OR)-weighted and population-standardized genetic risk score (GRS) method. In this method, each SNP is first standardized against the general population and then multiplied for all SNPs. Thus its expected mean in the general population will always be 1.0, regardless of the number of SNPs used in calculation, and its values can be simply interpreted as relative risk to that of the general population. These two important features of population-standardized GRS makes the interpretation and implementation of an individual's risk comprehensible. We also applied two benchmarks, baseline and calibration, to ensure the reliability of GRS values.

This work aims to provide procedures to build a simple and interpretable risk score in multiple ethnicities and provide guidance on medical management. We will also discuss challenges and future work to address the gaps in the process of clinical test development and return of results.

## PgmNr 794: Germline genetic variation in 3 multiplex bladder cancer pedigrees.

**Background.** Bladder cancer (BC) is the sixth most common cancer in the US. Familial BC is rare and implies a genetic component. An excess of BC is observed in Lynch syndrome (LS) (*MLH1*, *MSH2*, *MSH6*, *PMS2*). In addition, *GSTM1*, *NAT2*, *UGT1A8/10*, *ERCC2*, *CCNE1*, *TERT*, *TP63* and others are implicated by GWAS. **Methods.** To identify BC-associated germline variation, we exome-sequenced 2-3 affected individuals (with DNA availability) from 3 multiplex BC pedigrees, each with 3-6 affecteds; Family A was the first published BC pedigree (1967). We evaluated pedigree-specific segregating variants and pathogenicity using InterVar, ClinVar, REVEL, CADD, MetaSVM and HGMD. **Results.** We identified 72, 134 and 92 segregating variants in the 3 families respectively. We observed 1-4 likely pathogenic (LP) variants in each family; the majority of variants were of unknown significance (VUS), likely benign (LB) or benign (B). There was no overlap in the pedigrees among the segregating variants; 4 genes were shared by the pedigrees in pair-wise comparisons. Comparison of segregating variants in the 3 families to known significant BC GWAS hits identified only *NBN* in Family B. We observed 2 B variants in *MLH1* (although predicted deleterious by REVEL, CADD and MetaSVM and reported as disease-causing (DM) in HGMD) and 1 VUS in *MSH2* (although predicted deleterious by REVEL and MetaSVM and reported as likely DM in HGMD) in families B and C respectively. We identified 1 *NBN* (LP) variant (Nijmegen breakage syndrome 1 gene, critical for chromosomal stability) and 3 *BRCA1* (all B) alleles in pedigrees B and C respectively. No LS-associated variants were found in Family A; however, we observed a heterozygous LP variant in *CFTR* and variants in 3 DNA repair-related genes: *RECQL* (LB), *SPDR* (VUS) and *CUL4A* (VUS). Aside from DNA repair genes, we observed predicted deleterious alleles in *ME1*, *STEAP3* (Family A); *IDH1*, *ACADS* (Family B); and *VAV2*, *ITGAV*, *PRKCE* (Family C). **Conclusions.** We identified multiple variants segregating in familial BC that were pedigree-specific. Genes implicated in DNA repair and the DNA damage response may play an important etiologic role in BC. However, other biological pathways, e.g. angiogenesis (*VAV2*, *ITGAV*, *PRKCE*), apoptosis and cell cycle (*STEAP3*) and acetyl-CoA-mediated oxidation (*ME1*, *IDH1*, *ACADS*) may be involved as well.

## PgmNr 795: Polygenic risk score for prostate cancer by ~80 loci identified by genome-wide association study in Japanese population.

---

Genome-wide association studies (GWAS) in the European and multi-ethnic populations have discovered ~170 loci associated with genetic risk for prostate cancer (PCa). In contrast, genetic studies on PCa risk in the Asian populations still lag behind. To expand our knowledge of PCa genetics in the Japanese population, we conducted a GWAS (5,088 cases and 10,682 male controls) and a replication study (4,818 cases and 73,261 male controls). As a result, we identified 14 novel SNPs were associated with PCa risk. They included rs1125927 (*TMEM17*,  $P = 3.95 \times 10^{-16}$ ), rs73862213 (*GATA2*,  $P = 5.87 \times 10^{-23}$ ), rs77911174 (*ZMIZ1*,  $P = 5.28 \times 10^{-20}$ ), and rs138708 (*SUN2*,  $P = 1.13 \times 10^{-15}$ ). For seven of the 14 novel loci, minor allele frequencies were significantly lower in Caucasians than in Japanese. Furthermore, by combining the newly identified SNPs with previously known ones, we computed polygenic risk score based on 82 SNPs and stratified the polygenic risk for Japanese PCa cases. Early-onset PCa cases and cases with family PCa history were significantly enriched in the genetically high-risk (upper 5%) population ( $P = 0.00221$  for cases with age < 60 years old and  $P = 0.00339$  for cases with PCa family history). Our study provides important insight into genetic mechanisms of PCa and facilitates PCa risk stratification in the Japanese population.

## PgmNr 796: Mitochondrial DNA haplogroups and susceptibility of neuroblastoma.

Neuroblastoma is a childhood malignancy that arises from the developing sympathetic nervous system. Although mitochondrial dysfunctions have been implicated in the pathophysiology of neuroblastoma, the role of mitochondrial DNA (mtDNA) has not been extensively investigated.

To determine whether mtDNA haplogroups influence risk of developing neuroblastoma. We conducted a case-control study to explore potential association of major European mtDNA haplogroups with the susceptibility of neuroblastoma. The mtDNA haplogroups were identified from genotyping SNP array data, of two independent neuroblastoma cohorts. Our results indicate that mtDNA haplogroup K was significantly associated with reduced risk of neuroblastoma in the discovery cohort consisting 1,474 cases and 5,699 controls (odds ratio 0.72,  $P = 0.004$ ). The association was replicated in an independent cohort (odds ratio 0.69,  $P = 0.014$ ) of 930 cases and 3,611 controls. Meta-analysis was performed by combining the two studies. The association remained highly significant after correction for multiple testing (odds ratio = 0.71,  $P = 2.02 \times 10^{-5}$ ,  $P_{corrected} = 1.62 \times 10^{-4}$ ).

To examine if haplogroup K is associated with a particular subtype of neuroblastoma, patients were further classified into low, intermediate, and high risk groups based on the Children's Oncology Group criteria, and each of three risk groups were tested against controls. The association between haplogroup K and high-risk neuroblastoma was significant in both discovery and replication samples. This association was further confirmed by a meta-analysis of the two datasets (odds ratio 0.58,  $P = 1.79 \times 10^{-4}$ ).

To analyze the impact of mtDNA haplogroups on gene regulation in neuroblastoma, transcriptome profiles of 99 neuroblastoma primary tumors, including five samples of haplogroup K, were characterized by RNA sequencing. This identified 708 differentially expression genes. Gene functional enrichment analysis further indicated that up-regulated genes are significantly enriched in 'immune system process' (GO: 0002376) and 'T cell aggregation' (GO: 0071593) pathways, while down-regulated genes are enriched in 'neurogenesis' (GO:00220088) and 'nervous system development' (GO: 007399) pathways in K haplogroup neuroblastoma when compared with non-K haplogroup neuroblastoma.

These findings provide new insights into the genetic basis of neuroblastoma, implicating

mitochondrial DNA encoded proteins in the etiology of neuroblastoma.

## PgmNr 797: Point mutation and somatic copy number analysis reveals drivers of clonal expansions in normal tissue adjacent to head and neck squamous carcinoma.

---

The presence of genetically distinct cell populations within an individual, known as clonal mosaicism, has long been cataloged in the context of cancer. Recent advances in technologies and statistical methods have enabled more sensitive detection of clonal mosaicism in non-cancerous tissues, of which blood has been the most comprehensively profiled.

To gain a broader view of clonal mosaicism in other tissues, we conducted a pan-tissue survey of somatic mega-base scale chromosomal alterations (sCNAs) in normal tissue adjacent to tumor (NAT) of TCGA patients using a sensitive haplotype-based method for detection of allelic imbalance. Our results showed significant differences in the rate and genomic distribution of sCNAs across different tissues. NAT samples from head and neck squamous carcinoma (HNSC) patients exhibited one of the highest mosaicism rates (25%) and enrichment for sCNAs in 9q ( $p = 1e-7$ ). To better catalog mosaicism in HNSC NAT, we expanded upon our survey of sCNAs to include single nucleotide variants and indels (SNVs). We generated SNV calls for NAT using exome sequencing data (59 NAT with paired blood; median = 18 SNVs in NAT). For contrast, we profiled SNVs in matched tumor tissues (58 sets; median = 179 SNVs).

The presence of sCNAs in NAT was positively associated with a higher SNV burden ( $p = 0.008$ ). For tumors, sCNA and SNV burden did not show an association. To gain insights into drivers of clonal expansions, we tested for genes under positive selection by modeling the ratio of synonymous to non-synonymous mutations. In HNSC NAT, *PPM1D* ( $q = 2.3e-4$ ) and *FAT1* ( $q = 0.02$ ), showed evidence of positive selection. *FAT1* mutations were exclusive to NAT with sCNAs. In the adjacent tumor tissues, we observed evidence of positive selection for *FAT1* ( $q = 5.6e-17$ ), but not for *PPM1D*. In NAT, sCNAs spanned SNVs in HNSC driver genes (*EP300*, *FAT1*, *NOTCH1*, *TP53*) that were not detected in the adjacent tumor. We tested for enrichment of HNSC driver mutations in NAT with sCNAs. Putatively deleterious SNVs in HNSC driver genes showed a positive association with sCNAs ( $p = 0.002$ ; adjusted for SNV burden). This association, and the overall higher SNV burden in NAT with sCNAs, suggests that sCNAs may serve as a biomarker for clonal expansions with a higher potential for progression towards malignancy. Our findings corroborate previous reports of a positive association between sCNA burden in oral premalignant lesions and progression towards invasive disease.

## PgmNr 798: Genetic association of cytochrome and DNA repair gene variants with concomitant cisplatin-based chemoradiotherapy (CRT) in cervical cancer patients.

---

### Abstract

Efficacy and toxicity due to Concomitant cisplatin-based chemoradiation (CRT) limit therapeutic effectiveness. This is attributed to genetic variability and is a major challenge in current clinical practice. Single nucleotide polymorphisms (SNPs) in cytochrome and DNA repair genes were analyzed for their association with treatment outcome of CRT in cervical cancer patients.

**Purpose of the Study:** Genetic associations may help to predict treatment outcomes and can be used as biomarkers to screen patients prior to treatment.

**Objective:** To genotype several SNPs in cytochrome (*CYP1A1*, *CYP2E1*, *CYP2D6*) and DNA repair (*XRCC1*, *XRCC2*, *XRCC3*, *XRCC4*, *RAD51*, *OGG1*, *MGMT*) genes in cervical cancer patients and correlate with treatment outcome viz. clinical response, vital status, toxicity, and overall survival after CRT.

**Methods used:** All patients received pelvic external beam radiotherapy (total dose of 50 Gy in 25 fractions) with weekly concomitant cisplatin (40 mg/m<sup>2</sup>) followed by three applications of high dose rate (HDR) intracavitary brachytherapy 7 Gy/fraction at a one-week interval. Weekly hemogram and renal function tests were done in all patients. SNPs in cytochrome and DNA repair genes were successfully genotyped by PCR-RFLP, ARMS-PCR methods and analyzed for their association with treatment outcome of CRT. The follow-up included response evaluation criteria in solid tumors (RECISTver1.0) after one month of treatment and primary endpoint was taken as overall survival (OS). Genotypic effects on OS were evaluated by Kaplan-Meier function and the Cox proportional hazards model. SPSSver21.0 was used with  $P < 0.05$  as statistically significant.

**Key Results:** Out of 227 cases, 85.5% were responders (CR+PR) and 14.5% poor/non-responders. Disease recurrence was significantly decreased in women with 'TA+AA' genotypes of *CYP2E1*+7678T/A while those with 'TC+CC' of *CYP1A1*-3801T/C showed better overall survival. Most of the cases with 'GC+CC' genotypes of *RAD51*+135G/C and 'GA+AA' of *XRCC1*+399G/A were found to be alive at the end of the study period. Individuals with GA+AA of *XRCC2*+31479G/A showed significantly increased risk of cervical cancer but no association with survival.

**Conclusion:** *RAD51*+135G/C and *XRCC1*+399G/A showed significantly better overall survival in cervical cancer patients after CRT. Such genetic studies will lead to the development of prognostic regimens and treatment strategies, a step towards personalized medicine.

## PgmNr 799: Common variant genetic background modifies risk of breast cancer among carriers of pathogenic germline risk variants.

### Authors:

### Affiliations:

1) Color Genomics, Burlingame, California.; 2) Center for Genomic Medicine and Cardiology Division, Department of Medicine, Massachusetts General Hospital, Boston, MA; 3) Cardiovascular Disease Initiative of the Broad Institute of MIT and Harvard, Cambridge, MA; 4) Harvard Medical School, Boston, MA

DNA sequencing of individuals affected by breast cancer reveals a pathogenic or likely pathogenic (P/LP) variant in 5-10% of individuals. While carriers of a P/LP variant have a several-fold increased risk of breast cancer, many do not develop cancer. The causes of this incomplete penetrance are currently unknown. Here, we demonstrate that common variant background, assessed in the form of a genome-wide polygenic score (GPS), modifies the penetrance of P/LP variants for risk of breast cancer. We performed panel-based genetic testing on 13,914 women, 1,805 of whom had a P/LP variant in one of 12 genes known to be associated with hereditary breast cancer: *BRCA1*, *BRCA2*, *TP53*, *PTEN*, *STK11*, *CDH1*, *PALB2*, *CHEK2*, *ATM*, *NBN*, *BARD1*, or *BRIP1*. We also performed low-coverage whole genome sequencing at a mean depth of 0.2X and subsequent imputation to calculate a recently validated GPS for breast cancer (Mavaddat 2019 AJHG) on all 13,914 women. We found no significant interaction between GPS and presence of a P/LP variant ( $p=0.384$ ) in a multivariate logistic regression, suggesting that GPS is an independent risk factor for breast cancer. The odds ratio (OR) increase per standard deviation change in GPS was similar among P/LP carriers (OR per SD of 1.46, 95% CI 1.29-1.70) and non-carriers (OR 1.59, 95% CI 1.49-1.70). When subsetting to only *BRCA1* and *BRCA2* carriers, GPS increased breast cancer odds by 1.41 per SD increase (95% CI 1.15-1.72). We investigated whether this effect varied by gene, assessing GPS effects in four genes with over 200 P/LP carriers. We observed no interaction between GPS and carrier status in carriers of P/LP variants in *BRCA1* ( $p=0.31$ ), *BRCA2* ( $p=0.22$ ), *ATM* ( $p=0.43$ ), and *CHEK2* ( $p=0.07$ ). P/LP variant carriers in the lowest quintile of the GPS had risk comparable to that of noncarriers, with an odds ratio 1.29 (95% CI 0.92-1.79). By contrast, individuals who carried both a P/LP variant and a high GPS -- defined as the top quintile of the GPS -- had 3.73-fold increased odds for breast cancer (95%CI 2.94-4.74).

In conclusion, our results demonstrate that rare P/LP variants and common variant genetic background additively impact risk for breast cancer and that a lower GPS can offset the risk conferred by a P/LP variant. Our results suggest that a risk model that integrates both monogenic and polygenic risk can improve risk stratification and counseling for breast cancer, especially for individuals with moderate penetrance P/LP variants.

## PgmNr 800: Validation of PRS scores for breast cancer risk in carriers of *BRCA1/2* pathogenic variants.

---

The penetrance of breast cancer in carriers of pathogenic variants (PVs) in *BRCA1* and *BRCA2* (*BRCA*) varies widely. Factors influencing penetrance include birth cohort, pregnancy and breast feeding history, and genetic modifiers. Genome-wide association studies have identified risk variants for breast cancer specific to *BRCA* PV carriers as well as for breast cancer in the general population. Polygenic risk score (PRS) models have been developed to predict cancer risk in *BRCA* PV carriers, however most of the validation studies have been done on women ascertained in high-risk clinical settings due to previous cancer diagnoses. The goal of this study was to evaluate PRS models and identify those most predictive of breast cancer risk in *BRCA* PV carriers unaffected at ascertainment. Genotypic and phenotypic data for evaluating models were ascertained through the OSU Clinical Cancer Genetics, Geisinger MyCode, kConfab, Inherited Cancer Registry and the Breast Cancer Family Registry studies. Only women who were unaffected at the time of ascertainment or testing were included in the study with the exception of some women with cancer in the Geisinger population-based cohort. As genotypes from existing GWAS level-data were used for analyses, individuals/studies that were missing more than 20% of genotypes for any given model were excluded. Multiple published models were used including *BRCA1* specific breast cancer, *BRCA2* specific breast cancer, 77-single nucleotide variant (SNV) and estrogen-receptor negative (ER-) models. For *BRCA1* carriers, 390 women and 148 breast cancer events were included in the analysis. The model with the highest Area under the Curve (AUC) was the ER- model (AUC=0.61, p-value<0.0001). For *BRCA2*, 369 women were included and 140 breast cancer events occurred. The most predictive model for *BRCA2* PV carriers was a *BRCA2* specific breast model (AUC=0.56, p-value=0.029). We also separated individuals into groups by risk (bottom 20%, top 20% and middle 60%) and performed Kaplan Meier analysis for cancer free survival. The ER- model separated the bottom 20% of *BRCA1* PV carriers from the other risk groups (p=0.037). The *BRCA2* specific model separated the top 20% risk group from the other groups, but the low risk group had more events than the middle group. In summary, PRS models for breast cancer risk in unaffected *BRCA* PV carriers show promise for more refined risk estimates, but there is room for improvement.

## PgmNr 801: Exploratory whole-transcriptome profiling of functional neural markers of cognitive function during aromatase inhibitor therapy for breast cancer.

### Authors:

J.D. Merriman <sup>1</sup>; R. Lam <sup>2</sup>; G. Yu <sup>1</sup>; C.M. Bender <sup>3</sup>; Y.P. Conley <sup>3</sup>; B.E. Aouizerat <sup>2</sup>

### Affiliations:

1) Meyers College of Nursing, NYU, New York, NY; 2) Bluestone Center for Clinical Research, NYU, New York, NY; 3) School of Nursing, University of Pittsburgh, Pittsburgh, PA

---

**Purpose:** Most breast cancer survivors are postmenopausal and receive endocrine therapy with an aromatase inhibitor (AI), which may influence cognitive function. Between 25% and 60% of breast cancer survivors report cognitive problems before and during AI therapy. Cognitive problems may include difficulty concentrating and remembering. Dysregulated gene expression may be associated with functional neural markers of these cognitive problems. The purpose of this study was to explore relationships between variability in whole-transcriptome differential gene expression and neural activation before and during AI therapy.

**Design:** This exploratory, hypothesis-generating study included 11 postmenopausal women with breast cancer recruited from a Comprehensive Cancer Center and 9 age-matched healthy women (controls). Patients were assessed before AI therapy, and 6 and 18 months after starting AI therapy. Controls were assessed at yoked intervals.

**Methods:** Blood was collected immediately proximal to neuroimaging using a 3-Tesla Siemens Trio magnetic resonance imaging scanner. RNA isolation and RNA-Seq data collection were completed in bulk. After quality control processing, sequence reads were aligned to the human genome and mapped to known genes based on annotations using Ensembl GRCh38 v95. Differential gene expression for patients versus controls and pathway analysis were done using DESeq2 and GAGE, respectively. SPM-12 was used to extract neural activation in brain regions of interest during the Emotional Faces N-Back task. Normalized gene counts were correlated with fMRI parameter estimates using Spearman's rank correlation.

**Results:** At baseline, pathways involved in sensory perception, stimulus detection, neural function, and cytokine function were perturbed (FDR  $q < 0.1$ ). *FDXR*, involved in mitochondrial function, was upregulated in patients versus controls (FDR  $q = 0.009$ ). We found trends for correlations between *FDXR* gene expression and neural activation in the left amygdala ( $\rho = 0.39$ ,  $p = 0.086$ ) and hippocampus ( $\rho = 0.38$ ,  $p = 0.098$ ). Six months after initiating AI therapy, pathways involved in sensory and neural function remained perturbed (FDR  $q < 0.05$ ). *FDXR* gene expression no longer differed between patients and controls. Eighteen months after beginning AI therapy, pathways involved in sensory function remained perturbed (FDR  $q < 0.001$ ).

**Conclusion:** Mitochondrial dysfunction may play a role in cognitive problems experienced by patients with cancer before systemic therapy.

## PgmNr 802: Enrichment of cancer related genes and signaling cascades in the acquired CNVs of human induced pluripotent stem cell lines.

We have previously described the genomic integrity of human induced pluripotent stem cells (hiPSCs) generated within the NHLBI NextGen program. Here, we focus on the genomic regions with instability to identify potential enrichments of biological processes and pathways. We performed gene set enrichment analysis (GSEA) for genes mapping to regions with acquired copy number variations (CNVs) in the hiPSCs. GSEA was done sequentially to understand differences in regions with repetitive CNV acquisition over the 149 lines with at least one acquired CNV: Set 1/ Set 2/ Set 3/ Set 4 included genes mapping to regions of acquired CNVs in  $\geq 1$ ,  $\geq 2$ ,  $\geq 3$  and  $\geq 4$  lines. Using the 'GO-Slim Biological Process' annotation and an FDR of 5%, the set of 470 annotated genes showed enrichment in a variety of biological processes. Among these, we identified two cancer related signaling cascades that were overrepresented: "JNK cascade" (GO:0007254) (FDR-P=0.01) and "I-kappaB kinase/NF-kappaB signaling cascade" (GO:0007249) (FDR-P=0.04). Interestingly, the fold enrichment (FE) of these cascades increased markedly as we went from Set 1 through to Set 4. For the JNK cascade the FE is 5.51 for the genes in Set 1, 8.07 for Set 2, 17.46 for Set 3, and 26.35 for Set 4. Similarly, for I-kappaB kinase/NF-kappaB cascade, FE increased from 4.64, to 8.07, 13.81 and 18.94, respectively. In addition, we also identified the overrepresentation of "IL-6 production" (GO:0032635) (FDR-P=0.002) with FE raising from 12.93 to 21.05, 45.52 and 68.72. Elevated levels of IL-6 stimulate hyperactivation of JAK/STAT3 signaling pathway that promotes tumor growth and progression. The sub-chromosomal

region chr20q11.2 was the most recurrent aberrant region and was detected in 16 hiPSC lines (15 duplications and 1 deletion). The core overlap region of the duplications encompasses 15 genes including cancer associated loci *ID1*, *BCL2L1* and *TPX2*. Overall, hiPSCs acquired deletions included tumor suppressor genes whereas the acquired duplications included oncogenes. In conclusion, our results confirm that some sub-chromosomal regions are particularly susceptible to genomic instability, and that in this large set of hiPSCs from NextGen, the acquired CNVs show a specific enrichment for cancer related genes.

## PgmNr 803: Comprehensive transcriptome-wide association study of prostate cancer risk reveals large number of non-coding gene associations.

### Authors:

---

The genetic etiology of prostate cancer is highly polygenic, and over 100 independent genome-wide significant risk loci have been identified by large GWAS to date. However, most of these loci do not lie in close proximity to protein-coding genes and are presumed to be regulatory in nature. Recent methodological advances for integrating tissue-specific gene expression eQTL analysis results with GWAS summary statistics has led to improved identification of disease gene associations mediated through transcriptomic dysregulation. In this study, we leveraged a large normal prostate tissue eQTL dataset to conduct a transcriptome-wide association study (TWAS) of prostate cancer risk based on SNP association results from the recent PRACTICAL case-control GWAS meta-analysis. Our eQTL dataset consisted of 471 samples of normal prostate tissue from prostate/bladder cancer patients with available RNA-Seq and imputed Illumina Infinium 2.5M genotype data. RNA-Seq data were processed using ENSEMBL gene annotation to comprehensively characterize expression patterns of all RNA species. In addition, 441 samples also had corresponding small RNA-Seq performed to characterize miRNA expression. We applied the FUSION TWAS software to train expression prediction models for all expressed genes with a minimum degree of heritability ( $h^2$  range: 0.02 – 0.98), resulting in 13049 total genes eligible for TWAS analysis. Based on a significance threshold of  $FDR < 0.05$ , we identified 703 significant genes associations with prostate cancer risk: 6 miRNAs, 204 lncRNAs (known and novel), 383 protein-coding genes, and 110 other RNA species. Among protein-coding genes, gene-set analysis via WebGestalt revealed significant enrichment ( $FDR < 0.05$ ) for genes related to Gene Ontology terms involving embryonic morphogenesis and development (e.g., GO:0060173, GO:0048568, GO:0035108). Among the 320 total non-coding genes associated in our TWAS, 83 (26%) had no local protein-coding gene TWAS hits within 500kb, suggesting the risk effects conferred at those loci are mediated through these non-coding transcripts. Other loci demonstrated clustered dysregulation of multiple proximal genes, with over 50 gene associations identified in the MHC region alone. These findings suggest that additional efforts untangling the gene expression regulatory networks of the prostate transcriptome, including the roles of non-coding genes, will be critical to fully elucidating the molecular mechanisms of prostate cancer risk.

## PgmNr 804: Genetic ancestry versus environmental differences in oncogenic mutations and driver genes in lung adenocarcinoma.

---

Cancers differ significantly between ethnic backgrounds, but the etiology and impact of these differences are poorly understood. We estimate genetic ancestry of over 1000 individuals with lung adenocarcinoma (LUAD) cancer in the Dana-Farber *Profile* tumor sequencing cohort and quantify the influence of genetic ancestry on recurrent somatic alterations. From roughly 700 mutation phenotypes (including somatic single-point mutations, insertions/deletions, and fusions), we identify 31 mutations significantly associated with at least one of five major ancestry groups (FDR adjusted  $p < 0.05$ ). We replicate the established association between mutation in EGFR gene and Asian ancestry ( $p = 2.2 \times 10^{-7}$ ). Surprisingly, we also find that non-Asian ancestries, such as Ashkenazi Jewish ( $p = 4.6 \times 10^{-3}$ ) and African ancestry ( $p = 4.0 \times 10^{-3}$ ), are significantly associated with EGFR as well. In addition to EGFR, we identify many novel genes significantly associated with ancestry differences (FDR adjusted  $p < 0.05$ ), including the association of Native American ancestry with KEAP1 mutations ( $p = 5.9 \times 10^{-5}$ ), and Asian ancestry with NOTCH2 mutations ( $p = 3.2 \times 10^{-5}$ ) and ARID1 mutations ( $p = 1.6 \times 10^{-3}$ ). Using multivariate models, we identify multiple mutations independently associated with each ancestry, including six mutations with Jewish ancestry, five mutations with African ancestry, and four mutations with European ancestry and East Asian ancestry. We also find significant differences between all continental ancestry groups for tumor mutational burden (TMB), which is an emerging prognostic indicator for immunotherapy and may point to ancestry-specific treatment selection criteria. Lastly, to better understand genetic versus environmental contributions, we compare discrepancies between self-reported ethnicity and derived ancestry in mutation phenotypes and find that most are explained by genetic differences. Taken together, our results suggest that somatic mutations differ between ancestries at many more genes than previously thought.

## PgmNr 805: Genome-wide association study identifies common genetic variants associated with prognosis of hepatocellular carcinoma.

### Authors:

H. Chen; D. Jiang

[View Session](#) [Add to Schedule](#)

**Affiliation:** Infectious Diseases and Hepatology Unit, Nanfang Hospital, Southern Medical University, Guangzhou, China

---

### Aim

Hepatocellular carcinoma (HCC) is one of the most common cancers and the third most common cause of cancer mortality worldwide. The prognosis of HCC is poor, with a 5-year survival rate less than 30%. As an important aspect of tumor heterogeneity, genetic variation may influence the proliferation and metastasis of HCC. The aim of this study is to identify single nucleotide polymorphisms (SNPs) associated with overall survival of HCC patients.

### Methods

464 Chinese HCC patients with surgical treatments from two cohorts (OPS-1, OPS-2) and 641 Chinese HCC patients without surgical treatment from NonOPS cohort were enrolled in this study. Genome-wide genotyping analysis for the patients in OPS-1 and NonOPS was conducted using Illumina Human OmniExpress BeadChips, while for those in OPS-2 was conducted using Illumina Asian Screening Array. The following inclusion criteria were used to filter SNPs: 1) call rate > 95%, 2) minor allele frequency > 0.1 and 3) P for Hardy-Weinberg equilibrium > 0.001. Imputation analysis was done by referencing Haplotype Reference Consortium (HRC1.1). Cox proportional hazards regression under three models (additive, dominant and recessive) with adjustment for age at onset and sex, followed by meta-analysis, were used to analyze data.

### Results

After quality control, 4,830,338 SNPs, 4,908,943 SNPs and 3,133,930 SNPs were left for OPS-1, NonOPS and OPS-2, respectively. Of which, 95 SNPs in 19 blocks (additive model), 70 SNPs in 20 blocks (dominant model) and 145 SNPs in 42 blocks (recessive model) showed consistently suggestive significance ( $P < 0.05$ ) with the same direction of associations across the three cohorts. When a joint analysis of the patients in the three cohorts was performed, rs10020174, a SNP located in the intron region of *MARCH1* was significantly associated with overall survival of HCC under recessive model ( $HR = 8.50$ ,  $P_{meta} = 4.40 \times 10^{-10}$ ). Besides rs10020174, another SNP located in *PRKD1* (rs17096078) achieved a suggestive level of significance ( $HR = 1.29$ ,  $P_{meta} = 7.1 \times 10^{-6}$ ) under dominant model.

### Conclusion

By integrating three HCC cohorts, we identified several common genetic variants that potentially influence overall survival of HCC patients. Our findings may improve the understanding of the biology of the disease and suggest biological targets for pharmaceutical intervention.

## PgmNr 806: Germline testing in African American women with invasive breast cancer.

### Authors:

R. Ellsworth <sup>1</sup>; L. Lovejoy <sup>2</sup>; S. Rummel <sup>2</sup>; C. Shriver <sup>3</sup>

---

**Background:** Although African ancestry is not included in the NCCN guidelines for BRCA1/2 genetic testing, African American women (AAW) are at increased risk of being diagnosed at a young age and/or with triple negative breast cancer. Improved understanding of the frequency and nature of cancer predisposition genes may improve the care of women with breast cancer and the development of risk reduction strategies, we evaluated the utilization and results of germline testing of cancer predisposition genes in AAW with invasive breast cancer.

**Methods:** 546 self-described AAW with invasive breast cancer enrolled in the Clinical Breast Care Project from 2001-2017. Eligibility status for genetic testing was assessed using the NCCN guidelines version 1.2019. In patients without clinical panel testing performed and with an available genomic DNA sample, targeted sequencing across 94 cancer predisposition genes was performed. .

**Results:** Of the 60% of patients meeting NCCN criteria, 37% of underwent clinical testing, resulting in a mutation frequency of 13%, including mutations in ATM (n=2), BRCA1 (n=7), BRCA2 (n=5) and TP53 (n=1). High-risk women tested in the research setting had a mutation frequency of 9% including BRCA1 (n=2) and BRCA2 (n=2) and single carriers of mutations in BLM, CHEK2, MLH1, MUTYH, PALB2, PMS2 and RECQL4. Within 111 low-risk women, the mutation frequency was 5% with mutations in BRCA2 (n=3), PMS2 (n=1), SBHD (n=1) and TSC2 (n=1). Six women had previously unreported variants in BRCA1, BRCA2, TP53, ALK and RB1 and 29% of the women had VUS in genes including BRCA1 and BRCA2.

**Conclusions:** Translating NCCN eligibility into pursuit of germline testing remains a challenge as only 33% of the high-risk women underwent clinical testing and 40% of the mutation carriers within the high-risk group were detected in the research setting. Furthermore, 5% of low-risk women were mutation carriers. In addition, while the majority (66%) of mutations detected were in BRCA1 or BRCA2, multi-gene testing allowed for an additional 50% of mutation carriers to be identified. Because identification of germline mutations may alter patient management and prevent secondary cancers, it is critical to identify and address barriers such as evolving NCCN guidelines, cost, and patient preference, to testing and optimize the selection of AAW for genetic testing.

## PgmNr 807: A custom genotyping array for detecting disease associations in men of African descent reveals population-level heterogeneity in the genetic risks of prostate and other cancers.

---

Although prostate cancer is the leading cause of cancer mortality for African men, the vast majority of known disease associations have been detected in individuals who have European ancestry. Furthermore, most genome-wide association studies have used genotyping arrays that are hindered by SNP ascertainment bias. To overcome these disparities in genomic medicine, the Men of African Descent and Carcinoma of the Prostate (MADCaP) Network has developed a genotyping array that is optimized for studies of African populations. The MADCaP Array contains more than 1.5 million markers and an imputation backbone that successfully tags over 94% of common genetic variants in African populations. This array also has a high density of markers in genomic regions near known cancer associations, including 8q24. We assessed the effectiveness of the MADCaP Array by genotyping over 800 prostate cancer cases and controls from seven urban study sites in sub-Saharan Africa. We find that genes mirror geography: samples from Ghana and Nigeria cluster together and samples from Senegal and South Africa yield distinct ancestry clusters. Cases and controls are ancestry-matched. We identify highly differentiated loci in Africa (including rs3817963, rs2294008, rs5919432, and rs6465657), and include allele frequencies at cancer-associated loci as an additional, novel resource. Genetic risks of prostate cancer are heterogeneous across African populations: polygenic risk scores for prostate cancer are lower in Senegal and higher in Nigeria.

Significance: The MADCaP Array enables investigators to identify novel Africa-specific disease associations and to fine-map genetic loci that are associated with prostate and other cancers.

## PgmNr 808: MEDUSA: Phylogenetic analysis of mesothelioma tumours by multiregional sampling, whole exome sequencing, and copy number analysis.

---

### Background:

The Mesothelioma evolution: Drugging somatic alterations (MEDUSA) project aims to investigate the genomic evolution and heterogeneity of malignant pleural mesothelioma and identify genomic changes early in mesothelioma evolution that can be targeted by drugs. For 20 malignant pleural mesothelioma patients, we have analysed the exomes of at least four regions of the tumour and paired whole blood.

### Methods

Using paired tumour-normal analysis with the software Sequenza, we have called copy number alterations specific to the tumour, and used the software Tumult to reconstruct a phylogeny of the tumour for each of the 20 patients.

### Results

We show that mesothelioma shows extensive heterogeneity in copy number changes, and accumulates typically between 100-200 copy number gains and losses while evolving in a branching pattern. We identify and validate copy number alterations that occur truncally, early in the evolution of the tumour, and are recurrent across patients, including homozygous loss of *CDKN2A* and *MTAP*, heterozygous loss of *MTOR*, and heterozygous loss of *BAP1*. Losses of these key genes are observed in some other patients, but only in a subset of regions, suggesting that they have occurred later in the evolution of the tumour compared to truncal changes.

### Conclusions

As truncal changes are likely to be present throughout the tumour, identifying them highlights potential Achilles' heels for drug targeting and treatment.

## PgmNr 809: Polygenic risk scores generated from European GWAS poorly predict prostate cancer risks in African populations.

### Authors:

M. Kim <sup>1</sup>; C. Simonti <sup>1</sup>; M. Harlemon <sup>1,2</sup>; L. Petersen <sup>3</sup>; I. Agalliu <sup>4</sup>; T. Rebbeck <sup>5</sup>; J. Lachance <sup>1</sup>; MADCaP Network

### Affiliations:

1) School of Biological Sciences, Georgia Institute of Technology, Atlanta, GA; 2) Clark Atlanta University, Atlanta, GA; 3) Centre for Proteomics and Genomics Research, Cape Town, South Africa; 4) Albert Einstein College of Medicine, Bronx, NY; 5) Dana Farber Cancer Institute, Harvard Medical School, Boston, MA

---

Men of African descent have the highest incidence and mortality of prostate cancer compared to men with other ancestries. However, most GWAS have used European study cohorts. Because of this, GWAS may do not always replicate well in other populations, and this can lead to misestimated polygenic risk scores (PRS). To alleviate disparities in genomic medicine, the Men of African Descent and Carcinoma of the Prostate (MADCaP) Network has developed a novel genotyping array that is optimized for studying prostate cancer in men of African descent. Applying the MADCaP Array to 399 African cases and 403 African controls, we test whether previously ascertained disease associations are able to successfully replicate across continents. For example, rs5919432 (a CaP-associated SNP that at Xq12) has elevated risk allele frequencies in MADCaP cases compared to African controls. We also examine whether prostate cancer associations near recombination hotspots are less likely to be replicated across continents. Using a curated set of 141 prostate cancer-associated loci from Schumacher et al. 2018, PRS of 802 men of African ancestry from the MADCaP Network and 240 men of European ancestry from 1000 Genomes Project were calculated. Comparing PRS distributions of individuals from seven African study sites and five European populations, we find that the predicted risks of prostate cancer are significantly higher for African men than European men. Among MADCaP study sites, individuals from Dakar, Senegal and Abuja, Nigeria show the lowest and highest predicted risk of prostate cancer, respectively. Overall, we find that PRS generated from European GWAS do a poor job of predicting prostate cancer risks in urban African populations. Using ADMIXTURE, we identify genetic ancestries that are correlated with increased risk of prostate cancer. Additional analyses include testing the effectiveness of PRS generated from non-European GWAS, assessing whether individuals with severe prostate cancer (i.e., higher Gleason scores) have higher PRS scores, and correcting for biases that can occur when generating PRS.

## PgmNr 810: SJLIFE WGS: A resource of curated genetic variation data generated from whole-genome sequencing of >3,000 long-term survivors of pediatric cancer.

### Affiliations:

1) Department of Computational Biology, St. Jude Children's Research Hospital, Memphis, TN; 2) Department of Epidemiology and Cancer Control, St. Jude Children's Research Hospital, Memphis, TN

---

Germline mutations in cancer predisposition genes contribute to ~10% of pediatric cancers, but their full impact on subsequent neoplasms and chronic health conditions after treatment is largely unknown. To enable genetic research on pediatric cancer survivors, we generated whole-genome sequencing (WGS) data at >30X coverage for 3006 participants enrolled in the St Jude Lifetime Cohort Study (SJLIFE) comprised of 2433 Caucasians, 308 African-Americans, 11 Asians, and others with admixed ethnicity. WGS was also performed for a community control group (SJLIFE controls) of 341 individuals without a history of childhood cancer. Genotype calls were determined by simultaneously optimizing the thresholds of read count and variant allele fraction and maximizing genotype concordance with SNP array. Over 93 million single-nucleotide variants (SNVs) were identified; 5.8 million of which were classified as “invalid” using a curation pipeline, which evaluates distributions of read coverage and variant allele fraction across samples, as well as Hardy-Weinberg disequilibrium and excess of heterozygosity for each site. Interestingly, 0.8 million of our invalid SNVs were considered passing quality control in gnomAD, suggesting that additional curation of public databases may be needed. Compared to gnomAD, over 30 million SNVs are unique in SJLIFE, the majority (80%) of which were singletons. We were able to replicate previously reported associations of *ARID5B* (17 SNPs in one LD block) with acute lymphocytic leukemia (ALL). However, we also found SNVs with significant associations by comparing to gnomAD, but the results were not replicated using other control cohorts. For example, the alternate allele frequency (AF) of rs374896001 is 0.09 in SJLIFE survivors of ALL while the AF in gnomAD, TOPMed, and SJLIFE controls are 0.0002, 0.27, and 0.16, respectively. These results demonstrate that SJLIFE WGS complements existing public data sets by enriching the content of genetic variation in human population. The data set not only serves as an important resource for genetic research on pediatric cancer and survivorship, but also provides a useful control for other genetic studies. SJLIFE genomic data are publicly available on the St. Jude Cloud ([https://platform.stjude.cloud/requests/cohorts?dataset\\_accession=SJC-DS-1002](https://platform.stjude.cloud/requests/cohorts?dataset_accession=SJC-DS-1002)) and full access has already been granted to 15 investigators from 11 research institutions.

## PgmNr 811: RCCD1: A potential pleiotropic target for ovarian and breast cancers.

### Authors:

N. Safi

[View Session](#) [Add to Schedule](#)

**Affiliation:** cedars Sinai Medical Center, Los Angeles, CA.

<sup>2</sup>Centre for Cancer Genetic Epidemiology, University of Cambridge, Cambridge, UK;

### Introduction:

Genetic variance in RCCD1 is identified as a potential pleiotropic risk factor of breast, ovarian and prostate cancers. Quantitative trait association of RCCD1 with expression changes of susceptibility genes suggests the putative role of this gene in cancer acquisition. This finding merited experimental evaluation of this gene as a novel therapeutic target of breast and ovarian cancer. RCCD1 is involved in numerous biological pathways including estrogen receptor, P53 signaling, Epithelial-to-Mesenchymal Transition via TGFb, and DNA damage responses. Recently we used chromosome conformation capture (4C) to investigate the interaction of RCCD1 promoter with possible candidate causal variants at the 15q26 pleiotropic risk locus in breast and ovarian normal cell lines (MCF10A and FT246) and cancer cell lines (BT549, MCF7 and UWB1.289, KURAMOCHI). In this study, we created and genotyped cell line models of RCCD1 KO and OX to functionally validate the initial 4C results. Selected cell lines were analyzed for downstream targets of RCCD1. Immunofluorescent analysis of polyclonal RCCD1 KO cell lines showed that RCCD1 depletion is correlated with E-cadherin colocalization. E-cadherin is regulated by RCCD1 and is related to Mesenchymal-to-Epithelial Transition. Our results showed that RCCD1 expression is also correlating with P53 mutated, N-cadherin, and Vimentin, which suggest the causative role of RCCD1 in development of breast and ovarian cancer. Further experiments will validate if RCCD1 can act as a therapeutic or preventive target for these cancers.

---

Pancreatic neuroendocrine tumor (PNET), arising from the endocrine tissues of the pancreas, is often diagnosed inadvertently and present with multiple metastases in the liver and local lymph node. The evolutionary principles underlie the emergence of metastatic traits in PNET remain exclusive. Here, we present a rare case of PNET with multiple metastases in the liver and lymph nodes over a period of 12 years. We investigated both genetic and immunologic components in longitudinally collected tumors using whole-exome and immuno-repertoire sequencing. A hypermutation in the primary tumor (i.e., a prevalence of 84.0 per MB) and significantly reduced mutation burden in metastases showed that metastasis occurred before the accumulation of mutation in the primary tumor. We demonstrated that polyclonal seedings have contributed to multiple metastases by both linear and branching spread patterns. In addition, the progression of metastatic tumors was modulated by heterogeneous immune microenvironments with varied T cell receptor (TCR) repertoires. Our findings provided an important implication for the evolution of long-term survival tumors, and the anti-tumor immunotherapy for metastatic tumors especially at later stages such as PNET.

## PgmNr 813: Scans of positive selection in urban African populations reveal recurrent targets of adaptation.

**Authors:**

M. Quiver; J. Lachance; MADCaP Consortium

[View Session](#) [Add to Schedule](#)

**Affiliation:** Georgia Institute of Technology, Atlanta, Georgia.

---

Most existing studies of natural selection in Africa have focused on rural populations, and the evolutionary genetics of urban African populations are relatively understudied. Here, over 800 individuals from sub-Saharan Africa were genotyped using the Men of AAfrican Descent and Carcinoma of the Prostate (MADCaP) Array. These individuals were sampled from seven urban study sites. MDS and ADMIXTURE analyses reveal three major clusters in the genetic data analyzed in this study. Using the MADCaP Array, population branch statistics (PBS) were calculated for 1.5 million loci to identify targets of positive selection in African populations. PBS scores were calculated for three evolutionary branches: Senegal, South Africa, and Ghana-Nigeria. Integrating scans of positive selection with PheWAS data from the UK Biobank, we identify phenotypes that tend to be associated with selected loci in urban African populations. Many positive selected loci are in the located MHC region of chromosome 6. This pattern is especially strong for the Senegalese branch. In addition, X chromosomal loci are enriched for high PBS scores. This may be due to selection acting on recessive alleles in hemizygous males. We also find that many positively selected loci appear to be involved in blood-related phenotypes, including hematocrit and neutrophil percentage. SNPs with high PBS scores in urban African populations include rs17202519, rs113430757, rs9786075, rs12851390, and rs9991733.

## PgmNr 814: Therapeutic yield of canonical splice variants among 325 solid tumor cases.

---

In contrast to being routinely evaluated for disease association in inherited disorders, canonical splicing mutations are often not evaluated for precision medicine in clinical oncology, despite tumorigenic importance. To assess the relevance of canonical splice variants in clinical oncology, we retrospectively analyzed their therapeutic potential across 325 patients tested at our laboratory. Fastq data from our 212 gene ActionSeq™ NGS panel was mapped, aligned and called using a customized BWA/GATK pipeline and variants annotated using snpEff. The resulting +/- 1,2 variants were first functionally assessed by predictive tools and literature review, and then tier-classified according to joint AMP/ASCO/CAP cancer interpretation guidelines. Therapeutic significance (Tier I and II) was determined by the availability of indicated FDA approved therapies or clinical trials recruiting for aberrations of the identified gene. 46 splice variants were detected in 40/325 (12.3%) cases. 28/46 (61%) variants across 26/325 (8%) patients were determined to have therapeutic potential with clinical trials recruiting for aberrations in the gene. These 28 variants were distributed across a variety of primary tumors including brain (50%), lung and ovarian (11%), and fallopian tube (7%). *TP53* was the most recurrently mutated gene in this cohort with 9/28 splice variants detected, followed by *NF2* 3/28. 2/46 variants met Tier I criteria (*MSH6* and *BRCA2*), and 26/46 were classified as Tier II. A single variant was classified as Tier IV (benign) and the remainder (17/46) were classified Tier III (unknown significance). Putative access to 15 off-label FDA drugs in the clinical trial setting were identified for 13/28 variants. An average of 2.5 trials per variant were identified with 34 unique trial associations in total. These trials produced an average of 2.3 targeted drugs per variant with 30 unique drugs across 13 unique drug classes in total. 5/25 patients with therapeutic splice variants detected would have had a tier III only report otherwise. Similarly, 10/25 had 1 therapeutic variant reported originally. These results support the clinical validity of canonical splice evaluation, suggesting its incorporation in routine clinical reporting for solid tumors would be beneficial. This notion is bolstered by the fact that the yield rate for splicing mutations was greater than other commonly reported alterations in this cohort including CNV deletions, fusions, and in-frame indels.

## PgmNr 815: Landscape of germline genomic variations across 31 cancer types.

Germline predisposition alleles have been identified in several tumor suppressor genes and oncogenes. While most of the studies have focused on analysis of a single cancer type, germline variants explain only a small fraction of heritable cancers. To expand the current catalogue of germline cancer predisposition alleles we analyzed whole genome sequencing of tumor and matched normal samples on 200 clinical cases representing 31 different cancer types. Tumor tissue was sequenced to achieve mean genome coverage of 80x and normal tissue at 40x. Germline variant calling was performed on the matched normal samples to identify SNVs, indels, CNVs and structural variants. Mitochondrial DNA heteroplasmy and copy number were estimated using in-house developed pipeline. Variant calls were annotated, filtered and prioritized in relation to the tumor type. Prioritized germline variants were evaluated in the tumor sample to assess their biological impact. Following ACMG guidelines for variant classification we identified pathogenic and likely-pathogenic germline variants that were either shared by multiple samples with the same cancer type or shared across cancer types indicating common etiology. Within specific individual samples we identified synergistic combinations between germline and somatic variants and their possible mechanism of action. We further investigated the contribution of inherited mutations towards somatic tumor mutation burden, tumor heterogeneity and clonality. Germline variants were discovered in genes such as AIP, APC, BRCA2, CHEK2, EPHB2, GPR101, MLH1, MSH2, MSR1, MUTYH, PALB2, PIGN, PPP2R1B, PTEN, RAD51C, SDHA, SDHB, SMO, TP53 in diverse cancer types such as pancreatic cancer, renal cancer, lung adenocarcinoma, hepatocellular carcinoma, meningioma, papillary thyroid carcinoma, melanoma, neuroblastoma, osteosarcoma, and desmoplastic small round cell tumor. Here, we present our findings of how the identification and classification of inherited mutations can provide additional understanding of individual cancers and can potential clinically benefit the treatment of cancer patients.

## PgmNr 816: Integrating multi-platform genomic datasets for kidney renal clear cell carcinoma subtyping using stacked denoising autoencoders.

Clear cell renal cell carcinoma (ccRCC) is highly heterogeneous and is the most lethal cancer of all urologic cancers. We developed an unsupervised deep learning method, stacked denoising autoencoders (SdA), by integrating multi-platform genomic data for subtyping ccRCC with the goal of assisting diagnosis, personalized treatments and prognosis. We successfully found two subtypes of ccRCC using five genomics datasets for Kidney Renal Clear Cell Carcinoma (KIRC) from The Cancer Genome Atlas (TCGA). Correlation analysis between the last reconstructed input and the original input data showed that all the five types of genomic data positively contribute to the identification of the subtypes. The first subtype of patients had significantly lower survival probability, higher grade on neoplasm histology and higher stage on pathology than the other subtype of patients. Furthermore, we identified a set of genes, proteins and miRNAs that were differential expressed (DE) between the two subtypes. The function annotation of the DE genes from pathway analysis matches the clinical features. Importantly, we applied the model learned from KIRC as a pre-trained model to two independent datasets from TCGA, Lung Adenocarcinoma (LUAD) dataset and Low Grade Glioma (LGG), and the model stratified the LUAD and LGG patients into clinical associated subtypes. The successful application of our method to independent groups of patients supported that the SdA method and the model learned from KIRC are effective on subtyping cancer patients and most likely can be used on other similar tasks. We supplied the source code and the models to assist similar studies at [https://github.com/tjgu/cancer\\_subtyping](https://github.com/tjgu/cancer_subtyping).

## PgmNr 817: Deep learning prediction of chemotherapy response using multi-omics features.

### Authors:

S. Guo<sup>1</sup>; S.J. Schrod<sup>1,2</sup>

---

Combining deep learning algorithms with multi-omics data provide an opportunity to improve precision medicine, especially for personalized therapy treatment. In this study, we investigated the performance of deep-learning algorithms applied to multi-omics genomic data from the Cancer Genome Atlas (TCGA) project. Drug response status including complete response (n=815), partial response (n=102), stable disease (n=182) and clinical progressive (n=892) across 32 cancers were evaluated. For computational efficiency and classifier performance, we proposed an approach using Sure Independence Screening (SIS) and Gini impurity index (SII) for feature selection from ultrahigh dimensional genomic feature set followed by conditional generative adversarial networks (CGAN) to produce predictive models for chemotherapy response, internally validated by 10-fold cross-validation. mRNA, miRNA, and methylation datasets were used both independently and jointly. For the miRNA-based prediction, we identified 23 highly informative features, including miR-141, miR-200c, miR-205, miR-9, and miR-338, which, in combination, produced an AUC=0.64 for discriminating complete and partial response from stable disease and clinical progressive endpoints. Using mRNA-seq data, we identified 264 highly informative features including *MYCBP*, *KLF15*, *IGIP*, and *GRIA3*. The mRNA-based predictive model yielded an average AUC=0.71. The DNA methylation model attained a higher level of performance with AUC=0.81 (95% CI: 0.78-0.84). Combining mRNA-seq, miRNA, and methylation data improved the predictive performance with an accuracy of 84.2% and an AUC=0.86 (95% CI: 0.82-0.90). Functional enrichment analysis for mRNA and DNA methylation selected features showed enrichment for the antioxidant response pathway and basal transcription factors associated with the platinum drug resistance (PDR) pathway. Importantly, our chemotherapy response classifier substantially outperforms a predictive model focused on mRNA and methylation features within PDR pathway (hsa01524 in KEGG) AUC=0.62, demonstrating that taking a broad approach using genome-wide multi-omics data dramatically improves discrimination. In summary, this work demonstrates that applying deep-learning algorithms to multi-omics data can generate informative predictive models for chemotherapy response across numerous cancers.

## PgmNr 818: Identifying novel therapeutic targets in cancers by analysis of genes insensitive to gene dosage changes.

Structural changes introduced by chromosomal instability are a hallmark of cancer. They are thought to result in tumor growth advantage by modulating the copy number of driver genes (oncogenes and tumor suppressors). Unlike point mutation and indels, these structural changes are generally large and influence the copy number of hundreds of genes including both driver and non-driver genes. Understanding the functional consequences of these structural changes is one of the fundamental challenges hindering the advances of genomic medicine.

We find that many of these induced gene dosage changes can be detrimental to tumor fitness. The expanding tumor clones often uncouple the expression of these genes from their copy numbers through additional regulatory changes. We hypothesize that by restoring the expressions of these genes, we can induce a flux of signaling detrimental to the tumor, thus achieving therapeutic benefits.

To discover the relevant regulatory changes, we use machine learning to build cancer specific regulatory networks from gene expression, methylation, miRNA, promoter and enhancer activity data. We model the effects of perturbations on the transcription factors that regulate the expressions of uncoupled genes on various phenotypes (i.e., immune infiltration, proliferation and cell cycle) determining tumor fitness. We introduce a Bayesian approach that quantifies the degree to which a copy number predicts the expression of a gene in an individual sample, allowing us to identify targets in individual samples. Finally, We systematically examine autologous SNP 6.0 array and RNA sequencing data in the cancer genome atlas (TCGA) using our approach. We discover a list of novel targets such as *TAP1/2*, whose gene expressions are consistently uncoupled from copy numbers in an appreciable number of patients. Functional validations are underway as part of the NCI cancer target discovery and development (CTD<sup>2</sup>) project.

## **PgmNr 819: Germline testing in colorectal cancer: Increased yield and precision therapy implications of comprehensive multigene panels.**

### **Authors:**

S. Yang; E. Esplin; S. Michalski; D. Pineda; S. Lincoln; R. Nussbaum

[View Session](#) [Add to Schedule](#)

---

**Background:** Studies suggest that the prevalence of germline abnormalities in homologous recombination deficiency (HRD) genes and other cancer genes not traditionally associated with colorectal cancer (CRC) may be more common in patients with CRC than previously appreciated. Herein, we investigate the landscape of pathogenic/likely pathogenic (P/LP) variants in CRC and the efficacy of comprehensive multigene panels identifying candidates for precision therapies.

**Methods:** DNA sequencing and exon-level copy number analysis were performed at a commercial diagnostic laboratory in a convenience sample of >9000 patients (pts) referred because of a personal history of colon cancer between 2013 and 2018. The genes requisitioned varied but consistently included 14 genes on a hereditary CRC panel; the patient data were de-identified and further analyzed for all 83 genes on a large hereditary cancer syndrome panel under an IRB-approved protocol.

**Results:** P/LP findings were identified in 2101 of 9669 pts (21%), 1838 (19%) pts when MUTYH heterozygotes are excluded. When restricted to five Lynch syndrome (LS) genes, only 9% of patients had a P/LP finding, which increased to 15% when 19 guidelines-based CRC genes were assessed. 137 pts (1.4%) had two or more P/LP variants. P/LP variants were in MLH1, MSH2, MSH6, PMS2, CHEK2, APC, MUTYH, BRCA2, ATM, BRCA1, PALB2, RAD50, BRIP1, TP53, EPCAM, among others, of which 1.4% were BRCA1/2.

When patients heterozygous for recessive conditions are excluded, 8% had P/LP variants in genes classically associated with CRC (i.e. LS genes, APC) or were biallelic for MUTYH, and 9% had P/LP variants in cancer risk genes not commonly associated with CRC. Using a comprehensive multigene panel approach, P/LP variants in genes with known therapeutic implications, such as in HRD and mismatch repair deficiency, were detected in 1408 (14%) of patients, and 1670 (17%) had P/LP variants in genes with established clinical management guidelines.

**Conclusions:** This study suggests that 1 in 5 patients with CRC harbor actionable germline variants, up to one-half of which remain undetected when only LS genes are tested. Over 50% of patients eligible for germline-based precision cancer therapy would be missed by germline testing limited to the LS genes. Comprehensive panel testing identified candidates for precision treatment and established management recommendations, and have clinical implications for both pts and their at-risk family members.

## PgmNr 820: Computational identification of mutator-derived lncRNA signatures of genome instability for improving clinical outcome of breast cancer.

---

**Motivation:** Emerging evidence revealed the critical roles of long non-coding RNAs (lncRNAs) in maintaining genomic instability. However, genome instability-associated lncRNAs and their clinical significance in cancers remain largely unexplored.

**Results:** We developed a mutator hypothesis-derived computational frame combining lncRNA expression profiles and somatic mutation profiles in a tumor genome and identified 128 novel genomic instability-associated lncRNAs in breast cancer as a case study. We then constructed a genome instability-derived two lncRNA-based gene signature (GILncSig) which stratified patients into high- and low-risk groups with significantly different outcome and was further validated in the independent patient cohort. Furthermore, the GILncSig correlated with genomic mutation rate in both ovarian cancer and breast cancer, indicating its potential as a measurement of the degree of genome instability. Interestingly, we found that the GILncSig was able to divide TP53 wild-type patients into two risk groups, with the low-risk group showing significantly improved outcome and the high-risk group showing no significant difference compared with those with TP53 mutation.

**Conclusions:** This study provided a critical approach and resource for further studies examining the role of lncRNAs in genome instability, and identified a genome instability-derived lncRNA signature which may have important value in outcome prediction and customized decision-making in breast cancer.

**Keywords:** genome instability; mutator phenotype; long non-coding RNAs

## **PgmNr 821: Prevalence of *UGT1A1\*28*, *UGT1A1\*93*, *UGT1A1\*60*, *ABCC5*, and *ABCG1* and their impact on toxicity in Iraqi cancer patients treated with irinotecan.**

### **Authors:**

A. Al-Talqani; S. Kathem

[View Session](#) [Add to Schedule](#)

**Affiliation:** College of Pharmacy, University of Baghdad, Baghdad, Iraq

---

Irinotecan-induced neutropenia and diarrhea are life-threatening toxicities that limit the use of the drug. These toxicities influenced by distinct interindividual variability due to gene polymorphism. In this prospective, longitudinal and multicenter study, 64 patients were participated to estimate the prevalence of *UGT1A1\*28*, *UGT1A1\*93*, *UGT1A1\*60*, *ABCC5* and *ABCG1* allele polymorphisms in Iraqi cancer patients treated with irinotecan-based therapy. In addition, the study aims to assess the relation between the polymorphic alleles and toxicity in standard- and reduced- dose of irinotecan. We showed that the prevalence of one vs two polymorphic allele of *UGT1A1\*28*, *UGT1A1\*93*, *UGT1A1\*60*, *ABCC5* and *ABCG1* were (35.9 vs 9.4 %), (54.7 vs 3.1 %), (17.9 vs 4.9 %), (39.1 vs 40.6 %) and (48.4 vs 0.0 %) respectively. Results revealed a significant ( $P<0.05$ ) relation between *UGT1A1\*28* allele and incidence of severe diarrhea and neutropenia (grade 3 and 4). In addition, we report a significant ( $P<0.05$ ) relation between the occurrence of *UGT1A1\*93* allele or *UGT1A1\*60* allele and incidence of severe (grade 3 and 4) neutropenia or diarrhea, respectively. Further, when Irinotecan dose reduced by 25-35%, we reported a significant ( $P<0.05$ ) reduction in the incidence of severe (grade 3 and 4) neutropenia and diarrhea in patients having *UGT1A1\*93* allele polymorphism, while non-significant change observed with other polymorphic alleles. In summary, we found that polymorphic alleles of *UGT1A1\*28*, *UGT1A1\*93*, *UGT1A1\*60* are strong determinants of toxicity that should be well considered in the treatment with irinotecan that necessitates dose modification.

## PgmNr 822: Results from clinical exome sequencing for cancer risk assessment in primary care patients who screen positive for genetic risk.

---

Background: Identifying hereditary cancer conditions provides the opportunity for screening or surgical intervention in those at risk. The Cancer Health Assessments Reaching Many (CHARM) study is performing clinical exome sequencing for 880 participants who score at increased risk for hereditary cancer using the B-RST<sup>TM</sup> 3.0 (positive or moderate risk) or PREMM<sub>5</sub> ( $\geq 2.5\%$  risk threshold) screening tools for hereditary breast and ovarian cancer syndrome and Lynch syndrome, respectively, or have limited family information. Here we summarize the findings reported for the first 200 CHARM study participants. Methods: Clinical exome sequencing includes annotation of 39 high and moderate penetrance hereditary cancer associated genes and 78 adult onset, medically actionable incidental finding (IF) genes. All pathogenic and likely pathogenic (P/LP) variants identified in hereditary cancer associated genes are reported; variants of uncertain significance (VUS) are only reported in genes related to the participant's history. P and loss-of-function LP variants are reported in IF genes. Results: Of 200 participants, 142 (71%) screened at increased risk on the B-RST<sup>TM</sup> 3.0 and/or PREMM<sub>5</sub> tool. Twenty of 200 participants (10%) had a P/LP variant in a hereditary cancer gene reported; 9 were in genes related to their personal or family history. Five of the remaining 11 participants with a P/LP cancer associated gene variant had limited family information. Six of 118 (5%) participants with a positive or moderate risk B-RST<sup>TM</sup> 3.0 screen had a P/LP breast or ovarian cancer variant compared to 3 of 82 (4%) participants who did not score at increased risk. Three of 51 (6%) participants with a positive PREMM<sub>5</sub> screen had a P/LP colon cancer variant compared to 6 of 149 (4%) participants who did not score at increased risk. Fifteen participants (8%) had a cancer risk related VUS reported. Two participants (1%) had an IF P variant unrelated to cancer reported. Discussion: The rate of findings reported to date in the different results categories is consistent with previous estimates for hereditary cancer testing and non-cancer IFs. While the proportion of participants with a P/LP variant was slightly higher in those who scored at increased risk, half of the P/LP results were in individuals without a known related personal or family history. These findings have implications for implementing cancer risk assessment screening tools and targeting genetic testing at a population level.

## **PgmNr 823: *Functional annotation of cancer somatic variants to guide radiotherapeutic decisions: The radiogenomic atlas.***

### **Authors:**

J.A. Castrillon <sup>1</sup>; B.D. Yard <sup>1</sup>; A.P. Petty <sup>1</sup>; M.E. Abazeed <sup>1,2</sup>

---

**Background:** Despite effectively guiding targeted drug therapy, genetic biomarkers do not currently inform the personalized use of radiotherapy. An understanding of the interplay between the cancer genome and ionizing radiation has the potential to predict cellular response to radiotherapy and therefore guide its clinical use.

**Methods:** We previously developed a high-throughput cancer cell line profiling platform that measures radiation survival and leverages cancer genomic data to advance knowledge of radiation tumor biology. We analyzed the radiation response of 533 cancer cell lines annotated by the Cancer Cell Line Encyclopedia (CCLE) and identified single-nucleotide variants (SNVs), copy number alterations and gene expression changes associated with radiation sensitivity. To annotate functional variants, we developed a new profiling schema that permits the unary assessment of SNVs in SV40 immortalized BEAS2B lung cells. To achieve this, vector constructs from 96 genes, comprising >500 unique SNVs, were generated using a high-content, site-directed mutagenesis approach that creates and integrates the variant into lentiviral vectors resulting in its stable expression under a PGK or EF1a promoter. The radio-protective *NFE2L2 E79K* gain-of-function variant and isogenic controls were used to calibrate relative radiation survival of individual SNVs tested in multiple tranches. Nominated SNVs were validated by colony forming assay. Selective SNVs that were confirmed to alter radiation sensitivity were profiled by 28 bioactive compounds in order to query the genetic dependency similarities between commonly used anti-tumor drugs and radiation.

**Results:** We show that top radioresistant alleles include both common and rare cancer variants. SNVs within *ARAF*, *BRAF*, *CTNNB1*, *EGFR*, *MAP2K1* and *PIK3CA*, among others were identified. A subset of KEAP1 loss of function variants were found to confer a dominant-negative phenotype by stabilizing NRF2 levels. Using our integrated drug sensitivity platform, we show that the association between the sensitivities of cells to radiation and anti-cancer drugs vary on the basis of the SNV in a drug class specific manner (e.g. DNA crosslinkers, epigenetic modifiers, mitotic spindle and DNA replication inhibitors, *et cetera*).

**Conclusion:** We present the largest radiogenomic profiling effort of cancer SNVs to date. Our atlas is poised to serve as a key resource that will help guide radiation treatment delivery.

## PgmNr 824: Exploring the role of mutant *p53* in somatic osteosarcoma.

### Authors:

D. Chachad <sup>1</sup>; H. Beird <sup>2</sup>; C. Vera <sup>3</sup>; W. Wang <sup>3</sup>; G. Lozano <sup>1</sup>

---

Osteosarcomas are malignant bone tumors that show rapid progression and pulmonary metastases. Studies in the field of osteosarcoma have not conclusively addressed important questions cooperating alterations that lead to tumorigenesis and metastasis, or the cell of origin for osteosarcomas. However, a growing body of research shows *p53* to be one of the most frequently mutated genes in osteosarcomas. Spontaneous mutations in the *p53* DNA-binding domain are missense in nature and exhibit gain of function (GOF) activities which are mediated mostly through its interaction with other transcriptional regulators, via its functional and highly active transactivation domain. *p53* mutants are classified as conformational (*p53*<sup>R172H</sup>) or contact mutants (*p53*<sup>R245W</sup>). Previous studies indicate that these mutants manifest transformation in unique ways. However, the mechanisms by which these hotspot mutants exert their tumorigenic potential remains to be evaluated. We hypothesize that *p53*<sup>R172H</sup> and *p53*<sup>R245W</sup> are independent tumor-initiating events that regulate different transcriptional programs for osteosarcoma formation. We have developed genetically engineered mouse cohorts that express either *p53*<sup>R172H</sup> or *p53*<sup>R245W</sup> specifically in osteoblasts after Cre-mediated recombination, resulting in 100% penetrant osteosarcomas. Additionally, after Cre-mediated recombination, while one allele of *p53* expresses the mutant, the other allele is deleted, which allows us to study GOF for that specific mutant.

The murine primary tumors exhibit extensive copy number variation thereby recapitulating human osteosarcomas. Preliminary data from our cohorts show differences in terms of survival and metastatic incidence, with *p53*<sup>R172H</sup> being more potent than *p53*<sup>R245W</sup>. RNA-seq analyses of primary tumors also suggest that the transcriptomes regulated by these respective mutants are different. Additionally, immunohistochemistry analyses show that *p53*<sup>R245W</sup> is more stable than *p53*<sup>R172H</sup>. Studies are ongoing to identify dysregulated pathways and mechanisms by which these mutations in *p53* give rise to metastatic osteosarcoma. These studies will help us identify novel targets mediating transcriptional GOF of respective mutants.

## PgmNr 825: Common non-coding genetic variation as a clinically actionable biomarker of melanoma immunotherapy toxicity.

Perleman, Department of Dermatology, New York University, New York, New York; 6) Istituto Nazionale Tumori-Istituto di Ricovero e Cura a Carattere Scientifico, Fondazione G. Pascale, Naples, Italy

While immunotherapy (IT) improved the clinical outcome of metastatic cutaneous melanoma (CM), ~60% of patients do not respond to treatment. Furthermore, 65-80% of patients treated with IT experience immune-related adverse events (irAEs). We have recently shown that host immunity may affect IT response and prognosis by demonstrating the association of these outcomes with immune-related expression quantitative trait loci (ieQTLs). In this study, we investigated whether ieQTLs also impact risk of irAEs in IT-treated CM patients. By interrogating a healthy twin cohort expression dataset (MuTHER), we have identified 50 ieQTLs most significantly associated with the expression of 265 immune genes. These 50 SNPs were genotyped using the MassARRAY system in 195 anti-CTLA-4-treated patient samples collected as part of a multi-institutional collaboration. Multivariable logistic regression adjusting for age at treatment, study center and gender was used to test for association of germline variants with irAEs. We found a significant association with severe irAEs in anti-CTLA-4-treated patients for rs7036417 (OR=8.62; 95%CI=3.02-24.64; p=5.77E-05). In this analysis, having two copies of the alternate allele of rs7036417 results in patients being 8.6 times more likely to develop severe irAEs. Having two copies of rs7036417 in lymphoblastoid cell lines is associated with higher expression of SYK, suggesting that high SYK expression is associated with increased risk of severe irAEs. In this study, we report that rs7036417, an eQTL in SYK, is associated with an increased risk of severe irAEs. SYK is known to interact with B-cell and Fcγ receptors and its inhibition has been effective in patients with rheumatoid arthritis, one of the most common irAEs. Our study points to the need of a systematic investigation of non-coding genome in discoveries of novel biomarkers in pharmacogenomics applications. The effects observed for the associated ieQTLs with ICI toxicity, further support the notion that the clinical relevance of non-coding common genetic variation in pharmacogenomics loci, likely due to the absence of selection pressure, will be substantially enhanced, as opposed to common variants associated with disease risk.

## PgmNr 826: Mutation burden and I index for detection of microsatellite instability in colorectal cancer by targeted next-generation sequencing.

### Authors:

---

ext-generation sequencing (NGS) panels are widely used for defining tumor mutation profiles and determining treatment approaches. We performed targeted NGS with 382 colorectal cancer genes with known microsatellite instability (MSI). After exclusion of germline alterations, the load of somatic mutations and small insertion/deletion (indel) alterations were determined. In the test set, 79 patients with 41 microsatellite-stable (MSS) and 38 MSI tumors were included. There were 120 MSS and eight MSI-high tumors in the validation set. The number of somatic mutations of whole samples were distinguished into three groups: mutant functional polymerase epsilon catalytic subunit, MSI, and MSS tumors. The median numbers of somatic and indel mutations in MSI tumors were higher. The indel mutation to whole mutation ratio (I index) was higher in MSI tumors. Hypermutation and low I index of polymerase epsilon catalytic subunit mutant tumors, a somatic mutation load cut-off of  $\geq 40$ , and an I index of  $\geq 9\%$  were selected as the criteria for detecting MSI tumors with high sensitivity and specificity. With the analysis of alteration patterns of homopolymer genes, a higher median number of homopolymer mutations in MSI tumors was observed. Mutated homopolymer  $\geq 5$  was selected as the criterion for detecting MSI tumors. MSI in colorectal cancer can be detected by targeted NGS panels with high sensitivity and specificity using somatic mutation load and I index. Additionally, further investigation was performed with same criteria for analysis of targeted NGS using cell-free DNA.

## PgmNr 827: Development of a large scale liquid biopsy platform for classification of microsatellite instability.

Identifying patients whose cancer is driven by microsatellite instability and mismatch repair deficiency may lead to successful treatment with FDA approved immune checkpoint blockade therapy. We aim to identify such patients using a low cost, sensitive and highly accurate liquid biopsy whole genome assay.

To date we have generated >7000 cfDNA whole genomes at ultra low pass coverage (0.1x - 1x) from a wide range of cancer indications. Using the iChor analysis tool we are able to routinely generate tumor purity estimates and copy number profiles at large scale as well as provide research teams with important quality control metrics for selecting the most useful cases for additional deep sequencing assays (exomes or targeted panels). We find that only 17% of blood samples assayed by our lab contain > 10% ctDNA and the remaining will require ultra sensitive approaches to mutation profiling and MSI classification. Current platforms for determining MSI status in tumor samples (tissue staining or DNA sizing assays) are not transferable to circulating cell free DNA applications. Moreover, standard next generation sequencing protocols pose a challenge to classify MSI cases because PCR errors inherent in the library preparation and sequencing process can mimic MSI deletion events. A genome-wide approach to compute sample level MSI scores from >23 Million potential MSI loci may offer enough statistical power to accurately detect MSI samples at low tumor purity. To test this, we generated mixtures of MSI cell line DNA with normal DNA and performed whole genome sequencing to depths ranging from 0.1x - 0.5x coverage. Using this data and the novel algorithm MSIdetect developed in the Broad Cancer Program, we demonstrate accurate classification of MSI cases down to 0.5% tumor fraction. With further optimization of analysis algorithms and additional sequencing innovations it may be possible to push the limit of detection to 0.1% and lower. This platform and analysis pipeline together will form the foundation for a CLIA grade assay capable of delivering both tumor purity estimates and MSI classification on patient cfDNA samples.

## PgmNr 828: Integrated analysis of genomic data in ovarian cancer to facilitate precision medicine.

---

Ovarian cancer is the deadliest of the gynecological malignancies due to the prevalence of late-stage diagnosis and chemoresistance. The development of precision medicine for ovarian cancer has the potential to positively impact patient survival. In order to advance the goal of precision medicine, we used transcriptomic profiling and metabolomic analysis to characterize heterogeneity among tumors pre- and post-treatment with standard of care platinum-based chemotherapy. We recapitulate subtypes of ovarian cancer described by previous groups using gene expression. In addition, we generated metabolomic profiles for ovarian tumors. Integration of gene expression and metabolomic data showed that TCA cycle metabolism is linked to increased cellular proliferation in tumor tissue. Further, we show that gene expression patterns associated with DNA damage and stress response are induced following platinum therapy. Induction of immune response is variable among patients following platinum treatment and proliferation is generally reduced after therapy. We also show that over half of patients change gene-expression subtype following platinum treatment. While current standard of care treats patients of each subtype similarly, looking toward the future, these data show that initial treatment and response may help direct subsequent selection of therapy. We also profiled patient ascites to determine the extent to which gene expression signatures useful for subdividing patients persist in metastatic cells. We show that in nearly half of our cases, the signature of the subtype remains detectable in the ascites. However there are some significant changes associated with ascites compared to tumor samples from the same patient. Namely there is up-regulation of genes associated with proliferation and cell migration as well as up-regulation of signaling pathways such as MAPK and TGF $\beta$ . These analyses suggest profiling of metastatic cells might also be informative in determining therapies that specifically target metastatic cells. Our data provide further insight into the heterogeneity that exists ovarian cancer tissues and analysis of matched post-treatment tissues and ascites cells gives a more complete view of transcriptomic and metabolomic profiling that can lead to delineation of the clinically relevant profiles to be used in the pursuit of precision medicine for ovarian cancer.

## PgmNr 829: Effect of *KRAS* mutations on extracellular vesicle content and function in human pancreatic ductal epithelial cells.

### Authors:

R.L. Dittmar<sup>1,2</sup>; M.C. Tai<sup>1</sup>; A. Maitra<sup>1,3,4</sup>; A.M. Killary<sup>1,2</sup>; S. Sen<sup>1,2</sup>

---

Activating mutations in *KRAS* occur in over 90% of pancreatic ductal adenocarcinomas (PDAC), the most deadly cancer by organ site with a five year survival of 9%. Mutations in this “undruggable” PDAC driver gene are believed to be the initiating genetic alteration in PDAC, potentially occurring years before malignancy. *KRAS* is mutated in bona fide PDAC precursor lesions, including mucinous cystic lesions, and promotes many hallmarks of cancer, including tumor microenvironment (TME) remodeling. While *KRAS* mutations are known to alter the TME, their effect on extracellular vesicles (EVs), small membrane-bound mediators of cell-to-cell communication in TME have not been well characterized. We hypothesize that *KRAS* mutations not only alter EV content, but also affect the TME, driving cystic lesions towards PDAC development. Given that EV cargo reflects the content of the cells releasing them, EVs may provide a “snapshot” of the biology of tumor initiating cells, potentially making them circulating biomarkers for early PDAC detection.

To address this hypothesis, we profiled microRNAs (miRNAs) in EVs from a human pancreatic ductal epithelial (HPDE) cell line with wildtype *KRAS* and a cell line derived from these same cells stably expressing *KRAS*<sup>G12V</sup> that were injected into mice and formed tumors (KRAST). After isolating EVs, we profiled their miRNA content using the HTG miRNA Whole Transcriptome Assay, which simultaneously profiles 2,083 miRNAs. Using this technique, we identified 18 miRNAs significantly differentially abundant in EVs from KRAST cells v. HPDE cells with FDR < 0.1. Additionally, we isolated EVs from 22 pancreatic cyst fluid samples and profiled miRNA content. A total of 330 miRNAs were significantly differentially abundant between pre-malignant cyst fluid EVs and benign cyst fluid EVs, while a total of 923 miRNAs were significantly differentially abundant between malignant cyst fluid EVs and benign cyst fluid EVs (FDR < 0.1). Several of these miRNAs were also significantly differentially abundant in EVs from pancreatic cyst fluid samples, whose *KRAS* mutation statuses were detected either by ddPCR or targeted sequencing. We are currently doing functional studies to identify the impact of these alterations on the pancreatic ductal epithelial cell microenvironment. Understanding the effects of *KRAS* mutations on EV content and function should lead to urgently needed sensitive and specific cyst fluid biomarkers for early detection of PDAC.

## PgmNr 830: Germline sequencing of advanced prostate cancer patients in the BARCODE2 trial.

---

**Background:** The BARCODE2 trial (NCT02955082) is a European Research Council supported study investigating the response to platinum chemotherapy in men with advanced prostate cancer (PrCa) and a germline mutation in a DNA repair gene. We present the germline DNA sequencing results for 100 men who underwent genetic screening.

**Methods:** Eligible men with advanced PrCa consented to trial entry and provided a blood sample for DNA extraction and sequencing. All patients were known to have metastatic castration resistant PrCa (mCRPC) and had been treated with one or both of: Docetaxel chemotherapy and an androgen receptor targeted agent. Next generation sequencing (NGS) using a customised 115 gene panel (Agilent Technologies) was carried out on a MiSeq machine. Protein truncating variants (PTVs) in DNA repair genes by NGS were validated by Sanger sequencing. Patients found to carry a PTV were eligible to receive carboplatin upon disease progression.

**Results:** 100 patients have undergone genetic testing. The mean age of patients entering the trial was 67 (range 46-84). 22 patients (22%) carried one or more PTVs in a DNA repair gene that would qualify them for carboplatin treatment in the study: 4 carriers of a *BRCA2* variant and 3 carriers of a variant in *ALKBH3*, 2 carriers of an *ATM* variant and 2 carriers of a *PALB2* variant. One of the *ATM* variant carriers and one of the *BRCA2* variant carriers also carried a PTV in *POLQ* and 2 further carriers of the same *POLQ* variant were identified. One carrier was identified to carry a variant in each of the following genes: *MRE11A*, *PARP2*, *BLM*, *CHEK2*, *EXO1*, *LIG4*, *FANCD2*, *MSH5* and *PMS1*. Of the 21 identified PTVs, 11 are classified as pathogenic or likely pathogenic in ClinVar. There was no significant difference in the age at PrCa diagnosis between carriers and non-carriers (mean age 59 years vs 60; t-test p=0.29). There was also no difference in the presence of a family history of cancer in a first degree relative.

**Conclusion:** The initial NGS results in the BARCODE2 trial demonstrate a higher frequency of germline mutations in mCRPC patients compared with previously published data. This study is ongoing and aims to sequence 450 patients. If the frequency of germline mutations in men with advanced PrCa is confirmed to be 20% or higher, this would support the roll-out of routine genetic testing in the oncology setting to identify men who may benefit from targeted treatments such as platinum chemotherapy and PARP inhibitors.

## PgmNr 831: Genomic and immune landscape characteristics associate with improved overall survival of melanoma patients.

---

Tumor-specific indicators, such as tumor mutation burden (TMB) have been shown to affect overall survival (OS) in melanoma. Recently, pan-cancer analyses from The Cancer Genome Atlas (TCGA) discovered specific tumor immune signatures predictive of overall survival (OS), yet it is unclear how these interact with other prognostic markers, independently of immunotherapy (IT). We aimed to combine the immune landscape signatures with TMB and other prognostic markers to improve melanoma OS prediction in patients, independent of IT. We examined the whole-exome data in conjunction with the molecular, clinical and immune features from 278 metastatic melanomas from TCGA, not treated by IT, to develop an improved prognostic model of melanoma OS. Using the discovery (N = 139) and validation (N = 139) design we performed multivariate Cox proportional hazards (Cox HR) models, adjusted for age and tumor stage at primary diagnosis, to identify interaction between TMB and melanoma immune features (n=59), refining the prediction of melanoma OS. We identified 4 immune features that were significantly associated with OS in both the discovery and validation cohorts. The multivariate Cox HR models revealed that IFN- $\gamma$  response (IFN- $\gamma$  R) and macrophage regulation (MR) signatures in combination with TMB were the most significantly associated with OS ( $p = 8.80E-14$ ). After further refinement, we observed that patients with high TMB, high IFN- $\gamma$  R and high MR had significantly better OS compared to high TMB, low IFN- $\gamma$  R and low MR (HR=2.8,  $p = 3.55E-08$ ). This association was not observed in low TMB patients. We show, for the first time, that genomic (TMB) and tumor immune features are significantly associated with improved OS, independent of IT. Further analysis of patients revealed that high TMB associates with improved OS in patients with high IFN- $\gamma$  R and MR but not in low IFN- $\gamma$  R and MR. Hence, this data provides first evidence that patients with high TMB have distinct OS outcome depending on other tumor immune features. Beside the biological link between TMB and IFN- $\gamma$  and MR, our data suggest that these associations may significantly improve the current melanoma prognostic models.

## PgmNr 832: Assessment of germline structural variants in pediatric cancer survivors for cancer predisposition.

Few studies have comprehensively evaluated the prevalence and potential impact of germline structural variants (SVs) on cancer predisposition. Whole genome sequencing (WGS) studies of germline samples from cancer patients provides an opportunity to explore the currently underappreciated prevalence of germline SVs and their role in cancer predisposition.

Here we examine germline WGS data from 2,986 pediatric cancer survivors along with 344 healthy controls from the St. Jude Lifetime Cohort Study to identify germline SVs (e.g., deletions, inversions, insertions and translocations) in coding and noncoding potentially-regulatory regions of the genome associated with cancer predisposition. Secondary neoplasms were reported in 439 of these survivors allowing further assessment of genetic predisposition caused by germline SVs. We applied a copy number variant (CNV) detection algorithm CONCERTING in conjunction with three SV detection algorithms, CREST, Delly, and a novel algorithm SEASULT to identify germline SV candidates. SEASULT identifies SVs by *de novo* assembly of soft-clipped and discordant reads which improves both sensitivity and accuracy of SV analysis. Curated public polymorphic SV and CNV datasets, in addition to control WGS data, aided removal of nonpathogenic polymorphic SVs. Patient clinical and family history data and publicly available genomics data facilitated assignment of pathogenicity likelihood of the remaining SVs. Initial analysis revealed 1,017 deletion SVs in potentially-regulatory (74), exonic (230), or intronic (713) regions of a set of 1,028 cancer-related genes. Two survivors harbored deletion SVs, previously unreported, which included the 5'UTR and first exon of the gene related to their primary diagnoses (e.g., *RB1* in retinoblastoma and *WT1* in Wilms tumor). Two potentially-regulatory and one exonic *BRCA* deletion SVs were observed in survivors with a family history of breast cancer, suggesting increased likelihood of a secondary neoplasm. Other survivors displayed hemizygous loss of genes (e.g., *CDKN2AIP*, *CFHR1*, *MLH3*, *PTCH2*, and *SBDS*) that may be involved in cancer predisposition. Furthermore, preliminary analysis of germline insertion SVs revealed a 565bp insertion of *ROBO1* on chr3.p12.3 within the second exon of *NF1* on chr17q11.2 in a patient presenting with café-au-lait spots and a bilateral optic nerve glioma. These findings highlight the importance of examining germline SVs for comprehensive analysis of cancer predisposition.

## PgmNr 833: Identification of *CLDN6* as a novel tumor-promoting gene in gastric cancer.

---

In this study, we aimed to identify novel tumor-promoting drivers that would be highly expressed in gastric cancer (GC) and contribute to the worse prognosis in patients with GC. Through genome-wide screening for genes overexpressed in GC tumors compared to adjacent non-tumorous tissues and genes whose expression levels were positively correlated with worse overall survival using publicly available datasets, we identified *CLDN6* as one of the candidate genes promoting GC, particularly Lauren's intestinal subtype of GC. *CLDN6* immunoreactivity was detected in a part of Lauren's intestinal type of GC, and correlated with worse overall survival. Silencing endogenous *CLDN6* in *CLDN6*-expressing GC cell lines inhibited cell proliferation and cell migration/invasion abilities. Microarray-based comprehensive gene expression analysis revealed that inhibition of *CLDN6* induced suppression of the Hippo signaling pathway through suppressing transcription of the *YAP* gene. Our findings suggested that aberrant expression of *CLDN6* might play an important role in malignant progression of GC, particularly its intestinal type, through Hippo signaling pathway at least in part; furthermore, *CLDN6* might be a possible prognostic marker and therapeutic target in a subset of GC.

## PgmNr 834: A variational autoencoder model for accurate imputation of drug response.

### Authors:

---

Accurate imputation of drug response in large cohort is critical for the understanding of mechanisms underlying drug sensitivity and resistance. Most cancer pharmacogenomics data are obtained from preclinical studies, such as cell lines and mouse models and suffer from limitations such as small sample sizes and heterogeneity. In this study, we developed a deep variational autoencoder model followed by Elastic Net regression to predict drug response based on baseline gene expression profile. With systematic evaluation and computational benchmark, we demonstrated high accuracy rates of the prediction models that outperformed current in-silico methods [7/24 drugs with in-sample Pearson Correlation Coefficient (PCC) > 0.7 and 21/24 with PCC > 0.6] and then applied them in The Cancer Genome Atlas (TCGA) data for 33 cancer types. We found some drugs, especially those of targeted therapies, achieved the best performance when their prediction model were trained using only cell lines with solid tumor origin while some drugs, especially those with cytotoxicity, achieved the best performance when using all types of cell lines. With the TCGA multi-omics data, we found the response profile of two groups of compounds showed significantly different molecular associations, where samples sensitive to cytotoxicity compounds had an increased tumor mutation burden but such a pattern was not observed in targeted compounds. Both known mutation-drug associations (e.g., Lapatinib with HER2+, PF2341066 with MET, and genes with BRAF inhibitors) and novel associations were identified, which were further broken down to mutation clusters (hot spots). For example, FGFR3 was found sensitive to the MEK inhibitor AZD6244 with its two clusters: one on the 248-249<sup>th</sup> amino acids and the other on the 370:371:373<sup>th</sup> amino acids; and MDM4, instead of MDM2, was found most significantly associated with Nutlin-3, which is a MDM2 inhibitor. In addition, mutant tumor suppressor genes were depleted from sensitive samples to EGFR/BRAF/MEK inhibitors. A systematic screen of gene expression signatures revealed biomarkers for each drug, including significant associations between increased Tumor Inflammation Score (TIS) with RAF265 (a BRAF inhibitor), Paclitaxel, and Nutlin-3, and a significant association between decreased expression of stroma genes and Lapatinib (HER2 inhibitor) in breast cancer. Collectively, these results provided valuable insights to understand the mechanisms underlying drug response.

## PgmNr 835: Assessing a causal relationship between circulating lipids and breast cancer risk via Mendelian randomization.

### Importance

A number of epidemiological and genetic studies have attempted to determine whether levels of circulating lipids are associated with risks of various cancers, including breast cancer. If alteration of lipid levels reduced risk of breast cancer, this could present a target for disease prevention.

### Methods

We assessed a potential causal relationship between genetic variants associated with plasma lipid traits and risk for breast cancer using Mendelian randomization (MR). Data from genome-wide association studies in 210,967 subjects from the Million Veterans Project were used to construct genetic instruments for plasma lipid traits. The effect of these instruments on breast cancer risk was evaluated using genetic data from the BCAC consortium based on 137,045 breast cancer cases and 119,078 controls. We employed single-trait MR for each lipid trait (HDL, LDL, and TG), and multivariable MR accounting for correlation between lipid traits and body mass index. We also used independent associations at core HDL or LDL genes for locus-specific MR. We tested for genome-wide genetic correlation between each lipid trait and breast cancer risk using LD-score regression, and local genetic correlation using p-Hess.

## Results

We observed that a 1-SD genetically determined increase in HDL or LDL levels is associated with an increased risk for all breast cancers (HDL: OR=1.09, 95% CI=1.03-1.15,  $P=1.7\times 10^{-3}$ ; LDL: OR=1.06, 95% CI=1.02-1.12,  $P=4.7\times 10^{-3}$ ). Multivariable MR analysis, which adjusted for the effects of LDL, TG, and body mass index, further improved the strength of this observation for HDL (OR=1.07, 95% CI=1.03-1.10,  $P=8.6\times 10^{-5}$ ). We did not observe a difference in this relationship when stratified by breast tumor estrogen receptor status. In our locus-specific MR of independent associations at core HDL genes, we found locus-specific associations with breast cancer at *ABCA1*, *APOE-APOC1-APOC4-APOC2* and *CETP*; and in meta-analysis across loci (OR=1.11, 95% CI=1.06-1.16,  $P=1.5\times 10^{-6}$ ). Finally, we find evidence for local genetic correlation between lipid levels and breast cancer at the *ABO* locus.

## Conclusions

Genetically elevated plasma HDL levels appear to increase breast cancer risk. Future studies are required to understand the mechanism underlying this putative causal relationship, with the goal to develop potential therapeutic strategies aimed at altering the HDL-mediated effect on breast cancer risk.

## PgmNr 836: Neoantigen discovery workflow: Accurate prediction of immuno-oncology targets.

### Authors:

Neoantigens are peptides on the surface of cancer cells that may activate the immune system. Multiple novel therapeutic approaches involve identifying neoantigens and predicting which neoantigens can be leveraged to trigger immunity-induced tumor regression.

We present a novel method (workflow) for neoantigen discovery and prioritization using Next Generation Sequencing (NGS) data which process tumor-normal pairs of whole exome sequencing (WES) samples and tumor gene expression data. Our method considers multiple dimensions of genomic features including phasing of mutations, the influence of both somatic and germline mutations, and positions of all transcripts and mutations on start and stop codons. This Neoantigen workflow (also known as a pipeline) is a combination of tools (e.g. BWA, GATK4) and is described in Common Workflow Language (CWL). Here, individual tools are associated with Docker containers enabling both configurability of all relevant parameters and full reproducibility across an abundance of computational environments.

This neoantigen discovery workflow has been tested throughout the last two rounds (Round 2 and Round X) of the Tumor Neoantigen Selection Alliance (TESLA) Challenge organized by the Parker Institute for Cancer Immunotherapy. Within Round X, TESLA provided flow-cytometry-validated peptide-HLA sets for more than 10 patients. Our neoantigen discovery workflow detected the majority of confirmed candidates. Detailed results will soon be published by the TESLA organizers.

Accurate, reproducible, and rapid discovery of neoantigen candidates represents a foundation for personalized cancer vaccine development. Paired with a cloud environment, this Neoantigen workflow has the potential to fulfill the demands for rapid turn-around of accurate predictions within a clinically compliant environment for a large number of patients.

## PgmNr 837: Spatial characterization of tumor immune microenvironment by multiplex IF in breast ductal carcinoma in situ.

---

**Background:** Ductal carcinoma in situ (DCIS) is an abnormal proliferation of epithelial cells within the ducts of the breast, accounts of around 15% of all newly diagnosed breast cancer cases, with an estimated 60,000 patients being diagnosed in the US each year primarily due to the adoption of mammographic screening. However, the risk of invasive breast cancer or death in a patient diagnosed with pure DCIS is less than 1%. Therefore, there is significant overtreatment, with DCIS being characterized as a form of cancer. In this study, we evaluated the tumor microenvironment to quantify the composition and spatial distributions of immune phenotypes in a longitudinal cohort of primary DCIS and matched recurrent DCIS or invasive ductal carcinoma (IDC) tissues.

**Methods:** We performed multiplex immunofluorescence (mIF) using three customized immune marker panels including Checkpoint protein panel (PD-1, PD-L1, CD3, CD8, CD68 and pancytokeratin AE1/AE3), T cell panel (CD3, CD8, Granzyme B, CD45RO, FOXP3, AE1/AE3) and Myeloid panel (Arginase 1, CD68, CD11b, CD33, CD14, CD66b, AE1/AE3). Fourteen primary DCIS with seven matched DCIS (7) or IDC (7) recurrences were examined with Vectra automated quantitative pathology imaging system and inForm software (PerkinElmer).

**Results:** The density of macrophages was higher in primary DCIS samples with invasive recurrence as compared to the ones with DCIS recurrence as well as the ratio of cytotoxic T to regulatory T cells, whereas the density of monocytes was higher in primary DCIS with DCIS recurrence. There was no significant difference in other immune cell types in the primary DCIS time point. All patients had a significant decrease in macrophages from primary DCIS to recurrent DCIS, whereas an increase was observed when they recurred as IDC. Spatial analysis showed that there was a higher probability of occurrence of cytotoxic T and memory T cells around tumor cells in primary DCIS samples that had an invasive recurrence. Higher Cytotoxic T cell density was significantly associated with ER negativity in invasive recurrent samples.

**Conclusions:** Our findings shed light on the composition and distribution of immune cells as a putative predictor of DCIS to IDC progression. A subset of myeloid cells correlated with invasive

recurrence suggesting deeper investigation, including further spatial analyses, of the local immune microenvironment in larger, clinically informative cohorts is warranted.

## PgmNr 838: Longitudinal assessment of the 313-SNP based polygenic risk score for breast cancer risk prediction in a Dutch prospective cohort.

### Authors:

I.M.M. Lakeman <sup>1</sup>; J. van Rooij <sup>2</sup>; R. Ruiter <sup>3</sup>; C.J. van Asperen <sup>4</sup>; A.G. Uitterlinden <sup>2,3</sup>; P. Devilee <sup>1,5</sup>

### Affiliations:

1) Human Genetics, Leiden University Medical Centre, Leiden, Netherlands; 2) Internal Medicine, Erasmus Medical Center Rotterdam, the Netherlands; 3) Epidemiology, Erasmus Medical Center, Rotterdam, the Netherlands; 4) Clinical Genetics, Leiden University Medical Center, the Netherlands; 5) Pathology, Leiden University Medical Center, the Netherlands

### Purpose

Breast cancer associated SNPs, summarized in a Polygenic Risk Score (PRS) are presently not used to guide the appropriate starting age for breast cancer screening. At this moment the most predictive PRS for breast cancer is based on 313 SNPs. The aim of this study is to validate the performance of the 313-SNP PRS in a Dutch prospective cohort and explore the utility of risk stratified screening.

### Materials and Methods

We included women from the Rotterdam study, a Dutch prospective cohort study started in 1989 with >70% response rate. Phenotypic information was available with 25 years of follow-up. Genotyping was performed with the Illumina 550k and 610k array for 6670 women aged 45 years or older. After imputation with the HRC1.1 and 1KG reference panels, the standardized 313-SNP-based PRS (sPRS), per 1 standard deviation (SD) in controls from the Breast Cancer Association Consortium (BCAC) was calculated. Cox regression analysis, adjusted for birth year and age at inclusion, was performed to estimate the association between the sPRS and incident breast cancer risk.

### Results

Of all included women with an average age of 66, 145 had prevalent breast cancer and 323 developed incident breast cancer during follow-up. These women had a higher sPRS, mean 0.45 (SD=1.06) for cases with in situ carcinoma (N=37) and 0.51 (SD=1.06) for cases with invasive carcinoma (N=431) compared to 0 (SD=1.01) in all 6202 controls, and 0.05 (SD=0.98) in 842 of these controls with other tumors than breast cancer. Breast cancer risk increased by sPRS with an Hazard Ratio (HR) per SD=1.56, 95%CI [1.40-1.73], and compared with the middle sPRS quintile, the lowest quintile had an HR of 0.57, 95%CI[0.38-0.87] and the highest quintile an HR of 1.81, 95%CI[1.32-2.50]. We noticed a slightly smaller effect of the sPRS for in situ compared to invasive breast cancer risk only (HR=1.45, 95%CI[1.02-2.01], and 1.58, 95%CI[1.41-1.76], respectively).

### Discussion and conclusion

The 313-SNP PRS can be used for breast cancer risk stratification in the Dutch population and seems specific for breast tumors and not for other tumor types. Further analyses are being performed that include other breast cancer risk factors (i.e., reproductive and lifestyle factors), which are available for the majority of the included women. Furthermore, the added value of the 313-SNP PRS on long- and short-term breast cancer risk prediction and screening stratification will be explored.

## PgmNr 839: Genomic elucidation on the roles of HPK1 in inflammation and immune microenvironment during pancreatic cancer development.

---

Pancreatic ductal adenocarcinoma (PDAC) is one of the most common pancreatic malignancies and it is the third most lethal cancer among all cancers. It was believed that genetic factors (e.g., Kras mutation) combined with nongenetic events (e.g., inflammation and pancreatitis) were responsible for PDAC development. Heterogeneity and immunosuppressive nature of tumor microenvironment are among the leading contributors to the lack of effective treatment for PDAC. Recent studies demonstrated that a loss function of hematopoietic progenitor kinase 1 (HPK1) is correlated with PDAC progression and tumor immunosuppressive status. To elucidate the role of HPK1 in inflammation and immune microenvironment during pancreatic cancer development, we carried out comprehensive genomic and epigenomic studies using: **(1) mouse pancreatic cancer cell lines bearing the mutations of K-RAS only, K-RAS/p53 or K-RAS/p53 plus HPK1 non-functional mutation, respectively; (2) transgenic (TG) mice bearing HPK1 overexpression in three different genetic constructs identical to the above cell lines; (3) a human PDAC tumor tissue.** Our RNA-seq results from mouse cancer cell lines identified 1,459 significant differentially expressed genes (DEGs) in response to recovered active HPK1 level. KEGG pathway analysis on the DEGs indicated an enrichment in cell cycle, cell division and DNA repair. TG mouse inflammation models were utilized to study the role of HPK1 in different stages of chronic pancreatitis induced pancreatic cancer development. RNA-seq results based on TG mouse models identified 392 DEGs in response to HPK1 overexpression in the early stage, and a KEGG pathway analysis indicated that these DEGs were enriched in fatty acid metabolism, p53 pathway and IL-17 pathway. We are currently performing 10X Genomics scRNA-seq, scATAC-seq and scVDJ-seq on human PDAC sample in order to characterize the patient pancreatic tumor cell population heterogeneity and the immunosuppressive microenvironment, as well as a comprehensive bioinformatics data analysis integrating the genomic data derived from all cell lines, TG model and patient sample. The outcome of this study will allow us to gain a deep insight into the roles of HPK1 in pancreatic cancer development. It may eventually lead to identification of novel diagnostic and prognostic biomarkers, development of new therapeutic targets and better treatment strategy for pancreatic cancer.

## PgmNr 840: Prevalence of germline mutations in expanded cancer predisposing genes in patients with sporadic renal cell cancer.

### Authors:

R. Metpally <sup>1</sup>; S... Krishnamurthy <sup>1</sup>; D.J. Carey <sup>1</sup>; H. Williams <sup>2</sup>; Regeneron Genetics Center

**Purpose:** Hereditary renal cancer accounts for up to 5% of all renal cell carcinoma (RCC) cases. Germline testing is recommended in patient with early onset (age  $\leq 46$  y) and family history of the disease. Recent data from Nordic twin studies and Iceland reported that familial contribution is between 38 to 58% suggesting that many more RCC predisposing genes are yet to be discovered. To address this, we evaluated the prevalence of germline mutations in 450 plausible cancer predisposing genes (CPGs) in RCC. **Methods:** We reviewed the records of all patients (PT) with sporadic RCC (no family history, n=511) within our institutional MyCode-DiscovEHR cohort (n=92,455). Corresponding Whole Exome Sequencing data was analyzed, and variant pathogenicity accessed employing ACMG guidelines for all 450 CPGs. **Results:** In our cohort, we had 387 patients with clear cell (ccRCC), 74 papillary (pRCC), 27 chromophobe (chRCC), 11 mixed and 12 other RCCs. The mean age of onset of RCC was 61.65 years (SD, 11.24). One hundred and forty-seven (**29%**) of 511 patients with sporadic RCC cancer had either predicted loss-of-function variants (pLOF) or ClinVar pathogenic or likely pathogenic (CP/LP;  $\geq 1$  gold star review status) germline mutation. Germline alterations were found in 99 of 450 cancer predisposing genes tested. Germline mutations accounted for 27.4%, 35.1%, 25.9%, 27.3%, 41.7% in ccRCC, pRCC, chRCC, mixed, and other RCC respectively. The top altered genes include *CHEK2* (5.4%), *MUTYH* (5.4%), *SERPINA1* (4%), *ATM* (3.4%), *PDE11A* (3.4%), *PYGM* (3.4%), *TYR* (2.7%), *TYRP1* (2.7%), *BRCA2* (2%) and *COL4A3* (2%). 28 out of 147 patients (19%) had germline alteration in more than one CPG. 5.2% of patients also had homozygous or compound heterozygous mutations (Cys282Tyr, His63Asp, Ser65Cys) in homeostatic iron regulator (*HFE*) gene associated with hemochromatosis known to increase cancer risk. We observed 6% of patients with copy number variation in these CPGs. We found no difference in the age of onset among germline positive vs negative sporadic RCC patients. **Conclusion:** In our cohort, germline mutations were identified in 99 CPGs, well beyond the 18 genes currently used for RCC germline testing. Overall 37% (29% pLOF + CP/LP; 5.2% *HFE*; 6% CNVs) of sporadic RCCs patients have germline variations. Pending functional and clinical validation, these genes may represent a more updated landscape of RCC predisposing genes

## PgmNr 841: From biobanking to precision medicine.

The Estonian Biobank was founded in 2000 as a volunteer-based biobank, and now, 19 years later, it contains a collection of health and genetics data of close to 200 000 individuals, approximately 20% of the adult population of the country. The Human Genes Research Act (passed in 2000) allows regular updating of data through linking to national registries, enabling long-term follow-up of the cohort and re-contacting biobank participants. A nationwide technical infrastructure (X-road) for the secure electronic exchange of medical data has also been established and is maintained by the state. This allows creating disease trajectories on all participants from birth, based on information stored in the medical systems, including ICD-10 diagnoses, prescriptions, lab tests and electronic medical records. To date, 152 000 individuals have been genotyped with Illumina's Global Screening Array, and the whole genomes of 3,000 individuals and whole exomes of 2500 individuals have been sequenced. This serves as a population-based imputation reference. Using these data, I will report 3 pilot projects where personalized medicine is implemented in Estonia: familiar hypercholesterolemia (FH), breast cancer and drug response. Using a **"genetics first approach"**, we discovered many new FH patients in the biobank based on LoF variants only not detected by the medical system and for over 50% of the cases the treatment was changed after cardiology checkup. We are conducting several pilot projects in order to work out the best ways to return health related research data back to the individuals at the biobank. For that purpose, we have developed decision support tools for several major diseases, including risk estimates based on **polygenic risks scores (PRS)** for breast cancer and pharmacogenomics based recommendations based on CPIC. Today, over 2,000 participants of the Estonian Biobank have received genetics-based counselling and the feedback has been very positive based on questionnaires collected before, right after and 6 months post-counselling. Validation studies using PRS for coronary heart disease and breast cancer are ongoing in the two largest hospitals in Estonia. As all these data will be transferred to the medical system within the next few years, personalized medicine as 4P medicine (personalized, predictive, preventive and participatory) has reached the point of no return in Estonia.

# PgmNr 842: Enrichment of rare germline variants in DNA repair and cell cycle genes in chronic lymphocytic leukemia.

## Background

Chronic lymphocytic leukemia (CLL) is among the most heritable cancers, with 60% of disease risk genetically determined. However, 75% of the genetic heritability of CLL remains unexplained by GWAS and linkage studies. Previously, we identified ATM as the first CLL risk gene. Here we leverage a deep-learning-based germline variant calling algorithm to explore germline mutational enrichment in DNA repair and cell cycle genes in CLL.

## Methods

A case-control analysis was conducted using gene-based mutational enrichment analysis of 50 established cancer predisposition DNA repair and cell cycle genes (DRG). Germline variants in cases and controls were called and filtered using identical methods. In the discovery phase, a total of 569 non-Finnish European CLL cases and 8,608 ancestry-matched, unselected controls were compared for enrichment in pathogenic variants. An FDR correction was applied and genes with a q-value < 0.1 were considered significant. Variants were also called in an independent cohort of 314 Spanish CLL patients for which ancestry-matched controls are in process.

## Results

Our analysis identified CHEK2 pathogenic variants as significantly enriched in CLL cases compared to controls. Enrichment was observed in both CHEK2 LOF alterations (cases: 2.6%, controls: 0.7%) and the separately assessed low-penetrance (LP) allele c.599T>C (cases: 2.1%, controls 0.3%). Enrichment remained significant after removal of the known founder variant 1100delC. Overall, CLL patients were 2.1-15.6 times more likely to carry CHEK2 pathogenic variants compared to controls (LOF: OR = 3.8, 95%CI = 2.1-6.8, q-value<0.01; LP: OR = 7.7, 95%CI = 3.6-15.6, q-value < 0.001). In addition, 4 CHEK2 LOF variants were observed in the Spanish cohort (1.3%), although no LP variants.

## Conclusion

Our analysis of a large CLL discovery cohort using a high-sensitivity variant calling algorithm supports CHEK2 as a potentially novel CLL predisposition gene that may explain a portion of the missing monogenic heritability of CLL. In addition, this study highlights the DNA repair and cell cycle regulation pathways as potential drivers of CLL susceptibility.

## PgmNr 843: Identifying differential gene induction responsible for varying cisplatin response by bridging non-cancer and cancer cell models.

### Authors:

L. Mortensen; A.L. Stark

[View Session](#) [Add to Schedule](#)

**Affiliation:** University of Notre Dame, Notre Dame, IN.

---

Cisplatin is a widely available chemotherapeutic drug, shown to be successful in combatting various types of cancer through the formation of platinum adducts, contorting DNA. However, chemotherapeutic resistance is a major complication in platinum-based chemotherapies and causes many patients to not be effectively treated. It remains unclear why certain patients are intrinsically resistant and non-responsive to the same cisplatin treatment that other patients are sensitive to. We propose that differences in gene regulation cause the observed differential response to cisplatin treatment. This project compares protein expression patterns observed in cisplatin resistant and sensitive HapMap lymphoblastoid cell lines (LCLs) to the expression signatures generated in multiple cancer models. Beginning with the LCL protein expression at 2, 6, and 12 hours post 5 $\mu$ M cisplatin treatment, genes of interest were selected by analyzing the sign of the slope observed in expression profiles of 482 transcription factors and cell signaling molecules from 6-12 hours after treatment. The 95 genes identified with differential expression slopes were then classified based on their functional role in the cell, where eight proteins involved in cisplatin's canonical mechanisms of action (apoptosis and DNA damage) were selected for study in cancer models. Expression for selected genes (*APTX*, *ATF2*, *BCL2*, *CORO1A*, *HDAC2*, *NF- $\kappa$ B1*, *SMC1A*, and *STAT3*) was quantified at 6, 12, 24, and 48 hours post treatment with 5 $\mu$ M cisplatin in cancer cell models. Comparing the expression induction patterns observed in LCLs to the cancer cell models will yield both global and cancer type-specific molecular insights into contributors to cisplatin resistance mechanisms. Utilizing the existing LCL data as an intrinsic genetic marker for cisplatin sensitivity or resistance, we have been able to classify selected genes as contributing to cisplatin resistance or sensitivity mechanisms. This project's identification of resistance-contributing factors among different cancer models will enhance understanding of the molecular and genomic complexities of cisplatin resistance. This allows for the unique translational potential to modulate those candidate genes contributing to resistance in order to sensitize cancer cells to cisplatin. Because cisplatin resistance is a major problem, being able to sensitize resistant patients would be enormously impactful in bettering patient outcomes and the lives of those affected.

The identification of heritable factors that predict clinical outcome of prostate cancer (PrCa) can both improve early diagnosis of potentially aggressive and lethal cases, and reduce overtreatment of indolent disease. However, to date, few heritable genetic risk factors for PrCa have been demonstrated to be specifically associated with aggressive disease.

Here, we report a case-case study that compared the prevalence of germline pathogenic variants in 787 men with aggressive PrCa and 769 men with non-aggressive PrCa. Since most of the genes currently identified as PrCa susceptibility genes are also involved in, or are putatively associated with, predisposition to breast and/or ovarian cancer and Lynch syndrome, we designed a panel targeting *ATM*, *BARD1*, *BRCA1*, *BRCA2*, *BRIP1*, *CDH1*, *CHEK2*, *FANCM*, *HOXB13*, *MLH1*, *MRE11A*, *MSH2*, *MSH6*, *MUTYH*, *NBN*, *NF1*, *PALB2*, *PMS2*, *PTEN*, *RAD50*, *RAD51C*, *RAD51D*, *RECQL*, *RNASEL*, *STK11* and *TP53*. Our analysis focused on rare genetic variants predicted to lead to loss of function and/or classified as pathogenic/likely pathogenic (P/LP) in ClinVar.

We observed 94 P/LP variants in 88/787 (11.2%) men with aggressive PrCa and 80 P/LP variants in 73/769 (9.5%) men with non-aggressive PrCa (Fisher's exact test  $P=0.28$ ). The prevalence of *BRCA2* P/LP variants in men with aggressive PrCa (20/787, 2.5%) exceeded that observed in men with non-aggressive PrCa (4/769, 0.5%) ( $P=0.001$ ). One man in each group carried two P/LP *BRCA2* variants. Other genes in which the prevalence of P/LP variants was higher in men with aggressive disease included *ATM* (11 (1.4%) men with aggressive PrCa, and five (0.7%) men with non-aggressive PrCa, respectively,  $P=0.21$ ), *CHEK2* (10 (1.3%) and five (0.7%) men, respectively,  $P=0.30$ ), and *BRCA1* (five (0.6%) and two (0.3%) men, respectively,  $P=0.45$ ).

Our results support previous reports that rare P/LP germline variants are enriched in men with aggressive PrCa compared with men with non-aggressive disease. Further and extensive internationally coordinated studies are required to confidently classify rare pathogenic variants

identified in panel-testing. Evidence is accumulating in relation to genetic information about *ATM* in the clinical management of men with prostate cancer but more data is required to interpret variation in the many other genes currently included on commercial tests for which there is currently an insufficient evidence-base for clinical translation.

## PgmNr 845: Targeting DDI2 to potentiate proteasome inhibitor-induced cell death in triple negative breast cancer cells.

---

Despite widespread proteasome addiction in cancer cells, proteasome inhibitors (PIs) have failed to effectively treat most types of cancer. One explanation for this failure is utilization of the NRF1-mediated proteasome bounce-back response, a compensatory cellular mechanism that occurs during proteasome inhibition to evade PI-induced cell death. The response requires the activation and nuclear translocation of a transcription factor, NRF1 (alias for NFE2L1), which is proteolytically-cleaved into its active form by a protease DDI2. During proteasome inhibition, NRF1 promotes the transcriptional synthesis of new, uninhibited proteasomes via the activation of proteasome-related genes to relieve PI-induced cell stress and prevent apoptosis. The goal of this study was to evaluate DDI2 as a therapeutic target to inhibit the NRF1-mediated proteasome bounce-back response to potentiate PI-induced cell death of a triple negative breast cancer (TNBC) cell line *in vitro*. Pulse-chase experiments using a p97 inhibitor, cycloheximide, and an FDA-approved PI, Carfilzomib (CFZ), were followed by subcellular fractionation and western blot to compare NRF1 retrotranslocation from the ER membrane to the nucleus and processing between wild-type and *DDI2* knock-out NIH 3T3 fibroblasts. Cell viability and caspase-3 assays were used to compare the sensitivity of DDI2-deficient and DDI2-competent TNBC cells to CFZ. CFZ treatment of TNBC cells co-expressing wild-type and protease-dead DDI2 (p.D252A) was followed by western blot and cell death assays to analyze NRF1 processing and CFZ sensitivity, respectively. *DDI2* knock-out in NIH 3T3 fibroblasts impairs NRF1 processing to the active form, but not NRF1 translocation to the nucleus. DDI2-deficient TNBC cells are more sensitive to CFZ-induced cell death. Protease-dead DDI2 behaves in a dominant-negative fashion in the TNBC cells to impair NRF1 processing and potentiate CFZ-induced cell death. Our results show that depletion of DDI2 or loss of its protease activity increases the sensitivity of TNBC cells to PI-induced cell death *in vitro*. Previous attempts at using PIs alone or in combination with other cancer therapeutics have failed to effectively treat most types of cancer. A combinational approach using a DDI2 protease inhibitor with CFZ or other FDA-approved PIs may expand the repertoire of cancer types in which PIs can effectively kill cancer cells to improve patient outcomes.

## PgmNr 846: Prostate cancer risks for male *BRCA1* and *BRCA2* mutation carriers: Results from the prospective EMBRACE cohort study.

---

**Background:** *BRCA1* and *BRCA2* mutations have been associated with prostate cancer (PCa) risk but a wide range of risk estimates has been reported, based mostly on retrospective studies. Previous absolute risk estimates from retrospective studies may not be widely applicable today due to the rapid rise in population PCa incidence with the increased use of the PSA test.

**Aim:** To provide prospective estimates of the relative and absolute risks of PCa associated with *BRCA1/2* mutations.

**Material and Methods:** EMBRACE is a prospective cohort study of *BRCA1* and *BRCA2* mutation carriers identified through clinical genetics centres in the UK and Republic of Ireland since 1998. We followed the unaffected male *BRCA1* (N=376) and *BRCA2* (N=447) mutation carriers to estimate age-specific incidences, standardised incidence ratios (SIRs) relative to population incidences, and absolute risks of developing PCa. We also assessed risk modification by family history and mutation location, and the risks of high- and low-grade PCa.

**Results:** Sixteen *BRCA1* and 26 *BRCA2* mutation carriers were diagnosed with PCa during a median follow-up of 5.6 years. *BRCA2* mutation carriers had a SIR of 4.45 (95% confidence interval [CI] 2.99-6.61), and absolute risk of PCa of 60% (95% CI 43%-78%) by age 85. For *BRCA1* mutation carriers, the overall SIR was 2.35 (95% CI 1.43-3.88), with higher SIR at ages <65 (SIR=3.57, 95% CI 1.68-7.58), and absolute risk of 29% (95% CI 17%-45%) by age 85. However, the *BRCA1* SIR was not consistently statistically significant in sensitivity analyses that assessed potential screening effects. The PCa risks for *BRCA2* mutation carriers increased with the number of first or second degree relatives diagnosed with PCa (hazard ratio [HR]=1.68, 95% CI 0.99-2.85). Mutations in the ovarian cancer cluster region of *BRCA2* (c.2831-c.6401) showed weaker association with PCa risk (HR=0.37, 95% CI 0.14-0.96) compared to mutations outside this region. For *BRCA2* mutation carriers, there was

a stronger association with Gleason score  $\geq 7$  (SIR=5.07, 95% CI 3.20-8.02) than Gleason score  $\leq 6$  PCa (SIR=3.03, 95% CI 1.24-7.44).

**Conclusion:** The results confirm the high risk of aggressive PCa for *BRCA2* mutation carriers, and give some support for a weaker association in *BRCA1* mutation carriers, particularly at younger ages. The absolute risk estimates will be informative for the development of screening programs to facilitate early detection of PCa for male *BRCA1* and *BRCA2* mutation carriers.

## PgmNr 847: Identification of drug-interacted non-coding somatic mutations by pan-cancer analysis.

### Authors:

---

It's a valuable topic and challenge to access a detailed treatment guideline for precision medicine, a detailed biomarker panel to seek optimal treatment for individuals. Great efforts from genomics to proteomics have developed lots of biomarkers, but there are still few projects talking about the non-coding somatic mutations, the important part deciding tumor heterogeneity, may cause drug resistance or sensitivity in indirect ways. Here we introduce a strategy to identify drug-interacted non-coding somatic mutations with clinical information and genomics data supplied by TCGA. For each mutation-drug pairs, patients are divided into four groups by they used drug or not and with or without this mutation, then log-rank test are calculated in pairs. we mainly focus on these mutation-drug pairs like: mutation has no effect in non-therapy groups but is significant prognostic in therapied groups while durg is significant effective in patients without mutation but no effect in patients with mutation groups. We calculate trans-eQTL effect of these mutations with corresponding drugs' related genes supplied by drugbank database. These drug-interacted mutations are much more likely to cause abnormal expression of drug related genes than those negative results. These mutations mainly cause drugs' enzymes and transporter overexpression and lead to drug resistance instead of drug's target genes. Cellline data from GDSC also proved the expression of enzymes and transporter genes are more likely to be correlated with IC50 levels than drug's targets. PPI network analysis results suggests the more distant interaction genes number may cause these drugs' enzymes and transporter genes are more sensitive to the global change in tumor cells. Doxorubicin's related enzyme *NDUFS7* suffer the most number of mutations affected. Most of these mutations which cause *NDUFS7* overexpression will lead to drug resistance. But only half of these mutations which cause *NDUFS7* low expression will lead to drug sensitivity. It's supposed to be some compensation mechanism exists. Meanwhile, we found the expression balance between *CYP2D6* and *CYP2C9* will influence the drug sensitivity of Tamoxifen while *CYP2C9* is just the one target of Anastrozole, thus the combination of these two drug is proved to have the greast effect than single one. Our work is the first to explore the relations between non-coding somatic mutation and cancer drug. Our findings may provide some guidance to clinical medication.

## **PgmNr 848: *Ex vivo* drug screening and genomic profiling to guide individualized treatments for children with relapsed or refractory solid tumors and leukemias.**

### **Background**

The implementation of precision medicine in pediatric cancers faces unique challenges. Pediatric cancers are fundamentally different from adults with lower frequencies of genetic mutations and fewer options for targeted therapies. The ultimate goal of this study was to evaluate feasibility of personalized treatment options based on *ex vivo* drug screening and genetic testing for pediatric patients with recurrent and/or refractory cancers.

### **Methods**

In this pilot study, four patients with recurrent cancers have been enrolled to date. The functional drug screening test (DST) panel encompassed 40 formulary drugs frequently used at Nicklaus Children's hospital and 47 non-formulary drugs approved by FDA for cancer treatment as well as drugs from phase III and IV clinical trials. Drug sensitivity score (DSS) was calculated for each drug based on cancer cells' response. DST results were then combined with results from the genetic screen in an attempt to match actionable mutations with selective targeted therapies.

### **Results and discussion**

Fresh tumor samples from four patients with recurrent acute myeloid leukemia, recurrent osteosarcoma and recurrent sclerosing spindle cell rhabdomyosarcoma were obtained and tested. Genetic testing alone did not provide enough information to guide treatment because of the lack of drug resistance or sensitivity information in publicly available databases and scientific literature. In addition, turnaround time on genetic testing did not allow results to be used in a timely manner. In contrast, *ex vivo* DST returned between 10 to 30 treatment options for each patient. Two patients treated on protocols guided by DST responded or currently show stable disease. Remarkably, DST provided valuable information to the oncologists on drug dosing and treatments that may not be effective, allowing them to avoid these selections. Despite the limitations of *ex vivo* DST and challenges in implementation, it remains a very promising strategy for patients with refractory and recurrent cancers for which physicians are often guessing what the most appropriate treatment should be.

## PgmNr 849: Longitudinal tracing of TNBC tumors reveals distinct patterns of response: Molecular profiling results from randomized Phase II clinical trial (ARTEMIS; NCT02276443).

### Authors:

S. Seth <sup>1</sup>; L. Guo <sup>1</sup>; G. Rauch <sup>1</sup>; B. Adrada <sup>1</sup>; H. Piwnica-Worms <sup>1</sup>; A. Thompson <sup>2</sup>; E. Mittendorf <sup>3</sup>; J. Litton <sup>1</sup>; W. Symmans <sup>1</sup>; G. Draetta <sup>1</sup>; A. Futreal <sup>1</sup>; S. Moulder <sup>1</sup>; J. Chang <sup>4</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) The University of Texas MD Anderson Cancer Center Houston, TX; 2) Baylor College of Medicine Houston, TX; 3) Dana-Farber/Brigham and Women's Cancer Center Boston, MA; 4) The University of Texas Health Science Center, Houston, TX

**Background:** The heterogeneity of TNBC results in varied responses to NAST: 30-40% of patients (pts) have pathologic complete response (pCR) with excellent prognosis. Those with residual disease, have a much higher risk of recurrence. Longitudinal profiling assesses biologic response to NAST and mechanisms of resistance. **Methods:** Pts with stage I-III TNBC began a planned 4 cycles of Adriamycin-based chemo (AC). Biopsies were performed pre (mandatory) and post (optional) AC. Volumetric change by ultrasound (VUS) at completion of AC (or progression) was calculated. Pts with sensitive disease received subsequent taxane-based (T) therapy. Pts with insensitive disease were offered phase II trials. Pathologic response was assessed at surgical resection in 47 pts. Matched samples, pre and post AC (N = 48 pts) underwent transcriptomic and genomic profiling. Samples were classified into six previously identified ARTEMIS subtypes of TNBC (ART-Type). Immune deconvolution and estimation was performed using RNA-Seq profiles. Differential pathway-level analysis was performed comparing pre and post AC samples. **Results:** There was heterogeneity in response to AC with 4 predominate patterns of biologic response (Table). In 48% of cases the ART-Type of the tumor switched after AC, with androgen receptor like (LAR) and immune modulatory (IM) showing greatest stability. Tumors with enrichment in EMT or those with no significant dysregulation after AC (Groups C + D) were associated with less immune modulation and lower rates of pCR compared to those with depleted EMT (A and B) (8.7% vs 45.8%,  $p = 0.0078$ ). **Conclusions:** Molecular profiling of longitudinal TNBC samples reveals distinct response patterns in tumors and their micro-environments upon treatment with AC. These patterns were indicative of pathologic response in this cohort; however, they require validation in a separate cohort.

Biologic Response Class (n = 48)	Enriched Hallmark Pathways	Depleted Hallmark Pathways	Pathologic Response pCR/total (n = 47)	% pCR (p-value)
A	Heme metabolism Basophil/Neutrophil lineage (immune deconv.)	EMT, MYC, G2M checkpoint	7/18	38.9% (0.19)
B		EMT	4/6	66.7% (0.04)

C	No significant change	No significant change	2/17	11.8% (0.09)
D	EMT, Inflammatory response, IL6_JAK_STAT3, Allograft rejection, Angiogenesis, Coagulation	MYC, G2M checkpoint, E2F	0/6	0.0% (0.16)
total			13/47	27.7%

## PgmNr 850: The ORIEN Avatar Program: Building a massive oncology health data and genomics resource through collaborative partnership.

Genomic oncology has a growing but largely unrealized capacity to transform research, drug and diagnostics development, and patient care. To fully realize this potential there is need to develop a data resource containing tumor and germline genomic information, medical histories, and outcomes for large numbers of past and present cancer patients. Such resource would foster basic research, facilitate drug trials for agents targeting rare markers, and usher in the era of artificial-intelligence-enabled predictive medicine. Building such a resource at scale has been hindered by a variety of operational, institutional, and contractual barriers, which we have overcome through ORIEN, the Oncology Research Information Exchange Network. ORIEN is an alliance of 19 U.S.-based cancer centers based on the principles of Collaboration, Inclusiveness, Data accessibility, and Partnerships. Under a universal protocol, patients are consented for a longitudinal, prospective study, providing clinical information and tissue specimen, consenting to data sharing, and enabling proactive matching to clinical trials based on molecular profile during their lifetime in the ORIEN Avatar program. To date, over 215,000 patients have been consented. Molecular profiling funded by a precompetitive consortium of pharmaceutical companies is performed using next generation sequencing to generate deep exome data of each patient's tumor and matched constitutional DNA as well as whole transcriptome tumor RNA data. Molecular data, as well as health and demographic information, are collected and stored uniformly across the network. As of 2019, over 9,600 patients have been profiled by NGS. M2Gen, the coordinating center integrates clinical, molecular and patient reported data. All data storage and management follow IRB, CAP, CLIA, and HIPAA regulatory guidelines. This data warehouse is proactively queried as emerging therapies or clinical trials become available, and to provide evidence-based decision support at point-of-care. De-identified data is made available for ORIEN members and for participating pharmaceutical companies for collaborative research studies. In addition, ORIEN Avatar can create *in silico* patient communities to identify patients with similar molecular and clinical profile for study enrollment and to permit recontact for potential trial enrollment. Thus, the ORIEN Alliance constitute a vast infrastructure and resource for genomic oncology, to the benefit of all stakeholders.

## PgmNr 851: Pan-cancer pharmacogenetics: Targeted sequencing panels or exome sequencing?

Understanding the genetic background of cancer is essential to enhance personalized cancer therapy. Various knowledgebases are available, describing the potential therapeutic consequences of genomic mutations. Pharmacogenetic information in these knowledgebases shows limited overlap and thus seems complementary to each other. In this study, five of these knowledgebases: The Cancer Genome Interpreter, Database of Evidence for Precision Oncology, the Jackson Laboratory Clinical Knowledgebase, the Precision Oncology Knowledgebase, and the Clinical Interpretations of Variants in Cancer, were aggregated in one meta-knowledgebase containing 8326 pharmacogenetic interactions with 3132 genomic mutations. Approximately 86% of the variants are described in just one of the five knowledgebases. Only 355 of these mutations were also discovered as driver mutations in the Pan-Cancer Atlas. Nine contemporary pan-cancer targeted sequencing panels: The Ion AmpliSeq Comprehensive Cancer Panel, the xGen Pan-Cancer Panel v2.4, the TrueSight Oncology 500 panel, the QIAseq Targeted Human Comprehensive Cancer Panel, the AVENIO ctDNA Targeted Kit, the AVENIO ctDNA Expanded Kit, the AVENIO ctDNA Surveillance Kit, the FoundationOne CDx panel and FoundationOne Liquid panel, were compared with the meta-knowledgebase and the genomic mutations in the Pan-Cancer Atlas. The xGen Exome Research Panel, representative for exome sequencing, was also included in the analysis. Overall, the xGen Exome Research Panel outperforms cancer-specific targeted sequencing panels in terms of analyzed genes, clinically relevant cancer mutations, cancer fusion genes, and pharmacogenetic interactions. From the cancer-specific targeted sequencing panels, the xGen Pan-Cancer Panel v2.4, the TrueSight Oncology 500 panel, the Ion AmpliSeq Comprehensive Cancer Panel, the QIAseq Targeted Human Comprehensive Cancer Panel, and the FoundationOne CDx panel cover about the same number of clinical cancer variants and determine a consensus set of pharmacogenetic interactions. Unfortunately, these panels determine virtually none of the known cancer gene fusions. The other panels, optimized for liquid biopsies, target only a subset of pharmacogenetic interactions. These results provide insight into the relevance of the panels considering current pharmacogenetic knowledge on cancer.

## PgmNr 852: Differential responsiveness to BRAF inhibitors in melanoma.

---

Cutaneous melanoma is an aggressive disease representing one of the leading causes of mortality related to human cancers worldwide. In the recent years, major advances have been made in the clinical management of melanoma patients carrying BRAF mutations with the adoption of two BRAF specific inhibitors. The correct identification of cancer driving mutations is of paramount importance in cancer diagnostics as this allows the appropriate selection of targeted treatments and implementation of personalized therapies. To date, several methods are used in diagnostics to identify clinically relevant mutations. These methods include Sanger sequencing, immunohistochemistry, mutation-specific real-time polymerase chain reaction (q-PCR) and next generation sequencing (NGS) technologies. Of note, BRAF mutation is usually detected at the DNA level, while BRAF expression is generally not assessed prior to target treatment selection. When performing RNA-seq and Sanger sequencing on 15 melanoma cell lines, we found discordance between the results obtained by the two methods for three of the cell lines analyzed, specifically, these three cell lines showed a BRAF V600E mutation by Sanger sequencing but the mutation was not detected by RNA-seq. This prompted us to investigate whether this was due to a differential expression of BRAF WT and V600E alleles and whether these cell lines showed a different responsiveness to BRAF inhibitors as compared to the concordant WT and V600E mutant cell lines. Here we aimed at assessing whether a lower overall BRAF mRNA expression may correlate with a lower responsiveness to BRAF inhibitors. To our knowledge this question has not been previously investigated.

We found that three cell lines whose mutation assignment was discordant between the DNA and RNA level and that express very low level of BRAF mRNA respond less to BRAF V600E specific inhibitors. These finding should be validated in additional studies with cohort of a bigger size and employing tumor tissues rather than cell lines.

## PgmNr 853: Clinical relevance of *TP53* hotspot mutations in high-grade serous ovarian cancers.

### Authors:

M. Tuna <sup>1,2</sup>; Z. Ju <sup>3</sup>; K. Yoshihara <sup>4</sup>; C.I. Amos <sup>2</sup>; J.L. Tanyi <sup>5</sup>; G.B. Mills <sup>6,7,8</sup>

---

**Background:** Mutation of *TP53* is the most frequent genetic alteration in high-grade serous ovarian cancers (HGSOC). The impact of hot spot mutations of *TP53* and protein levels on patient outcomes in HGSOC has not been fully elucidated. In this study we aimed to assess clinical relevance of hot spot mutations of *TP53*. **Methods:** The study population (n= 791) comprised of HGSOC samples with *TP53* mutation from The Cancer Genome Atlas and other publicly available data. RPPA data was retrieved from MD Anderson TCPA portal, and clinical data from XENA. Univariate cox proportional hazards regression analysis was used to select variables that were correlated with survival time, and t-test was used to select differentially expressed proteins between selected groups. **Results:** We assessed the effects of different types of *TP53* mutations based on location, oncogenic function, type of mutation (missense, nonsense, frame shift, splice site, and indel) and individual hotspot mutations on patient outcomes in HGSOC. Only hotspot mutations were associated with patient characteristics and outcomes. Three hotspot mutations; G266, Y163C and R282 both alone and in aggregate were associated with a worsened overall (OS) and recurrence-free survival (RFS) compared with other hotspot mutations (HR = 0.21;  $p < 0.0001$  and HR = 0.41;  $p = 0.001$ ), other non-hotspot missense mutations (HR = 0.57;  $p < 0.0001$  and HR = 0.70;  $p = 0.008$ ), and all other mutations (HR = 0.53;  $p < 0.0001$  and HR = 0.67;  $p = 0.001$ ). Specific hotspot mutations were associated with different protein expression patterns consistent with different functions. **Conclusions:** This study provides evidence that individual *TP53* hotspot mutations have different impact on HGSOC patient outcomes and potentially *TP53* function. Thus assessment of the status of particular *TP53* aberrations could influence response to therapy, and selection of therapeutic agents.

## PgmNr 854: Functional multi-omic profiling identifies Aurora kinase inhibition as a therapeutic strategy in *RIT1*-mutant lung adenocarcinoma.

---

Treatment of lung cancer is evolving from standard cytotoxic to personalized treatment based on the molecular alterations unique to each patient's tumor. In our recent work with TCGA and others, we identified somatic mutations in the gene encoding the RAS-related small GTPase, *RIT1*, in lung adenocarcinomas. In addition, somatic *RIT1* mutations have also been identified in myeloid malignancies and germline *RIT1* mutations are found in the developmental "RAS-opathy," Noonan syndrome. In all these diseases, *RIT1* mutations are mutually-exclusive with other RAS/MAPK pathway mutations, including mutations in *EGFR*, *KRAS*, and *ALK*. Our previous analysis demonstrated that gain-of-function *RIT1* mutations induce potent transformation of rodent fibroblasts, and preliminary data indicates that the mechanism of *RIT1* signal transduction is likely to be distinct from that of other RAS GTPases, such as *KRAS*. To genetically dissect the signaling pathways downstream of *RIT1*, *KRAS*, and *EGFR*, we performed genome-wide CRISPR/Cas9 screens in three isogenic lung adenocarcinoma cell lines in which cell survival is dependent on the expression of the oncogene. Through integrative analysis of essential genes across the three cell lines, we identified synthetic lethal relationships unique and shared in each isogenic background. Among the dependencies identified was the requirement of aurora kinase pathway genes for survival of *RIT1*-mutant cells, raising the possibility of therapeutic aurora kinase inhibition in *RIT1*-positive tumors. To evaluate whether the dependence on Aurora kinases extended to small molecule inhibition, we performed a screen of 160 small molecules in clinical development or approved by the FDA. Consistent with our CRISPR/Cas9 results, we find that *RIT1*-mutant cells depend on Aurora kinase activity for survival. Interestingly, global proteomic and phosphoproteomic profiling identified *RIT1* regulation of mitotic spindle assembly genes. Taken together these results identify a new arm of *RIT1* signaling and nominate Aurora kinase inhibition as a potential therapeutic strategy in *RIT1*-mutated tumors.

## PgmNr 855: Cancer care and a tale of three molecular 'genomic' tests.

### Authors:

J. Wallace; B. Zimmermann; N. Liang; R. Swenerton; U. Do; S. Sawyer; J. Saucier; S. Parmar; A. Aleshin; N. Hook

[View Session](#) [Add to Schedule](#)

---

**Introduction:** The practice of oncology has largely evolved to treating cancer, based on tumor genomics. Genetic testing for hereditary cancer predisposition syndromes and somatic tumor testing for targeted therapy selection have advanced patient care. More recently, cell-free DNA analysis has been leveraged to develop patient-specific, bespoke assays for the detection of circulating tumor DNA (ctDNA) in cancer patients, to allow monitoring for molecular residual disease, recurrence, and treatment response. Here we present a patient diagnosed with cancer where three individual molecular tests are utilized in the care continuum.

**Case Presentation:** A 56-year old Caucasian female diagnosed with stage IIIC ovarian clear cell carcinoma, treated with total abdominal hysterectomy with bilateral salpingo-oophorectomy, omentectomy, appendectomy, lymph node sampling, peritonectomy, and optimal tumor debulking in June 2018. At that time, the patient was assessed with tumor molecular comprehensive genomic profiling and hereditary cancer predisposition syndrome diagnostic testing to identify potential inherited predisposition risk and inform treatment selection, available clinical trials, and potential use of PARP inhibitor therapy. Treatment with first-line adjuvant chemotherapy concluded in Oct 2018. In Jan 2019, the patient relapsed and enrolled in clinical trial GYO16, receiving pembrolizumab infusions with oral epacadostat. In Feb 2019, the patient was assessed for ctDNA using a bespoke assay designed from matched-normal whole exome sequencing. ctDNA was detected at 4.61 MTM/mL. Positive ctDNA results allow the opportunity to monitor treatment response and trending disease burden through longitudinal screening of ctDNA levels.

**Discussion:** Here we present an oncology patient where molecular testing was utilized in three unique ways to inform and monitor cancer treatment. It is important that genetic professionals become familiar with the increasing number of molecular genomic tests being incorporated into oncology, each with a unique purpose in the patient continuum of care. Patients and physicians may seek consultation from clinical genetic professionals to differentiate between molecular genomic tests incorporated into practice.

## PgmNr 856: Genome sequencing analysis identifies high-risk Epstein-Barr virus subtypes for nasopharyngeal carcinoma.

---

Epstein-Barr virus (EBV) infection is ubiquitous worldwide and is associated with multiple cancers, including nasopharyngeal carcinoma (NPC). The importance of EBV viral genomic variation in NPC development and its striking epidemic in southern China has been poorly explored. Through a large-scale genome sequencing of 270 EBV isolates and association study (discovery phase: 156 patients with NPC and 47 healthy controls; validation phase: 483 patients and 605 controls) of EBV isolates from China, we identified two non-synonymous EBV variants within *BALF2* strongly associated with the risk of NPC (odds ratio (OR) = 8.69,  $P = 9.69 \times 10^{-25}$  for SNP162476\_C and OR = 6.14,  $P = 2.40 \times 10^{-32}$  for SNP163364\_T). The cumulative effects of these variants contributed to 83% of the overall risk of NPC in southern China. Phylogenetic analysis of the risk variants revealed a unique origin in Asia, followed by clonal expansion in NPC-endemic southern China. We further explored a) the performance of NPC-associated EBV risk variants combined with the human susceptibility variants in risk prediction for NPC; b) the role of these risk variants in other EBV-associated malignancies; c) the role of the risk variants in EBV virus replication and immunogenicity. Our results provide novel insights into NPC tumorigenesis and its endemic in southern China. They also pave the way for identifying high-risk individuals and implementing effective intervention programs to reduce the disease burden in southern China.

## PgmNr 857: Copper (II) increases anti-proliferative activity of thymoquinone in colon cancer cells by increasing genotoxic, apoptotic and reactive oxygen species generating effects.

### Authors:

---

Colon cancer is one of the most common types of cancer in the world. It is the third most common cancer diagnosed in both men and women in the United States according to American Cancer society. Thymoquinone is the main active phenolic compound derived from the essential oil of the *Nigella sativa* plant seed, also known as black seed. While thymoquinone is an antioxidant, it has been reported in several studies that thymoquinone has dose-dependent pro-oxidant activity with Fenton reaction in the presence of transition elements such as iron and copper. Several studies showed that cellular copper is increased in different cancers and accumulated in the nucleus of the cells. The aim of this study was to investigate genotoxic, apoptotic, cytotoxic and reactive oxygen species (ROS) generating effects of thymoquinone together with copper in colon cancer cells. In the study, the pro-oxidant-acting doses of thymoquinone (10-60  $\mu\text{M}$ ) were administered to colon cancer cells (HT-29) alone and together with non-toxic dose (150  $\mu\text{M}$ ) of Copper (II) Sulfate ( $\text{CuSO}_4$ ) for 24 hours and the cytotoxic, apoptotic, genotoxic and ROS production activities were analyzed by MTT viability test, Acridin Orange / Etidium Bromide (AO/EB) double staining, alkaline single cell gel electrophoresis (comet assay) and  $\text{H}_2\text{DCF-DA}$  assay, respectively. MTT viability test showed that thymoquinone and copper have synergistic effect on colon cancer cells by decreasing  $\text{IC}_{50}$  value of thymoquinone from 50  $\mu\text{M}$  to ? 25  $\mu\text{M}$ . AO/EB double staining results were also supporting MTT results. Moreover, it was shown by comet assay that DNA damage was increased with synergic effect of thymoquinone and copper, and the tail intensity was increased from 25% to 67% with 40  $\mu\text{M}$  thymoquinone. Finally, the intracellular ROS was increased when thymoquinone and copper applied together comparing to thymoquinone alone. Our studies show that the application of redox active copper (II) with thymoquinone increases DNA damage, apoptosis and cell death by increasing the amount of intracellular ROS through pro-oxidant activity. Treatments targeting copper related pathway may open new therapeutic avenues in cancer treatment.

**Background:** Previous studies have identified several targetable oncogenic mutations in biliary tract cancer (BTC). However, reliable predictors of clinical response to therapeutic agents have not been established. This study aimed to identify predictors of clinical response to chemotherapy and immune checkpoint blockade in advanced BTC patients.

**Methods:** Genomic alterations in 54 patients with recurrent or metastatic BTC were investigated by targeted deep-sequencing for 524 key cancer genes using pre-treatment tumor tissues. The predictive value of genomic alterations, including copy-number alteration and mutational signatures, on response to chemotherapy and anti-PD-1/PD-L1 therapy, was assessed.

**Results:** Frequently altered genes included *TP53* (50.0%), *NOTCH1* (31.5%), *KRAS* (24.1%), *KMT2C* (22.2%), *BAP1* (22.2%), and *ERBB2* (22.2%) exhibiting highly heterogeneous distribution. Alterations in *BAP1*, *PBRM1*, *NKX2-1*, *CREBBP*, and *RAD51* were enriched in metastatic cases, while *FLT4* and *FGFR3* amplification were enriched in recurrent cases. Among 52 patients with first-line chemotherapy, *BAP1* deletion, *NOTCH1* alteration, and the homologous recombination deficiency (HRD) signature were associated with an early tumor shrinkage, while no benefit in progression-free survival (PFS) was observed. *FLT4* amplification was a favorable prognostic factor, while *ATM*, *CHEK2*, and *NF1* mutation were poor prognostic factors of PFS on chemotherapy. Furthermore, 21 patients received anti-PD-1/PD-L1 therapy after failure of chemotherapy, and the mismatch repair (MMR) signatures were significantly higher in the responding patients. By multivariate Cox analysis, old age, metastasis, and alterations in *ERBB2*, *CHEK2*, *MDM2*, and *NF1* gene were poor prognostic factors of overall survival.

**Conclusions:** This study identified molecular predictors associated with clinical response and outcome of therapeutic agents in advanced BTC. Particularly, mutational signatures associated with HRD and MMR correlated with the response to chemotherapy and anti-PD-1/PD-L1 therapy, respectively. These results provide general framework to select patients benefitting from therapeutic modalities based on molecular profile in advanced BTC.

## PgmNr 859: *HERC1* knockout cell model study provides insights on growth defect phenotypes.

The E3 ubiquitin-protein ligase encoded by *HERC1* (HECT And RLD Domain Containing E3 Ubiquitin Protein Ligase Family Member 1) plays a crucial role in regulating cell proliferation, energy sensing and cell membrane trafficking. Loss of function *HERC1* mutations have been associated to a variety of rare neurodevelopmental disorders (macrocephaly, dysmorphic facies, and psychomotor retardation) characterized by large head and overgrowth. In addition, altered *HERC1* expression level has been identified in a variety of cancer types. Increasing number of researches indicate that higher *HERC1* expression facilitate cancer patients' survival. Despite of significant role of *HERC1* in human disease, the underlying mechanism is still not clear.

To better understand the impact of *HERC1* mutations in growth defects and cancer, we studied the molecular and cellular phenotype of a *HERC1* knockout cell model. Our cell model showed that the loss of *HERC1* induces a significant upregulation of the mTOR signaling pathway and an increase in cell proliferation. Interestingly, the knockout cells were able to maintain these phenotypes even in unfavorable growth conditions by recycling cellular contents to maintain cell homeostasis and viability during nutrient starvation in a more efficient manner, i.e. increase of autophagy. These results provide us potential insights on the impact of *HERC1* in normal and abnormal cell proliferation. This will open the door of potential therapeutic measures for patients with impaired growth profile and *HERC1* mutated cancer types using *HERC1* as a novel biomarker and as a target for therapy.

## **PgmNr 860: Gene signature-based prediction of patient response to neoadjuvant chemotherapy with applications to triple-negative breast cancer.**

Neoadjuvant chemotherapy (NCT) is the current standard of care for Triple Negative Breast cancer (TNBC). While the clinical benefits of NCT have been illustrated through numerous clinical trials, more than half of the patients do not respond to NCT and yet suffer from side effects. Currently, no clinically applicable biomarkers are available for predicting NCT response in TNBC. Therefore, developing predictive biomarkers for NCT in TNBC is an unmet need. In this study, we introduce a generic computational framework to calculate a response probability score (RPS) which predicts patient response to NCT. This framework identified genes associated with NCT response and captured the pre-treatment gene expression profile difference between NCT responders and non-responders. We first validated this framework in ER+ breast cancer and showed that it predicted NCT response with equal performance as clinically used biomarkers including Oncotype DX and MammaPrint. Then, we applied this framework to TNBC data and for each patient we calculated a response probability score (TNBC-RPS). Our results indicate that the TNBC-RPS achieved the best accuracy for predicting NCT response compared with all previously proposed gene signatures. More importantly, a model including TNBC-RPS and clinical predictors predicted patient response to NCT in TNBC with an accuracy that was comparable to ER+ NCT response prediction. In addition, we demonstrated difference in NCT response mechanisms between ER+ breast cancer and TNBC. In conclusion, TNBC-RPS can accurately predict NCT response in TNBC and has the potential to be clinically used to aid physicians in stratifying patients for more effective NCT treatment.

## PgmNr 861: A reporter mouse model enabling image-based evaluation of CD8<sup>+</sup> T cell dynamics in immunocompetent allografts.

Immune cell recruitment to tumors is indispensable for the success of immunotherapy. In vivo bioluminescence imaging technology to visualize the location and functionality of immune cells is of great value for immuno-oncology research. Here, we describe the generation of a genetically engineered mouse model in which all CD8<sup>+</sup> T cells constitutively express a novel luciferase reporter Akaluc. On the C57/BL6 background, the IRES-Akaluc-EGFP expression cassette was inserted downstream of the stop codon, which allows the bioluminescence imaging of CD8<sup>+</sup> T cell location and function under physiological and pathological conditions. As expected, these engineered mice showed constitutive luciferase expression in lymphoid organs such as thymus, lymph nodes and spleen under normal conditions. Next, we modeled the CD8<sup>+</sup> T cell dynamics in the context of cancer immunotherapy. In the case of subcutaneously implanted mouse cancer cells such as MC38 colon cancer cells and antigenic SIY-expressing B16 melanoma cells (but not the regular B16 cells), the reporter mice showed enhanced T cell recruitment and infiltration into the tumor mass when treated with a mouse anti-PD-1 mAb. This apparent immune response was consistent with the eventual tumor regression. Besides, a similar level of T cell response was visualized when we treated tumor-bearing, PD-1-humanized mice with human anti-PD-1 mAb, suggesting the translatability of this type of reporter models.

Our study underscores the utilities of such reporter mice for uncovering the role of immune cells in tumor responses by revealing dynamics, interactions and distribution of various immune cells in tumor settings.

## PgmNr 862: Two point-NGS analysis of cancer driver genes in cell free-DNA of metastatic cancer patients.

---

**Background:** Despite the recognized efficacy of molecularly target agents in vitro, their use in routine setting is still hampered by the apparently low efficacy in vivo. Moreover, core biopsy of a single cancer site may not be representative of the whole expanding clones and cancer molecular profile at relapse may differ with respect to the primary tumor.

**Methods:** We assessed the status of a large panel of cancer driver genes by cell-free DNA (cfDNA) analysis in a cohort of 68 patients with 13 different solid tumors at disease progression. Whenever possible, a second cfDNA analysis was performed after a mean of 2.5 months, in order to confirm the identified clone(s) and to check the correlation with clinical evolution.

**Results:** The approach was able to identify clones plausibly involved in the disease progression mechanism in about 65% of cases. A mean of 1.4 mutated genes (range 1-3) for each tumor was found. Point mutations in *TP53*, *PIK3CA*, and *KRAS* and copy number variations in *FGFR3* were the gene alterations more commonly observed, with a rate of 48%, 20%, 16% and 20%, respectively. Two points NGS analysis demonstrated statistically significant correlation between allele frequency variation and clinical outcome ( $p=0,026$ ).

**Conclusions:** Irrespective of the primary tumor mutational burden, few mutated genes are present at disease progression. Clinical outcome is consistent with variation of allele frequency of specific clones indicating that cfDNA two point-NGS analysis of cancer driver genes could be an efficacy tool for precision oncology.

## PgmNr 863: Immunogenomic profiling for predicting outcome with advanced stage uterine serous carcinoma.

**Background:** The lethality of endometrial cancer is primarily due to disease with advanced stage (III or IV) at the time of diagnosis. Typically, a five-year survival rate of 83-97% is achieved for localized disease, in contrast to 43-67% for stage III disease and only 13-25% for stage IV disease. In addition to standard care, targeted therapies specific to individualized tumors, such as immunotherapy, are needed for advanced-stage patients. In this study, we focused on IFN $\gamma$  and TGF $\beta$  as key regulators in the tumor microenvironment (TME) and aim to identify immune-related gene signature in conjunction with IFN $\gamma$  and TGF $\beta$  signaling to predict serous uterine cancer outcome and response to chemotherapy.

**Method:** We conducted whole transcriptome analysis of matched tumor-normal samples from 38 high stage (Stage III and IV) uterine serous cancer patients who received chemotherapy with platinum-based therapy with taxanes. Immune-related genes were analyzed to identify differentially expressed genes separating overall survival (OS) and progression free survival (PFS). Additionally, IFN $\gamma$  18-gene expression score and TGF $\beta$  6-gene expression score were calculated by averaging the normalized and log transformed individual gene read counts. The optimized score cut off was selected to best separating the progression free survival. Then the cut off score was tested in The Cancer Genomic Atlas (TCGA) endometrial and ovarian cancer RNAseq datasets.

**Results:** A 16-gene immune signature was identified separating overall survival (OS) and progression free survival (PFS). The IFN $\gamma$  score of 2.46 was determined based on 18-gene expression derived from 38 high-stage uterine serous cancer samples with average age of 67 years (range: 56-82 years). Patients with score higher than 2.46 showed significantly longer PFS - 57.6 months vs 15months ( $p=0.002$ ) compared to the patients with score lower than 2.46. Then this IFN $\gamma$  based gene signature was then applied to TCGA endometrial cancer samples with RNAseq data. This signature predicted significant improvement in both PFS ( $p=0.001$ ) and OS ( $p=0.005$ ). Interestingly, high TGF $\beta$  score is correlated with worse PFS in these high stage serous patients, but not in TCGA endometrial cancer data.

**Conclusions:** Immune-related genomic signature can predict prognosis and response to chemotherapy in high stage serous endometrial cancer. Additional targeted markers relevant to TME may add more values for future therapeutic options.

## PgmNr 864: Individualized genetic network analysis reveals new therapeutic vulnerabilities.

### Authors:

---

Tumor-specific genomic alterations allow systematic identification of genetic interactions that promote tumor evolution and vulnerabilities, offering novel strategies for development of targeted therapies for individual tumors. We develop an Individualized Network-based Co-Mutation (INCM) methodology by inspecting over 2.5 million nonsynonymous somatic mutations derived from 6,789 tumor exomes across 14 cancer types from The Cancer Genome Atlas. Our INCM analysis reveals a higher genetic interaction burden on the significantly mutated genes, experimentally validated cancer genes, chromosome regulatory factors, and DNA repair genes, as compared to human genome-wide essential genes identified by CRISPR-Cas9 screenings on cancer cell lines. We find that genes identified in the cancer type-specific genetic subnetworks by INCM are significantly enriched in established cancer pathways, and the INCM-inferred putative genetic interactions are correlated with patient survival. By analyzing drug pharmacogenomics profiles from the Genomics of Drug Sensitivity in Cancer database, we show that the network-predicted putative genetic interactions (e.g., *BRCA2*-*TP53*) are significantly correlated with sensitivity/resistance of multiple therapeutic agents. We experimentally validated that afatinib has the strongest cytotoxic activity on BT474 ( $IC_{50} = 55.5$  nM, *BRCA2* and *TP53* co-mutant) compared to MCF7 ( $IC_{50} = 7.7$   $\mu$ M, both *BRCA2* and *TP53* wild type) and MDA-MB-231 ( $IC_{50} = 7.9$   $\mu$ M, *BRCA2* wild type but *TP53* mutant). Finally, drug-target network analysis reveals multiple druggable genetic interactions by targeting potentially tumor vulnerabilities. This study offers a powerful network-based methodology for identification of candidate therapeutic pathways that target tumor vulnerabilities and prioritization of potential pharmacogenomics biomarkers for development of personalized cancer medicine.

# PgmNr 865: Genome-wide association study of capecitabine-induced hand-foot-syndrome in colorectal cancer.

## Authors:

S. Dong; T. Wang; J. Zhang; Z. Wu; X. Li; P. Zhang; W. Jia

[View Session](#) [Add to Schedule](#)

**Affiliation:** State Key Laboratory of Oncology in South China, Sun Yat-sen University Cancer Center, Guangzhou, China

## Background:

Capecitabine, an oral prodrug of 5-fluorouracil (5-FU), is approved for first-line treatment of various malignancies, especially in colorectal cancer. Hand-foot-syndrome (HFS) is one of the common adverse events that limits its clinical use. Although HFS is not life-threatening, it always induces dose interruptions and reductions which adversely impacts treatment outcomes. Additionally, it also reduces patients' quality of life and hinder treatment compliance. Previous pharmacogenetics studies of HFS almost use candidate gene approach, but up till now, the pathophysiology and mechanism of HFS is still unclear, and the effective predictive biomarkers of HFS is yet to be found.

## Methods:

We used a two-stage GWAS design including a total of 1104 colorectal cancer patients who received capecitabine-based treatment in Sun Yat-sen University Cancer Center. HFS was graded according to NCI-CTCAE version 3.0. We performed a genome-wide association analysis in 514 patients, including 148 cases with grade 2-3 HFS and 366 controls with grade 0-1 HFS, and validated the top associations in an independent cohort of 590 patients. Sanger sequencing of the coding regions of *TYMS* was performed in 268 patients. All statistical tests were two-sided.

## Results:

In this retrospective study, we found the CRC patients in our cohort treated with capecitabine-based combination treatment had a lower HFS incidence, with a OR of 0.22 (95% CI = 0.22 - 0.50,  $P < 0.01$ ) compared with those treated by single-agent capecitabine, although patients almost received the same dose of capecitabine. Patients who had previously received fluorouracil-based chemotherapy treatment were more likely to develop HFS (OR = 1.89, 95% CI = 1.10 - 3.24,  $P = 0.021$ ). By genome-wide association study, we identified two variants, rs2853741 (OR = 2.01, 95% CI = 1.63-2.49,  $P_{\text{combined}} = 9.72 \times 10^{-11}$ ) in the promoter region of *TYMS*, and an intergenic polymorphism, rs1890775 (OR = 0.62, 95% CI = 0.5-0.76,  $P_{\text{combined}} = 3.91 \times 10^{-6}$ ) were strongly associated with HFS. *TYMS* an essential enzyme for DNA synthesis and repair is a critical target of capecitabine. Additionally, the coding regions sequencing of *TYMS* identified two novel variants in patients with severe HFS.

## Conclusions:

This genome-wide association study identifies two novel SNPs significant association with HFS in colorectal cancer patients in Chinese, which could help to elucidate the underlying mechanism of hand-foot-syndrome.

## PgmNr 866: Genomic analyses of L-asparaginase-induced pancreatitis in pediatric cancer patients.

### Authors:

---

**Background:** L-asparaginase is highly effective in the treatment of pediatric acute lymphoblastic leukemia. Unfortunately, the use of this treatment is limited by the occurrence of pancreatitis, a severe and potentially lethal adverse drug reaction, which occurs in 2-18% of patients. As previous studies have been unable to identify strong associations between clinical variables and susceptibility to L-asparaginase-induced pancreatitis, genetic factors are expected to play an important role in this adverse drug reaction.

**Objectives:** We sought to explore the role of these genetic susceptibility factors in L-asparaginase-induced pancreatitis in pediatric cancer patients.

**Methods:** Patients who were treated with L-asparaginase were recruited from 13 pediatric oncology units across Canada ( $n=284$ ) and extensive clinical data were collected for all patients. Genotyping was performed using the Illumina HumanOmniExpress and Global Screening Arrays and pancreatic gene expression profiles were imputed in these individuals using GTEx v7 and S-PrediXcan. Genome- and transcriptome-wide associations (GWAS and TWAS) were performed to identify associations with L-asparaginase-induced pancreatitis.

**Results:** GWAS analyses identified significant associations between genetic variants in *HLA-DQA1* and *-DRB1* and pancreatitis, while TWAS revealed that individuals experiencing L-asparaginase-induced pancreatitis exhibited lower expression levels of *HLA-DRB5*. Further interrogation of the TWAS data revealed an enrichment in genes involved in the somatic diversification of immune receptors.

**Conclusions:** These analyses uncovered an association between genetic variation in immune-related genes and the development of L-asparaginase-induced pancreatitis. These associations mirror previous associations with the *HLA* region and (i) pancreatitis induced by other drugs and (ii) L-asparaginase-induced hypersensitivity.

## PgmNr 867: Transcriptome-wide association study of anthracycline-induced cardiotoxicity in pediatric cancer patients.

---

**Background:** Anthracyclines are highly effective chemotherapeutic agents; however, their clinical utility is limited by severe anthracycline-induced cardiotoxicity (ACT). Genome-wide association studies (GWAS) have uncovered several genetic variants associated with ACT, but these findings explain only a portion of its heritability.

**Methods:** To provide an in-depth examination of the genetics underlying ACT, we conducted a transcriptome-wide association study (TWAS) using our previous GWAS summary statistics (n=280 patients) to identify gene expression-related associations with ACT. Z-scores were used to describe the differential expression of genes between cases and controls. Next, we conducted gene set enrichment analyses in which a Wilcoxon rank sum test was used to compare mean  $Z^2$  statistics from each gene set with those of all other genes in the TWAS. Finally, pathway analyses were conducted to investigate biological mechanisms underlying ACT.

**Results:** Three genes expressed in heart/arterial tissues were significantly associated with ACT in the TWAS: *GDF5* (Z-score=-4.30,  $P=1.70 \times 10^{-5}$ ), *FRS2* (Z-score=4.07,  $P=4.67 \times 10^{-5}$ ), and *HDCC2* (Z-score=4.01,  $P=6.08 \times 10^{-5}$ ). Significantly enriched gene sets consisted of genes essential in: mice ( $P=2.0 \times 10^{-7}$ ), culture ( $P=0.036$ ), and humans ( $P=1.36 \times 10^{-5}$ ), as well as genes differentially expressed upon treatment with the cardioprotectant all-trans retinoic acid (ATRA,  $P=1.53 \times 10^{-4}$ ) and genes up-regulated at lower doses of anthracyclines ( $P=3.60 \times 10^{-4}$ ). Pathway analyses revealed an overrepresentation of genes involved in ribosomal, spliceosomal, and cardiomyopathy pathways. Results from functional validation conducted to confirm the roles of *GDF5*, *FRS2*, and *HDCC2* in ACT will also be presented.

**Conclusions:** In summary, we have identified three novel genetic associations with ACT; determined that genes essential for survival, cardioprotection, and response to anthracyclines are important for development of ACT; and uncovered pathways dysregulated in patients with ACT, providing further insight into the mechanism of ACT.

## PgmNr 868: A genome-wide association study identifies five novel genetic markers for trastuzumab-induced cardiotoxicity.

**Purpose:** Trastuzumab has been administered to patients with HER2-positive cancer, however, the cardiotoxicity is identified as one of the life-threatening toxicities. Clinically useful biomarker for trastuzumab-induced cardiotoxicity has been expected to be developed. To identify novel genetic markers determining the risk of trastuzumab-induced cardiotoxicity, we performed a first genome-wide association study (GWAS) in Japanese population.

**Experimental Design:** We enrolled 481 patients who had been treated with trastuzumab and carried out a GWAS using 11 cases (with cardiotoxicity) and 257 controls (without cardiotoxicity). Top 100 single nucleotide polymorphisms (SNPs) which revealed the smallest  $P$  values in GWAS ( $P = 7.60 \times 10^{-7}$  -  $2.01 \times 10^{-4}$ ) were further examined using replication samples consisted of 14 cases and 199 controls.

**Results:** The combined analysis of the GWAS and replication study indicated possible association of five loci with trastuzumab-induced cardiotoxicity (HERADR1 on chromosome 13q14.3, HERADR2 on chromosome 15q26.3, HERADR3 on chromosome 17q25.3, HERADR4 on chromosome 4q25, and HERADR5 on chromosome 15q26.3,  $P_{combined} = 6.00 \times 10^{-6}$ ,  $8.88 \times 10^{-5}$ ,  $1.07 \times 10^{-4}$ ,  $1.42 \times 10^{-4}$ ,  $1.60 \times 10^{-4}$ , respectively). Furthermore, we developed a risk prediction model for trastuzumab-induced cardiotoxicity using five marker SNPs. The incidence of trastuzumab-induced cardiotoxicity in patients with risk score  $\geq 5$  was significantly higher (42.5%) compared to that in patients with score  $\leq 4$  (1.8%) ( $P = 7.82 \times 10^{-15}$ , odds ratio = 40.0).

**Conclusion:** We identified five novel genetic loci associated with trastuzumab-induced cardiotoxicity. These findings provide new insights into precision therapy for patients with HER2-positive cancer.

## PgmNr 869: Whole genome sequencing to identify predictive marker for the risk of drug-induced interstitial lung disease.

---

Drug-induced interstitial lung disease (DIILD) is one of the critical issues of chemotherapy for patients with cancer because the mortality of this adverse event is extremely high. To identify genetic variants determining the risk of DIILD, we carried out whole genome sequencing of germline DNA samples from 26 patients who developed DIILD, and conducted a case-control association study between these 26 cases and general Japanese population controls registered in the integrative Japanese Genome Variation Database (ijGVD) as a screening study. The associations of 42 single nucleotide variants (SNVs) showing  $P < 0.0001$  were further validated using an independent cohort consisted of 18 DIILD cases as a replication study. Combined analysis of the screening and replication studies showed a possible association of two SNVs with DIILD ( $P_{combined} = 1.87 \times 10^{-5}$  and  $5.16 \times 10^{-5}$ , respectively). Furthermore, in subgroup analysis of epidermal growth factor-tyrosine kinase inhibitor-induced ILD, we observed 7 candidate SNVs which were possibly associated with the ILD ( $P < 0.00001$ ). These SNVs might be applicable in predicting the risk of DIILD in patients receiving chemotherapy.

## PgmNr 870: Intelligent biomarker selection and individualized therapy.

The “precision medicine” approach with electronic health records (EHRs), lab systems, imaging, pathology and genomics attempts to match the most accurate and effective treatments with the individual patient, rather than one-size-fits-all monotherapy. Treatment response is heterogeneous. Therefore, individualized treatment effect (ITE) estimation and therapy selection from observational data are a central talk in the precision medicine. We want to select the optimal treatment for each individual to ensure that the right therapy is offered to “the right patient at the right time”. However, if it were to use a standard estimation platform for each treatment separately, the estimated treatment effects are the average effects in the population, which cannot be taken as individual effect. Unfortunately, estimating individualized treatment effects and design individualized therapy is beyond the state of the art of current medical knowledge. The true barrier we face is the challenge of developing intelligent algorithms for estimating individualized treatment effects and designing optimal individualized therapy via integrating imaging, HER, physiological and omics data. To meet the challenge, we develop a novel analytic platform that integrate auto-encoding, conditional generative adversarial networks (CGAN) and sparse techniques for individualized treatment effect estimation, biomarker selection and optimal therapy decision. We use auto-encoder for high dimensional feature data reduction, take counterfactual estimation as a missing value problem and adapt the well-known CGAN framework for imputing the counterfactual outcomes and estimating the individual treatment effects. After the individualized treatment effects are estimated, sparse regression methods will be used to select features (biomarkers), to predict treatment response and to select the optimal treatment for each individual. Due to the lack of ground truth, we conduct large scale simulations where imaging, omics and pathology features, treatment assignment and potential outcomes are generated, to evaluate the performance of the proposed algorithms. The algorithms are also applied to newly diagnosed acute myeloid leukemia (AML) of 256 patients, treated with multiple therapy at M. D. Anderson Cancer Center. Both simulation and real data analysis results show that the intelligent algorithms substantially outperform the state-of-the-art methods.

## PgmNr 871: Prospective modeling of genetic risk of thromboembolism in acute lymphoblastic leukemia in a competing risks setting.

---

Thromboembolism (TE), while an extremely rare event in healthy children, is a relatively common serious toxicity of acute lymphoblastic leukemia (ALL) treatment and contributes to substantial morbidity and mortality. Several SNPs, including functional SNPs, have been associated with TE in the general adult population. However, the impact of these SNPs in patients with ALL, particularly in children, remains uncertain. Since ALL patients are also at risk for other events (including non-TE related mortality and relapse), these so-called competing risks need to be taken into account in the prospective statistical modeling of the genetics of TE in ALL patients. We prospectively registered TE, mortality and other competing events in a cohort of 1,252 patients aged 1–45 years (91% <18 years) with ALL included in the Nordic Society of Pediatric Hematology and Oncology (NOPHO) ALL2008 protocol in the Nordic and Baltic countries (7/2008–7/2016). Based on previously published non-cancer data, we selected four SNPs: *F5* rs6025, *F11* rs2036914, *FGG* rs2066865, and *ABO* rs8176719. We constructed genetic risk scores using a combination of these SNPs and then modeled risk of TE in a competing risks setting. The 2.5 year cumulative incidence of TE was 7.1% (95% confidence interval (CI) 5.6–8.5). *F11* rs2036914 was associated with TE development (HR 1.52, 95% CI 1.11–2.07) and there was a borderline significant association for *FGG* rs2066865 (HR 1.37, 95% CI 0.99–1.91), but no significant association for *ABO* rs8176719 or *F5* rs6025. A genetic risk score based on *F11* rs2036914 and *FGG* rs2066865 was associated with TE development (HR 1.45 per risk allele, 95% CI 1.15–1.81), the association was strongest in adolescents 10.0–17.9 years (HR 1.64). If validated, a *F11* rs2036914/*FGG* rs2066865 risk prediction model should be tested as a stratification tool for TE prevention measures in patients with ALL. Current work is focusing on polygenic risk scores based on TE-GWAS Contortia summary statistics.

## PgmNr 872: Precision medicine: Predicting lung cancer drug responses.

Lung cancer ([MIM 211980]) causes severe healthcare problems worldwide. Here, we identified the drug response genes of tyrosine kinase inhibitors Erlotinib and Sorafenib, and showed that these genes can perfectly classify a small set of patients from the BATTLE clinical trial who were without biomarker mutations into responding and non-responding using machine learning and regression approaches. Using pathway and protein-protein interaction network analysis, we further showed that these genes are associated with kinase signaling pathways. Specifically, Erlotinib-associated genes are related to protein ubiquitination and DNA damage, and Sorafenib-associated genes are related to autophagy, apoptosis and proliferation, shedding light on causes for the drug resistance. Our analysis also suggests that ADORA3 could be is a good biomarker and target to counter Erlotinib resistance. Interestingly, our study suggests that some of these Erlotinib/Sorafenib-associated genes not only are drug-response biomarkers, but also are prognostic biomarkers for *EGFR* wild-type lung cancer patients. Our AI (artificial intelligence)-based drug response model has a potential to contribute significantly to precision medicine treatment of lung cancer patients.

## PgmNr 873: Effect of cisplatin on MAPK pathway gene expression is reversed by naringenin in HCT116 colorectal cancer cell lines.

Platinum agents are widely used to treat cancer inducing apoptosis and cell death by contorting the DNA with platinum adducts. Despite multiple platinum based therapies (cisplatin, carboplatin, oxaliplatin), resistance, poor response, and side effects still plague their use. The MAPK pathway is a critical pathway to study in cancer treatment due to its dysregulation in many cancers. In this project, we aim to understand the role of platinum-induced MAPK pathway expression. We began by assessing 5 genes in the MAPK pathway in HCT116 cells (colorectal cell line) after treatment with cisplatin and oxaliplatin. Cisplatin and oxaliplatin were found to induce MAPK pathway genes differently, suggesting that while platinum is the active component for both, their effect on MAPK signaling is distinct. Oxaliplatin did not induce a clear pattern across the pathway genes evaluated, while cisplatin did. All assayed genes demonstrated no change or downregulation until 48hr, where all genes showed significant upregulation by cisplatin. We then queried both DLD1 (another colorectal cancer cell line) and A549 (lung cancer cell line) treated with cisplatin to assess if the same MAPK pathway induction was seen. Interestingly, A549 cells revealed the opposite effect. Cisplatin treated A549 cells were observed to have minimal induced expression changes until 48 hr where significant downregulation of MAPK genes was observed. DLD1 did not have an observable pattern of induction across the pathway, suggesting that the effect of cisplatin on HCT116 is specific to that cancer subtype. To further understand the effects of cisplatin on the MAPK pathways in HCT116 cells, naringenin was identified as a broad inhibitor of the MAPK pathway. HCT116 cells were treated with cisplatin, naringenin, and a combination of cisplatin and naringenin. Surprisingly, at 48 hr post treatment, 4 out of the 5 genes assayed (CREB1, RAF1, MAPK1, and MAP2K1) demonstrated a significant reversal of the induction observed by cisplatin. Individual treatment of cisplatin and naringenin resulted in significant upregulation at 48 hr. However, combination treatment resulted in significant downregulation at 48 hr. These data suggest an intriguing interaction between cisplatin and naringenin affecting the MAPK pathway. The next steps include understanding the effect this interaction has on apoptosis and cell death with the ultimate goal of improving the effectiveness of cisplatin treatment in colorectal cancer.

## PgmNr 874: The Genetic Risk Estimate (GENRE) trial: Influence of a breast cancer (BC) polygenic risk score (PRS) on personalized approach to understanding BC risk and decision to take preventive medication.

### Authors:

S. Pruthi <sup>1</sup>; J.O. Kim <sup>2</sup>; D. Schaid <sup>5</sup>; A. Cooke <sup>2</sup>; C. Kim <sup>2</sup>; B. Goldenberg <sup>2</sup>; J. Sinnwell <sup>5</sup>; D. Grenier <sup>2</sup>; A. Degnim <sup>1</sup>; F. Couch <sup>4</sup>; C. Vachon <sup>3</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Division of General Internal Medicine- Breast Diagnostic Clinic, Mayo Clinic, Rochester, Minnesota.; 2) Cancer Care Manitoba, Winnipeg, Manitoba Canada; 3) Health Science Research, Mayo Clinic; 4) Lab Medicine and Pathology, Mayo Clinic; 5) Statistics and Informatics, Mayo Clinic

**Background:** Studies demonstrate breast cancer risk reduction of 50-65% with the use of preventive medications. Multiple barriers exist that negatively influence uptake including attitudes toward medications, risk perception and drug side-effects. A PRS comprised of 77 BC genetic susceptibility loci (Single Nucleotide Polymorphisms (SNP)) can be used to personalize breast cancer risk. We studied the influence of the addition of a PRS to standard risk calculator estimates on the decision to receive prevention medication.

**Methods:** Eligible women required either a 5 year Gail Model risk of  $\geq 3\%$  or 10 year Tyrer-Cuzick risk (IBIS) of  $\geq 5\%$ . Women with a history of BC or hereditary BC syndrome were excluded. High risk women were counseled at baseline using their Gail and IBIS risk scores and preventive medication options were discussed including benefits and risks. Participants completed a self-reported questionnaire at baseline to assess understanding of BC risk and decision to take preventive medication. Blood samples were obtained and genotyped for 77 SNPs, and an updated BC -PRS risk report was shared with study participants that reflected the IBIS and Gail risk predictions for 5 yr, 10 yr, & lifetime BC risk with and without the PRS. Post visit questionnaires assessed influence of PRS on decision to take preventive medication.

**Results:** 151 women in Canada & USA were enrolled on the study from 2016 to 2017. The median age was 56.1 (range 36-76.4), 35.6% were premenopausal, 98.7% were Caucasian and 64.7% had  $\geq 1$  family member with BC. Median 5yr, 10yr, & lifetime IBIS risk estimates were 3.8% (2.0-11.5), 7.9% (5.0-23.1), and 25.3% (5.5 to 92.2). After the BC-PRS risk estimate report was shared with the participant, the influence on their decision to take preventive medication significantly changed ( $p < 0.001$ ): 41.9 % were more likely to take preventive medication if there was an increase in the PRS risk estimate and 46.7 % were less like to take preventive medication if they had a decrease in the PRS risk estimate.

**Conclusion:** In high risk women, the personalized approach to BC-PRS risk estimates in addition to standard BC risk calculators significantly influenced the decision to take preventive medication. Future study is underway on how the PRS impacts uptake and adherence of preventive medication.

## PgmNr 875: Systematic establishment of robustness and standards in patient-derived xenograft experiments and analysis.

---

Patient-Derived Xenograft (PDX) models present valuable systems for demonstrating clinical translatability in preclinical testing of therapeutic agents. Large PDX collections, such as those in active development in the NCI PDXNet Consortium, provide a critical resource for assays of therapeutic efficacy. However, variation in experimental and assessment procedures among research groups often limit conclusions regarding the robustness of PDX results with regard to patient outcomes. To assess the sensitivity of PDX assays with regard to different institutional procedures, PDXNet conducted a study of temozolomide drug response, in replicate, on PDX models from three patients. Four PDX Development and Trial Centers (PDTCs) used internally developed SOPs that varied in procedures for establishment of xenografts, treatment dosing and scheduling, time period of study, and response criteria, with all sites blinded to the procedures and results of other groups. The three PDX models were chosen based on prior treatment experiments conducted by the NCI Patient Derived Models Repository, which showed one model was sensitive, one was resistant, and one had intermediate sensitivity. Drug responses measured by PDTCs were consistent across all testing groups, with each group correctly classifying the sensitive, resistant, and intermediate models. Additionally, to assess consistency in PDX genomic data, all PDTCs followed internal sequencing procedures to generate one exome-seq and one RNA-seq dataset per PDX model. All sequence data were analyzed on the Seven Bridges Genomics Cancer Genomics Cloud platform using benchmark optimized workflows for whole exome variant calling and RNA expression estimation. Across PDTCs variant calls derived from exome-seq data showed strong overlap within PDX models, but were affected by differing panels and variable read depth. RNA expression results showed strong batch effects, but following correction clustered by PDX model. Overall, our results show that drug responses and genomic data of PDX models from across different research institutions are consistent and robust. We report standardized SOPs for experimental procedures, response measurement and statistical assessment, and sequence analysis workflows based on these results. We expect these PDXNet standards to improve the use of PDX and other in vivo models in advancing cancer precision medicine.

## PgmNr 876: *TNS1*: A candidate gene for predisposition to and/or development of pheochromocytoma.

---

*TNS1* gene encodes the actin-binding protein Tensin 1 (TNS1). Tensin1 is an adaptor phosphoprotein linking integrin to the actin cytoskeleton; it is also involved in fibrillar adhesion formation. *Tns1* knockout (KO) mice develop kidney abnormalities; female mice have in addition reduced fertility. A *drosophila melanogaster Tns1* KO model is known as “*blistery*” due to defective wing unfolding and the consequent blister formation. Genome-wide association studies have linked *TNS1* to asthma, lung disease and colorectal cancer, and *TNS1* expression is reduced or absent in prostate and breast cancer cells. Recently our group identified a high frequency of *TNS1* mutations in patients with pheochromocytomas (PHEO). Among 27 patients where a known causative mutation was not found (including genes such as SDHx, NF1, RET, HRAS, EPAS1, VHL, and FH) we identified a total of 7 different *TNS1* coding sequence alterations, which were predicted to be damaging through in silico analysis (33.33% - 9/27). In order to access signaling pathways of *TNS1* and its functionality in PHEO, shRNA and siRNA approaches were used to knockdown *TNS1* in a human (h)PHEO cell line. Both gene and protein expression were decreased by quantitative real-time PCR and western blot, respectively. Quantitative real-time PCR was performed to access gene expression and cell viability was accessed by MTT assay. Our results show that decrease of *TNS1* expression in hPHEO cells led to decreased expression of collagen I and collagen II by 6-and 4-fold, respectively. On the other hand, *MMP3* expression was increased by 3-fold in these cells. hPHEO cells treated with *TNS1*s iRNA showed increased cell viability after 72 hours of treatment (p=0.02). Significant differences in cell viability after 24 and 48 hours of *TNS1*s iRNA treatment were not observed in this study. Taken together, our results suggest that *TNS1* dysfunction leads to higher cell viability and increased *MMP3* expression. These data are complementary to our previously reported finding of mutations in this gene both at the germline and tumor level in PHEOs (and other tumors). We speculate that *TNS1* defects may play an important role in PHEO predisposition and/or development and progression; *TNS1* could be yet another molecular target of new therapies for this and related tumors.

## PgmNr 877: A case of preimplantation genetic diagnosis for a female patient with a Peutz-Jeghers syndrome caused by a *de novo* deletion in the *STK11* gene: Next-generation sequencing contribution.

### Authors:

### Affiliations:

1) Medical Genetics, Hôpital Arnaud de Villeneuve, CHU de MONTPELLIER, MONTPELLIER, Occitanie, France; 2) Molecular genetics of Preimplantatory Diagnosis laboratory, Montpellier hospital, France; 3) Molecular genetics laboratory, Rouen hospital, France; 4) Gynecology department, Montpellier hospital, France; 5) Reproductive biology department, Montpellier hospital, France

### Aim

The aim was to propose a preimplantation genetic diagnosis (PGD) to a female patient suffering from a Peutz-Jeghers syndrome (hamartomatous polyps and mucocutaneous melanin hyperpigmentation) due to a *de novo* deletion (g.1222449\_1225004del) including exon 8 and its flanking intronic regions in the *STK11* gene.

### Methods

The deletion was initially identified by QMPFS and next-generation sequencing (NGS). The identification of the breakpoints by NGS has allowed to define a 2555 nucleotides deletion. The PGD protocol was based on the direct diagnosis of the deletion in addition to the study of polymorphic-linked microsatellite markers defining the 2 parental haplotypes. As PGD criteria did not allow analysis of fragment > 400 bp, we designed primers each sides of the breakpoints and in intron 7 in order to amplify simultaneously the wild-type (122 bp) and the mutated fragment (142 bp).

### Results

A prePGD workup was performed on DNA from the couple and each parents. At this stage, the *de novo* inheritance induced that the deletion could not be associated to a parental haplotype in this patient. However, familial segregation showed that the patient was fully-informative for 4 microsatellite markers and semi-informative for 2 markers, whatever the haplotype associated to the deletion. In our centre we did not perform polar body analysis. Thus, this PGD was accepted in condition of the analysis of at least 6 embryos (2 cells per embryo) with at least 2 affected embryos, in order to definitively associate the deletion to the correct haplotype. The first PGD cycle led to the freeze of 2 embryos at day 3, and the second one to the freeze of 4 embryos at day 2. Unfortunately, these 4 embryos did not develop correctly for a further transfer. Also we decided to analyze them to perform familial segregation and found the deletion in only one embryo. The 2 remaining frozen embryos were analyzed, one was affected and the second one displayed only one haplotype instead of 2, resulting in no transfer.

### Conclusion

Thanks to the identification of the breakpoints by NGS, the deletion was found and associated to the correct haplotype by the study of the embryos. This PGD for Peutz-Jeghers syndrome did not conduce to a transfer but a spontaneous pregnancy ensued for this couple. At our knowledge, this is a first

case of PGD for a *de novo* deletion. A similar request is performed in another centre in France.

## **PgmNr 878: Non-invasive screening using cell-free DNA as first line of screen at the first trimester in the Israeli population.**

### **Authors:**

D. Bercovich <sup>1</sup>; S. Horn-Saban <sup>2</sup>; R. Gershoni <sup>2</sup>

---

Non-invasive screening using cell-free DNA (cfDNA) from maternal blood has greatly improved the reliable detection of autosomal aneuploidies in recent years. To implementation this method, as a first line of screening test (first trimester screening), we used (for the first time in Israel), the Illumina NIPS platform, on 1444 cfDNA samples from the Israeli population. Maternal average age was 34.3 (min: 18.9; max: 48.6), gestational average age was 16.9 (min: 10.1; max: 34.7), average fetal fraction was 11% (min: >1%; max: 31%). Results were obtained for 1375 (95.2%) samples, of which 1255 (91.3%) derived from singleton and 120 from twins (8.7%) pregnancies. Singleton pregnancies resulted in 659 XY and 596 XX pregnancies. Normal karyotype was reported in 1350 (98%) and abnormal results were derived from the analysis of 28 samples of which 18 were clinically confirmed and 5 samples were normal (0.36% false positive). As far as we know, no false negative results were obtained. Abnormal karyotypes found included T21 (n=15), T18 (n=3), T13 (n=4) and one XXY. Out of the 69 samples which were not reported, 47 had low fetal fraction (less than 1%), 13 were at borderline values, in 6 samples the data was out of range and 3 were rejected because of technical parameters (0.21%). Overall we found that NIPS is a reliable and replaceable method to be used as first line prenatal screening. Other than this NIPS will continue to increase our insight into early gestational placental findings not previously well recognized.

## PgmNr 879: Cancer gene mutations in congenital pulmonary airway malformation patients.

---

Newborns affected with congenital pulmonary airway malformations (CPAMs) may present with severe respiratory distress. While surgical resection is the definitive treatment for symptomatic CPAMs, prophylactic elective surgery may be recommended for asymptomatic CPAMs owing to the risk of tumor development. However, the implementation of prophylactic surgery is quite controversial on the grounds that more evidence linking CPAMs and cancer is needed. The large gap in knowledge of CPAM pathogenesis results in uncertainties and controversies in disease management. As many known developmental genes control postnatal cell growth and contribute to cancer development as well, we hypothesized that CPAMs may be underlain by germline mutations in genes governing airways development. Sequencing of the exome of 19 patients and their unaffected parents. A more than expected number of mutations in cancer genes (false discovery rate  $q$ -value  $< 5.01 \times 10^{-5}$ ) was observed. The co-occurrence, in the same patient, of damaging variants in genes encoding interacting proteins is intriguing, the most striking being thyroglobulin (*TG*) and its receptor, megalin (*LRP2*). Both genes are highly relevant in lung development and cancer. The overall excess of mutations in cancer genes may account for the reported association of CPAMs with carcinomas and provide some evidence to argue for prophylactic surgery by some surgeons.

## PgmNr 880: Splicing-QTL analysis identified regulatory variants and their target genes at prostate cancer risk loci.

### Authors:

Y. Tian; L. Wang

[View Session](#) [Add to Schedule](#)

**Affiliation:** Pathology, Medical College of Wisconsin, MILWAUKEE, WI.

---

Genome-wide association studies (GWAS) have identified hundreds of single nucleotide polymorphisms (SNPs) associated with an increased risk to prostate cancer (PrCa). To build links between risk SNPs and potential genes, expression quantitative trait loci (eQTL) analysis has been widely used. To complement the eQTL analysis, we present splicing QTL (sQTL) analysis using RNA-seq data from benign prostate tissues (n=467). From our 2.5M Illumina genotype data, we first performed population-based imputation by Markov Chain Haplotyping (MaCH1) and selected risk variants by LDproxy ( $R^2 \geq 0.5$ ). We then applied RNA-Seq by Expectation-Maximization (RSEM) package to estimate transcript-level profiles. Integrating the SNP genotypes and RNA profiles, we applied sQTLseeker package to perform a distance-based splicing ratio analysis. With the input of transcript abundance (n=114,670) and risk SNPs (n=21,986) at PrCa loci, we identified significant associations in 1,533 SNP-transcript pairs ( $FDR \leq 0.1$ ). Among those were two sQTLs [rs4074037-*MUC1* (CA15-3) ( $FDR=9.9E-5$ ), rs10424178-*BABAM1* ( $FDR=0.056$ )], which were previously reported in other cancers. We also found new sQTLs including a common SNP (rs7247241) and its susceptible gene (*PPP1R14A*) ( $FDR=0.089$ ), with allele C being linked to a short isoform (ENST00000587515), leading to 50% shortened protein product. To functional characterize this new sQTL, we examined ENCODE ChIP-seq tags and found preferred CTCF binding for rs7247241-T allele in both prostate cell lines and immortalized lymphoblastoid cell lines. Bisulfite sequencing from ENCODE cell lines demonstrated a negative correlation between CTCF binding at this locus ( $\pm 75$ bp flanking region) and averaged methylation percentage ( $r=-0.512$ ). Interestingly, allele-specific methylation analysis showed a strong association of rs7247241-C allele and hypomethylation at this locus. To evaluate the role of the *PPP1R14A* short isoform, we examined the percent splice-in value (PSI) for the short isoform and observed significant downregulation in TCGA primary prostate tumors ( $p=6.21E-14$ ). Further analysis showed a positive association between the short isoform and relapse-free survival ( $p=3E-6$ ). Overall, by analyzing a large prostate-specific SNP genotype-gene expression database, we identified a set of sQTLs at PrCa risk loci. We characterized regulatory SNP rs7247241 and its role in controlling DNA methylation of flanking sequence, splicing event of target gene *PPP1R14A*.

## PgmNr 881: Mechanistic insights of inactivation of chitinase 3-like-1.

**Authors:**

N. Kishigami; K. Okawa; F. Oyama

[View Session](#) [Add to Schedule](#)

**Affiliation:** Kogakuin University, Hachioji, Tokyo, Japan

---

Chitinase-like proteins are structurally homologous to chitinase but lack the ability to degrade chitin. It is generally assumed that the lack of chitinase activity in chitinase-like proteins is due to the mutation of crucial residues within the conserved catalytic sequence. Chitinase 3-like-1 (Chi3l1), one of the chitinase-like proteins, is expressed in mice and human. Chi3l1 levels are increased in individuals with asthma, chronic obstructive pulmonary disease (COPD), cystic fibrosis, rheumatoid arthritis, inflammatory bowel disease, alcoholic cirrhosis and many types of malignant tumors. Thus, Chi3l1 may play important roles in the pathophysiological conditions. However, the contribution of the protein to the pathophysiology of the related diseases remains to be determined. Despite Chi3l1 has a relatively high sequence homology to chitotriosidase (Chit1), it lacks chitinase activity. Although we attempted to activate Chi3l1 by introducing two substitutions of amino acid (A139D and L141E) in the active center of the wild type Chi3l1, it remained inactive. We have shown that M at the position 61 is highly conserved in the mammalian chitinases. Although M61 is conserved in both mouse Chit1 and AMCase, Chi3l1 has I61. Thus, we predicted that the amino acid at the position 61 is involved in chitinase activity, and we attempted to activate Chi3l1 by introducing substitution of I61M. The Chi3l1 with amino acid substitution of I61M remains inactive. This result suggests that it is necessary to substitute multiple amino acids in addition to I61M to activate Chi3l1. Further studies are needed to activate Chi3l1, and it is currently under investigation.

## **PgmNr 883: Longitudinal immune and genomic monitoring reveals signatures of response and immune-related adverse events in cancer patients receiving checkpoint inhibitor therapy.**

Despite the remarkable success of immune checkpoint inhibitor (ICI) therapy, a significant number of patients develop severe and unpredictable immune-related adverse events (irAEs) affecting a wide variety of organs. Concerns over irAE have led to the exclusion of patients with autoimmune disease from ICI clinical trials. Role of host genetic and immune factors in mediating irAEs remain unclear and it is not clear if the manifestations of irAEs is associated with response to therapy. Here, we use multi-faceted approach to characterize changes in host immune system in 250 patients receiving ICI therapy at baseline and post immunotherapy. In addition, we assessed genetic predisposition to autoimmunity in these patients using the Illumina GSA SNP array and via targeted resequencing of over 150 immunoregulatory loci including the HLA region. In this meeting, we will present our initial genetic data, analysis of serum cytokine and autoantibody profiles and RNA sequencing on peripheral blood mononuclear cells (PBMCs) at baseline and post immunotherapy in patients with and without irAEs. Our preliminary findings suggest that patients who developed irAEs have lower baseline levels and greater post-treatment increases in key interferon gamma inducible cytokine/chemokine levels. Our preliminary autoantibody profiling data demonstrates that pre-existing quiescent humoral autoimmunity correlates with irAEs. We will present immune and genetic correlates of irAEs and response to therapy identified in our preliminary analysis. We are currently generating and integrating cytokine, autoantibody, RNA-seq data and genetic data and intersecting with clinical profiles of 250 patients to gain insight in to the mechanisms underlying irAE and to identify biomarker signatures predictive of irAEs and/or response. These findings may ultimately help identify high-risk patients, customize therapy, tailor monitoring, expand use of immunotherapy and prevent toxicities.

## PgmNr 884: Genetic polymorphism studies in alcoholic pancreatitis.

### Authors:

V. Aaren; G. Sudhakar

[View Session](#) [Add to Schedule](#)

**Affiliation:** Department of Human Genetics, Andhra University, Visakhapatnam, Andhra Pradesh, India

---

Chronic alcohol consumption is considered as a major cause of acute and chronic pancreatitis in many populations. To determine the genetic susceptibility to alcoholic pancreatitis (AP) in South Indian populations, 250 cases with alcoholic pancreatitis (AP), 250 alcoholic controls (AC) and an additional 320 healthy ethnic and sex-matched controls were recruited. Five of the previously associated genetic variations of exon 3, Arg47His G/A of *ADH2/ADH1B*; exon 8, Ile349Val G/A of *ADH3/ADH1C*; intron 6, T7678A of *CYP2E1*; *GSTM1*; and *GSTT1* genes were genotyped by PCR based Restriction Fragment Length Polymorphism (PCR-RFLP) analysis of blood DNA samples using gene and locus specific oligos. A detailed history of each case including the age, alcohol consumption (quantity and type of beverage), smoking, tobacco intake and other lifestyle factors were recorded. Gene polymorphisms were compared between alcoholic pancreatitis subjects (AP) vs alcoholic controls (AC) and alcoholic pancreatitis (AP) vs healthy controls (HC). Genotypic frequencies were calculated and odds ratios (OR) were determined using 2 × 2 contingency tables with 95% confidence intervals. Statistical significance for Odds Ratio (OR) was calculated by chi-square test using SPSS Version 16 software. Fisher's exact test was used when expected cell frequency was less than five. The association of the gene polymorphisms in patients and controls was examined using OR and Chi-square tests with CI 65%,  $P < 0.05$  was considered as significant. A significant association between *ADH3 Ile349Val* and AP when compared to the AC controls ( $P = 0.005$ ) and HC controls ( $P = 0.01$ ). No association was observed between markers *CYP2E1* T7678A compared to AP and controls ( $P = 0.42736$ ). Moreover, *GSTM1* ( $P = 0.7208$  and  $P = 0.42034$ ), and *GSTT1* ( $P = 0.3962$  and  $P = 0.20326$ ) genotypes were also not statistically associated with AP when compared to AC and HC controls. Similarly, lack of association between AP and *ADH2 / ADH1B* Arg47His gene polymorphisms were observed. The present data on the causes of pancreatitis may support more effective disease management, provide hope for a potential cure and aid in developing strategies for the prevention or treatment of alcoholic pancreatitis. We further conclude that a strong association with *ADH3* gene that might have a major influence on susceptibility to pancreatic cancer in south Indians, however future studies with other Indian populations are needed.

## PgmNr 885: Identify breast cancer risk-associated lncRNAs that play a role in DNA damage repair.

### Authors:

N. Abdou <sup>1,2</sup>; M. Moradi Marjaneh <sup>1</sup>; H. Sivakumaran <sup>1</sup>; K. Hillman <sup>1</sup>; S. Kaufmann <sup>1</sup>; L. Fachal <sup>3</sup>; A. Dunning <sup>3</sup>; S. Edwards <sup>1</sup>; J. French <sup>1</sup>

---

Genome-wide association studies (GWAS) have identified 196 independent signals that predispose to breast cancer. The vast majority of risk variants within these signals are located in intronic or intergenic regions. This suggests that distal regulatory elements such as transcriptional enhancers and/or noncoding RNAs contribute significantly to the risk of developing breast cancer. Many breast cancer susceptibility genes have been linked to DNA double-strand break (DSB) repair, where DSBs lesions evoke genomic instability and cellular lethality if not repaired. Furthermore, long noncoding RNA (lncRNA)-directed regulation of DNA damage repair pathways has been recently reported for different cancer types. Here, we use target RNA-sequencing to identify and catalogue all lncRNAs expressed from breast cancer risk signals that are induced in response to DNA damage. MCF7 breast cancer cells were treated with single ionizing irradiation (IR) dose to induce DSBs, and then RNA collected at 1, 6 and 24hr post-IR. De novo assembly of the sequencing reads identified 280 lncRNAs significantly induced at 1hr and 6hr post-IR timepoints (RPKM  $\geq$  0.5; FDR < 0.05), 166 of which are not currently annotated in existing databases. One of these lncRNAs called XLOC156282 is transcribed from the 4q21 breast cancer risk signal, which is associated with risk of developing estrogen receptor (ER)-positive. XLOC156282 is a two-exon, 4.6 kb nuclear transcript that is induced at 1 hr post-IR in normal breast cells and ER-positive breast cancer cells. XLOC156282 is antisense to ABRAXAS1, which encodes the BRCA1-A Complex Subunit Abraxas 1, a known DSB repair protein. To determine the function of XLOC156282, we used locked nucleic acid (LNA<sup>™</sup>) technology to silence XLOC156282 in MCF7 cells. Quantitative PCR confirmed that XLOC156282 knockdown resulted in reduced MRPS18C expression, but does not impact ABRAXAS1 mRNA levels or alternative splicing. MRPS18C encodes the Mitochondrial Ribosomal Protein S18C protein, which assists in protein synthesis within the mitochondrion, but has no reported role in breast cancer. Further studies are required to determine the mechanism(s) by which this XLOC156282 alters MRPS18C expression and how this potentially contributes to breast cancer development.

## **PgmNr 886: Heritable and somatic variation drive gene expression changes associated with survival in multiple myeloma.**

---

Multiple myeloma (MM), the second most common hematological cancer, has a poor prognosis and a 5-year survival of 50.7%. While new therapies have nearly doubled the survival rate, most patients still experience a relapse. The CoMMpass study, developed by The Multiple Myeloma Research Foundation, is a longitudinal clinical trial aimed at accelerating the discovery of more targeted treatments for MM. Clinical parameters and tumor specimens are collected from each of 1,147 patients at baseline and through out the 8-year period. Whole Genome, Exome and Transcriptome sequencing were performed on each tumor specimen to identify genetic determinants of clinical outcomes. This study has uncovered several somatic mutations and copy number alterations associated with tumor progression and response to therapy, and a novel classification of MM into 12 distinct subtypes based on gene expression. However, the contribution of germline genetic variation to gene expression changes and MM outcome remains poorly understood.

Genome-wide association studies have identified germline variants associated with MM risk, indicating inherited genetic susceptibility. MM exhibits a disparity in occurrence and mortality between sexes and ethnicities, with men and African Americans being at a higher risk than women or those of European ancestry. To better understand the genetic and biological basis of MM predisposition, we utilize a functional genomics approach to examine non-coding germline and somatic effects on gene expression and MM outcome. Data from 607 CoMMpass participants with available WGS and RNAseq from normal blood and baseline tumor specimens were used to map eQTLs, resulting in 3,929 genes with at least one cis-acting eQTL. We identified eQTLs modulating survival in MM patients and several regulatory variants with differential effects on tumor gene expression between sexes. Several eQTLs overlap MM GWAS risk loci, providing regulatory mechanisms connecting these loci to MM. To identify eQTLs overlapping open chromatin areas we performed ATACseq on male (3) and female (3) MM cell lines, and identified 371 eQTLs on accessible DNA regions. To functionally validate the eQTLs we performed CRISPR activation/interference in MM cell lines. Using integrated functional genomics approaches combined with clinical outcomes we have identified new regulatory regions associated with survival in MM, supporting the development of personalized medicine approaches for better treatments.

## PgmNr 887: Network pathways leading to discover biomarker candidates based on genomic profiles of racial differences in triple negative breast cancer.

### ABSTRACT

**Objective:** Triple negative breast cancer (TNBC) is more prevalent in African Americans (AAs), has a more aggressive clinical course including a higher mortality rate and increased occurrences of metastases. This study was designed to determine if racial differences at the molecular level might explain the more aggressive phenotype in AAs.

**Method:** Mutation profiling was performed on 51 AA and 77 CA tumor/normal pairs using Exome-Seq analysis and the GATK pipeline. Transcript expression analysis was performed on 35AA and 37CA samples and analyzed using the Tuxedo Suite tools. The importance coefficient ranking of genes was performed using the Machine Learning model, Support Vector Machine (SVM) to detect differences between the two racial groups. The novel network analysis was conducted for further Hub gene candidates applicable for biomarker selection.

**Results:** Genes with high frequency mutation rates such as MUC4 and TP53 were common to both racial populations, however genes that were less frequently mutated differed between the races suggesting that those cause the more aggressive nature of TNBC in AA women. JAK-Stat signaling was unique to the AA and PTEN and mTOR were unique to the CA profiles. SVM and co-expressed and interacted network analysis identified Interferon and Cytokine signaling pathways as more highly expressed in AA patients.

**Conclusion:** Many pathways identified by the mutational profiles were predicted to be down-regulated by the transcript expression profiles. Genes in ILK signaling pathway commonly found in both races can be examined as genetic targets to treat TNBC. Genes in the respective pathways, either unique to AA or unique to CA can be tested as genetic targets by race. The discovered Hub genes in the networks can be associated with a biomarker identification to differentiate the phenotypes of AA and CA.

## PgmNr 888: Investigating the role of ATRX in osteosarcoma progression.

Osteosarcoma (OS) is the third most prevalent pediatric cancer. Its high propensity of pulmonary metastasis makes the overall survival rate less than 30%. Despite advances in surgery and chemotherapy, the poor understanding of the genomic features has hampered the development of effective and specific treatments over the decades. OS is characterized by a high level of genomic instability including large chromosomal structure variations and epigenetic alterations. However, molecular mechanisms driving the genomic instability during OS development and progression is not well understood.

Previously, we and others analyzed whole exome/genome sequencing datasets of human OS primary tumor with matched blood samples and identified somatic inactivating mutations in *ATRX* (alpha-thalassemia / mental retardation, X-linked). *ATRX* belongs to the SWI/SNF family and plays fundamental roles in chromatin remodeling. As an epigenetic regulator, *ATRX* modulates histone H3.3 deposition, maintains chromatin configuration, resolves DNA superstructure such as G-quadruplex, and secures genomic integrity. Its role in genome maintenance and the tendency of recurrent mutations in OS patients suggest potential participation of *ATRX* loss-of-function in inducing genomic instability and reshaping the chromatin landscape during the cancer progression.

To understand the cellular functions of *ATRX*, we knocked down *ATRX* in OS cell lines using siRNA approach. *ATRX* knockdown in 143B and MNNG cells showed increased proliferation and migration potential, and the cellular morphology became more mesenchymal-like. N-cadherin protein level was also upregulated after *ATRX* knockdown, which indicates mesenchymal-like cell property. These results show that loss of *ATRX* leads to increase proliferation and prone to become mesenchyme with elevated migratory potential, which suggests a tumor suppressive role of *ATRX* in OS pathogenesis. Currently, we are developing *ATRX* knockout OS cell lines to examine the impacts of *ATRX* deficiency toward transcriptome alteration and epigenetic modification in OS by using CRISPR-Cas9 mutagenesis. Furthermore, to elucidate the tumor suppressive role of *ATRX* in OS development, conditional *Atrx* knockout mouse models are being established.

## PgmNr 889: Identifying functional variants at chr7p14.1 affecting pancreatic cancer risk.

---

Pancreatic ductal adenocarcinoma (PDAC), the third leading cause of cancer-related deaths, is often difficult to diagnose. An effort to identify common susceptibility loci for PDAC using genome-wide association studies (GWAS) has led to the identification of twenty loci for pancreatic cancer risk. One of these is at chr7p14.1 (rs12701838,  $P = 3.9 \times 10^{-9}$ ) which maps to the final intron of *SUGCT*. We used linkage disequilibrium (LD) analysis and a likelihood ratio of 1:1000 to identify 18 candidate functional variants. Expression quantitative trait locus (eQTL) analysis of the GTEx v7 pancreas data set demonstrated an association between 7p14.1 and *INHBA* (rs10279715, normalized effect score=0.29,  $P = 1.9 \times 10^{-5}$ ) with lower *INHBA* expression correlated to the risk genotype. *INHBA*, which is approximately 1 Mb downstream of rs10279715, is important for endocrine cell differentiation and insulin secretion. Furthermore, our transcriptome-wide analysis study (TWAS) identified *INHBA* as a gene-trait association signal for pancreatic cancer ( $Z = -5.11$ ,  $P = 3.2 \times 10^{-7}$ ). After conditioning on the lead GWAS SNP rs12701838, the *INHBA* TWAS signal is no longer significant ( $P = 0.81$ ). Co-localization analysis with the Coloc R package suggests the GWAS and eQTL signals share a single causal variant ( $PP = 0.74$ ). To identify functional variants lying within regulatory regions identified in pancreatic samples, we are using CRISPR in pancreatic cancer cell lines to delete small genomic regions (~250 bp) each harboring a single variant and assessing the effects on *INHBA* and *INHBA-AS1* gene expression. Candidate regions will subsequently be examined for allele-specific effects with electrophoresis mobility shift assays, luciferase assays, and proteomics. Future work aims to elucidate the role of *INHBA* and the functional variant(s) in PDAC risk and pathogenesis.

## PgmNr 890: Evidence for an ancient *BRCA1* pathogenic variant and a novel *BRCA2* pathogenic variant in inherited breast cancer patients from Senegal.

### Authors:

J.P.D. Diop <sup>1</sup>; V. Bourdon-Huguenin <sup>4</sup>; A. Dem <sup>5</sup>; D. Diouf <sup>5</sup>; S.M.K. Gueye <sup>2</sup>; S.A. Ba <sup>1</sup>; Y. Dia <sup>1</sup>; R. Ndiaye <sup>1,2,3</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Laboratory of Cytology, Cytogenetics and Reproductive Biology, Aristide Le Dantec Hospital, Dakar, Senegal; 2) Faculty of Medicine, Pharmacy and Odontology, University Cheikh Anta Diop, Dakar, Senegal; 3) African Center of Excellence for Mother and Child Health (CEA-SAMEF); 4) Laboratory of Molecular Oncogenetics, Paoli-Calmette Institute, Marseille, France; 5) Joliot Curie Institute, Aristide Le Dantec Hospital, Dakar, Senegal

**Background:** *BRCA1* and *BRCA2* are the most incriminated genes in inherited breast/ovarian cancers. Several pathogenic variants of these genes conferring genetic predisposition have been described in different populations but rarely in subsaharan Africa. The objectives of this study were to identify pathogenic variants of the *BRCA* genes involved in hereditary breast cancer in Senegal and to search for a founder effect.

**Methods:** We recruited after free informed consent, 27 unrelated index cases diagnosed with breast cancer and each having a family history, and a control population of 48 healthy women and 48 women diagnosed with sporadic breast cancer. All *BRCA1* and *BRCA2* exons were Sanger sequenced for the first 15 index cases recruited. For the following 12, healthy relatives and controls, the recurrent pathogenic variant of *BRCA1* identified in the first group was genotyped by PCR. To search for a founder effect of the recurrent pathogenic variant of *BRCA1*, haplotype analysis of 7 microsatellites encompassing the gene was performed in 10 selected index cases with the pathogenic variant and 15 unrelated healthy controls. Mutation age was estimated using the following equation:  $G = \log/\log (1 - q)$ .

**Results:** Mutation screening identified a recurrent duplication of 10 nucleotides c.815\_824dupAGCCATGTGG, (p.Thr276Alafs) of *BRCA1*, in 15 index cases (detection rate 55.5%). Haplotype analysis showed a shared haplotype encompassing approximately 400 kb. Estimation of the age of the pathogenic variant suggested that it occurred approximately 1400 years ago and confirm a West African origin. The variant was also detected in healthy relatives of selected families. The genotyping method is now available as a first screening test in women at risk. For *BRCA2* gene, a novel pathogenic variant, c.5219 T >133 G; p.(Leu1740Ter) was identified in a proband from a consanguineous family along with three sisters and one daughter of the index case.

**Conclusion:** Our study identified a founder pathogenic variant of *BRCA1* predisposing to breast cancer and enabled the establishment of an affordable genetic test as a mean of prevention for Senegalese women at risk. Oncogenetic counselling and mutation screening for other causal genes should now be implemented in Senegal.

**Keywords:** Hereditary Breast Cancer, *BRCA1*, *BRCA2*, pathogenic variant, Senegal.

## PgmNr 891: Associations of *BRCA1/2* mutations with Chinese breast/ovarian cancer patients.

### Authors:

M. He <sup>1,2</sup>; M. Yan <sup>1</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Simcere Diagnostics Co., Ltd., Nanjing, 210042, China; 2) State Key Laboratory of Translational Medicine and Innovative Drug Development, Nanjing, 210042, China

**Background:** *BRCA1* and *BRCA2* are well-characterized predisposition genes associated with breast and/or ovarian cancers. However, the majority of the studies has been conducted in the western populations. The genomic impacts on Chinese breast and/or ovarian cancer patients require further assessments of the *BRCA* genes and identifications of potential novel ones.

**Patients and methods:** In this study, 276 patients with clinical diagnosis consist of 139 breast cancer (BC; including 1 male; age (mean  $\pm$  standard deviation):  $48 \pm 11$ ) and 139 ovarian cancer (OC; including 1 male; age:  $54 \pm 10$ ) while two patients are both BCs and OCs. In addition, 402 individuals (male to female ratio: 1:1, age:  $43 \pm 13$ ) are in-house controls with no BC/OC or other cancers examined at the time that the study was initiated. Whole-exome sequencing (WES) was conducted and the association between BCs/OCs and the in-house controls was assessed. The other East Asians (total 7,209) in Genome Aggregation Database (gnomAD) was used as an additional set of controls in this study. Cohort allelic sums test (CAST) was used for the comparisons between cases and controls at the gene level. Fisher's exact test was used to estimate the significances of the single variants between cases and controls. All P values were adjusted by the Benjamini-Hochberg false-discovery rate (FDR) multiple testing correction.

**Results:** Mutations in both *BRCA1* and *BRCA2* were dramatically enriched in the cases. Compared to the in-house controls, *BRCA1* and *BRCA2* showed gene-based significance, with the FDR-adjusted p-values being 0.006 and 0.003 in BC, 0 and 0.008 in OC, and 0 and 0.0003 in both BC and OC cohorts, respectively. While compared to the other East Asians in the gnomAD, the adjusted p-values of *BRCA1* and *BRCA2* were  $5.61\text{e-}5$  and  $1.89\text{e-}5$  in BC,  $4.18\text{e-}15$  and  $2.77\text{e-}4$  in OC, and  $5.83\text{e-}15$  and  $7.65\text{e-}9$  in both BC and OC. Additionally, *PRKRA* also showed high significance while compared to the other East Asians in the gnomAD, with adjusted p-values of  $6.16\text{e-}15$ ,  $4.18\text{e-}15$  and  $5.83\text{e-}15$  in the BC, OC, BC and OC subsets, respectively.

**Conclusions:** *BRCA1/2* were confirmed to be associated with the occurrence of BC/OC in the Chinese patients in contrast to either in-house controls or the other East Asians in the gnomAD. Furthermore, *PRKRA* might play a role in the onset of BC/OC in Chinese descent. Further work is required to expand the patient size to provide more solid confirmations.

## PgmNr 892: Classifying variants of unknown significance in the BRCA1-PALB2 binding interface.

**Authors:**

C.A. Hurd; M.D. Stewart

[View Session](#) [Add to Schedule](#)

**Affiliation:** Biology, Texas Christian University, Fort Worth, Texas.

---

BRCA1 (Breast Cancer associated protein 1) and PALB2 (Partner and Localizer of BRCA2) are two tumor-suppressing proteins that have been shown to associate with each other in the DNA damage response to repair double-stranded breaks through homologous recombination. Mutations in both *BRCA1* and *PALB2* have been shown to be associated with increased breast and ovarian cancer risk in accordance with their role as tumor suppressors. Genetic databases currently have lists of variants of unknown significance (VUS) for these two corresponding genes gathered from previous studies. Our research aims to establish an *in vitro* biochemical model to predict the effect of VUS in the BRCA1 and PALB2 interaction domains. NMR titrations and isothermal titration calorimetry show that our minimized wild-type interaction domain constructs interact *in vitro*. We are using site-directed mutagenesis to recreate known VUS in these minimized constructs. Through comparison with wild-type binding affinities and affinity of known detrimental mutant proteins, we can establish the effect of the VUS on the crucial interaction. We will present our *in vitro* model system and ongoing data collection from *BRCA1* and *PALB2* variants of unknown significance.

## PgmNr 893: Mutational analysis of chromosome 16q in wilms tumors.

**Authors:**

E. Kitamura; C.-S. Chang; J.K. Cowell; L. Hawthorn

[View Session](#) [Add to Schedule](#)

**Affiliation:** Georgia Cancer Center, Augusta University, Augusta, GA

---

**Objective:** Wilms tumor (WT) is the most common childhood renal tumor and affects approximately 1 in 10,000 children in Europe and North America. Chromosome 16q deletion (del) or loss of heterozygosity (LOH) has been associated with recurrence and adverse prognosis in WT. Our study aims to identify genes implicated in the adverse event on chromosome 16q.

**Method:** We performed exome-sequencing on 8 WTs with chr16q del/LOH from our legacy collection. In addition, we analyzed 42 exome-seq data of WT patients from the TARGET database. The fastq data were aligned by BWA v.0.6.1 software and variants were detected using haplotypcaller. The detected variants were annotated by VEP and filtered using custom cut-offs to search for somatic mutations. We compared the mutational profiles of total 50 WTs between with and without chr16q del/LOH. Also we searched signaling pathways in association with the mutational profiles in WT using Ingenuity Pathway Analysis.

**Results:** In this study, a total of 24,271 variants predicted as damaging and/or deleterious were found in 10,789 genes. By comparing these variants between WT with and without chr16q del/LOH, we identified 131 homozygous somatic variants with putative loss-of-function in 91 genes on chr16q. Pathway analysis showed that cilia-related signaling pathways such as sonic Hedgehog (SHh), Wnt signaling and Notch signaling are highly mutated in WTs with chr16q del/LOH.

**Conclusion:** The results suggest that the signaling pathways are involved in poor prognosis in WT, providing a possibility of using key genes in the pathways as biomarkers for diagnosis and treatment of aggressive WT and investigating mechanism leading to adverse prognosis.

## PgmNr 894: SVFX: A machine learning framework to identify pathogenic structural variations in disease studies.

---

A rapid decline in sequencing cost has enabled large-scale genome sequencing studies feasible. One of the fundamental goals of these studies is to catalog all variants of functional consequence. Numerous methods and tools are being developed to interpret point mutations, small insertion, and deletions. However, there is a lack of methods for understanding the functional consequence of genomic structural variations. Structural variations play a crucial role in various diseases by altering the sequence and three-dimensional structure of the genome. In this work, we build a machine learning based workflow that leverages genomics, epigenomics, and conservation metric to assign a pathogenicity score to somatic and germline structural variations in various diseases. We apply this workflow on structural variants present in six different cancer types. Overall, our predictor achieves high accuracy in identifying pathogenic germline and somatic structural variations. In particular, our predicted pathogenic somatic variants are enriched among known cancer genes and many cancer-related pathways, including Wnt signaling, Ras signaling, DNA repair, and ubiquitin-mediated proteolysis. Finally, we note that our framework is highly flexible can be easily extended to identify pathogenic germline structural variations in other disease-specific studies.

## PgmNr 895: The Reactome pathway knowledgebase: Linking human genetic variation to disease.

---

Human reaction space is a network of processes whose extensive connectivity undoubtedly contributes to maintenance of homeostasis in the face of environmental stresses. This connectivity also undoubtedly contributes to the difficulty of predicting the effects of a genetic variation on a whole-organism phenotype given its effects on a protein's function at a molecular level.

Pathway databases like Reactome enable the comprehensive, detailed annotation of reaction space in the framework of a data model that supports the organization and analysis of molecular-, cell-, and tissue-level data to investigate effects of changes in the functions of one or more gene products, to provide better genotype-phenotype predictions. Reactome is an open-source, expert-curated, peer-reviewed knowledgebase. Its holdings now comprise 12,505 human reactions organized into 2,272 pathways involving 11,109 proteins encoded by 10,840 different human genes, 2,042 small molecules (of which 185 are drugs), and 12,206 complexes. The database provides the molecular details of a wide range of cellular processes ranging from metabolism and signal transduction to development and neuronal systems. These annotations are supported by 30,027 literature references. The roles of variant forms of 305 proteins, both germline and somatically arising, have been annotated into disease-variant forms of 968 reactions and additional reactions that capture the effects of small molecule drugs on these disease processes. Variants are chosen for annotation based on guidelines and data from ClinGen and Cosmic.

Reactome thus provides a powerful tool for analyzing expression data to identify the specific parts of reaction space affected by a disease process or environmental stress, and is a useful starting point for investigating possible propagating effects of the loss of activity of single genes or gene combinations.

---

The last few years has seen widespread genetic testing for germline variants in *BRCA1* for assessment of breast and ovarian cancer risk. However, this trend led to an increase in findings of *BRCA1* variants of uncertain clinical significance (VUS). Carriers of VUS cannot be told whether they are at increased risk or not. While for those with a strong family history of cancer risk assessment can be based on clinical factors, those without a family history, ~½ of all carriers, have no such alternative. Thus, the determination of pathogenicity associated with a VUS is a critical barrier to the implementation of precision medicine.

Classification of missense variants, the largest class of *BRCA1* VUS, can be based on a multifactorial statistical model that incorporates data on family history, co-segregation, and co-occurrence with a known pathogenic variant in the same gene. Currently, functional data is used as supporting evidence for classification but are not yet integrated in these multifactorial statistical models. We expect that functional data will be critical for the classification of rare variants. Previously we compiled all functional data for missense variants in *BRCA1* into an interactive web tool called *BRCA1* Circos (<https://research.nhgri.nih.gov/bic/circos/>). We have now updated and greatly expanded our comprehensive database of functional assays for *BRCA1* missense variants.

We identified 35 published articles describing 129 sets of functional experiments leading to 3,427 results assessing the functional impact of missense variants on *BRCA1* functions. Altogether, 1,005 unique (out of a possible 11,009) missense variants were tested at least once. To harmonize results we used the thresholds and classifications described by the original authors and converted all results into “functional impact” or “no functional impact”. We used a panel of 298 known reference variants (252 benign or likely benign and 45 pathogenic or likely pathogenic) to calculate sensitivity and specificity for every assay. There were 46 and 242 variants (out of 463 tested more than once) that scored as “functional impact” or “no functional impact” consistently in every assay tested, respectively. This work is the first step to harnessed functional data on missense variants of *BRCA1* for clinical annotation. Generating a comprehensive picture of *BRCA1* variants using validated assays can accelerate the classification of VUS.

## PgmNr 897: Population-wide screening for germline variants of hereditary cancer genes in 12K unselected colorectal cancer and 27K controls in Japan.

**AIM.** Colorectal cancer (CRC) is one of the most common cancers in Western countries and Japan. A few % of CRCs can be attributed to recognizable hereditary germline variants of susceptibility genes, predominantly the DNA mismatch repair genes (Lynch syndrome), and universal genetic screening has been proposed for CRCs. Now there are a number of variants of these genes aggregated and annotated in several databases, but still most are VUS and sometimes ethnic-specific. Hence it is require to have a large-scale variant dataset in a specific ethnic group.

**METHODS.** We here sequenced coding regions of eleven genes (*MSH2*, *MSH6*, *MLH1*, *PMS2*, *EPCAM*, *APC*, *MUTYH*, *SMAD4*, *PTEN*, *STK11*, and *TP53*) in 12,347 unselected CRC patients and 27,706 controls (60~yo) without any cancer and cancer family history by our high-throughput method (*Nat Commun* 9:4083, 2018). The samples were collected by Biobank Japan (BBJ) from locations all over Japan. We assigned their clinical significances using ACMG and Genomics and the Association for Molecular Pathology guidelines as well as ClinVar.

**RESULTS.** We identified 1,900 variants in the eleven genes and annotated them as 210 pathogenic variants, 261 benign ones, and 1,429 VUS, of which 30% were not registered in ClinVar and novel. Some variants annotated as pathogenic or VUS in ClinVar were observed frequently in the Japanese control population, such as p.Leu582Val and p.Thr151Thr of *MLH1*, p.Lys1358fs of *MSH6*, and p.Lys845Glu of *MSH2*. In total, 1.5% of the unselected CRC patients and 0.014% of the controls had a pathogenic variant. The pathogenic variants of *MSH2* (OR =10), *MLH1* (OR =18), *MSH6* (OR =6), and *APC* (OR=47) were significantly associated with CRC development in Japanese population ( $P$ -value  $<10^{-4}$ ). One recurrent mutation of *MSH6* (p.Phe1088fs) was found in Japanese CRCs. All of 21 truncating or pathogenic variants of *APC* in this CRC cohort were located not in the mutation cluster region, indicating their attenuated phenotype. Furthermore, from the genome-wide SNP chip data, we called CNVs or SVs of the target genes and confirmed SVs of *MSH2/EPCAM*, *MLH1*, and *APC* by MLPA (n=23).

**COCLUSION.** In unselected Japanese CRC cases, pathogenic variants or CNVs of *MSH2*, *MLH1*, *MSH6* and *APC* were observed in 1.7%. This is the largest study, to the best of our knowledge, of CRC heredity and would contribute to development of guidelines for genetic testing and variant interpretation for familial and sporadic CRCs.

## **PgmNr 898: Functional classification of selected exonic splicing variants occurring outside of canonical 5' and 3' exon boundaries in cancer-predisposing genes.**

---

Sequence variants that affect mRNA splicing account for 10-15% of disease-causing mutations in cancer-predisposing genes. A majority of these occur at the 5' and 3' exon-intron boundaries, and the potential impact on splicing often can be predicted based on known sequence conservation at splice acceptors and splice donors. Sequence variants located outside of canonical splice sites also may alter mRNA processing through the use of cryptic splice sites or through the alteration of exonic splicing enhancers and silencers. The effects of these types of variants on mRNA processing are more difficult to predict and require experimental verification to determine splicing outcomes for accurate variant classification. In this IRB-approved study, we assessed the effects of eight variants of uncertain significance (VUS) identified during clinical testing of cancer-predisposing genes. RNA was extracted from blood of VUS carriers and reverse transcribed for analysis of aberrant splicing. Seven of the eight variants analyzed occur in exonic regions, outside of exon-intron boundaries. Of these, five variants were shown to produce a complete splice defect and were upgraded to likely pathogenic mutations. One variant, *BRCA2* c.68-2A>G, occurs at a consensus splice acceptor and could be classified as likely pathogenic based on splicing predictions. Our RNA results raise the possibility that a functional transcript could be produced, and therefore the classification remains VUS. Investment in RNA studies is integral to a robust variant classification program in hereditary cancer risk testing. Our laboratory RNA analyses continue to provide valuable information that may ultimately alter patient medical management, with implications for their family members.

## PgmNr 899: Flow variant assays of the double strand break repair pathway improve risk classification for women receiving cancer panel sequencing.

---

About 10% of breast cancer is thought to be hereditary and caused by mutations in genes known to increase risk of cancer, especially those in the double strand break (DSB) repair pathway. Hereditary cancer gene sequencing panels can identify mutations in a fraction of high-risk patients and families, i.e., those with multiple affected members and earlier age of diagnosis. The remainder of patients has variants of uncertain significance (VUS) or negative results and, thus, their risk is not properly assessed. This issue of unclear risk can be mitigated using flow variant assays (FVAs), a functional approach for identifying defects in the DSB repair pathway. Defects in the repair process are identified in cells treated with radiomimetic agents using flow cytometry. To account for heterogeneity in individual assays, results are combined using logistic regression to calculate risk probability scores. Based on sensitivity of 0.91 and specificity of 0.99 for risk probability scores, Bayesian analysis showed that all VUS would be reassigned to the pathogenic ( $>0.99$ ) or likely pathogenic categories ( $>0.90$ ), if risk probability scores were high. Conversely if risk probability scores were low, VUS would be considered benign ( $<0.01$ ) or likely benign ( $<0.10$ ). Within a cohort of 119 women seeking genetic counseling and testing based on personal and/or family history that was considered to be high-risk, 16 (13%) were found to have mutations and 33 (28%) were found to have VUS. Among these women, 7 (6%) were reassigned to the population risk category by virtue of not inheriting a familial mutation. Among a subgroup of 43, including 24 with VUS, 15 (34%) were reassigned to the low-risk category based on their low-risk FVA probability scores and 28 (65%) were confirmed as high-risk based on their probability scores. A subject with a mutation in the APC gene also had a high-risk probability score, suggesting crosstalk with the DSB repair pathway or misreporting of the mutation as pathogenic. Thus, FVAs represent a highly accurate adjunct for identifying those with germline DSB repair defects that were missed by panel sequencing and for reassigning risk to population risk for those that had VUS or negative test results.

## PgmNr 900: Partitioned heritability and functional enrichment reveal ovarian cancer risk variants in histotype-specific enhancers that disrupt transcription factor binding sites.

Genome wide association studies (GWAS) have identified 41 regions associated with risk of epithelial ovarian cancer (EOC). Given that the vast majority of these variants lie in the non-coding genome, and that regulatory landscapes are highly tissue specific, we hypothesized that EOC risk alleles disrupt regulatory regions and function through their interaction with epigenomic features in cell types relevant to EOC.

We applied computational tools to identify functional mechanisms at GWAS risk loci for EOC. We first estimated the heritability explained by common SNPs for each EOC histotype and found that the current known risk loci of high grade serous ovarian cancer (HGSOC) account for approximately 6% of narrow sense heritability ( $h_g^2$ ). Moreover, we partitioned SNP-heritability across non-cell-type-specific functional categories and observed a significant contribution of regulatory elements to EOC heritability, e.g. Promoter ( $p = 0.016$ ), and Super-enhancer ( $p = 0.02$ ). To understand how risk variants residing in regulatory elements affect cancer development through the epigenomic landscape, we collected epigenomic datasets for a total of 121 cell and tissue types, from public resources (Roadmap Epigenomics and ENCODE) and in-house generated ChIP-seq. We identified significant enrichment of EOC risk variants in cell and tissue specific active regulatory elements marked by H3K27Ac. Histotype specific analysis of credible causal SNPs identified histotype-specific patterns of enrichment in regulatory elements. Credible causal SNPs for HGSOC were enriched in H3K27Ac only in HGSOC tumors, and depleted in ovarian surface epithelium, demonstrating that germline risk variants for EOC are located within regulatory elements that are active in tumor, rather than precursor normal tissues, but also add to the existing evidence that ovarian surface epithelium are unlikely the cell of origin for HGSOC. We predicted the effect of credible causal variants within H3K27Ac regions in EOC related cell types on transcription factor binding sites. The most frequently broken motif was REST, which is disrupted by 19 SNPs and has been implicated as both a tumor suppressor and an oncogene.

Overall, these systematic analyses guide comprehensive interpretation of EOC risk variants. Functional annotation with epigenomic data from relevant cell types can identify putative causal

regulatory elements and transcription factor binding sites that are disrupted by risk variants for EOC.

## PgmNr 901: Genome-wide analysis of ovarian super-enhancer associated lncRNAs implicates *WT1-AS* in inherited risk of high-grade serous ovarian cancer.

Long non-coding RNAs (lncRNAs) are critical regulators of gene expression and have emerged as both targets and effectors of super-enhancers (SEs). SEs are large regions of active chromatin associated with particularly high levels of target gene expression and are major drivers of dysregulated gene expression in cancer. We explored SE-associated lncRNAs in epithelial ovarian cancer (EOC) susceptibility by integrating *in silico* and experimental studies with genome-wide association study (GWAS) data from over 60,000 cases and controls. SEs were mapped using H3K27ac chromatin immunoprecipitation (ChIP-seq) and transcriptomic profiling in ovarian cancer precursor cells—fallopian tube secretory and ovarian surface epithelial cells (FTSECs and OSECs, n=2 per cell type) – and four different tumor histotypes (n=5 each). A total of 5,711 SEs were identified and linked to putative target genes by correlating ChIP-seq signal with gene expression, or using gene-enhancer pairings from the GeneHancer database. 61% of SEs were associated with lncRNA expression, and 126 SE-lncRNA pairs coincided with susceptibility regions identified by GWAS ( $p < 10^{-5}$ ). We prioritized SE-lncRNA pairs at risk loci by identifying lncRNAs which were either (1) exquisitely sensitive to transcriptional inhibitors (and therefore highly likely to be SE-regulated), or (2) exhibited risk-SNP *cis*-eQTL associations in normal and/or tumor tissues. This prioritized 10 SE-lncRNA pairs including *TIPARP-AS1* and *LINC00886* (3q25.31), *CTD-2245E15.3* (5p15.33), *SNHG7* (9q34.2), *MAP3K14-AS1* and *HOXB-AS3* (17q21.32), and *TTC28-AS1* (22q12.1). These analyses also identified 13 putative novel risk regions (GWAS p-value:  $10^{-8}$ -5). Novel high-grade serous EOC risk loci included chromosome 11p13 (index SNP rs910515, OR=0.92,  $p=2.9 \times 10^{-6}$ ), where SE signal is associated with expression of *WT1-AS*, a lncRNA expected to regulate WT1, a key transcription factor in high-grade serous EOC. *WT1-AS* was downregulated after THZ1 treatment (fold-change=-2.2) and *WT1-AS* expression is positively correlated with *WT1* expression in primary tumors ( $\rho=0.67$ ,  $p < 2.2 \times 10^{-6}$ ), suggesting *WT1-AS* positively regulates *WT1* expression *in cis*. In summary, we integrated epigenomic and transcriptomic profiles of ovarian tissues with GWAS data to identify SE-lncRNA axes that may play a role in EOC risk. Functional follow-up studies to elucidate the mechanisms at these regions are ongoing.

## PgmNr 902: Ultra-deep targeted sequencing of the tumor suppressor gene *DEAR1* identifies heterogeneous mutations in ductal carcinoma *in situ*.

---

Little is known regarding the genetic drivers of the transition from ductal carcinoma in situ (DCIS) to invasive ductal carcinoma (IDC) of the breast. *DEAR1* (annotated as *TRIM62*) has previously been found to be an important regulator of cellular polarity and negative regulator of TGF $\beta$ -mediated epithelial-mesenchymal transition (EMT), a process intimately linked to tumor progression and invasion. Using ultra-deep targeted next generation sequencing (NGS), *DEAR1* was found to be frequently mutated in patients with DCIS alone and in those with concurrent DCIS and IDC. *DEAR1* exonic variants previously reported in IDC were identified, as well as novel missense and nonsense variants. Orthogonal validation of select variants was completed via digital PCR. *In-vitro* functional screens of select variants identified in DCIS indicated that these variants led to the abrogation of tumor suppressor functions of *DEAR1*. Moreover, analytical sensitivity of the assay to detect substitutions and indels at the lower limit of detection was determined using custom engineered spike-in constructs. Frequent mutation of *DEAR1* in DCIS suggests its role as a driver in DCIS progression and supports the utility of ultra-deep sequencing for the discovery of rare variants that could have major impact on patient prognosis and stratification for precision medicine approaches.

## PgmNr 903: CRISPR-Cas9 generated allelic series of rat mutations confirms *Tox3* as a breast cancer susceptibility gene.

Diagnoses of breast cancer in the US now exceed 250,000 cases a year, posing a huge clinical burden. Because risk is influenced by genetics and the environment, studies on susceptibility have largely been neglected outside of high-penetrance alleles. Independent genome-wide association studies (GWAS) have repeatedly identified a group of common, low-penetrance variants in populations of women of European ancestry that exist in high linkage-disequilibrium ( $r^2 > 0.9$ , tag SNP minor allele frequency  $\approx 0.24$ ) on *16q12.1* that strongly, and uniquely associate with risk of developing Estrogen Receptor-positive (ER+) breast cancer, the most common subtype of the disease. These variants are associated with reduced expression of the gene *Tox3*, a poorly-characterized transcription factor that is highly expressed in the luminal epithelium of the mammary gland and also been shown to functionally alter the expression of Estrogen Receptor (ER) responsive genes in breast cancer cells. To model the effect of the risk-associated locus, our lab used CRISPR-Cas9 to generate an allelic series of mutations in highly-conserved, orthologous regions of the rat genome. The deletion mutations were targeted toward the promoter and/or upstream regulatory regions and cause decreased transcript-level expression of *Tox3* in the mammary gland of our novel rat model. Results from 7,12-dimethylbenz[a]anthracene-induced mammary carcinogenesis experiments showed a significant increase in multiplicity and advanced pathological staging of tumors that arise in low-*Tox3*-expressing rats, as compared to wild type. The tumors were found to be ER+ and progesterone receptor positive (PR+) and resemble human adenocarcinoma of the breast. Of importance, tumors that arise in the mutant rats continue to express low levels of the gene and appear more invasive. Analysis of RNA-sequencing data from these tumors identified subsets of differentially-expressed genes that support the phenotype observed in this rat model and the human data. Our findings highlight the importance of this new approach, which used CRISPR-Cas9 genetic engineering technology to model GWAS-identified loci and confirmed *Tox3* is a breast cancer susceptibility gene.

## PgmNr 904: Functional analysis of three PALB2 germline variants of unknown significance seen in breast, skin, and renal cancers.

### Introduction

The PALB2 protein is essential to RAD51-mediated homologous recombination (HR) repair. Germline monoallelic *PALB2* pathogenic variants confer significant risks for breast cancer. However, majority of *PALB2* variants remain classified as variants of unknown significance (VUS). We aim to functionally and mechanistically evaluate three rare *PALB2* VUS.

### Methods

Patient-derived lymphoblastoid cell lines containing the VUS were analyzed for nuclear localization and foci formation of RAD51 as a measure of HR efficiency. To understand the mechanism underlying the HR deficiency, PALB2 nuclear localization was assessed using immunofluorescence studies.

### Results

Among these VUS, c.3251C>T (p.Ser1084Leu) occurred in a patient with metastatic breast cancer while c.1054G>C (p.Glu352Gln) and c.1057A>G (p.Lys353Glu) were seen in patients with squamous cell carcinoma of skin and renal cell carcinoma respectively. Variant c.3251C>T was located within the WD40 domain which normally masked the nuclear export signal sequence responsible for nuclear delocalization of PALB2. Correspondingly, c.3251C>T displayed aberrant cytoplasmic localization of PALB2 which led to an impaired RAD51 nuclear localization and foci formation. On the other hand, both c.1054G>C and c.1057A>G showed intact HR functions and nuclear localization of PALB2, consistent with their locations within non-functional domains. Additionally, the prevalence of c.1054G>C was similar among healthy controls and patients with breast cancer, suggestive of its non-pathogenicity.

### Conclusion

Our studies provided the functional evidence to support the consideration of c.3251C>T as a likely pathogenic variant, and c.1054G>C as a likely benign variant. More epidemiologic evidence is needed for the reclassification of c.1057A>G.

## PgmNr 905: Detection of somatic L1 insertions in single nuclei from cancer tissues.

### Authors:

---

Long interspersed element-1s (L1s) are transposable elements that proliferate in human genomes. L1 retrotranspositions are endogenous mutagens that cause insertional mutations in chromosomes and have caused over 150 cases of genetic diseases. Recently, our group found somatic insertions in Barrett's esophagus-, pancreatic-, colon- and gastric cancer. These insertions are present in both pre-cancer and cancer, suggesting that L1 insertion events occur before or very early during cancer development. From these findings using bulk gDNA from cancer patients, however, we could not know the number and varieties of L1 retrotransposition events varying among individual cells and how the cells which have de novo somatic insertions are distributed in pre-cancerous and cancer tissues. To further understand somatic L1 retrotransposition which contributes to cancer induction, we established a new method to detect L1 insertions from single nuclei based on capturing circularized L1 fragments containing 3' flanking gDNA. Using this method, we investigated L1 insertions in single nuclei from colon cancer, liver metastasis, and normal liver. We found that our L1-seq technique identifies many candidate somatic L1 sequences in single nuclei at their 3' ends. However, the great majority of these sequences turned out to be either unannotated non-reference L1s or multiple displacement amplification (MDA) chimeras. We now believe that it is imperative that potential somatic L1 insertions in single nuclei be characterized completely at both their 5' and 3' ends, including their TSDs and flanking genomic DNA. By PCR and Sanger sequencing at the 5' and 3' junctions, we found nine new L1HS insertions that were not observed in bulk gDNA study from same patient. From further investigation in single nuclei, we found five other insertions that had been previously observed in bulk gDNA from same patient. In addition, we have found four insertions in the pancreatic cancer case. Three are in cancer and metastasis, one is only in metastasis. Thus, using this new technique we can find new L1 insertions in single nuclei that are not found in bulk gDNA study. Based on these and future data, we should be able to determine how the new L1 insertions spread in cancerous cells.

## PgmNr 906: Characterization of 331g/a polymorphism of rp gene and identification of viral oncogene hmtv virus as genetic markers for the improvement of breast cancer management in CHU Yaounde Cameroon.

Characterization of 331g/a polymorphism of rp gene and identification of viral oncogene hmtv virus as genetic markers for the improvement of breast cancer management in CHU Yaounde Cameroon

**NGUEDIA KAZE N<sup>1</sup>**, CHEDJOU,J.P<sup>1</sup>, MBACHAM W<sup>1,2</sup>.

University of Yaoundé I

Faculty of medicine and Biomedical Sciences

**Background:** Breast cancer is a real public health problem in Cameroon, where more patients with this cancer usually die a year after diagnosis, as it is still based on histological examination, mortality due to cancer is far from decreasing. Since cancer is an accumulation of molecular changes, the +331 G/A polymorphism of PgR gene (progesterone receptor) and viral oncogene HMTV (Human Mammary Tumor Virus) has been recently considered as a molecular markers associated with breast cancer. Due to that we fixed our objectives to characterize these markers.

**Aim and objectives:** characterization of +331 G/A polymorphism of PgR gene (progesterone receptor) and viral oncogene HMTV (Human Mammary Tumor Virus) by semi-nested PCR to understand etiological factor of that cancer in Cameroon.

**Method:** We carried out a case control study, in which 26 cases diagnosed positive for breast cancer at the CHU of Yaounde were recruited through the identification of archived biopsies. Blood samples were also collected from 20 women recruited using a questionnaire and a inform concern sign by each of them. +331 G/A polymorphism in the PgR gene was identified using NlaIV endonuclease by PCR-RFLP, and HMTV viral oncogene by hemi-nested PCR. The data were analyzed using Microsoft Excel and SPSS v20.

**Results:** We got a mean age of 57,73 +/- 9,87 in our cancerous group with the predominance of infiltrant duct carcinoma at grade II of SBR. An Odd Ratio of 1.268 with Confident Interval of 95% 1.004-1.664 proving that there is a significant association between 331G/A mutation and breast cancer with P-value of 0.026, obtained by comparing the mutant group (AA) 28,5% and wild genotype (GG). In addition, 3 cases were detected with the HMTV virus, one was found in the cancer group and two in the control group.

**Conclusion:** These results indicate that, HMTV is considered as viral cause and can predispose to breast cancer, beside 331 G/A polymorphism is an associated risk factor of that cancer.

**Key words:** Breast cancer, progesterone receptor, +331G/A PgR gene polymorphism, Human Mammary Tumor Virus.

## PgmNr 907: Contribution of PALB2 germline pathogenic variants in breast and ovarian cancer in Greece.

### Authors:

### Introduction:

Germline pathogenic variants in *PALB2* (Partner And Localizer of BRCA2) are rare, attributing for approximately 1-2% of familial breast cancer cases, while weaker but growing evidence suggests association with other homologous-recombination-deficiency associated malignancies, such as ovarian, prostate and pancreatic cancer, but also diffuse gastric cancer. We sought to assess the frequency and spectrum of *PALB2* mutations in a large cohort of Greek patients.

**Materials and Methods:** In total, 1958 (1301 breast and 657 ovarian) cancer patients fulfilling the NCCN criteria for genetic testing have been analyzed by Trusight Cancer panel, which targets 94 genes associated with cancer predisposition. All participants have signed informed consent prior to genetic testing.

**Results:** In total, ten distinct loss-of-function *PALB2* variants have been identified in 30 unrelated patients, of which 28 and 3 were diagnosed with breast and ovarian cancer (one patient had both diagnoses), respectively, resulting in a frequency of 2.15% and 0.46% of the breast and ovarian cancer group, respectively. Of note is that all ovarian cancer cases displayed high-grade serous histology, while 6/28 of breast cancer cases were triple-negative and 3/28 developed metachronous contralateral tumors. Mean age at breast cancer diagnosis was 43.7 years (range 32-61 years). Cascade testing was offered in 23 family relatives.

Interestingly, three recurrent variants were identified, i.e. found in >3 unrelated patients; one of those, c.2257C>T / p.(Arg753Ter) was recently shown to be a Greek founder. In addition, three recurrent missense variants [p.(Leu931Arg), p.(Leu1143His), and p.(Ser1165Leu)], which are predicted deleterious by *in silico* tools and have been shown to segregate with disease in our families, are rare in public databases and are therefore, classified as likely pathogenic, following ACMG guidelines. When also taking into account likely pathogenic variants, frequency of *PALB2* causative/likely causative alterations would calculate to 2.77% (36/1301) of the breast and 0.91% (6/657) of the ovarian cancer patients.

**Conclusions:** *PALB2* pathogenic/likely pathogenic variants account for a proportion of hereditary breast and ovarian cancer burden in individuals of Greek descent, with a spectrum exhibiting heterogeneity, but also strong founder effects. These patients can potentially benefit from targeted therapies, such as PARP inhibitors, as well as tailored clinical management.

## PgmNr 908: ANO7 expression shows association with the clinical outcome of prostate cancer.

---

Prostate Cancer (PCa) is the most frequently diagnosed cancer among men in developed countries. The effectiveness of PSA screening remains controversial and new molecular biomarkers are needed to improve screening and clinical management of the disease.

*ANO7* gene (*NGEP-L*) encodes for a member of the TMEM16 superfamily of transmembrane proteins predominantly expressed in prostate epithelial cells. Studies have suggested a role for ANO7 as calcium activated chloride channel and scramblase protein potentially involved in cell structure, adhesion and motility processes. Genome Wide Association studies (GWAS) and fine-mapping analyses have identified three independent PCa susceptibility signals with the credible set of candidate causal variants centred within the *ANO7* gene including nonsynonymous variants as top candidates.

In order to further investigate this association and the potential role of *ANO7* in PCa, we have performed a meta-analysis of germline mutations from 877 PCa samples from whole exome and targeted gene panel sequencing studies. We have also carried out immunochemistry staining of ANO7 protein in tissue microarrays (TMAs) including 475 PCa cases from the Transatlantic Prostate Group (TAPG). Finally we have overexpressed *ANO7* gene in the prostate epithelial normal cell line RWPE-1 and carried out proliferation, viability and migration analysis in 3D cultures along with RNA sequencing pathway analysis.

Next Generation Sequencing (NGS) meta-analysis identified a total of 55 cases carrying deleterious or likely-deleterious *ANO7* mutations. Of these mutations, 11 were classified as protein truncating variants (PTV). PTV carriers status showed significant association with Gleason score  $\geq 8$  ( $p=0.0485$ ). Analyses of the immunohistochemistry results showed significant association between low ANO7 expression and poor survival ( $p<2.2\times 10^{-16}$ ). This remained significant in a multivariable analysis including grade group, serum PSA and extent of disease ( $p=0.006$ ). In addition, functional assays in 3D cell culture showed greater viability in the RWPE-1 overexpressed clones compared to *ANO7*-ve control ( $p<0.0001$ ).

In conclusion, these results show evidence that *ANO7* expression associates with clinical outcome of prostate cancer and further functional analyses will provide insights into the molecular mechanisms underlying this association.

## PgmNr 909: Candidate gene polymorphism study in South Indian men with prostate cancer.

---

Prostate Cancer (PCA) is the second most common cancer diagnosed in men and fifth leading cause of cancer related death in men globally. Prostate Specific Antigen (PSA) is the clinically used marker available for PCA screening however, it lacks specificity and sensitivity. To develop a non-invasive molecular marker. Androgen receptor (AR) and Cytochrome P450 3A5\*3 (CYP3A5\*3) gene polymorphisms were evaluated which play an important role in the metabolism of testosterone.

Aim of the present study was to evaluate AR CAG repeats and CYP3A5\*3 gene polymorphism in men with PCA, benign prostate hyperplasia (BPH) and controls from South Indian men.

Genomic DNA was isolated and a three step PCR procedure was carried out using specific primers for AR and CYP3A5 genes. CAG repeats in AR gene and CYP3A5 genotype was analyzed by agarose gel electrophoresis (AGE). Odds ratios (OR) and chi-square were calculated using MedCalc<sup>R</sup> version 18.2.1.

AR with short (<22) CAG repeats and 'GG' genotype of CYP3A5 gene was identified in **61%** of PCA patients, whereas BPH and controls had these genotypes in 10% and 13% respectively. There is a significant difference of AR <22 CAG repeats with CYP3A5\*3 GG genotype with PCA ( $X^2 = 50.105$ , 95%CI- 35.4494 to 58.3715, **P<0.0001**) when compared with controls.

This is the first case-control study exhibiting an association of AR and CYP3A5 gene polymorphisms in combination, with PCA indicating that these molecular markers can differentiate PCA from benign hyperplasia and also identifying men who are at a risk of developing PCA.

## PgmNr 910: Circulating tumor DNA content varies in different fractions of plasma.

---

Circulating tumor DNA (ctDNA) in plasma has been used as a biomarker for cancer detection and outcome prediction. It is well known that ctDNA accounts for a small fraction of plasma cell-free DNA. To sensitively detect such low level ctDNA, multiple experimental and computational approaches have been evaluated, including size selection and molecular barcoding. However, few studies have systematically examined the effect of variable processing of plasma to generate fractionated plasma samples for ctDNA content comparison. To address this issue, we performed a five consecutive physical and chemical precipitations of plasma samples from 9 pre-selected small cell lung cancer (SCLC) patients with high tumor burden. We collected five precipitate fractions (fraction 1: cells and large debris, fraction 2: debris and large vesicles, fraction 3: large microvesicles, fraction 4: fibrin, fraction 5: exosomes) and one leftover supernatant (fraction 6) for a total of 54 fractionated specimens. Since all 6 fractions were derived from the same 1ml of plasma by sequential precipitations, we were able to compare fragment size and ctDNA contents in different fractions from the same patients. Fragment size analysis showed dramatic differences from a peak of 7-10kb in the first precipitation fraction 1 (500g centrifugation) to 140-160bp in final supernatant fraction 6 after 5 precipitations. After low-pass whole genome sequencing in each of the 54 samples, we calculated ctDNA content using a novel copy number-based algorithm. This analysis showed relatively high ctDNA content in the fractions of large vesicles (median=20.18%) and small vesicles (exosomes) (median=20.45%), but the highest ctDNA content in the fraction 6 of "leftover supernatant" (median=27.04%) after multiple precipitations. Comparatively, median ctDNA content in whole plasma from the same 9 patients was 23.34%. Our study provided a new insight into fragment size and ctDNA content variations in different fractions of plasma. DNA from supernatant after sequential centrifugation contains more ctDNA than total plasma cfDNA. It is worth mentioning that the plasma fractionation may allow maximum use of valuable plasma samples for a wide variety of studies. Our result will provide timely guidance in the emerging field of liquid biopsy.

## PgmNr 911: Nanopore ultra-long read sequencing provides insights into structural variation in cancer genome.

Genomic structural variants (SVs), the major hallmarks of cancer genomes, can promote tumor progression by perturbing gene structures and expression control, which contribute to the tumor heterogeneity and evolution. Despite their importance, the ability to detect and characterize SVs at the molecular level is limited by short-read sequencing approaches: large and complex SVs thwart efforts to detect them and correctly define their structures. Single-molecule DNA sequencing technologies offer significantly longer read lengths which can facilitate the detection and analysis of highly rearranged cancer genomes. In this study, we generated deep coverage of ultra-long reads from three glioblastoma (GBM) patient-derived neurospheres and characterized the full-spectrum of SVs with our customized SV caller Picky. From over 100 Gb of nanopore ultra-long reads with N50 length over 50 Kb, we presented the unbiased survey of full-scale SV landscapes in GBM cancer genomes. Leveraged by the long read lengths, we detected complex SVs with low allele frequency and provided SV with phasing information. Particularly, we uncovered SVs affecting genes with known oncogenic activities. Comparing the SVs in the primary and recurrent tumors from the same patients, we revealed rearrangement events associated with tumor relapse and characterized their genomic features associated with chromatin organization and transcriptional regulation. A complete understanding of the structure and distribution of SVs in cancer genome will empower the cancer research community to reveal mechanisms that induce genome instability, identify prognostic signatures of tumor progression and suggest targets for novel treatment strategies.

## PgmNr 912: Evaluation of copy-number variants as modifiers of breast and ovarian cancer risk for *BRCA1* and *BRCA2* pathogenic variant carriers.

---

Germline pathogenic variants in *BRCA1* and *BRCA2* (*BRCA1/2*) confer a high risk of breast and ovarian cancer. These risks are modified by environmental and genetic factors. Genome-wide studies of *BRCA1/2* pathogenic variant carriers have identified strong associations between single nucleotide polymorphism and breast and ovarian cancer risk. Copy number variants (CNVs) make a significant contribution to our genetic variation but are largely unexplored as modifiers of breast and ovarian risk in *BRCA1/2* pathogenic variant carriers. We have conducted a genome wide association study of germline CNVs in 15,679 *BRCA1* and 10,981 *BRCA2* pathogenic variant carriers from the Consortium of Investigators of Modifiers of *BRCA1/2* (CIMBA) using genotype data generated by the OncoArray Network. Analyses were based on the modeling the retrospective likelihood of observing the CNV conditional on the observed phenotype. We identified 241 gene loci that were associated (unadjusted  $p < 0.01$ ) with breast and/or ovarian cancer risk. For *BRCA1* pathogenic variant carriers, we identified 16 deletions associated with breast cancer and 28 deletions associated with ovarian cancer risk. For *BRCA2* pathogenic variant carriers, we identified 18 deletions associated with breast cancer and 52 deletions associated with ovarian cancer risk. Deletions in *BRCA1* were associated ( $p = 1.9 \times 10^{-4}$ ) with a 1.8-fold risk of breast cancer in the *BRCA1* pathogenic variant carrier cohort. We also identified risk-associated CNVs in several genes (*LSP1* and *TERT*) identified by previous SNP based analyses as candidate modifier genes. CNV deletions in the gene *SULT1A1* were associated with decreased breast cancer risk ( $RR = 0.5$ ,  $p = 9.8 \times 10^{-3}$ ) but increased ovarian cancer risk ( $RR = 3.3$ ,  $p = 7.3 \times 10^{-3}$ ) in *BRCA1* pathogenic variant carriers. We selected the *SULT1A1* gene for functional analysis as it is important for detoxification of carcinogens, steroid hormones (e.g., estrogen), and medications (e.g., tamoxifen). We showed that expression of *SULT1A1* was positively correlated with copy number status in breast and ovarian tissue. Breast cancer cell lines (MCF7 and MCF10A) containing CRISPR-Cas induced heterozygous pathogenic variants in *BRCA1* are being utilised to assess the functional impact of *SULT1A1* depletion. In summary, our study has provided evidence that multiple CNV loci with overlapping genes modify risk of breast and ovarian cancer in *BRCA1/2* pathogenic variant carriers.

## PgmNr 913: Identification and functional follow up of a locus at 12q24.33 associated with progression-free survival in ovarian cancer.

Genome-wide association studies have identified many loci for cancer risk, but very few for cancer outcome. Epithelial ovarian cancer (EOC) is one of the most chemosensitive of the solid tumours and has a high initial response rate to platinum/taxane treatment, but the median progression free survival (PFS) is only 18 months, and most women relapse within 5 years. We conducted a GWAS of PFS in 2352 women with EOC who had undergone cytoreductive surgery followed by standard carboplatin and paclitaxel chemotherapy. We identified seven variants at 12q24.33 associated with PFS at genome-wide significance, tagged by rs10794418 ( $P=1.47e-08$ ). The association with PFS was stronger for endometrioid (HR 2.48; 95% CI 1.57-3.92) than for serous (HR 1.17; 95% CI 1.07-1.27) EOC. The only gene in the region associated with PFS in EOC patients treated with standard chemotherapy was *ULK1* ( $P=0.02$ ), with higher expression associated with shorter PFS. In addition, expression analysis in 310 EOC patients showed that rs10794418 was associated with expression of *ULK1* ( $P=0.009$ ), with the T allele associated with shorter PFS being associated with increased expression. We performed chromatin conformation capture using the *ULK1* promoter as a bait and tiling across the associated variants. This identified consistent looping in both serous and endometrioid EOC cell lines. The variants lie in a putative regulatory element (PRE), marked by H3K27Ac marks in ovarian cells. Luciferase reporter assays show that the PRE acts as a silencer in A2780 and OVCAR8 EOC cell lines but no differential effect was seen with the two variants that could be tested. Electrophoretic mobility shift assays are underway. Inhibition of *ULK1* can inhibit autophagy and sensitises some cancer cell lines to chemotherapy. We therefore treated TOV112D and OVCAR8 EOC cell lines with carboplatin and paclitaxel in addition to an inhibitor of ULK1, SBI0206965. SBI0206965 had some efficacy as a single agent but exhibited no synergy with chemotherapy *in vitro*, but we will also test this combination *in vivo*.

---

An increasing number of myeloid neoplasia is reported in association with germline alterations in genes involved in hematopoiesis and lineage differentiation, and clinicians are becoming more aware of the contribution of germline alterations to myeloid neoplasia. The wider utilization of multiplex germline testing using next-generation sequencing and microarray platforms has led to a deluge of sequence variant alterations for which pathogenicity interpretation continues to be challenging. Despite the implementation of ACMG/AMP guidelines for sequence variant interpretation, the number

of variants of uncertain significance (VUS) and curation discrepancies remain elevated. To address this hurdle, the Clinical Genome Resource (ClinGen) Myeloid Malignancy Variant Curation Expert Panel (MM-VCEP) was initiated as a collaboration between the American Society of Hematology and ClinGen to perform disease-/gene-specific modifications for inherited myeloid malignancies. This team consists of expert clinicians, clinical laboratory diagnosticians, and researchers interested in developing and implementing standardized protocols for expert interpretation of germline variation in inherited myeloid malignancies. The MM-VCEP began optimizing ACMG/AMP rules on *RUNX1* associated familial platelet disorder with predisposition to acute myeloid leukemia (FPD/AML). The optimization of the ACMG/AMP guidelines encompasses disease-/gene-informed specifications or strength adjustments of existing rules, included calculation of minor allele frequency thresholds, functional domains and mutational hot spots identifications, functional assay thresholds, and phenotype-specific guidelines. Preliminary rules were further validated and refined using a pilot set of 52 variants with benign/likely benign, pathogenic/likely pathogenic, VUS and conflicting assertions in ClinVar, covering various types of SNVs (missense, nonsense, frameshift, splice-site, in-frame duplication, synonymous and intronic variants) and CNVs (intragenic deletions). The application of *RUNX1*-specific ACMG/AMP criteria resulted in the resolution of conflicting variants and reduced the number of VUS. In summary, the ClinGen MM-VCEP aims to develop recommendations to optimize ACMG/AMP criteria for standardization of variant interpretation in myeloid leukemia genes and make expert-reviewed and interpreted variants available to the hematology community through ClinVar to support patient care and research.

## PgmNr 915: Distinct microbial communities that differ by race, stage, or breast-tumor subtype in breast tissues of non-Hispanic black and non-Hispanic white women.

---

Growing evidence highlights an association between an imbalance in the composition and abundance of bacteria in the breast tissue (referred as microbial dysbiosis) and breast cancer in women. However, studies on the breast tissue microbiome have not been conducted in non-Hispanic Black (NHB) women. We investigated normal and breast cancer tissue microbiota from NHB and non-Hispanic White (NHW) women to identify distinct microbial signatures by race, stage, or tumor subtype. Using 16S rRNA gene sequencing, we observed that phylum Proteobacteria was most abundant in normal (n=8), normal adjacent to tumor (normal pairs, n=11), and breast tumors from NHB and NHW women (n=64), with fewer Firmicutes, Bacteroidetes, and Actinobacteria. Breast tissues from NHB women had a higher abundance of genus *Ralstonia* compared to NHW tumors, which could explain a portion of the breast cancer racial disparities. Analysis of tumor subtype revealed enrichment of family *Streptococcaceae* in TNBC. A higher abundance of genus *Bosea* (phylum Proteobacteria) increased with stage. This is the first study to identify racial differences in the breast tissue microbiota between NHB and NHW women. Further studies on the breast cancer microbiome are necessary to help us understand risk, underlying mechanisms, and identify potential microbial targets.

## PgmNr 916: Effects of 3300 del A-1061 Ter *BRCA1* frameshift mutation on breast carcinogenesis.

**Affiliation:** Department of Medical Technology, Faculty of Allied Health Sciences, Thammasat University, Patumthani, Thailand

---

*BRCA1* gene mutation increases risk of hereditary breast/ovarian carcinogenesis. Superoxide dismutase enzyme protects oxidative stress in human. This report describes the effects of 3300 del A-1061 Ter *BRCA1* mutation at exon 11 for oxidative stress induction and may cause breast carcinogenesis. The effects of this mutation was studied by MTT dye reduction technique and superoxide dismutase (SOD) activity assay. The results showed that the percentage of cell viability of mutant cells in different H<sub>2</sub>O<sub>2</sub> concentrations was less than the percentage of cell viability of wild type cells ( $P < 0.05$ ). This mutation causes oxidative stress through superoxide dismutase activity inhibition ( $P < 0.05$ ). 3300 del A-1061 Ter *BRCA1* mutation can effect oxidative stress and lead to breast carcinogenesis.

---

The steady-state abundance of proteins plays a crucial role across broad cellular processes and biological pathways. While considerable effort has been made to characterize the regulatory impact of genetic variation on steady-state mRNA abundance, with few exceptions, the genetic regulation of proteins is still largely unmapped. In this work we integrate protein and mRNA abundance measured in prostate cancer samples ( $n = 56$ ) together with common genetic variation to elucidate the regulatory landscape and trace the causal molecular cascade.

First, we performed a local protein quantitative trait loci (pQTL) analysis using 6,697 protein groups quantified through mass spectrometry (Sinha, Huang, Livingstone et al. Cancer Cell 2019). Overall, we identified 13 (11) genes with pQTLs at an FDR  $< 0.1$  (0.05) localized within 100kbp of transcription start-sites (TSS). To establish the validity of our findings, we compared pQTL results with a recently published plasma protein pQTL analysis in a much larger cohort ( $n=3,301$ ). We found a significant overlap of total genes assayed in both studies (OR=1.4;  $P=8 \times 10^{-8}$ ) indicating that we were well powered to replicate our findings. Focusing on the 13 genes with prostate pQTLs, 4 were assayed in plasma and 3 were plasma pQTLs, which suggests a shared regulatory landscape between plasma and prostate tumors.

Next, we performed a local expression quantitative trait loci (eQTL) analysis using 28,692 genes measured by RNA-seq. We identified 182 (152) genes with eQTLs at an FDR  $< 0.1$  (0.05) with 143/182 localizing within 100kbp of the TSS. To validate our eQTL findings, we recapitulated our analysis in the Cancer Genome Atlas (TCGA) prostate adenocarcinoma (PRAD) cohort. We saw a significant overlap of all genes assayed in both studies (OR=6.8;  $P<2 \times 10^{-16}$ ). Of the 182 genes with prostate eQTLs, 46 were found in TCGA with all 46 eQTLs replicating, demonstrating the generalizability of our results.

To quantify the shared underpinnings of steady-state mRNA and protein abundance in prostate tumors, we next computed the similarity of measured expression levels. We found that the average rank correlation across 6,756 genes was  $r=0.19$  (95CI[0.185, 0.195]). We also estimated the average mediating effect of eQTLs on pQTLs while accounting for shared environmental effects and observed  $\beta=0.45$  (95CI[0.09-0.8]). Our findings shed light on the causal regulatory cascade of genetic variation, mRNA, and protein abundance in prostate cancer tumors.

## PgmNr 918: Human papillomavirus (HPV) 16 genetic variants affect *E7* viral oncogene protein expression and transformation.

**Introduction:** The HPV16 E7 oncoprotein is expressed in cervical cancer cells and serves as a tumor-specific antigen target for immunotherapy. E7 genetic conservation is critical to carcinogenesis. Our previous study of 5,570 HPV16 infected subjects found that cancer-free controls with benign HPV16 infections had significantly more E7 nonsynonymous and nonsense variants compared to cancers from around the world. This work also identified two rare variants in a putative enhancer in the viral upstream regulatory region (URR) that were associated with a reduced risk of cancer. To investigate whether the E7 variants affect protein function, or cell invasion, we expressed individual E7 wild-type and mutant proteins.

**Methods:** The full length HPV16 E7 coding region was cloned and modified by site-directed mutagenesis. Variants found in both controls (H9R, D21N, N29S, E33K, T56I, D62N, S63F, S63P, T64M, E80K, D81N, P92L, P92S); and precancers (P6L, D14E, N29H, H51N, R77S) were generated. Proteins were expressed in HeLa (cervical cancer) and HEK293 (embryonic kidney) cell lines and steady state levels of nuclear and cytoplasmic protein were determined by western blotting. The variants identified in the HPV16 URR were studied by electrophoretic mobility shift assays (EMSA).

**Results:** The H9R, E33K, E80K, D81N, P92L and P92S mutants found in the control group showed significantly lower E7 protein levels, indicating a defect in translation, or stability. In contrast, the P6L and R77S variants found in precancers had E7 levels similar to wild-type E7. Interestingly, the D14E variant, found in pre-cancer, had little effect on colony formation in NIH3T3 mouse fibroblasts soft agar cultures, whereas the E33K mutation from the control group reduced growth in soft agar. The EMSA demonstrated that the protective URR variants were associated with the loss of binding of yet unidentified transcription factors in HEK293, HeLa and MCF7 (human breast cancer cells) nuclear lysates. From the sequence, CEBP/A and RUNX are the most likely candidates.

**Conclusions:** Taken together, these data demonstrate molecular differences between HPV16 E7 coding and regulatory mutants that might explain population-based variation in cancer risk of HPV16 variants.

## PgmNr 919: Variants in *LRRC34* reveal distinct mechanisms for predisposition to papillary thyroid carcinoma.

---

Papillary thyroid carcinoma (PTC) arises from thyroid follicular epithelial cells and accounts for over 90% of all thyroid cancer diagnoses. PTC demonstrates high heritability and a low somatic mutation burden relative to other cancers. Furthermore, heritable high-penetrance pathogenic mutations have been largely absent from familial and sporadic PTC cases. We therefore hypothesized that the genetic risk predisposing to PTC is mainly due to a combination of low penetrance variants. In order to discover these variants we used genome-wide association studies (GWAS). The most recent GWAS revealed the association of thyroid cancer with a missense variant, rs6793295, at 3q26 in a gene called *LRRC34*.

In addition to rs6793295, we observed a second missense variant, rs10936600, in high linkage disequilibrium (LD) with rs6793295. We hypothesized that missense variants in *LRRC34* would result in a change of affinity for its binding partners. Therefore, we performed a mass spectroscopy screen and found that RANBP1 binds less to missense *LRRC34* as compared to the wild-type isoform. Furthermore, overexpression of the missense *LRRC34* caused a significant reduction in RanGTP levels and an increase of cells undergoing apoptosis.

We then characterized a second LD block containing several regulatory variants upstream of *LRRC34*. We conducted luciferase assays on these variants and found a pattern of allele-specific expression for three regulatory variants. Microarray analysis of cells knocked down for *LRRC34* disclosed perturbations in genes involved in cellular movement and cell cycle. The effects of *LRRC34* knockdown reduced the migration of thyroid cancer cells.

To further explore the role of the five functional variants (two missense and three regulatory variants) at 3q26 with PTC risk we performed haplotype analysis in an Ohio cohort (2718 cases/3210 controls). We observed three significant haplotypes: all risk alleles (odds ratio [OR] = 1.23), all protective alleles (OR = 0.79), and risk missense alleles with protective regulatory alleles (OR = 0.72). These data indicate that regulatory variants might negate or mitigate the risk of bearing risk alleles for *LRRC34* missense variants.

In conclusion we have demonstrated two separate mechanisms dictating PTC risk at 3q26 using both biochemical and genetic techniques. Further studies to refine and characterize additional risk loci will enable a comprehensive understanding of the germline genetics of thyroid cancer.

## PgmNr 920: Alternative splicing of *APOBEC3B* as a preventive mechanism for APOBEC-mediated mutagenesis.

**Background:** APOBEC3B (A3B), a member of the cytidine deaminase family of enzymes, is considered as one of the major endogenous mutagens in tumor genomes. A3B can cause C-to-T or C-to-G mutations within the TCA and TCT motifs commonly referred to as APOBEC mutational signature. The loads of APOBEC-signature mutations have been correlated with A3B mRNA expression levels in tumors, but the factors that regulate the expression of this enzyme remain largely unknown. Here, we explored the role of alternative splicing on the expression of A3B and its consequences on mutagenesis.

**Results:** The human genome assembly GRCh37 (hg19) annotates three mRNA isoforms of A3B. These include a canonical isoform with eight exons, here referred as A3B1, and two alternatively spliced isoforms – one occurs due to cryptic acceptor site in exon 6 (A3B2), and the other – due to skipping of exon 5 (A3B3). Using a combination of *in silico* protein structural analysis and *in vitro* deamination assays, we determined that A3B2 and A3B3 protein isoforms are non-mutagenic, but their production reduces the levels of the canonical mutagenic isoform, A3B1. Specifically, exon 5 skipping, a major splicing event in A3B, not only reduced expression of the mutagenic A3B1 isoform but also targeted the resulting transcript for nonsense-mediated decay. Increased exon 5 skipping was significantly associated with lower APOBEC mutational signature load in bladder and lung tumors in TCGA, and longer progression-free survival in patients with non-muscle-invasive bladder cancer. Using exon-trap assays, we determined that skipping of exon 5 was dependent on weak branch point sites in intron 4. Treatment with pladienolide B, which inhibits SF3B1 splicing factor and prevents spliceosome engagement at weak branch point sites, reduced the expression of mutagenic A3B enzyme and its *in vitro* deamination activity, validating the potential role of exon 5 skipping in the regulation of A3B associated mutagenesis.

**Conclusions:** Our results suggest that alternative splicing of A3B is an intrinsic preventive mechanism for APOBEC-mediated mutagenesis, and can be harnessed to control this mutational process in clinically relevant conditions.

## PgmNr 921: A functional network of gastric-cancer-associated splicing events controlled by dysregulated splicing factors.

Although several genes have known oncogenic splice forms in gastric cancer, the full scope of the role of aberrant splicing in gastric oncogenesis remains unclear. In this study, we developed a network of aberrant splicing in gastric cancer by elucidating tumor-associated (TA) alternative splicing events (ASEs) and their upstream regulators. RNA-sequencing of 19 tumor-normal pairs revealed 118 TA ASEs and 8 splicing factors (SFs) with dysregulated protein and RNA expression in gastric cancer. We constructed a network model of gastric-cancer-associated splicing based on correlations between ASE splicing ratios and SF transcript levels, and independently validated the model by analysis of TCGA data (323 gastric tumors, 31 normal samples). This model contained three clusters centered on the SFs *PTBP1*, *ESRP2*, and *MBNL1*. Individual knockdown of these SFs in gastric cell lines drove TA ASEs observed in gastric tumors, confirming causal links between the dysregulated SFs and downstream ASEs. Knockdown of SFs altered transwell migration rates in directions consistent with expected roles in oncogenesis and with the observation that TA ASEs disproportionately affected cytoskeletal-organization genes. This computational analysis followed by in-vitro experimentation indicated that concomitant SF dysregulation and generation of TA ASEs contribute to gastric oncogenesis.

Epithelial ovarian cancer (OC) is the fifth most lethal cancer among women, with more deaths than any other gynecological cancer. Each ovarian cancer subtype (clear cell, endometrioid, high-grade serous and mucinous) is characterized by distinct molecular drivers, risk factors and clinical behaviour. Transcriptional regulation is highly histotype-specific. While each OC harbors around 10,000 non-coding somatic variants, the contribution of non-coding somatic mutations to OC development is currently not known.

We performed H3K27ac chromatin immunoprecipitation and transcriptome sequencing in primary tumors for the four different subtypes of invasive OC. Histotype-specific regulatory elements (REs) were enriched in enhancers ( $P < 0.001$ ). In silico prediction of putative target genes for histotype-specific REs identified genes (*WFDC2*,  $P = 5.5 \times 10^{-5}$ ) and pathways (PI3K-Akt signaling,  $P < 0.002$ ) known to be involved in OC development. Some genes (e.g. *PAX8* and *CA125*) are associated with super-enhancers (SEs) in all OCs, while others are histotype-specific, including *PPP1R3B* which is associated with SEs in clear cell OCs only. Knockdown of *PPP1R3B* in clear cell OC cells significantly reduced intracellular glycogen content, a signature feature of this histotype.

To identify frequently mutated regulatory elements (RE) we integrated the ovarian cancer epigenetic profiles with whole genome sequencing data from 232 OCs. We identified a cluster of nine single nucleotide variants in the *KLF6* promoter ( $P = 8.2 \times 10^{-8}$ ) at chromosome 10p15, and seven mutations in an enhancer near the *HIST1* gene cluster at 6p22.1. Stable knockout of a 635 bp region in the 6p22.1 enhancer induced downregulation of two of our predicted target genes, *ZSCAN16* and *ZSCAN12* ( $P = 6.6 \times 10^{-4}$  and  $P = 0.02$ ), and *ZKSCAN3* and *HIST1H2AI*, which are previously predicted targets of this

enhancer. Globally, there was an enrichment of mutations in active binding sites for TEAD4 ( $P=6 \times 10^{-11}$ ) and its binding partner PAX8 ( $P=2 \times 10^{-10}$ ), a known lineage-specific transcription factor in OC. In addition, REs associated with *PAX8* expression comprised the most frequently mutated set of enhancers in OC ( $P=0.003$ ).

In summary, we have characterized histotype-specific epigenomic and transcriptomic landscapes in OC and defined likely functional REs based on somatic mutation analysis of ovarian tumors. Taken together these data indicate that somatic mutations disrupt the PAX8 transcriptional network during tumor development.

## PgmNr 923: Hemimethylation analysis.

**Authors:**

S. Sun

[View Session](#) [Add to Schedule](#)**Affiliation:** Mathematics, Texas State University, San Marcos, TX.

---

DNA methylation is an epigenetic event that involves the addition of a methyl-group to a cytosine (C) site that pairs with a guanine (G) site (i.e., CG site). This event plays an important role in both cancerous and normal cell development. Previous studies often assume symmetric methylation on both DNA strands. However, asymmetric methylation, or hemimethylation (methylation that occurs only on one DNA strand), does exist and has been reported in several cancer studies. Due to the limitation of previous DNA methylation sequencing technologies, researchers could only study hemimethylation on specific genes, but the overall genome-wide hemimethylation landscape remains relatively unexplored. With the development of advanced next generation sequencing techniques, we can now measure methylation levels on both the forward and reverse strands at single CG sites in an entire genome. Analyzing hemimethylation patterns may potentially reveal genes or regions related to tumor growth. For our research, we identify hemimethylated CG sites in cancer by analyzing publicly available methylation sequencing data. Meanwhile, we also identify hemimethylation patterns by grouping consecutive hemimethylated sites based on their methylation states, methylation “M” or un-methylation “U”. These patterns include regular hemimethylation clusters (e.g., MMM on one strand and UUU on another strand) and polarity (or reverse) clusters (e.g., MU on one stand and UM on another strand). We then map these hemimethylation clusters and sites to corresponding genes and study the functions of these genes. Our results reveal that hemimethylation does occur across the entire genome and highly hemimethylated genes may influence tumor growth or suppression.

## PgmNr 924: Dissecting the chromatin landscape of relafusion driven ependymoma.

### Authors:

S.C. Mack<sup>1,2</sup>; A. Arabzade<sup>1,2</sup>; Y. Zhou<sup>1,2</sup>; J. Yi<sup>2,3</sup>; B. Deneen<sup>2,4</sup>; C.Y. Lin<sup>1,2</sup>

---

Ependymoma is the third most common pediatric brain tumor, with treatment to this date remaining surgical resection and radiation. Over 70% of supratentorial ependymoma are characterized by an oncogenic fusion between *C11ORF95* and *RELA*. ***C11ORF95-RELA* fusion is frequently the sole genetic driver detected in ST ependymoma, thus ranking this genomic event as a lead target for therapeutic investigation.** *RELA* is a transcription factor central to mediating NF- $\kappa$ B pathway activation in processes such as inflammation, cellular metabolism, and chemotaxis. Whether *C11ORF95-RELA* hyper-activates the NF- $\kappa$ B pathway during ependymoma development and is required for tumor maintenance is unclear. How *C11ORF95-RELA* protein expression directly modulates the epigenome and transcriptome is unknown. **We hypothesize that: (1)** *C11ORF95-RELA* establishes specific transcriptional programs through remodeling of distinct chromatin patterns, and **(2)** *C11ORF95-RELA* stability is required for tumor maintenance and represents a direct target for chemical and genetic screening. To address these hypotheses we utilized both chromatin profiling of *C11ORF95-RELA* paired with proteolysis targeting chimera (PROTAC) based perturbation experiments. We found that *C11ORF95-RELA* fusion: 1) Drives nuclear localization, 2) Associates with active chromatin regions, and 3) Essential for tumor growth. We conclude that ependymomas arise during development through a single oncogenic fusion event that remodels chromatin landscapes to promote tumorigenesis.

## PgmNr 925: Multi-omic approach highlights novel role for mismatch repair protein in Lynch syndrome.

**Authors:**

M. Devall; C. Dampier; S. Eaton; J. Bryant; G. Casey

[View Session](#) [Add to Schedule](#)

**Affiliation:** University of Virginia, Charlottesville, VA.

---

**Introduction:** Lynch Syndrome (LS), is characterized by germline mutations in one of four key mismatch repair genes. This leads to a 50-70% lifetime risk for colorectal cancer (CRC) as well as a significantly increased risk for other cancers such as endometrial cancer and stomach adenocarcinoma. Furthermore, LS cancers are phenotypically distinct from cancer evolved from other molecular events. However, our understanding of LS is somewhat limited. Indeed, as of 2019 very few studies have investigated epigenetic alterations in LS patients, an analysis of which may provide additional insight into this complex syndrome and the pathways in which it is differentially regulated. To bridge this gap, here we utilize a novel 3D organoid model derived from human colon biopsies taken during routine colonoscopy to explore differences in non-cancerous cells between LS and healthy controls (CTL) at the methylomic and transcriptomic level.

**Methods:** Normal 3D colon organoids were generated from 7 LS and 9 control subjects and subjected to Illumina EPIC array, a platform that targets over 850k methylation sites, and RNA-Sequencing. Following standard analysis guidelines for both platforms, normalized gene expression levels and M-values were correlated to explore potential overlay between methylome and the transcriptome. Further, we employed WGCNA at both omic layers to identify common networks of dysregulation. TCGA data from CRC were used as a validation dataset.

**Results:** Here, we identify over 33,000 differentially methylated positions and over 20 spatially correlated differentially methylated regions (DMR). Importantly, our most significant DMR correlates to a mismatch repair gene not currently associated with LS. Further, we find a strong correlation between aberrant methylation and gene expression changes in matched samples. Finally, by using publicly available CRC data downloaded from TCGA we are able to validate a number of differences both at the methylation and expression level.

**Conclusions:** By utilising 3D organoid models, we not only identify significant differential methylation across 20 differentially methylated regions, but also highlight a role for a novel DNA mismatch repair protein in LS. Our study provides a new insight into the role of DNA methylation in LS and should warrant further investigation.

## PgmNr 926: Epigenetic features of repetitive elements in breast cancer development.

### Authors:

Repetitive elements (REs) are rich regulatory factors in the human genome. Recent studies have reported that REs are involved in the epigenetic reactivation of oncogenes in tumorigenesis, and the global hypo-methylation of REs has been associated with cancer development in various cancer types. However, the role of the site-specific RE epigenetic features in cancer development is not well understood. In this study, we investigated the site-specific DNA methylation (DM) at REs and their influence on breast cancer development. For each ethnic group of African American (AA) and European American (EA) women, we generated genome-wide DM profiles for 17 tumor and 17 age-matched normal breast tissue samples, using the TruSeq Methyl Capture EPIC platform that covers 31,159 Alu and 25,374 LINE-1 elements. RE-specific DM levels were calculated as average methylation levels across CpGs in each RE sequence. We identified 18 REs (10 Alu and 8 LINE-1) and 64 REs (23 Alu and 41 LINE-1) were differentially methylated (*Bonferroni* corrected p-value < 0.05) between tumor and normal in EA and AA women, respectively. Race-specific differential methylation of REs was observed. Differentially-methylated Alu elements are enriched in signaling pathways for EA women and cell replication, enzyme regulation, and transcription regulation for AA women. Further, differentially-methylated LINE-1 elements are enriched in immune system activities for EA women and cell apoptosis and cell differentiation for AA women. To further understand the regulatory potential of RE methylation on gene expression, we conducted association analyses between site-specific RE methylation and gene expression. We observed both *cis*- and *trans*- regulation of the RE methylation on gene expression, and the identified genes were enriched in cancer-related pathways and networks. Our study suggests that the site-specific RE methylation may play a role in breast cancer development through regulating cancer-related genes and pathways. Future research is warranted to replicate these findings and understand the complex regulatory mechanisms related to REs.

## PgmNr 927: A pan-cancer approach to predict core transcriptional regulatory circuitries identifies important nodes in high-grade serous ovarian cancer.

---

Lineage-specific transcriptional 'master' regulators can be co-opted to drive oncogenesis and thus represent potential therapeutic targets as they often are tumor-specific genetic dependencies. We therefore developed an approach to predict these transcription factors across 34 distinct tumor types by identifying those with high levels of cell-type-specific expression. As a proof-of-concept, we mapped the core regulatory circuitry (CRC) of master regulators in high-grade serous ovarian cancer (HGSOC) as it is the most lethal gynecologic malignancy. This analysis revealed *PAX8*, *SOX17*, and *MECOM* as putative CRC members, of which *PAX8* is a known urogenital regulator and ovarian cancer biomarker. Genes encoding these factors were found proximal to especially large super-enhancers in primary HGSOC tissues. Chromatin immunoprecipitation sequencing experiments in ovarian cancer cell lines confirmed that *PAX8*, *SOX17*, and *MECOM* co-occupy the genome at genes critical for ovarian cancer biology as well as at those encoding each putative master regulator; RNA-seq after knockdown of each factor identified largely overlapping target gene sets for *PAX8* and *SOX17*, with a convergence on cell cycle and angiogenesis pathways. *MECOM* fulfils some expectations of a master regulator – it is a lineage-specific essential gene, positively regulates *PAX8*, but *negatively* regulates *SOX17*; with *SOX17* and *MECOM* exhibiting opposing effects on critical epithelial and mesenchymal genes. In *in vitro* assays, knockdown of *PAX8* and *SOX17* reduces cell number and perturbs cell cycle progression, *PAX8* and *MECOM* knockdown impairs cancer cell clonogenicity, and *SOX17* knockdown increases apoptosis. Finally, ovarian cancer cells are sensitive to transcriptional inhibitors THZ1, JQ1 and THZ531, and *PAX8*, *SOX17* and *MECOM* are all downregulated following treatment with one or more of these small molecules, indicating a dependency on continuous high-level expression of these factors. In summary, our data suggest that *PAX8* and *SOX17* are important CRC factors in HGSOC, with largely overlapping but also factor-specific molecular and functional roles. Our data also implicate *MECOM* as a non-canonical master regulator in HGSOC. Contribution to the better understanding of the CRC governing HGSOC, as well as other tumor types, aids in predicting key molecular regulators and future therapeutic avenues in this devastatingly underserved disease.

## PgmNr 928: Association of DNA methylation marks with breast cancer risk in a Singapore population.

---

**Background:** Heritable methylation marks associated with breast cancer risk have recently been identified through epigenome-wide DNA methylation analysis of germline DNA samples from Australian multiple-case breast cancer families. Of the 24 methylation marks identified, four were replicated in an independent nested case-control study. **Aim:** The objective of this current study was to determine if these four methylation marks are associated with breast cancer risk in our Asian population. **Methods:** Germline DNA from 185 *BRCA*-negative breast cancer cases and 204 matched healthy controls were subjected to bisulfite conversion. Pyrosequencing was performed for the CpG sites cg18584561, cg01741999, cg03916490 and cg27639199 using the PyroMark (Qiagen) platform. Odds ratios (OR) and 95% confidence intervals (CI) for breast cancer risk were calculated using logistic regression based association analysis, with a *P*-value of  $\leq 0.05$  considered statistically significant. **Results:** Only one of the four methylation marks, cg03916490, was found to be associated with breast cancer risk in our Singapore cohort (OR = 1.0486, 95% CI = 1.0283 - 1.0702, *P* = 3.06E-06). The remaining three methylation marks cg18584561 (OR = 1.0041, 95% CI = 0.9844 - 1.0242, *P* = 0.686), cg01741999 (OR = 1.0043, 95% CI = 0.9836 - 1.0267, *P* = 0.687) and cg27639199 (OR = 1.0047, 95% CI = 0.9975 - 1.0121, *P* = 0.199) did not have statistically significant associations with breast cancer risk. **Conclusion:** Our findings suggest that replication studies in additional populations are necessary for newly discovered DNA methylation marks.

## PgmNr 929: Mechanisms by which mutant p53 drives metastatic triple negative breast cancer.

---

Breast cancer is a heterogeneous disease comprised of four molecular subtypes defined by whether the tumor-originating cells are luminal or basal epithelial cells. Breast cancers arising from the luminal mammary duct often express estrogen receptor (ER), progesterone receptor (PR), and human epidermal growth receptor 2 (HER2). Tumors expressing ER and/or PR are treated with anti-hormonal therapies, while tumors overexpressing HER2 are targeted with monoclonal antibodies. Breast tumors that do not express these proteins are known as “triple negative breast cancer” (TNBC) and are the most aggressive subtype with the highest mortality rates and no targeted therapy. There is a pressing need to identify regulatory factors in TNBC. 88% of human TNBCs harbor a *TP53* alteration yet the regulatory roles of mutant p53 are poorly understood. We will investigate the *in vivo* gain-of-function (GOF) mechanisms of mutant p53 involved in development of metastatic TNBC.

We have generated a somatic mouse model for p53R245W (murine counterpart to human p53R248W). The conditional allele expresses wild type p53, which converts to mutant p53 upon Cre recombinase activation. Ductal injection of adenovirus-Cre into the mouse mammary gland allows mutant p53 expression in a few cells surrounded by a normal stroma and immune system. Studies in our somatic breast cancer model indicate p53<sup>R245W</sup> mice give rise to metastatic triple negative tumors. We hypothesize that transcriptomic changes associated with p53R245W GOF mechanisms drive metastatic TNBC.

Using an integrated genomics approach, we will investigate how p53R245W contributes to breast cancer metastasis by ChIP-seq and RNA-seq to discover transcriptional co-factor(s) and target genes mediating mutant p53 GOF. We have queried the publicly available METABRIC human breast cancer dataset to identify genes differentially expressed between breast tumors harboring p53R248W/Q mutations compared to p53 null breast tumors. RNA-seq of p53R245W tumors from our model revealed upregulation of genes common to human breast tumors. Gene set enrichment analysis revealed enrichment of cell cycle pathways. This common gene signature will be used to predict co-factors mediating p53R245W GOF and perform ChIP-seq to define the transcriptome driven by mutant p53 in metastatic TNBC. Data from these studies will provide a better understanding of the GOF mechanism of the p53<sup>R245W</sup> hotspot mutation and its contribution to metastatic TNBC development.

## PgmNr 930: Enhancer-promoter chromatin interactions in endometrial cells reveals biologically relevant candidate target genes at endometrial cancer risk regions.

### Authors:

T. O'Mara; A. Spurdle; D. Glubb; Endometrial Cancer Association Consortium

---

Genome-wide association studies (GWAS) have identified 16 genetic regions associated with endometrial cancer risk. As is typical of GWAS, the vast majority of endometrial cancer risk-associated variants at these regions are non-coding. To identify potential target genes of these endometrial cancer risk variants, we have generated chromatin looping data associated with the H3K27Ac histone mark (characteristic of promoters and enhancers) using HiChIP in an E6E7/hTERT immortalised glandular endometrial cell line and three endometrial cancer cell lines (Ishikawa, JHUEM-14 and ARK-1).

Stratified LD score regression of promoter-associated loops demonstrated significant enrichment of endometrial cancer heritability in the immortalised normal and two of the three cancer cell lines after conditioning on the baseline LD-model (3.83-8.84 fold,  $P_{\text{Bonferroni}} < 0.03$ ), highlighting the potential role of these loops in mediating the effects of GWAS risk variants.

Intersection of promoter-associated loops with endometrial cancer risk-associated variants identified 103 candidate target genes at 13 of the 16 endometrial cancer risk regions. Among these candidates there was an over-representation of targets for miR196a, a microRNA that was itself one of the 103 candidate target genes identified by our HiChIP data. Mining expression quantitative trait loci (eQTL) data from whole blood ( $N = 31,684$ ; Võsa *et al* BioRxiv 2018) or endometrial tumours ( $N = 336$ ; Lim *et al* PNAS 2018), we found expression of 22 of the 103 candidate genes to be associated with risk variants.

Using protein-protein interactions, coupled with functional annotation and “guilt-by-association” analysis, we prioritised 387 proteins that interacted with proteins encoded by the candidate target genes. This set was highly enriched for proteins encoded by known endometrial cancer driver genes (10-fold;  $P = 8 \times 10^{-9}$ ), suggesting that candidate target genes may affect endometrial cancer development through these interactions. Pathway analysis including the 387 prioritised interacting proteins and 103 candidate genes revealed enrichment of many cancer-related pathways, including “Pathways in Cancer” ( $P = 2 \times 10^{-56}$ ), as well as immune- and hormone-related pathways. Our study illustrates the power of H3K27Ac HiChIP chromatin looping analyses in identifying biologically relevant targets of risk associated variants, and provides avenues for translation of GWAS results.

## PgmNr 931: Aberrant C<sub>p</sub>G islands promoter hypermethylation in *Runx3* has potential as a diagnostic predictor in oral squamous cell carcinoma.

### Authors:

---

**Introduction:** Oral squamous cell carcinoma (OSCC) is traditionally associated with extrinsic factors such as tobacco use and alcohol consumption. No such associations have been established in studies conducted in Nigeria so far. Therefore, OSCC development may involve molecular events, which information is largely lacking in Nigerian cohorts, and extrinsic factors. **Objective:** As such, this study to our knowledge is the first of its kind in Nigeria designed to identify molecular predictive diagnostic biomarkers for OSCC. **Methods:** A 12 year hospital-based retrospective analysis of patients' demographic data was conducted. A profile of aberrant C<sub>p</sub>G islands methylation in *Runx3* was done by methylation-specific polymerase chain reaction (MSP) with DNA extracted from 67 formalin-fixed paraffin-embedded (FFPE) blocks of OSCC tissue. Numerical data of C<sub>p</sub>G islands methylation in *Runx3* for gender, age, tumor location and histologic class were computed and presented as frequencies and percentages. Pearson's Chi-square test was used to assess association between gender, age, tumor location, histologic class and *Runx3* promoter hypermethylation. For all analyses,  $P \leq 0.05$  was considered significant. **Results:** *Runx3* promoter hypermethylation were observed in 45.0% (30/67) of the OSCC tumor samples, while 55.0% (37/67) were not methylated. No association was established between *Runx3* promoter hypermethylation with gender ( $P = 0.157$ ), age ( $P = 0.223$ ) and histologic class ( $P = 0.199$ ). A strong association was however observed between promoter hypermethylation of *Runx3* and tumor location ( $P = 0.010$ ). **Conclusion:** This study showed that aberrant C<sub>p</sub>G islands promoter hypermethylation of *Runx3* seem to be prevalent in OSCC, and that in combination with tumor location, may serve as a diagnostic predictor for OSCC.

## **PgmNr 932: The Ovarian Cancer Regulatory Atlas (OCRA): An integrative epigenomic-transcriptomic approach to characterizing ovarian cancer cells and their cells of origin.**

### **Authors:**

Ovarian cancer is a heterogeneous disease that can be subdivided pathologically into five histotypes: high-grade serous (HGSOC), low-grade serous (LGSOC), mucinous (MOC), endometrioid (ENOC) and clear cell (CCOC) carcinoma. HGSOC is thought to originate from secretory epithelial cells of the fallopian tube, while CCOC and ENOC appear to develop from endometriosis. The cell of origin for MOC is unknown, however MOC resembles gastric and intestinal adenocarcinoma. These histotypes differ not only in their cell of origin but also their genetics, risk factors, treatment and ultimately prognosis. Given gene expression is highly regulated and cell type specific, studies have attempted to distinguish these histotypes based on their transcriptional profiles. Despite consortia efforts (ENCODE) having shown that epigenomic landscapes of disease are also highly cell type specific and ultimately control gene regulation, a large scale atlas of the ovarian cancer epigenomic landscape has been missing from the field. Ovarian cancer risk variants identified through GWAS require evaluation in their relevant histotype-specific cell type to identify candidate causal genes. Hence we set forth to generate the Ovarian Cancer Regulatory Atlas (OCRA) to characterize the epigenomic and transcriptomic profiles of normal and ovarian cancer cells in a histotype specific manner to provide a landscape for functional annotation of risk SNPs, eQTL SNPs, TWAS SNPs and somatic mutations.

Here we describe the integrative analysis of >25 ovarian normal and cancer cell epigenomic profiles for histone modification patterns, DNA methylation and RNA expression. From integrative RNAseq analysis with ChromHMM/StatepaintR state calls, we have established global maps of regulatory elements, defined histotype specific regulatory modules and identified key regulators of these modules based on transcription factor motif enrichment and regulator expression. This atlas reveals that ovarian cancer genetic risk variants are enriched in cell type specific epigenomic marks and highlights OCRA as a valuable resource for interpreting the molecular basis for ovarian cancer risk and progression.

## PgmNr 933: Single cell transcriptomic and epigenetic characterization of inter and intra tumor heterogeneity in Glioblastoma.

---

Glioblastoma is the most common form of primary brain tumor in adults and remains one of the deadliest of human cancers. Intra-tumoral heterogeneity in glioblastomas remains a major challenge in therapeutic development. While single cell based RNA profiling has yielded insights into this heterogeneity, the resolution of these techniques is limited and the pertinence of RNA-based profiling to epigenetic landscape remains unclear. To better address these issues, we have developed and applied single nuclei ATAC-Seq (snATAC-Seq) methods to clinical glioblastoma specimens secured from distinct regions of a tumor and compared these profiles to those derived using single nuclei RNA-Seq (snRNA-Seq). We found that snATAC-seq could identify CNVs at the single cell level with high resolution (20KB), and these CNVs define distinct tumor sub-populations in different geographic locations of the tumor. Using aberrant CNVs as a marker for cells derived from the glioblastoma, we found significant representation of cells with aberrant CNVs that harbor transcriptomic profiles suggestive of normal oligodendrocyte progenitor cell and astrocytes, suggesting potential for these cells to be tumor cells of origin. Our results indicate a combination of snRNA-seq and snATAC-seq as a valuable molecular platform for characterization of glioblastoma heterogeneity.

## PgmNr 934: Open chromatin informed analyses of transcription factor cooperation in high-grade serous ovarian cancer.

Ovarian cancer is the most lethal gynecological cancer, with approximately 14,000 deaths per year in the US alone. High-grade serous ovarian cancer (HGSOC) is the most common histological subtype of ovarian cancer, characterized by specific genetic risk factors, biomarkers and cells of origin. Transcription factors (TFs) are critical players in gene regulation, are commonly deregulated in several cancer types, and are a major class of cancer cell dependencies. TFs are often studied in isolation, although they typically operate within complexes, with interactions with other DNA-binding proteins (including other TFs) often occurring in a context-dependent manner. We have identified putative master TFs in ovarian cancer histotypes and precursor cells, and in this study, our goal was to identify evidence of TF cooperation specific to HGSOC. Our approach is to use a motif-based approach to identify TF binding sites in open chromatin regions assayed using ATAC-seq on HGSOCs and normal fallopian tube epithelial cells, the major precursor for this tumor type. The tumor samples profiled were also included as part of The Cancer Genome Atlas cohort, for which gene expression, methylation and miRNA profiling is also available. We identified ~60-185,000 open regions per sample, ~11% of open regions coincided with promoters, the remaining peaks were categorized as putative enhancers (flanked by H3K27ac signal, a mark of active chromatin) or putative repressors (not flanked by H3K27ac). Within putative enhancers we observed an enrichment of motifs for factors already known to be associated with HGSOC, such as WT1, KLF5, FOXM1 and PAX8, plus novel factors not previously implicated in ovarian cancer (TGIF2, NR2F6). We focussed on PAX8, a known lineage-specific essential gene and attractive therapeutic target for ovarian cancer. We searched for evidence of TF cooperation using SpaMo, which detects significantly enriched spacings in a set of sequences between pairs of motifs. We identified hybrid binding sites for PAX8 together with SOX-family and TEAD-family TFs. We are now characterizing the expression of gene targets of the hybrid motifs during tumorigenesis. In parallel we are exploring small molecule and genetic disruption of the PAX:SOX interface targeting as a novel therapeutic strategy for HGSOC, a tumor type for which novel treatment approaches are urgently needed.

## PgmNr 935: Robust messenger RNA (mRNA) markers in blood for lung cancer diagnosis.

Lung cancer (LC) is the leading cause of cancer deaths worldwide with more than 1.6M deaths each year. The major risk factor for developing LC is cigarette smoking, but air pollution is also rapidly rising as a risk factor. Despite progress in therapies, the overall survival rate is low, with only 18.6% 5 year survival. These devastating numbers are mainly due to LC being diagnosed at late stages, for which few can be cured. Early detection of LC is crucial to achieve efficient treatment and to increase survival. However, there are limitations to current methods for early detection of LC as they are too invasive and represent potential health hazards, necessitating improved tools to detect LC at an early stage. Blood-based gene expression profiling is an alternative, or additional tool as blood samples are easily available, essentially non-invasive, and can be collected at a low cost.

We sampled blood from 123 LC patients at the St. Olavs university hospital, and 180 controls from two different biobanks sampled on two different blood tubes (PAXgene and Tempus) and used Illumina (HT-12 v4) microarrays to measure whole blood gene expression. We did three analyses: (i) finding biologically relevant gene expression differences between cases and controls, (ii) finding a robust set of genes to be used as a panel to identify presence of LC in blood, and (iii) identifying differences between patients with different pathological traits such as stage and histology. We collected phenotype data from questionnaires and hospital medical records, and evaluated the potential effects of CRP, tumor size, gender, and smoking habits.

By comparing cases and controls, we identified 382 significant genes (Bonferroni adjusted  $p < 0.05$ ) with biological relevance. When evaluating these on our test set, we found 51 genes that were robust as they were unaffected by either technical issues in sampling systems, biobank differences, gender, or pathological traits such as LC subtype or stadium. These findings were confirmed in three validation sets. By analysing the cases separately we found 6 genes distinguishing squamous cell carcinoma from other LC subtypes, and 6 genes distinguishing early from late stage LC patients. Pathway analyses and a literature survey indicated that the identified genes show biological relevance for cancer development and lung related diseases.

## PgmNr 936: *Prdm14* transcriptional output is a determinant of testicular germ cell risk.

### Authors:

Genome wide association studies (GWAS) in humans have identified 25 Type II Testicular Germ Cell Tumor (TGCT) susceptibility loci that contain candidate risk genes with putative roles in germ cell biology or tumorigenesis. Functionalization of these GWAS discoveries can potentially lead to advances in screening of at-risk individuals and novel targeted therapies. Spontaneous TGCTs occur at a measurable frequency only in the 129 family of inbred mouse strains. Several single gene mutations modify TGCT susceptibility by enhancing or suppressing baseline incidence in 129/SvImJ mice. We propose that 129/SvImJ inbred mice can serve as a model to reveal risk genes within human TGCT susceptibility loci and to determine the mechanisms through which these genes influence tumor risk.

We used CRISPR/Cas9 genome editing directly in 129/SvImJ mice to generate a knockout allele of PR Domain 14 (*Prdm14*), a candidate GWAS risk gene for human TGCTs. *Prdm14* is a critical determinant of primordial germ cell specification during embryogenesis and an important epigenetic regulator of the naïve pluripotent state. We report that both partial and complete loss of *Prdm14* expression significantly increase tumor incidence in 129/SvImJ mice. Tumors in both heterozygous and homozygous *Prdm14* knockout animals originate during embryogenesis as pluripotent embryonal carcinoma cells (ECCs) that differentiate to form teratomas in adult testes. In homozygous *Prdm14* knockout embryos, the few germ cells that populate the testis express core components of pluripotency; however, most germ cells fail to initiate expression of the naïve pluripotency marker and germ cell licensing factor DAZL. By embryonic day (E)13.5, *Prdm14* deficient germ cells robustly express the primed pluripotency factor OTX2, likely in response to somatic cell-derived TGF-beta superfamily signaling. Moreover, *Prdm14* deficient germ cells begin to transform into foci of OTX2-positive ECCs by E13.5, two days prior to wild-type 129 embryonic testes.

We conclude that reduced transcriptional output of *Prdm14* promotes tumor initiation. We hypothesize that loss of *Prdm14* expression disrupts epigenome remodeling events necessary for regulating genes critical to establishing and maintaining germ cell lineage identity. In the absence of germ cell lineage restriction, *Prdm14* deficient “germ cells” are proposed to transform into primed pluripotent ECCs in response to TGF-beta superfamily signaling in the embryonic testis.

---

ENCODE comprises thousands of functional genomics datasets, and the encyclopedia covers hundreds of cell types, providing a universal annotation for genome interpretation. However, for particular applications, it may be advantageous to use a customized annotation. Here, we develop such a custom annotation by leveraging advanced assays, such as eCLIP, Hi-C, and whole-genome STARR-seq on a number of data-rich ENCODE cell types. A key aspect of this annotation is comprehensive and experimentally derived networks of both transcription factors and RNA-binding proteins (TFs and RBPs). Cancer, a disease of system-wide dysregulation, is an ideal application for such a network-based annotation. Specifically, for cancer-associated cell types, we put regulators into hierarchies and measure their network change (rewiring) during oncogenesis. We also extensively survey TF-RBP crosstalk, highlighting how SUB1, a previously uncharacterized RBP, drives aberrant tumor expression and amplifies the effect of the well-known oncogenic TF MYC. Furthermore, we show how our annotation allows us to place oncogenic transformations in the context of a broad cell space; here, many normal-to-tumor transitions move towards a stem-like state, while oncogene knockdowns show an opposing trend. Finally, we organize the resource into a coherent workflow to prioritize key elements and variants, in addition to regulators. We showcase the application of this prioritization to somatic burdening, cancer differential expression and GWAS. Targeted validations of the prioritized regulators, elements and variants using siRNA knockdowns, CRISPR, and luciferase assays demonstrate the value of the ENCODE resource.

## PgmNr 938: Extrachromosomal DNA function as mobile enhancers and global transcriptional amplifiers in cancer.

Extrachromosomal, circular DNA (ecDNA) is emerging as a prevalent oncogenic alteration in cancer genomes, which frequently carries amplified oncogenes and plays important roles in tumorigenesis and progression by offering cancer cells selective growth advantages. While the presence of ecDNA and their structure information were characterized by standard genomic approaches, the mechanism(s) by which ecDNA are deployed to modulate cancer progression and to contribute to cancer drug resistance is not yet well understood. Here we leveraged the ChIA-PET chromatin interaction assay, which interrogates both general spatial chromatin organization and protein factor mediated long-range chromatin interactions, to advance the discovery of ecDNAs and to characterize genome-wide ecDNA-mediated chromatin contacts that functionally impact transcriptional programs in cancers. Data from RNA polymerase II-associated chromatin interactions in glioblastoma patient-derived neurosphere cultures suggested that ecDNA mediated extensive intra-extrachromosomal and widespread trans-chromosomal interactions. EcDNA-chromatin contact foci were characterized by broad and high-level H3K27ac signals converging predominantly on chromosomal promoters, and corresponding increased gene expression levels, suggesting a major regulatory role in genome-wide activation of chromosomal gene transcription in *trans*. Deciphering the chromosomal targets of ecDNAs revealed an association with actively expressed oncogenes spatially clustered within ecDNA-chromatin connectivity networks. Our results suggest that ecDNAs, beyond the manifestations of oncogene amplification, function as transcription-amplifying elements to activate oncogene expression in human cancers.

## PgmNr 939: Chromatin folding domain disruptions by somatic genomic rearrangements in human cancers.

**Authors:**

K. Akdemir

[View Session](#) [Add to Schedule](#)**Affiliation:** Genomic Medicine Department, MD Anderson Cancer Center, Houston, TX.

---

Genomic material within the nucleus is folded into successive layers in order to package and organize the long string of linear DNA. This hierarchical level of folding is closely associated with transcriptional regulation and DNA replication. Genes within the same folding domain demonstrate similar expression and histone-modification profiles. Therefore, boundaries separating different domains have important roles in reinforcing the stability of these domain-wide features. Indeed, domain boundary disruptions in human genetic disorders or human cancers lead to misregulation of certain genes, due to *de novo* enhancer exposure to promoters. However, the frequency of boundary disruptions in human cancers, and whether there are recurrently affected boundaries in specific cancer types, remains unclear. In this study, in order to understand effects and distributions of somatic structural variations (SVs) across chromatin folding domains, we utilized 288,457 high-confidence somatic structural variations from 2658 tumor-normal paired high-coverage whole genome sequencing datasets across 43 different tumor types. We comprehensively profiled SVs effects on the domain boundaries and the regulation of genes in human cancers. Our findings demonstrate that the impact of chromatin folding domain disruptions is substantially varied across tumor types. Notably, different types of structural variants affect distinct genomic regions such as deletions affect inactive chromatin regions whereas duplications predominantly affect active boundary sites. Complex rearrangements such as chromothripsis (involving concomitant SVs) are the most prevalent class of structural variations in cancer genomes which can drastically change chromatin folding maps in the cancer genomes. To test the effects of SVs on genome architecture in primary human tumors, we generated high-resolution Hi-C data from fresh frozen osteosarcoma samples. Indeed, we were able to observe the catastrophic effects of the complex rearrangements on chromatin folding patterns in tumor samples. Overall, our work highlights the role of structural variations on restructuring the chromatin organization and rewiring transcriptional programs in cancer cells.

## PgmNr 940: Abnormal X chromosome dosage causes replication delays and polyploidization.

---

We previously described the derivation of haploid human embryonic stem cells by artificial activation of unfertilized eggs. Haploid stem cells are a powerful tool for genetic screens and for investigating why normal human development requires a diploid genome. However, haploid cells spontaneously diploidize by endoreplication, due to unknown reasons thought to be related to aborted mitoses. We sequenced the genomes of proliferating haploid and isogenic diploid cells and inferred the dynamics of genomic DNA replication by copy number analysis. Strikingly, ~2% of the genome failed to normally replicate in haploids, being drastically delayed such that the duration of S phase was extended by ~50% and replication continued into mitosis. The genomic regions with replication delays were composed of “naked” chromatin and corresponded almost exactly to under-replicated regions in polyploid cells of the mouse placenta. Haploid cells have one X chromosome that is expressed at similar levels as autosomes, in contrast to female diploid cells in which one X chromosome is developmentally inactivated leading to reduced levels of gene expression. We show that diploid cells that have undergone X chromosome reactivation, and recently-diploidized cells that have yet to inactivate the X chromosome, have replication delays similar to haploids. X chromosome dosage is also altered in polyploid placental cells and in breast cancers, which are often polyploid. We conclude that abnormal X chromosome gene expression exerts a trans-effect on autosomal replication, causing replication delays that lead to endoreplication and polyploidization in normal, pathological, and experimental systems.

## **PgmNr 941: Harnessing the immune response in chronic hepatitis B to regulate the epigenome in hepatocellular carcinoma (HCC).**

---

Current treatments for HCC are limited and 5-year survival for all stages combined has been reported less than 10% and with a median survival of 10 months following diagnosis. In addition, the mortality rates of patients with HCC remained poor in comparison to patients with other leading causes of cancer. The main reason for the poor survival seen in patients with HCC is partly due to the late presentation in major patients. In addition, for HCC patients the availability of certain treatments, chronic hepatitis B (CHB) infection is one of the major risk factors for cirrhosis of the liver and hepatocellular carcinoma in developing country like Cambodia. The chromatin remodeling access in response of CHB to liver tissue has been linked to various immune cell populations and understand their role in the pathologies of the diseases. In this study, we detected large numbers of tumor specific effector T-cells in the blood and biopsy of HCC patients but fail to mount effective immune responses. Moreover, the presence of suppressive regulatory T-cells (Treg) inhibit anti-tumor immune function. A set of experiments was designed an attempt to increase our understanding on how CD8+ Treg may disrupt anti-tumor response and by what mechanisms they are induced. CD8+Treg infiltrating HCC demonstrated a suppressive phenotype. The co-culture of nai?ve CD8+ T-cells with tumour-conditioned mouse dendritic model induces a population of CD8+Treg through an IDO dependent mechanism. This population of induced T-cells could suppress via the CD39-adenosine pathway. The findings of the mechanisms involved in the induction of CD8+Treg by DC and the involvement of CD39 in the suppressive capacity of these novel T-cells, may guide the development of future immunotherapeutic in HCC.

### Introduction

Glioblastoma multiforme (GB) is one notable example of miRNA-modulated neoplasms. Given its unique tissue-specific expression signature, proper miRNA profiling can help to discriminate from other types of brain tumors.

The study aimed (1) to evaluate the expression signature of a panel of miRNAs and targets as diagnostic and prognostic biomarkers in primary GB, and (2) to develop a validated GB-specific custom-designed miRNA assays.

### Methods

#### *Pilot study phase:*

Expression pattern of a bioinformatically-selected panel of seven miRNAs (miR-34a, -16, -17, -21, -221, -326, -375), ten genes (*E2F3*, *PI3KCA*, *TOM34*, *WNT5A*, *PDCD4*, *DFFA*, *EGFR*, *SOX2*, *OCT3/4*, *NANOG*), and four lncRNAs (*ROR*, *GAS5*, *MALAT1*, *H19*) was performed using qRT-PCR.

Immunohistochemistry staining for five proteins (VEGFA, BAX, caspase 3, P53, BCL2) was carried out. *MGMT* promoter methylation was assessed for molecular subtyping.

#### *Biomarker panel development phase:*

A comprehensive data analysis of bioinformatics databases, previous literature and commercially available pre-designed miRNA PCR arrays within the market were carried out to develop a putative GB-specific transcriptomic (96-well plate) panel.

### Results

A significant up-regulation of five miRNAs (miR-16, -17, -21, -221, and -375), four genes (*E2F3*, *PI3KCA*, *WNT5A*, *SOX2*), two lncRNAs (*ROR* and *H19*), and two proteins (VEGFA and BCL2), and down-regulation of miR-34a, five other genes (*DFFA*, *PDCD4*, *EGFR*, *OCT3/4*, *NANOG*) and two lncRNA (*MALAT1* and *GAS5*) in brain cancer tissues. ROC analysis revealed that miR-34a, miR-17, and *MALAT1* had the highest diagnostic performance. Over-expression of *ROR*, *H19* and VEGFA and down-

regulation of TOM34, MALAT1, BAX, and p53 had poor survival. Hierarchical clustering classified patients into four groups based on gene panel signature. Competitively endogenous RNAs network of the lncRNA-miRNA-mRNA was constructed.

Next, we have developed a highly enriched panel of 84 deregulated miRNAs that could have a potential role in GB pathogenesis. Functional analysis classified miRNAs into four distinct clades. Further GB specimens, primary cultured cells and sera were collected from different geographic locations and transcriptomic analysis is still in progress.

### **Conclusion**

The explored microRNA-target dysregulation could pave the road toward developing potential therapeutic strategies for GB. Application of the newly designed array, after its validation, can provide more accurate data about diagnosis and/or prognosis.

Super-enhancers (SEs) are large domains of active chromatin that typically regulate genes important for cell state. SE landscapes are reprogrammed during tumorigenesis to dysregulate the expression of key oncogenes and tumor suppressor genes. Many studies have now shown that variants discovered through genome-wide association studies are enriched in noncoding transcriptional enhancers; but currently, the role of SEs in disease susceptibility is less well understood. We evaluated the role of SEs, defined by H3K27ac chromatin immunoprecipitation sequencing analysis of epithelial ovarian cancers (EOC) and precursor cells, in mediating the genetic risk of EOC. We identified 311-1338 SEs per sample; these were enriched at genes associated with actin cytoskeleton organization and extracellular structural pathways (in normal cells) and cell signaling and cellular organization pathways in tumors. At 25/76 of candidate causal loci, multiple candidate causal alleles overlap with ovarian super-enhancers, suggesting SEs may be involved in mediating risk. Risk SNPs associated with an overall risk for EOC tend to be distributed across EOC, prostate, and breast cancer-relevant SEs. In contrast, histotype-specific risk-associated SNPs tend to be distributed across OC-relevant SEs. A risk locus at 3q25 marked by index SNP rs7651446, (odds ratio = 1.59,  $p = 1.5 \times 10^{-34}$ ), is tagged by 79 candidate causal risk SNPs, more than half of which coincide with SEs detected in EOC precursor cells (ovarian and fallopian tube epithelia) but not in ovarian cancer cells. We hypothesized that SNPs at the 3q25 locus modulate activity of SEs that regulate *in cis* the expression of genes involved in the identity of normal tissue precursors, and that these genes are downregulated during tumorigenesis. Preliminary experiments comparing EOC samples and precursor cell lines highlight two candidate genes at the locus, *SSR3*, and *TIPARP*, as candidate susceptibility genes regulated by the normal tissue SEs at this locus. We therefore established stable shRNA-mediated knockdown models for *SSR3* and *TIPARP* in normal EOC precursor cell lines to study the roles of these genes in ovarian cancer development. RNA-seq profiling identified an enrichment of cell cycle-associated genes following *SSR3* knockdown, and flow cytometry confirmed a G1 arrest. In summary, we have identified a potential role for super-enhancers at the 3q25 serous EOC risk locus and identified *SSR3* as a novel candidate risk gene.

## PgmNr 944: Epigenome-wide association study of whole blood from kidney cancer patients indicates hypomethylation of a *PCBD2* intronic region.

Kidney cancer (KC) is the fourteenth most common cancer worldwide, the incidence of which accounts for approximately 4% of all cancers. Since it has no pathognomonic signs or valuable biomarkers, KC is usually found by chance during abdominal examination via palpation or medical examination for hypertension. Recent studies have shown that DNA methylation status can serve as biomarkers in the diagnosis of several diseases. However, epigenetic biomarkers for KC still remain unidentified; therefore, we aimed to identify blood-based DNA methylation biomarkers for KC.

For this, we performed targeted-bisulfite sequencing of whole blood samples obtained from 50 KC patients and 50 control individuals. Epigenome-wide association analysis for KC was then conducted. We found 6 significantly hypomethylated CpGs in KC blood cells (Bonferroni-corrected  $p < 1.59 \times 10^{-8}$ ). They were located in the second intron of the *PCBD2* gene in chromosome 5 at dense DNase I hypersensitivity sites. Moreover, they did not have transcription factor binding sites. Interestingly, the region exhibited high homology with the light strand of mitochondrial DNA in humans, and likely translocated from mitochondrial DNA as a cluster of 5 kilobases during the evolutionary process from Chimpanzees and Neanderthals. Cis-expression-quantitative trait methylation (cis-eQTM) analysis results using our multi-omics database, iMETHYL (<http://imethyl.iwate-megabank.org/>), also suggested that the DNA methylation profiles of 3 out of 6 CpGs significantly affected *TCF7* and *VDAC1* expression, the abnormal expression of which is related to the onset of cancer. Furthermore, protein-protein interaction analysis using the GPS-Prot database showed that the *PCBD2* protein interacted with 34 proteins, including products of the cancer-related gene, *HNF1A*, and proto-oncogene, *MET*. In summary, we identified 6 significantly hypomethylated CpGs in a *PCBD2* intronic region in KC whole blood samples. Therefore, blood-based examination of *PCBD2* methylation profiles has the potential to clinically support KC diagnosis.

## **PgmNr 945: A two-stage epigenome wide association study identifies novel pancreatic cancer susceptibility loci by leveraging public controls.**

---

To investigate the role of DNA methylation in pancreatic cancer, we conducted an epigenome-wide association study (EWAS) using DNA samples from peripheral blood and the Illumina Infinium EPIC BeadChip at over 850,000 CpG sites across the epigenome. In this two-stage EWAS study, 44 pancreatic cancer cases and 20 controls in the discovery stage and 23 cases and 22 controls in the validation stage from a case control study conducted at MD Anderson Cancer Center were matched by age, gender, BMI, diabetes and smoking status. We increased the number of controls in the discovery stage from 20 to 556 by integrating public data from the Framingham Heart Study. We successfully removed the batch effects between the two datasets from different sources, as shown by the visualization of unsupervised learning. We discovered and replicated six significantly differentially methylated CpG probes (DMPs) and three regions (DMRs) between cases and controls in the discovery and validation stages. Furthermore, one of the three DMRs, which is a non-coding RNA region, was replicated in an external prospective cohort of 13 incident cases and 26 matched controls from the Women's Health Initiative Study. By performing causal inference using bidirectional Mendelian randomization analysis, we found evidence of directional relationships of the associations between DMPs and pancreatic cancer. RNA-sequencing analysis also illustrated the functional consequences of DMPs/DMRs on the cancer risk.

## PgmNr 946: Transcriptome interactions between Epstein-Barr viruses and human host cells at single-cell resolution.

**Authors:**

---

Epstein-Barr virus (EBV), is a common human virus that affects people all over the world differently. EBV infection can be asymptomatic, or cause infectious mononucleosis as well as lymphoid or epithelial malignancies. Research oriented to identify factors underlying the outcome of the infection have focused on the viral life cycle as well as in the interactions between the host and the EBV by using RNA-seq data. However, the mechanisms underlying the infection outcomes remain unknown.

Using high-throughput droplet-based scRNA-seq technology, we measured the single-cell transcriptome profile of GM12878 and GM18502—two lymphoblastoid cell lines established by in-vitro infection with EBV of B cells of female donors with European and African ancestry, respectively. We compared the transcriptome profiles of 7,045 cells from GM12878 and 5,189 from GM18502 against the profile of 1,228 uninfected B cells from a peripheral blood sample, and evaluated the regulatory interactions between viral and host genes using a single-cell gene regulatory network (scGRN) method for cells in different cell cycle phases.

We found 255 and 299 differentially expressed genes when compared the expression profile of the uninfected B cells against cells of GM12878 and GM18502, respectively. Enrichment analysis showed that, for both cell lines, these genes are related with EBV infection and the B cell receptor signaling pathway; however, an association with the Kaposi-sarcoma related with a herpesvirus infection pathway was only recovered on the GM18502 cell line (q-value = 0.016). This result match with previous reports suggesting an increased susceptibility to develop cancer in African populations due to oncogenic viruses as EBV. Comparison of the scGRN between EBV transcriptomes showed that genes are expressed variably between cycle phases and across samples. When the host-EBV interaction was compared, we found evidence that the interaction is more active in GM18502 than in GM12878 where the association with EBV infection pathway decreases after G1. In GM18502, we found an association with the viral carcinogenesis pathway during G1, which may be associated with cancer development and the activation of the EBV infection pathway during all the cell cycle phases.

Together, our results provide the transcriptome profile of EBV and host interaction with an unprecedented resolution, allowing to identify several possible mechanisms underlying the different outcome of the EBV infection.

## PgmNr 947: The role of transposable element methylation in aging and breast cancer development.

---

Nearly half of the human genome is comprised of repetitive sequences, most of which are derived from transposable elements (TE). TE can move and replicate in the genome and contribute to genome instability through insertional mutagenesis, gene expression regulation, and recombination. It is suggested that the mobility of TE is regulated by DNA methylation. Previous studies found that global hypo-methylation of TE increases with age, likely leading to an increase in mobility of TE and thus an increased susceptibility to cancer development. Limited studies have been reported on site-specific TE methylation and their relation to aging and cancer development. To understand the role of site-specific TE methylation in aging and breast cancer risk, we generated genome-wide DNA methylation profiles for 571 breast tissue (462 healthy normal and 109 tumor) samples using the Illumina TruSeq Methyl Capture EPIC Sequencing technology. We examined the association between the methylation of each of 176,987 Alu/LINE-1 CpGs and chronological age in normal breast tissue, and identified 438 Alu/LINE-1 CpGs associated with age. Genes annotated to these 438 TE-CpG markers are enriched in functions regulating transcription frequency, tumor necrosis factor production, cellular proliferation, and apoptosis. We further investigated the behaviors of the identified age-related TE-CpG markers in tumor and normal breast tissue. In age-matched analyses, we found that on average the identified 438 Alu/LINE-1 CpGs were hypomethylated in tumor compared to normal breast tissue (mean  $\Delta\beta = -0.03$ ;  $p=2E-11$ ). Further analyses with RNA-seq data from these tissue samples suggested that these age-related TE are overexpressed in tumor tissue compared to normal tissue, supporting the increased mobility of TE in the tumorigenesis. In line with our previous observations from epigenetic aging research that tumor breast tissue ages at a faster rate compared to healthy normal tissue, the current study identified specific age-related TE and showed that hypo-methylation of these TE was correlated with their overexpression, and the latter could lead to increased mobility of these TEs for cancer development. Our study provided support of the role of methylation at the identified TE in the processes of aging and tumorigenesis. Our current study examined approximately 3% of all TE CpGs. Future research will focus on the imputation of missing TE CpGs and the understanding the underlying molecular mechanisms.

## PgmNr 948: Epigenetic regulation of the *miR-137* Host Gene CpG island that spans *miR-137* and adjacent downstream sequence is associated with head and neck cancer.

### Authors:

H. Celesnik <sup>1,2</sup>; B. Cizmarevic <sup>3</sup>; U. Potocnik <sup>1,2</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Faculty of Medicine, Center for human molecular genetics and pharmacogenomics, University of Maribor, Maribor, Slovenia; 2) Faculty of Chemistry & Chemical Engineering, University of Maribor, Maribor, Slovenia; 3) Department of Otorhinolaryngology, Cervical and Maxillofacial Surgery, University Medical Centre Maribor, Maribor, Slovenia

---

**BACKGROUND:** Head and neck cancer, including oral squamous cell carcinoma (OSCC), is one of the most common malignancies worldwide. Despite numerous advances in diagnosis and treatment, OSCC prognosis is still poor due to its aggressive nature, which includes strong local invasiveness and lymph node metastasis. The 5-year survival rate is among the lowest in cancer patients at <50%. Elucidation of molecular mechanisms underlying this type of cancer is crucial for early detection and treatment and for increasing patient survival. MicroRNAs are endogenous small RNAs that control gene expression in various cellular and metabolic pathways. MicroRNA *miR-137* has been shown to suppress cell proliferation, migration and invasion, and its dysregulation has been observed in cancerous tissues. In OSCC, methylation of *miR-137* promoter has been linked to cancer development. However, methylation of the CpG island (CGI) that spans *miR-137* and adjacent downstream sequence has not yet been investigated in OSCC. We have set out to elucidate whether epigenetic regulation of this CpG island plays a role in head and neck cancer.

**PATIENTS AND METHODS:** Paired tumor and normal adjacent tissue samples were collected from 118 Head and neck cancer patients that were treated at the University Medical Centre in Maribor from 2016 to 2019. Specimens included oropharynx (36%), hypopharynx (21%), cavitas oris (19 %) and larynx (11%) primary tumors. Medical history and clinical data was collected for each patient, including tumor TNM classification, perivascular/perineural invasion, cancer recurrence and patient survival. The methylation levels of portions of the *miR137* Host Gene were determined by Combined bisulfite restriction analysis (COBRA) of bisulfite-modified tissue DNA and by bisulfite sequencing. Expression analyses were performed by qRT-PCR.

**RESULTS:** Methylation at various CpGs of the CpG island that contains *miR-137* and adjacent downstream sequence was significantly higher in cancer tissues compared to paired normal adjacent tissues ( $P < 0.05$ ). UCSC Genome Browser tracks reveal that this CGI contains various transcription factor binding sites and DNaseI hypersensitivity clusters. In agreement with our methylation data, *miR-137* expression was decreased in tumor tissues. The aberrant methylation levels in OSCC were examined in relation to patient survival, tumor grade, invasion and cancer recurrence.

## PgmNr 949: Three-day workflow and analysis pipeline for the low-input NGS Ion AmpliSeq™ Methylation Panel for cancer research.

### Authors:

---

**Introduction:** Strong associations between DNA methylation patterns and clinical phenotypes can be used as biomarkers for diagnosing diseases and guiding treatment. Currently there are multiple ways to determine methylation status, including whole genome sequencing, microarrays and amplicon-based approaches. The recently released Ion AmpliSeq™ Methylation Panel for Cancer Research is the first of its kind and demonstrates the capability to create a targeted panel leveraging the AmpliSeq™ technology on the NGS Ion S5™ sequencing platform.

The panel combines an easy three-day protocol with manual or automated library options, low input (10 ng to 20 ng starting), and a flexible multiplexed approach with quantitative information at single base pair resolution. The bioinformatics analysis has been streamlined into a downloadable plugin providing DNA methylation calls on both Watson and Crick strands and methylated:unmethylated ratios for each CpG. Samples tested to date include standard fresh frozen and FFPE.

**Methods:** A complete three-day end-to-end workflow has been developed starting from bisulfite conversion and progressing through library construction, template preparation, sequencing and data analysis. A subset of clinically relevant markers from the BLUEPRINT consortium was used to create the panel, which contains a total of 40 amplicons, with 31 of those being cancer markers associated with colon cancer, prostate cancer, leukemia and lymphoma. Amplicons were designed for both original strands, but only one of those two was chosen for the final panel.

Two control gDNA samples were used in the evaluation of the panel. The expected average methylation state across all CpGs was >98% for the first sample and <5% for the second. Testing was also performed with an equal mixture of these two samples.

**Results:** The Ion AmpliSeq™ Methylation Panel for Cancer Research showed good performance on both the >98% and <5% samples as well as the equal mixture.

**Conclusions:** The AmpliSeq™ Methylation Panel for Cancer Research offers high resolution, targeted and quantitative methylation analysis of clinically relevant targets with a three-day end-to-end workflow from low DNA input. The potential exists to design custom methylation panels.

For Research Use Only. Not for use in diagnostic procedures. Early access materials were provided by

Thermo Fisher Scientific to Dr. David Berman in support of this abstract, but no remuneration.

# PgmNr 950: Epigenome-wide association study of the herbicide glyphosate and DNA methylation.

## Background

Glyphosate, the most commonly used herbicide worldwide, is associated with endocrine disruption and potentially carcinogenesis, although the association with cancer is controversial. Exposure to many environmental toxicants has been linked to altered DNA methylation patterns in white blood cells, but the impact of glyphosate on the epigenome has not yet been evaluated.

## Methods

We conducted the first epigenome-wide association study of glyphosate exposure in a cohort of 182 postmenopausal women aged 45-65. Peripheral blood samples and two first-morning urine samples were collected. Glyphosate concentration was assessed in urine samples using liquid chromatography coupled to a triple quadrupole tandem mass spectrometer. DNA was extracted from white blood cells for quantification of DNA methylation using the Illumina Infinium MethylationEPIC BeadChip. For each CpG site, a linear model adjusted for age and race/ethnicity was fitted with creatinine-corrected glyphosate tertile as the predictor and methylation (M) value as the outcome. Sites with a false discovery rate  $q < 0.05$  were considered statistically significant.

## Results

178/182 (98%) of study participants had detectable glyphosate in their urine (LOD = 0.014 ng/mL). Glyphosate levels varied widely, with a mean of  $0.41 \pm 0.47$   $\mu\text{g}$  glyphosate/g creatinine, but did not significantly differ according to key confounding variables (including race/ethnicity, body mass index, smoking status, alcohol intake, and estimated white blood cell subtype distribution). DNA methylation at 156 CpG sites was significantly associated with glyphosate tertile. For most sites (125/156, 80%), methylation was inversely correlated with urinary glyphosate.

Glyphosate-associated sites were located in or near 115 genes, including *ESR1* and *IGF2*, which both have important roles in breast and other cancers. Gene ontology terms significantly enriched (adjusted  $p < 0.05$ ) for these 115 genes included regulation of transcription, Wnt signaling, and stem cell proliferation. Pathway analysis showed enrichment of several KEGG pathways, including proteoglycans in cancer and viral carcinogenesis.

## Conclusions

In a cohort of postmenopausal women, urinary glyphosate levels were associated with differential methylation at 156 CpG sites. Analysis of the genes found in or near these CpG sites indicated enrichment of cancer-related pathways. Further investigations are warranted to evaluate the effect of

glyphosate exposure on cancer risk.

## Background

Existing epidemiologic studies on pancreatic cancer risk associated DNA methylation biomarkers are limited by relatively small sample sizes and potential biases caused by selection bias, confounders, and reverse causation. To overcome these limitations, we performed a comprehensive study to systematically investigate associations of genetically predicted DNA methylation with pancreatic cancer risk.

## Methods

We used genotyping and DNA methylation data obtained in white blood cells from subjects of European descent included in the Framingham Heart Study (FHS, N=1,595) and established models using the elastic net method to predict DNA methylation based on genetic variants. We further conducted model external validation using data from the Women's Health Initiative (WHI, N=883), and selected 62,994 models with a prediction performance ( $R^2$ ) of  $>0.01$  in both internal and external validation stages. For association analyses with pancreatic cancer risk, we used data from 8,280 cases and 6,728 controls of European ancestry included in PanScan and PanC4 consortia downloaded from dbGaP. For CpG sites showing a significant association with pancreatic cancer risk, we further evaluated correlations of their methylation levels with expression levels of genes flanking these loci in blood, by using data from the Offspring Cohort of the FHS (N=1,367). Furthermore, for genes whose expression levels were correlated with DNA methylation levels, we assessed whether their genetically predicted mRNA expression levels in blood were also associated with pancreatic cancer risk.

## Results

We identified 47 CpGs showing an association with pancreatic cancer risk at a false discovery rate (FDR)  $< 0.05$ , including 15 CpGs located  $>500$  kb away from any risk variant reported in previous GWAS of pancreatic cancer. Among these 47 CpGs, methylation levels of 14 were correlated with expression levels of eight adjacent genes at  $p < 0.05$ . Among these eight genes, two had genetic prediction models built for their mRNA expression levels. Gene *ABO* showed a significant association with pancreatic cancer risk ( $p = 2.85 \times 10^{-12}$ ), confirming previous findings.

## Conclusion

In this large association study, we integrated genetic variants, DNA methylation and gene expression

data and identified multiple novel DNA methylation biomarkers for pancreatic cancer.

## PgmNr 952: *NOTCH1* expression correlates to *miR-27a*, *miR-34a*, *miR-145*, *miR-150*, and *miR-335* in human squamous cell carcinoma of the oral cavity.

*NOTCH1* is an important regulator of stemness, involved in epithelial-mesenchymal transition (EMT), which can be an initial step in the development of cancer metastasis. *NOTCH1* expression has been documented in a variety of cancers, including head and neck squamous cell carcinomas (HNSCC), where it was associated with poor prognosis. In HNSCC, it is believed that it can act as a tumor suppressor gene. However, based on expression in different cell lines, it has been considered as tumor suppressor and as oncogene, suggesting that NOTCH1 signaling is dependent on many regulatory factors, including microRNAs. Different microRNAs have also been shown to be related to *NOTCH1* expression in various cancers, but not in oral squamous cell carcinomas (OSCC). The aim of our study was therefore to analyze the expression of *NOTCH1* and its correlations to the expression of *miR-27a*, *miR-34a*, *miR-150*, *miR-145* and *miR-335* in OSCC tumor samples.

Our study included tumor samples of 90 patients with HPV-negative OSCC that have been divided in 4 groups: 29 patients with pT1/2 N0 M0, 35 patients with pT1/2 N+ M0, 5 patients with pT3/4 N0 M0, 21 patients with pT3/4 N+ M0. Expression of *NOTCH1* and miRNAs (*miR-27a*, *miR-34a*, *miR-150*, *miR-145* and *miR-335*) has been analyzed using quantitative real-time polymerase chain reaction.

Analysis has shown that *NOTCH1* was in moderate positive correlation with expression of all investigated miRNAs; with *miR-27a* ( $r_s=0.250$ ,  $p=0.02$ ), *miR-34a* ( $r_s=0.290$ ,  $p=0.01$ ), *miR-145* ( $r_s=0.233$ ,  $p=0.04$ ), *miR-150* ( $r_s=0.428$ ,  $p=0.001$ ) and with *miR-335* ( $r_s=0.254$ ,  $p=0.02$ ). Expression of all the tested miRNAs was also in correlation to each other.

Our results show a correlation between the expression of the analyzed miRNAs and *NOTCH1* in tumor samples of OSCC, suggesting regulation of these miRNAs by NOTCH1 or vice versa. To the best of our knowledge, this is the first report on positive correlation of NOTCH1 with analyzed miRNAs in OSCC tumor samples.

## PgmNr 953: The landscape of long non-coding RNAs in pediatric cancers.

---

**Background:** Long-non coding RNAs (lncRNAs) are emerging as key components of gene regulation in cancer. However, very few lncRNAs have been associated with pediatric cancers.

**Methods:** To characterize the lncRNA expression landscape of pediatric cancers, we analyzed RNA-sequencing data for 1,070 tumor samples from the Therapeutically Applicable Research Project (TARGET). This data set included three blood cancers: 282 acute myeloid leukemia (AML), 194 acute B-cell leukemia (B-ALL), and 244 acute T-cell leukemia (T-ALL), two kidney cancers: 128 Wilm's tumor (WT) and 61 rhabdoid tumors (RT), and 161 neuroblastoma (NBL). We performed a global analysis of lncRNA function using the lncMod method, in which expression data is modelled to identify lncRNA modulators that perturb transcription factor (TF) regulation of target genes. To further elucidate cancer-associated lncRNAs, we integrated ChIP-sequencing and chromatin interaction data, to identify lncRNAs regulated by TFs involved in the core transcriptional regulatory circuitry (CRC) of NBL and T-ALL.

**Results:** Our curated transcriptome catalog contains 14,636 known lncRNAs, of which 2087 were robustly expressed. We observed that 25-50% of all lncRNA expression is explained by approximately 5-10 highly expressed lncRNAs in each cancer. These included *MALAT1*, *GAS5*, *MEG3*, and *H19*, lncRNAs that are commonly dysregulated in various cancers. Across all the pediatric cancers, we observed 185,154 significantly dysregulated lncRNA-TF-target gene (lncMod) triplets. We assigned lncRNA modulators to hallmark cancer pathways via gene set enrichment analysis of their associated target genes. We observed significant enrichment for the MSigDB cell proliferation hallmark pathways (FDR < 0.01), across all the cancers, implicating 641 lncRNAs with this biological function. Analysis of lncRNA regulation revealed 449 and 80 lncRNAs regulated by cancer driver genes of the NBL and T-ALL CRC respectively; and included the *PVT1* and *CASC15* lncRNAs, both with known roles in driving these cancers. Differential expression analysis further prioritized the CRC-associated lncRNAs, *NR2F1-AS1* and *TBX2-AS1* in NBL, for functional validation. Silencing of *TBX2-AS1* with siRNAs (>80% knockdown) in an NBL cell line resulted in 50% decreased cell growth (p-value < 0.01) and elongated cell morphology.

**Conclusion:** Our results provide a comprehensive catalog of lncRNA expression and putative functional pathways for lncRNAs in pediatric cancers.

---

Triple negative breast cancers (TNBC: ER-,PR-,HER2-) constitute one sixth of invasive female breast cancer cases and are the most likely to develop resistance to treatment. This is largely due to the absence of successful targeted therapies, which are further hindered by the high intra-tumor heterogeneity associated with TNBC tumors. Cells in these tumors exist in distinct genetic and epigenetic populations that gain treatment resistance via clonal Darwinian evolution and through the epigenetic adaptation into drug tolerant persister (DTP) states. While breast cancer clonal evolution has been more thoroughly studied on the single-cell level, the underlying epigenetic heterogeneity and treatment induced cell-state transitions in TNBC tumors remain enigmatic. Single-cell Combinatorial Indexed Assay-for-Transposase-Accessible-Chromatin (sci-ATAC-seq) allows for the accurate description of the single-cell regulatory landscape through the mapping of promoter and enhancer accessibility and the identification of putative cell-state specific DNA binding transcription factor proteins. We carried out sci-ATAC-seq on four TNBC cell lines that were MEK inhibitor (trametinib) and DMSO treated (control), which revealed separate cell line specific MEK inhibitor driven DTP epigenetic states along with some regulatory features shared between the DTP cell states. This indicated that the epigenetic shifts were primarily cell line specific with some shared underlying epigenetic mechanisms for resistance. Using a recently-described framework for linking regulatory elements to target genes (Cicero), we identified commonly deregulated genes in cancer, such as EGR1, which were further confirmed via differential accessibility analysis between treated and control groups. Finally, we looked at the pseudotemporal ordering of cells to further understand the changing chromatin dynamics of cell lines along a treatment response curve. Next, we aim to understand the influenced pathways of cell line specific epigenetic shifts during DTP state acquisition.

## PgmNr 955: Unearthing a new wild-type p53 transcriptional signature *in vivo*.

---

Cell stress activates the tumor suppressor and transcription factor p53. This subsequently triggers downstream p53-dependent pathway activation through a myriad of p53 target genes. However, it has become apparent that focusing on a select handful of p53 target genes, out of the vast array of genes mediated by p53 transcriptional activation, may not only be too exclusive but could also be an inaccurate representation of transcriptional activity. By deleting *mdm2* and thus activating a p53 transcriptional program *in vivo*, we overlayed tissue-specific RNA-sequencing data with previously published p53 ChIP-sequencing and ATAC-sequencing data. We identified a new p53 transcriptional signature of 7 common differentially expressed genes: *Eda2r*, *Gtse1*, *Polk*, *Mdm2*, *Psrc1*, *Polk*, *Ccng1*, and *Zfp365*. We propose that these genes be added to the classically studied p53 target genes to serve as an *in vivo* signature for p53 transcriptional activation. Not only does this study provide novel insight into acute p53 transcriptional activity, but it can also serve as a resource for the field by providing invaluable p53-dependent tissue-specific transcriptomes.

---

Genome-wide association studies (GWAS) have proven successful in predicting genetic risk of disease using single-locus models; however, identifying single nucleotide polymorphism (SNP) interactions at the genome-wide scale is limited due to computational and statistical challenges. We address the computational burden encountered when detecting SNP interactions for survival analysis, such as age of disease-onset. To confront this problem, we developed a novel algorithm, called the Efficient Survival Multifactor Dimensionality Reduction (ES-MDR) method, which uses Martingale Residuals as the outcome parameter to estimate survival outcomes, and implemented the Quantitative Multifactor Dimensionality Reduction method to identify significant interactions associated with age of disease-onset. To demonstrate efficacy, we evaluated this method on two simulation sets to estimate the type I error and power. Simulations show that ES-MDR identifies interactions using less computational workload with adjustment for covariates. We applied ES-MDR on OncoArray Consortium data with 14,935 cases and 12,787 controls (SNPs = 108,254) to search over all two-way interactions to identify SNP interactions associated with lung cancer age-of-onset. We tested the best model in an independent data set from the OncoArray. Our experiment on the OncoArray identified many one-way and two-way models with a single-base deletion in the noncoding region of *BRCA1* (HR = 1.24,  $P = 3.15 \times 10^{-15}$ ), as the top marker to predict age of lung cancer onset. Through the results of our extensive simulations and analysis of a large GWAS study, we demonstrate that our method is an efficient algorithm that identifies genetic interaction models to predict survival outcomes.

## PgmNr 957: LDscore regression identifies novel associations between glioma and auto-immune conditions.

### Authors:

Duncan Comprehensive Cancer Center, Baylor College of Medicine, Houston, Texas, United States; 3) Duke Cancer Institute, Duke University Medical Center, Durham, North Carolina.; 4) Department of Neurosurgery, Duke University School of Medicine, Durham, North Carolina.

### BACKGROUND

Prior epidemiological studies in glioma have identified 25 germline risk variants, as well as risk associations with exposure to ionizing radiation (which increases risk) and history of allergies and aspirin use (which decrease risk). In this analysis we LDscore regression, which leverages single SNP associations and known patterns of linkage disequilibrium (LD) to estimate the genetic correlation between phenotypes, to confirm prior associations as well as attempt to identify novel phenotype associations for traits not previously assessed that may improve genetic prediction for glioma.

### METHODS

Summary statistics for all glioma, GBM, and non-GBM were obtained from a prior meta-analysis conducted by Melin, et al. Summary statistics for 13 immune- and atopy-related traits were obtained from the prior case-control studies and the UK biobank. Data were filtered to include only SNPs with imputation INFO value  $>0.7$ , and minor allele frequency  $>0.01$ , excluding SNPs within the HLA region. Pairwise genetic correlation between these traits was generated using LDSC. Associations were considered significant at  $p < 0.05$

### RESULTS

Significant negative correlations were identified between glioma and ulcerative colitis ( $rg = -0.4039$ ,  $p = 4.91 \times 10^{-10}$ ), celiac disease ( $rg = -0.2028$ ,  $p = 1.18 \times 10^{-4}$ ), lupus ( $rg = -0.0956$ ,  $p = 0.0083$ ), and multiple sclerosis ( $rg = -0.5755$ ,  $p = 4.46 \times 10^{-9}$ ). These associations were generally consistent in both GBM and non-GBM. There was a significant correlation between both self-reported ( $rg = -0.102$ ,  $p = 0.0233$ ) and doctor diagnosed ( $rg = -0.116$ ,  $p = 0.0305$ ) hayfever/allergic rhinitis and GBM only.

### CONCLUSIONS

This analysis demonstrates a genetic basis for previously identified protective effect of allergic rhinitis on GBM, and identifies novel associations between multiple auto-immune traits and glioma. Further studies are necessary in order to confirm these associations and identify the mechanism through which increased immune activity may lower risk of glioma.

## PgmNr 958: European genetic ancestry associated with risk of childhood ependymoma.

### Authors:

C. Zhang <sup>1</sup>; H. Hansen <sup>2</sup>; J. Gonzalez-Maya <sup>2</sup>; I. Smirnov <sup>2</sup>; J. Wiemels <sup>3</sup>; K. Walsh <sup>4</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Department of Epidemiology and Biostatistics, Univ California San Francisco, San Francisco, CA; 2) Department of Neurological Surgery, University of California San Francisco, San Francisco, CA; 3) Center for Genetic Epidemiology, University of Southern California, Los Angeles, CA; 4) Department of Neurosurgery, Duke University, Durham, NC

**Background:** Ependymoma is a histologically-defined central nervous system tumor most commonly occurring in children. Population-based differences in incidence by race/ethnicity exist within the US and worldwide, with individuals of European ancestry at highest risk. No large-scale genomic analyses of ependymoma predisposition have been conducted to date. We aimed to determine whether extent of European genetic ancestry is associated with ependymoma risk in US populations.

**Methods:** In a multi-ethnic study of Californian children (327 cases, 1970 controls), we estimated the proportions of European, African, and Native American ancestry among admixed Hispanic and African-American subjects and estimated European substructure among non-Hispanic White subjects using genome-wide data. We tested whether genome-wide ancestry differences were associated with ependymoma risk and performed admixture mapping to identify associations with local European ancestry.

**Results:** A 20% increase in European ancestry was associated with 1.31-fold higher odds of ependymoma among Hispanic and African-Americans (95% CI: 1.08-1.59,  $P_{meta}=6.7 \times 10^{-3}$ ), with a stronger association observed among Hispanic individuals (OR: 1.34, 95% CI: 1.09-1.67,  $P=6.2 \times 10^{-3}$ ). Among non-Hispanic Whites, European ancestral substructure was also significantly associated with ependymoma risk. Local admixture mapping revealed a peak at 20p13 associated with increased local European ancestry, and genotype association analysis in the region identified an association at rs6039499 that survived Bonferroni correction (OR=1.99; 95% CI=1.45-2.73;  $P=2.2 \times 10^{-5}$ ) but was not validated in an independent set of posterior fossa type A (PF-EPN-A) patients.

**Conclusions:** Inter-ethnic differences in ependymoma risk are recapitulated in the genomic ancestry of ependymoma patients, implicating regions to target in future association studies.

## PgmNr 959: Arsenic (+3) methyltransferase gene polymorphisms and arsenic metabolism in schistosomiasis associated bladder pathology in Eggua, Nigeria.

### Authors:

C.I. Anumudu <sup>1</sup>; A.T. Adeboye <sup>2</sup>; A.S. Adebayo <sup>2</sup>; H.O. Awobode <sup>3</sup>; R.D. Isokpehi <sup>4</sup>

---

Exposure to toxic inorganic Arsenic (iAs) in urogenital schistosomiasis (UGS) endemic areas may confer increased risk for bladder cancer. The severity of the adverse effects of iAs however depends on its metabolism which is highly variable. Genetic polymorphism in AS3MT enzyme responsible for arsenic metabolism, accounts significantly for these variations. The aim of this study was to investigate the association between *AS3MT* gene polymorphisms and Arsenic metabolism in relation to schistosomiasis associated bladder pathology. In total, 119 individuals from Eggua community in Southwest Nigeria were screened for schistosomiasis and bladder pathology. A digital arsenic test kit was used to assess total urinary arsenic concentrations of participants and determine level of arsenic exposure. The SNP *AS3MT/MET287THR* T>C (rs1191439) was genotyped using AS-PCR method. Prevalence of schistosomiasis and bladder pathology in the sample population was 5% and 30.25% respectively. Of the participants diagnosed with bladder pathology, only 5.6% tested positive for UGS. Total urinary arsenic concentration observed ranged from 0 to >0.8mg/L (mean of 0.16mg/L) with 75% above the World Health Organization (WHO) limit of 0.05mg/L. Observed allelic frequencies were 0.96 and 0.04 for wild-type T and mutant C alleles respectively. There was no significant relationship between *AS3MT* SNP, arsenic metabolism and schistosomiasis associated bladder pathology. However, low allelic frequency of the C-allele may suggest increased enzyme reactivity as urinary arsenic concentrations were relatively high indicating reduced arsenic body burden. Logistic regression analysis also showed that high total urinary arsenic concentration was significantly associated with reduction in likelihood of inducing bladder pathology.

## PgmNr 960: Genetic correlations between lung cancer and biomarkers using LD score regression.

### Authors:

A common approach in genetic association studies is to perform meta-analysis from several cohort-level genome-wide association studies (GWAS) of a single trait. Common diseases often show comorbidity with other traits and diseases, and understanding the genetic architecture that results in disease co-development may be more informative than studying individual phenotypes. Here, we examined the degree of overlap in the genetic contribution between lung cancer and biomarkers based on the genetic correlation.

Linkage disequilibrium (LD) score regression is an approach that aims to quantify the genetic correlation between phenotypes based on summary statistics from GWAS. This study aimed to identify possible biomarkers that are associated with lung cancer overall and histological subsets including adenocarcinoma, squamous cell carcinoma, and small cell carcinoma, within smoker versus nonsmoker subsets. GWAS summary statistics from OncoArray lung consortium data and the UK Biobank were used for multi-trait analyses and chromosomal regions related to cigarettes per day, smoking cessation, and initiation were removed to correct the potential confounding effects of smoking.

We identified numerous biomarkers showing high SNP heritability ( $h^2$ ), which is the proportion of phenotypic variance explained by all SNPs, and genetic correlation ( $r^2$ ) with lung cancer, but many effects varied according to whether or not SNPs associated with smoking were included or excluded from analysis.

Without removing smoking-related SNPs, both high concentrations of lactate and lower concentrations of acetate in the blood were genetically correlated with lung cancer. After removal of smoking-related SNPs, the presence of CD3 on double negative T-cells was the strongest association ( $r^2=0.54$ ,  $P=0.01$ ,  $h^2=0.38$ ) in never smokers, while the percentage of immunoglobulin-E in the B memory cells ( $r^2=-0.50$ ,  $P=0.04$ ,  $h^2=0.17$ ) and fatty acid lengths ( $r^2=-0.57$ ,  $P=0.04$ ,  $h^2=0.04$ ) were the strongest protective associations. Elevations of selected immunological biomarkers may identify a subset of nonsmokers at higher disease risk.

LD score regression provides an improved understanding of the genetic architecture between lung cancer and biomarkers. Mendelian randomization analyses will help elucidate the potentially causal relationship between immune-related biomarkers and risk of lung cancer.

## **PgmNr 961: LFSPRO: A risk prediction R package for probabilities of age-of-onset of multiple primary cancers and specific cancer types in families with Li-Fraumeni syndrome.**

---

Li-Fraumeni syndrome (LFS) is a rare autosomal dominant disorder associated with a germline *TP53* mutation that increases an individual's risk of a spectrum of cancers and multiple primary diagnoses. Penetrance estimations of multiple primary cancer (MPC) risk and cancer-specific (CS) risk associated with *TP53* germline mutations remains a challenge because of limited data available for statistically meaningful estimation, the difficulty of accounting for variables like previous primary cancer effect and ascertainment bias inevitable in rare diseases. We developed a non-homogenous Poisson process model to estimate the MPC penetrance from a large pediatric sarcoma cohort from MD Anderson Cancer Center (MDACC). We also developed a model under a competing risk framework that considers the pedigree structure into the penetrance estimation and corrects for ascertainment bias to address the *TP53* penetrance for three cancer subtypes, breast (BR), sarcoma (SA), and others (OT), on the same pediatric cohort. We have validated the risk prediction performance of the two sets of penetrance estimates via independent cohort datasets.

Using the validated penetrance estimates, we have updated our R package LFSPRO to calculate probabilities based on family cancer history for 1) whether the counselee is a *TP53* germline mutation carrier, 2) the counselee develops breast cancer, sarcoma or any other cancers as a first primary in future years, or 3) if the counselee already had a cancer, he/she develops a second primary cancer in future years. Incorporating LFSPRO into genetic counseling sessions could potentially facilitate clinical decision-making to both patients and their physicians. The accurate cancer risk assessment will benefit cancer survivors who desire better risk management of any future cancer development, as well as healthy individuals who are concerned about their future risk of cancers based on their family history. Genetic counselors and clinicians will be able to quantitatively assess counselee's risks in the future, provide evidence-based counseling for clinical actions and save evitable diagnostic resources.

## PgmNr 962: Association between obesity and the colorectal cancer prognosis using pathway activity inference approach from multi-omics data.

---

Obesity is increasing worldwide, potentially influencing prognostic outcomes in colorectal cancer (CRC) patients. Obesity is reported to have an association with CRC progression and prognosis in many previous epidemiologic studies. There have been several studies to explain its biological interaction using respective genomic profiles, but the results are inconsistent, and the mechanisms are not fully elucidated. Recently, methods for integrating the multi-omics profiles are applied in disease association studies. Here, we performed the association analysis between obesity and CRC prognosis using the integrative effect of multi-omics data. Clinical information and genomic data, including gene expression, methylation and copy number variation, from colorectal cancer patients were downloaded from the Cancer Genome Atlas (TCGA) database. We ran linear regression with each genomic data for body mass index (BMI) to select multi-omic features associated with obesity. To integrate these multi-omic features associated with obesity, a directed random walk-based pathway activity inference method was used to generate an integrated pathway activity matrix. KEGG pathway was used as a reference panel. Association analyses between the integrated pathway activities and CRC survival, locoregional lymph node metastasis and distant metastasis were done. Among 254 CRC patients, 120 (47.2%) had positive lymph nodes, and 29 (11.4%) had distant metastasis. There were 46 mortalities during follow-up (median, 20.5 months). Based on FDR < 0.1, there were 13 pathways significantly associated with overall survival, 2 with lymph node metastasis and 3 with distant metastasis. Alcoholism pathway was found to be significant both for overall survival and lymph node metastasis, which is typically observed in obesity population. In addition, Glycan synthesis, which has a crucial role in distant metastasis, was a significant pathway both for overall survival and distant metastasis. Integrated pathway activities for BMI showed a significant relationship with CRC overall survival, lymph node and distant metastasis. The pathophysiological effects of the pathways might be the potential mechanism linking obesity and CRC progression. This study warrants further validation in a larger CRC patient population to demonstrate the validity of biomarkers for CRC survival prediction, further potential targets for intervention to improve CRC prognosis.

## PgmNr 963: Sequencing DNA repair genes in 5,545 men with aggressive and non-aggressive prostate cancer.

---

**Introduction:** Few common genetic variants have been associated with the aggressive form of prostate cancer (PCa). Aggressive PCa may be attributed to multiple rare high-risk coding variants. We investigated whether such pathogenic variants in 20 DNA repair genes (Pritchard et al., NEJM 2016) associate with risk of aggressive versus non-aggressive PCa. **Methods:** Participants were from stage 1 of a multi-stage case-only investigation of men of European ancestry, including 2,770 with aggressive disease (died from PCa, stage T4/M1, or were both T3 and Gleason score $\geq$ 8 at diagnosis) and 2,775 with non-aggressive PCa (T1/T2 and Gleason score $\leq$ 6), who had germline whole-exome sequencing. A subset of highly aggressive cases died from PCa or had metastatic disease at diagnosis (n=2,134). Variants analyzed were rare (MAF<0.01) and either pathogenic based on ClinVar or likely to disrupt the protein based on IMPACT rating. Logistic regression was used to test associations between the burden of rare variants and aggressive PCa, adjusting for age at diagnosis, country, and three principal components. Linear regression was used to investigate the burden of rare variants on age at PCa onset. **Results:** Of non-aggressive cases, 9.3% carried at least one pathogenic variant in the 20 genes, compared to 13.0% of aggressive cases (OR=1.40, P=1.4x10<sup>-5</sup>) and 13.4% of highly aggressive cases (OR=1.47, P=3.8x10<sup>-6</sup>). *BRCA2* had the strongest evidence of association, with 2.5% of non-aggressive cases, 4.4% of aggressive cases (OR=1.73, P=1.2x10<sup>-4</sup>), and 4.7% of highly aggressive cases (OR=1.87, P=2.6x10<sup>-5</sup>) carrying rare pathogenic variants. Rare pathogenic *PALB2* variants were found in 0.11% of non-aggressive cases, 0.65% of aggressive cases (OR=6.19, P=5.1x10<sup>-4</sup>), and 0.70% of highly aggressive cases (OR=6.44, P=6.4x10<sup>-4</sup>). Carrying one pathogenic variant among the 20 genes was associated with a 1.0-year younger age at PCa onset (P=2.1x10<sup>-4</sup>). Carrying one pathogenic variant in *NBN* was associated with a 7.2-year younger onset (P=0.003), *BRCA2* with a 1.4-year younger onset (P=0.004), and *ATM* with a 2.3-year younger onset (P=0.01). **Conclusion:** In this large sequencing study, rare pathogenic variants in DNA repair genes were more common in aggressive than non-aggressive cases and associated with age at PCa onset. Nearly 2,000 genes identified in stage 1 are being sequenced in stage 2 in 14,000 additional aggressive and non-aggressive cases, which is expected to identify novel aggressive PCa genes.

## PgmNr 964: Fine-mapping of two differentiated thyroid carcinoma susceptibility loci at 2q35 and 8p12 in Europeans and Oceanians.

---

Differentiated thyroid carcinomas (DTC) are the most frequent type of thyroid cancers. DTC incidence is characterized by wide ethnic and geographic variation, with high incidence rates observed in Oceanian populations. Genome-wide association studies (GWAS) identified several DTC susceptibility loci including 2q35, 8p12, 9q22 and 14q13. While the 9q22 and 14q13 loci have been extensively investigated, signals at 2q35 and 8p12 have not been explored so far.

We investigated the role of the two later regions in the EPITHYR consortium (1,554 cases and 1,973 controls) and performed fine-mapping in Europeans, Melanesians and Polynesians to identified likely causal variants of DTC risk. Odds ratios (OR) testing the association between SNP and DTC were derived from a logistic mixed model. To identify likely causal variants, we employed several strategies, including conditional analyses to test for residual association after adjusting on the lead SNP and two Bayesian methods. The first one, Paintor, integrates association strength with genomic functional annotation data to improve accuracy in selecting plausible causal variants; the second one consists of a colocalisation analysis that integrates the tests of SNP-disease association and eQTLs data from thyroid tumour cells available in the PancanQTL database.

The SNPs previously reported to be associated with DTC in European GWAS at 2q35 and 8p12 were replicated while no significant association was found in Polynesians and Melanesians.

In Europeans, a variant located in intron 5 of *DIRC3* at2q35 was highlighted by the Bayesian methods with a posterior probability of causality (PP) of 0.84 with Paintor and a PP of 0.41 with the colocalisation analysis. The associated OR was 1.4 ( $p=1.6 \times 10^{-10}$ ). Although association with DTC in Melanesians and Polynesians was not significant, this SNP was also identified as potentially causal in these populations. This SNP is strongly associated with *DIRC3* and *IGFBP5* expression in thyroid tumour cells. At locus 8p12, the colocalisation analysis identified a SNP located in the promoter region of *NRG1* as potentially causal in the 3 ethnic groups ( $PP_{\text{Europeans}} = 0.67$ ,  $PP_{\text{Melanesians}} = 0.55$  and  $PP_{\text{Polynesians}} = 0.38$ ), with a significant association in Europeans ( $OR=1.2$ ,  $p=1.4 \times 10^{-3}$ ). This SNP is associated with *NRG1* expression.

Hence, we confirmed the role of 2q35 and 8p12 loci in DTC susceptibility.  
Furthermore, our fine-mapping data will help prioritizing variants for further functional studies.

## PgmNr 965: Polygenic risk score analysis in familial lung cancer.

Many studies have indicated that individuals with a family history of lung cancer are two- to three-fold more susceptible to lung cancer development than those without such a history. Familial cancer is defined as having two or more first- and second-degree relatives diagnosed with the same type of cancer. Genome-wide association studies (GWAS) have successfully identified thousands of associations for many complex traits and common disorders. One application of GWAS results is to predict an individual's risk of disease development using genetic propensities.

We used the summary statistics from previously published familial lung cancer GWAS and data from the Oncoarray lung cancer dataset for lung cancer cases with a family history (1,719 cases and 11,135 controls) to develop polygenic risk scores. We randomly selected 70% and 30% as discovery and validation data sets, respectively. The summary data were filtered by  $MAF > 0.01$  and  $INFO > 0.8$ . We applied different combinations of tuning parameters including genome-wide thresholds, LD clumping values, and weights in genetic risk score models. GWAS threshold P-values were set to  $5 \times 10^{-6}$ ,  $5 \times 10^{-5}$ ,  $5 \times 10^{-4}$ ,  $5 \times 10^{-3}$ , and,  $5 \times 10^{-2}$  and LD clumping  $r^2 = 0.2$ , 0.4, 0.6, and, 0.8, respectively. Polygenic risk scores were calculated by computing the sum of risk alleles, weighted by 1,  $\log(ORs)$ , Z, and  $Z^2$  scores from the summary statistics, respectively. We evaluated models by the area under the ROC curve (AUC) and odds ratios (OR) per 2 standard deviations.

We chose the combination of tuning parameters (threshold  $5 \times 10^{-6}$ , LD clumping  $r^2 = 0.2$ , weight  $Z^2$ ) that identified 6 SNPs since this combination had the best overall AUC in the polygenic risk score model. From the discovery stage, the AUC was 0.7591(95% CI=0.7460-0.7722) with an OR of 1.560(95% CI=1.370-1.775). The AUC was 0.7590(95% CI=0.7393-0.7787) with an OR of 1.501(95% CI=1.234-1.825) in the validation stage.

Identification and assessment of subgroups at high risk of lung cancer on the basis of genetic characteristics are critical. Polygenic risk score analysis can stratify individuals into risk categories based on their genetic variation and improve personalized interventions for precision genomics based medicine.

## PgmNr 966: Ethno-geographic germline protein-altering mutations in ATM predispose to lung adenocarcinoma.

---

Germline mutations cause 3–10% of cancers diagnosed yearly. However, only a few germline mutations responsible for lung cancer pathogenesis have been identified. Here, by performing associations of germline mutations in two independent datasets with a total of 39,146 individuals of European ancestry and investigating isoform expression values in 433 samples, we identified large-effect associations with a *ATM* L2307F (rs56009889) germline mutation in lung adenocarcinoma. We found that L2307F carriers had a significant 5.23-fold increased risk for lung adenocarcinoma (LAD) in the discovery dataset ( $P=6.47 \times 10^{-9}$ ) and a 2.48-fold increased risk in the replication dataset ( $P=0.01$ ), and exhibited no association with the risk of lung squamous cell carcinoma or of small cell lung cancer in either dataset. Additionally, all *ATM*-L2307F homozygotes had lung adenocarcinoma ( $P=0.004$ ), suggesting a significant role for L2307F in LAD pathogenesis. Despite being very rare in the general European population, L2307F was more common in the Israeli population (MAF=0.023) with conferring lung adenocarcinoma risk differently in geographic populations. Further investigating the difference in the main ethnic groups in Israel, including Jews and Arabs, we observed L2307F was found in 8.68% (MAF=0.042) Jews from Israel and 8.53% Jews (MAF=0.045) who lived in other countries, though Arabs have very low frequency. Among L2307F carriers, the ORs for LAD risk were 7.86 in Israeli Jews ( $P=2.12 \times 10^{-6}$ ) and 3.40 for the Jews in other countries ( $P=0.005$ ). Since *ATM* has alternative splicing in tissues, we identified rs56009889 can transcript in two isoforms that highly expressed in normal lung tissue. The two isoforms are the only ones that can produce longest *ATM* protein and contain all of 4 *ATM* functional domains. While L2307F was predicted to enhance *ATM* protein aggregation and have a pathogenic effect on the *ATM* protein, it has not been previously associated with either lung cancer or ataxia-telangiectasia. Our results demonstrate L2307F increased lung adenocarcinoma risk with large effects among heterozygotes and with very high effects among homozygotes, indicating the importance of *ATM* for lung cancer pathogenesis. The findings may be beneficial for lung cancer panel screening and familial inheritance research, suggest targets for lung cancer treatment for individuals with mutations of *ATM*, and greatly advance our understanding of lung cancer etiology.

## PgmNr 967: Development of a longitudinal tissue repository from a prospective veteran colonoscopy screening cohort.

---

Colorectal cancer (CRC) prevention and risk stratification efforts are greatly informed by further understanding the longitudinal variation in the DNA of individuals who progress from healthy to advanced neoplasia and cancer. The creation of a longitudinal tissue repository provides an opportunity to initiate these CRC progression analyses. We developed a longitudinal data and tissue repository from a prospective colonoscopy screening cohort of veterans. The Cooperative Studies Program (CSP) study #380 enrolled 3,121 asymptomatic veterans who underwent screening colonoscopy from 1994-1997 from 13 VA medical centers. Following participation in CSP #380, participants may have received colon-related procedures for routine clinical care. We sought to enhance the original study database with data and specimens from these clinical events. From a master list of CSP #380 participants, we utilized the VA electronic health records (EHR) to identify their exam dates from 1994 to 2009 and corresponding specimen identification numbers. Then each original site's pathology lab was contacted to determine whether these specimens were available for retrieval for research purposes. Following retrieval, specimens were recoded and stored at a central VA biorepository. We also utilized the VA EHR to capture medical history and physical exam information. Of the 13 original sites, 11 had specimens available for these participants. Specimen retrieval and storage has been completed for 8 sites with 3,404 tissues obtained from 680 participants. Due to local site specimen storage or destruction policies, 4 sites were only able to provide specimens from 2003-2009. An additional 4 sites were able to provide specimens across the full period of 1994-2009 (n=3,320; 641 participants). Among these 641 participants, 47.1% (n=302) have longitudinal specimens with both baseline specimens and specimens from any subsequent exam. There were 1,222 specimens preserved with Buoin's fixative, 1,580 with formalin-fixed paraffin (FFPE), and 602 in an unknown fixative. A DNA extraction pilot yielded mean DNA quantities of 8.32 ng/μL (SD= 8.94) in Buoin's and 66.42 ng/μL (SD= 42.65) in FFPE tissues. Continued development of this repository, which captures over 15 years of longitudinal data and specimens, will be a powerful tool for examining the CRC progression pathway. Details about the CSP #380 repository may be found here: <https://www.research.va.gov/programs/csp/cspeg/initiatives.cfm>.

## PgmNr 968: Breast cancer subtype GWAS in 1,312 Peruvian breast cancer patients.

**Background:** Breast cancer genome wide association studies (GWAS) have been mostly conducted in European populations. A previous GWAS study in Latinas found a protective variant on chromosome 6q25 (rs140068132), that is relatively common in populations with Indigenous American ancestry and almost absent in all other groups. In order to discover other population-specific variants, we conducted a GWAS in a sample of highly Indigenous American breast cancer patients from Peru. The median Indigenous American ancestry in the Peruvian breast cancer patients is high at 79%.

**Methods:** Blood samples and clinical data were collected from 1,619 women with breast cancer at the Instituto Nacional de Enfermedades Neoplásicas in Lima, Peru. Genotypic profiles for 1,307 women were generated using the Affymetrix Precision Medicine Research Array. Four major breast cancer subtypes were identified using immunohistochemical markers [luminal A, luminal B, triple negative (TN), and HER2 amplified]. Luminal A and Luminal B are hormone receptor positive subtypes and HER2 amplified and TN are negative. Genetic ancestry was determined using ADMIXTURE. Genome wide association analysis was conducted for luminal subtypes (luminal A and B) compared to non-luminal subtypes (TNBC and HER2 amplified) in PLINK with age at diagnosis and genetic ancestry as covariates. There were 865 women with luminal tumors and 357 women with non-luminal tumors. To confirm the relevance of the top GWAS hit, we analyzed tumor gene expression based on RNA-seq data by genotype in 47 samples.

**Results:** The top GWAS hit, rs34533620 and another SNP in LD with it, rs6459569, are located in the intron and coding region of the kinesin family member 13A gene (*KIF13A*), respectively, at 6p22 (OR = 2.75 and 2.34, respectively, 95% CI 1.85-4.08 and 1.62-3.37, P = 5.71\*10<sup>-07</sup> and 5.12\*10<sup>-06</sup>). RNA-seq data for *KIF13A* in a subset of 47 women showed that the expression level of this gene is higher in women with luminal tumors (N=28) compared to non-luminal tumors (N=16) (P=0.05). RNA-seq data for rs34533620 and rs6459569 showed the expression level of this gene is higher in women without the minor allele, G and C, respectively (P=0.13 and 0.03).

**Conclusions:** Our data suggests that a germline variant within the *KIF13A* gene may be associated with the risk of developing luminal breast cancer tumors compared to non-luminal tumors. This supports the importance of conducting genetic association studies in diverse samples.

## PgmNr 969: Validation of previously identified breast cancer SNPs in Black women.

### Affiliations:

1) Vanderbilt University Medical Center, Department of Epidemiology, 2525 West End Avenue, Suite 600, Nashville, Tennessee, 37203; 2) H. Lee Moffitt Cancer Center and Research Institute, Biostatistics and Bioinformatics Department, 12902 USF Magnolia Drive, Tampa, FL 33612

Young Black women bear a disproportionate burden of breast cancer (BC) compared to White women yet are underrepresented in clinical studies. Prior research suggests that 18% of the familial BC risk can be explained by common single nucleotide polymorphisms (SNPs); however, most research has been conducted on White women. The evaluation of BC SNPs can be used to assess BC risk for patients and physicians to make informed decisions about risk reduction options. Few studies have assessed the association of high-risk BC SNPs among Black women; therefore, the purpose of this study was to assess the association of previously identified high risk BC SNPs among a population-based sample of young Black women with BC.

Methods: Black women diagnosed with invasive BC at or before age 50 from 2009 to 2012 were recruited to the study through the Florida Cancer Registry. Clinical information was collected through data obtained from the state cancer registry supplemented by data abstracted from medical records. Saliva specimens were collected for SNP analysis on the Oncoarray platform. The SNPs included in the analysis were identified from previously published literature. Breast cancer subtype specific logistic regression models (BRCA+ vs. BRCA-, TNBC vs. Non-TNBC, BRCA+/TNBC vs. other patients, BRCA-/TNBC vs. other patients) were developed, odds ratios (OR), 95% Confidence Intervals (CIs) and uncorrected multiple comparison p-values ( $p < .05$ ) were compared to validate the statistical significance of the previously identified SNPs.

Results: Among 358 study participants, a total of 42 previously identified BC susceptibility SNPs were included in the analysis. Of the SNPs included in the analysis, SNP rs11242675 (OR 2.505; 95% CI: 1.267-4.953;  $p=0.008$ ), and SNP rs67397200 (OR 2.409; CI: 1.204-4.82;  $p=0.013$ ) increased the odds of BRCA-/Non-TNBC compared to other genetic and phenotypic subgroups. SNP rs67397200 (OR 0.34; CI: 0.163-0.71;  $p=0.004$ ) is suggestive of a lower odds of TNBC compared to Non-TNBC.

Conclusion: Our results suggest that a proportion of high-risk BC SNPs previously identified among White women also contributes to subgroup specific BC among Black women; however, it is likely that additional SNPs are yet to be identified among this understudied population. This information is needed to develop robust polygenic risk scores among Black women to estimate their individual risk for developing BC.

## PgmNr 970: Patterns of loss-of-heterozygosity (LOH) in tumor identifies deleterious germline variants in DNA damage repair genes in patients with lung cancer.

The bi-allelic inactivation model for pathogenic germline mutations is a widely accepted mechanism for tumor suppressor genes (TSG). We hypothesized that deleterious single nucleotide polymorphism (SNPs) in TSG could also be targeted by LOH in tumor leading to a cancer-promoting role. We employed an analytical framework by assessing tumor LOH for deleterious SNPs in TSG. 2686 lung cancer patients (pts) who underwent germline and somatic sequencing analysis for 468 genes by MSK IMPACT between January 2014 and May 2016 were analyzed. For each truncating or missense SNP predicted as deleterious/damaging (minor allele frequency <2% in genome aggregation database gnomAD), we assessed whether pts were heterozygous in their normal DNA, and what proportion of these with LOH were homozygous for the mutant allele in the tumor DNA. The background LOH rate was estimated using synonymous variants in the same gene. Statistical significance was computed using fisher exact test. Frequencies of the candidate SNPs were compared to population frequencies in gnomAD. We identified *ATM* *p.Leu2307Phe* and *RAD52* *p.Ser346Ter* as significantly enriched in lung cancer pts compared to gnomAD controls corrected for population stratification. 63 (2.3%) pts carried the *ATM* SNP, of whom 58 had lung adenocarcinoma. 29% pts showed LOH of the WT allele compared to 12% background LOH ( $p<0.0001$ ) whereas LOH of the mutant allele was in 12.7% pts. The frequency of the *ATM* SNP was higher in females (4.1% vs male 2.1%;  $p\text{-value}=0.03$ ), light-smokers (<5 pack years of smoking history (6.6%) vs smokers (2.8%)  $p=0.003$ ) and pts with *EGFR* oncogenic mutations [8.9% vs 3%,  $p=0.02$ ]. The pattern of LOH in tumor for 89 (3.3%) pts carrying the *RAD52* SNP varied based on somatic mutation profile. Pts with oncogenic *EGFR* mutations who carried the *RAD52* SNP showed 35% LOH of WT allele compared to 12% background LOH rate ( $p<0.01$ ). Interestingly, LOH of the mutant allele in *EGFR* driven tumors was observed in 14% compared to 45% in pts with oncogenic *KRAS* mutations. In lung adenocarcinoma patients, *RAD52* SNP carriers had a higher frequency of somatic *MYC* amplification (12% vs 5% in non-carriers,  $p=0.003$ ) and a poorer prognosis compared to patients carrying the wild type allele (adjusted HR=1.6, 95%CI=1.06-2.6;  $p\text{-value}=0.02$ ). In conclusion, an analytical framework for germline discovery by

assessing patterns of LOH in tumors identified novel deleterious lung cancer susceptibility alleles in DNA damage repair pathways.

## **PgmNr 971: Genetic evidence for a causal relationship between testosterone levels and cancer risk in females, but no effect in males.**

### **Authors:**

---

Testosterone is the primary circulating androgen. Testosterone is produced in the testes of males although it is also produced at much lower levels in female ovaries. Previous observational findings have suggested that serum testosterone level might be linked with increased risk of developing cancer among both males (particularly prostate cancer) and females, however it is difficult to establish causality. Using large-scale phenotypic and genetic data from UK Biobank (UKB), we performed Mendelian randomization (MR) analyses to explore the relationship between serum testosterone levels and overall cancer risk. We extracted data for 46,155 adults with malignant cancer (excluding keratinocyte tumours) and 264,638 healthy controls of white British ancestry. Given the differing production of testosterone in males and females, we used recently released UKB testosterone data to derive separate instruments for MR using autosomal SNPs in cancer-free males (213 SNPs, total  $r^2=0.09$ ) and females (147 SNPs, total  $r^2=0.05$ ). Reflecting the sex-specific metabolism and production, the genetic correlation in testosterone levels across the sexes was very low (LD-score,  $rg=0.01$ ,  $p=0.7$ ).

Genetically-predicted elevated serum testosterone level was associated with overall cancer risk in females (OR 1.09; 95% C.I.[1.03, 1.15] per 1 SD increase in serum testosterone level), but not in males. Stratified analyses for individual female cancers showed most common cancers were not associated with testosterone, apart from breast (OR 1.18 [1.06, 1.31]) and endometrial cancers (OR 1.80 [1.49, 2.19]). Although testosterone is required for prostate cancer growth, there was no association with prostate cancer (OR 0.99 [0.90, 1.09]). We used a multivariable framework to adjust for BMI, measured levels of serum lipids and sex-hormone binding globulin; effect sizes for genetically predicted testosterone and breast cancer and endometrial cancer were essentially unchanged.

We replicated our UKB findings using two-sample MR using summary statistics from publicly available consortia data from BCAC (breast OR 1.15 [1.08, 1.22]) and PRACTICAL (prostate OR 1.01 [0.93, 1.09]). While Our UKB analysis found a small non-significant increase in risk of ovarian cancer with increased testosterone, this result was not borne out in OCAC (OR 0.89 [0.80, 0.97]). These powerful genetic analyses suggest a causal effect of testosterone on some hormone-driven cancers in females.

## PgmNr 972: Cervical somatic mutations detected in HPV18 and HPV45 precancerous lesions are related to disease progression.

Invasive cervical cancer (ICC) is a heterogeneous disease caused by persistent human papillomavirus (HPV) infection. Worldwide, HPV16, HPV18 and HPV45 are responsible for 76% of ICC cases. For unknown reasons, ~90% of HPV infections clear and only a minority of women progress to precancer and subsequently ICC. Distinct somatic mutational profiles have been well-characterized for cervical cancer but had never been evaluated in precancers.

To investigate whether somatic mutations in the human DNA are related to disease progression, we evaluated exfoliated cervical cells from 2,991 women (plus 228 serial specimens) HPV16-, 18-, or 45-positive with benign transient infections ( $\leq$ CIN1), precancers (CIN2, CIN3, adenocarcinoma *in situ* [AIS]), or ICC in the NCI-Kaiser PaP prospective cohort.

We evaluated 1303 controls, 1532 precancers and 156 ICC cases using a custom Ion AmpliSeq gene-panel of 40 established gynecological somatic driver genes at ~600x coverage. We first compared the frequency of known recurrent somatic mutations (i.e. hotspots), reported in multiple TCGA ICC, in our controls, precancers and cancers, by histology and calculated the risk (odds ratio [OR]) of progression from a benign infection to precancer and cancer. We also looked for somatic mutations in the serial samples collected prior to the final diagnosis of precancer/cancer. We plan to integrate the human somatic data with viral genomic data to investigate the viral-host genetic interaction.

Somatic mutations were detected in earlier lesions at a lower frequency, and they were distinct for adenocarcinoma vs. squamous cell carcinoma. For HPV18+ and HPV45+ specimens, the prevalence of mutations was significantly higher in AIS (11%;  $p=2.3 \times 10^{-3}$ ; OR=4.4, CI=1.7-11.6) and adenocarcinoma (28%;  $p=6.4 \times 10^{-8}$ ; OR=13.4, CI=5.2-34.2), compared to the controls (3%). The mutations observed in the controls were distinct and the average allele fraction, a proxy for cellular clonal expansion, was significantly lower in controls (0.03) compared to precancers (0.08) and cancers (0.15) ( $p=6.7 \times 10^{-5}$ ). In all case samples with a mutation and a serial sample, we detected the same mutation in the samples collected from 1 to 4 years prior to diagnosis of precancer/cancer. This is the first study to investigate somatic driver mutations in cervical precancers and serial samples, and our findings suggest that these somatic mutations help drive the transition of

precancers to cancer.

## PgmNr 973: Genetic colorectal cancer risk variants are associated with increasing adenoma counts.

---

**Background:** Colorectal cancer (CRC) screening guidelines suggest genetic evaluation in those with more than 10 lifetime pre-cancerous colonic polyps, termed “adenomas.” However, the genetic basis of most individuals with high cumulative adenoma counts will remain unexplained. Further studies are needed to characterize low-penetrance germline factors in those with increased cumulative adenomas.

**Aim:** To investigate if known CRC or adenoma-risk single nucleotide polymorphisms (SNPs) are associated with increasing cumulative adenoma counts in a prospective **screening** cohort of Veterans.

**Methods:** The CSP #380 screening colonoscopy cohort includes a biorepository of selected individuals with baseline advanced neoplasia and matched individuals without neoplasia (n=612). Blood samples were genotyped using the Illumina Infinium Omni2.5-8 GWAS chip and associated cumulative adenoma counts were summed over 10 years. A corrected Poisson regression (adjusted for age at last colonoscopy, gender, and race) was used to evaluate associations between higher cumulative adenoma counts and 43 pre-specified CRC-risk SNPs or a subset of these SNPs shown also to be associated with adenomas in published literature. SNPs were evaluated singly or combined in a Genetic Risk Score (GRS). The GRS was constructed from only the eight literature adenoma-risk SNPs and calculated based on the total number of present *risk* alleles (0-2) summed across all SNPs per individual (both weighted for published effect size and unweighted).

**Results:** Four CRC-risk SNPs were associated with increasing mean adenoma counts ( $p < 0.05$ ): rs12241008 (gene: VTG1A), rs2423279 (BMP2/HAO1), rs3184504 (SH2B3), and rs961253 (FERMT1/BMP2), with *risk* allele risk ratios (RR) of 1.31, 1.29, 1.24, and 1.23, respectively. Only one of eight known adenoma-risk SNPs was significant in our dataset (rs961253; OR 1.23 per *risk* allele;  $p = 0.01$ ). An increasing weighted GRS was associated with increased cumulative adenoma counts (weighted RR 1.58,  $p = 0.03$ ; unweighted RR 1.03,  $p = 0.39$ ).

**Conclusion:** In this CRC screening cohort, four known CRC-risk SNPs were associated with increasing cumulative adenoma counts. Additionally, an increasing burden of adenoma-risk SNPs, as measured by a weighted GRS, was associated with higher cumulative adenoma counts. Future work will evaluate predictive tools based on a precancerous, adenoma GRS to better risk stratify patients during CRC screening, and compare to current CRC genetic risk scores.

## PgmNr 974: Genome-wide association study of differentiated thyroid cancer in European and Oceanian populations in EPITHYR consortium.

---

Differentiated thyroid cancer (DTC) is the most frequent endocrine malignancy. Its incidence varies considerably around the world with high incidence reported in some Pacific islands such as Hawaii, New Caledonia (NC), and French Polynesia. Ethnic differences in incidence have also been noted with for instance higher rates in Melanesians than in other ethnic groups in NC. The causes underlying these geographic and ethnic variations are still unknown and a role of environmental and genetic factors, as well as changes in screening practices are suspected. Few susceptibility loci have been identified so far and most of the recent genome-wide association studies (GWAS) have had limited sample sizes.

In order to identify new DTC susceptibility loci, we conducted a GWAS using data from the EPITHYR consortium that included subjects from 7 population-based case-control studies from Metropolitan France, Polynesia, New Caledonia, Cuba, and Belarus. A total of 3,527 individuals of European ancestry (1,554 cases/1,973 controls) and 649 individuals of Oceanian ancestry (301 cases/348 controls) were genotyped using the OncoArray (Illumina). After imputation, the analyses were based on about 9 million SNPs in Europeans and 7 million SNPs in Oceanians. Odds ratios (OR) were calculated using logistic mixed models with the genetic relationship matrix as random effect, adjusted for age, sex, and study. Analyses were stratified by sex, ethnic group, age group (<50, ≥50 years-old), histology (papillary/follicular), and size of carcinoma (<10mm/≥10 mm).

Our results confirmed the susceptibility loci reported previously at *2q35*, *8p12*, *9q22* and *14q13*. While no significant loci were reported in Oceanian populations, we reported a new significant locus at *1p31* in Europeans (OR= 0.52,  $p=3.10^{-8}$ ), which was more striking in subjects younger than 50 years. In subgroup analyses, we observed another significant signal at *1p32* in the oldest group and in cases with a microcarcinoma. Interestingly, the *1p31* lead variant was also associated to the expression of *NFIA* in thyroid tumour cells, a gene that is involved in the regulation of cell proliferation. The *1p32* variant is correlated with a SNP in *FAF1*, a gene involved in apoptosis that had previously been associated with DTC risk in a candidate gene study. Replication analyses are ongoing and will be presented.

In conclusion, this study provides further insights into the genetic susceptibility of DTC.

---

Background: Recent small-scale epidemiological and experimental studies have provided evidence supporting an association between variation in the human gut microbiome and colorectal cancer (CRC). However, despite compelling results from *in vivo* and *in vitro* models, few findings have translated between model organisms and human studies have been unconvincing in their ability to offer causal evidence. Reasons for these discrepancies are mainly due to the challenges in multi-omic technologies (e.g., sequencing and metagenomics) and sensitive experimental models. Additionally, epidemiological studies within this context have been of cross-sectional or case-control design; therefore, confounding of lifestyle and behavioural factors, reverse causation and bias are particularly important limitations to consider. The evidence that has been lost in translation impedes any opportunity for harnessing the gut microbiome – a uniquely malleable trait – for improving population health. Mendelian randomization (MR) is a method that uses human genetic variation (usually single nucleotide polymorphisms, SNPs) as instruments to proxy for a clinically relevant trait to improve

causal inference.

**Methods:** Here, we used MR to interrogate the causal impact of the gut microbiome on CRC combining summary-level data from genome-wide association studies (GWASs) of host genotype and gut microbiome variation from the Flemish Gut Flora Project (FGFP) and two German cohorts (n=3890) with the Genetics and Epidemiology of Colorectal Cancer Consortium (GECCO, n=120328). All analyses were conducted in MR-Base and pleiotropy was assessed using PhenoScanner and MR-TRYX.

**Results:** Of the 157 microbial traits (MTs), including presence, abundance and diversity metrics, assessed in the GWAS of the gut microbiome, there was evidence for a host genetic contribution to 13 MTs. Of these, we found evidence that presence of a genus within a certain order of bacteria increased the risk of CRC by 8% (95% CI: 2-15%; P=0.02). There was no strong evidence that the SNP used as an instrument was associated with other traits, reducing the likelihood of pleiotropy.

**Conclusions:** Our study confirmed previous observational evidence suggesting that genera within this certain bacterial order are more present in CRC cases than controls and provides further evidence that this observation may be due to a causal impact of these bacteria on CRC.

## **PgmNr 976: Mapping the genomic and epigenomic interaction landscape in triple negative and non-triple negative breast cancer.**

### **Authors:**

J. Wu; T. Mamidi; C. Hicks

---

Breast cancer (BC) is the most diagnosed cancer among women in the US and the second leading cause of cancer-related death in women. Majority of the BC respond to endocrine and targeted therapy and generally have good prognosis. However, a significant proportion are triple negative breast cancer (TNBC), the most aggressive and lethal form of BC. Patients with TNBC have poor prognosis, a significantly increased risk of relapse and shorter survival rates than patients affected by non-TNBC. Currently, there are no targeted therapies for TNBC, cytotoxic chemotherapy remains the only effective therapeutic modality. The molecular mechanisms underlying the differences between TNBC and non-TNBC are poorly understood. Genes may play a strong role but epidemiological studies suggest that BC risk is largely determined by a complex interplay between genetic (both germline and somatic) and epigenetic alterations, and a broad range of environmental factors. Therefore, discovery of molecular markers and targets for the development of novel therapeutics must consider joint analysis of genomics and epigenomic alterations. Recent advances in high-throughput genotyping and sequencing technologies have provided opportunities for comprehensive analysis of germline, somatic and epigenetic alterations. Traditionally, analysis of genomic and epigenomic alteration has largely been carried out as separate research endeavors. Here we advocate an integrated approach that leverages germline mutation information from GWAS and somatic mutation information from The Cancer Genome Atlas (TCGA) and integrates it with information on DNA methylation using gene expression as the intermediate phenotype from TCGA to map the genomic and epigenomic interaction landscape in TNBC and non-TNBC. Preliminary results from this integrative analysis reveal the genes containing germline and somatic mutations also epigenetically altered. We discovered genomically and epigenomic altered molecular signatures associated with each type and distinguishing the two types of BC. Additionally, we discovered multiple gene regulatory networks and multiple signaling pathways enriched for germline, somatic and epigenetic alterations in each type of BC. Our investigation demonstrates that integrative analysis is a powerful approach to mapping oncogenic interactions and cooperation among germline, somatic and epigenomic changes shaping the TNBC and non-TNBC phenotypes.

## PgmNr 977: A novel next-generation sequencing platform for hereditary cancer risk evaluation.

---

**Background:** Hereditary cancer is a group of inherited disorders featured by increased cancer risks. Multiple cancer types are included such as, hereditary breast and ovarian cancer syndrome, Cowden syndrome, Lynch syndrome and others. Understanding one's genetic risk of cancer is critical for prevention and treatment, especially to those with family history of cancers. An NGS panel test has been developed in house to help evaluate the individual risk of hereditary cancer. **Methods:** 27 genes that are well-known to play important roles in cancer (*APC, ATM, BARD1, BMPR1A, BRCA1, BRCA2, BRIP1, CDH1, CDK4, CDKN2A, CHEK2, EPCAM, MLH1, MRE11A, MSH2, MSH6, MUTYH, NBN, PALB2, PMS2, PTEN, RAD50, RAD51C, RAD51D, SMAD4, STK11 and TP53*) are evaluated by the NGS panel test. NGS sequencing results were analyzed using NextGene software to detect sequence variants, while NGS read depth analysis is used to help with the assessment of possible copy number changes. MLPA is incorporated in this test for the examination of duplication/deletion of the PMS2 gene to exclude the influence of the pseudogenes which are highly homologous to PMS2. Sequencing variants are curated following the ACMG guidelines by experienced genomic scientists. Pathogenic, likely pathogenic and variants of uncertain significance are reported. **Results:** 164 samples were involved in this study. Majority of the patients in this cohort had either personal or family history of malignant cancers. Analysis found 122 reportable variants in 77 samples. Among these variants, 15 of them from the ATM, BRCA1, BRCA2, CHEK2, MUTYH and PALB2 genes are pathogenic, including 9 stop-gain, frameshift and splicing site variants. 3 samples had likely pathogenic variants in the CHEK2 gene. Among 59 samples, there were 104 variants of unknown significance in 25 genes. No variants have been detected in PTEN and SMAD4 so far. No copy number changes have been detected with this test. **Conclusion:** Our recent NGS panel for hereditary cancer study is a useful tool to evaluate one's risk of cancer. useful tool for assessing cancer predisposition. Due to present limitations on variant classification, VUS are identified at a rate of ~ 6 times that for pathogenic or likely pathogenic variants. Further functional studies and large-scale correlation studies are needed to better classify the VUSs.

## PgmNr 978: The first study evaluating the distribution of gBRCA1/2 mutations within the ovarian cancer cluster region in ovarian cancer patients using Japan CHARLOTTE study data (Characterizing the cross-sectional approach to ovarian cancer: Genetic testing of BRCA).

### Authors:

K. Yoshihara <sup>1</sup>; T. Enomoto <sup>1</sup>; D. Aoki <sup>2</sup>; Y. Watanabe <sup>3</sup>; J. Kigawa <sup>4</sup>; N. Takeshima <sup>5</sup>; H. Inomata <sup>6</sup>; K. Hattori <sup>6</sup>; H. Tsuda <sup>7</sup>; T. Sugiyama <sup>8</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Department of Obstetrics and Gynecology, Niigata University Graduate School of Medical and Dental Sciences, Niigata, Niigata, Japan; 2) Department of Obstetrics and Gynecology, Keio University School of Medicine; 3) Department of Obstetrics and Gynecology, Tohoku Medical and Pharmaceutical University; 4) Department of Obstetrics and Gynecology, Matsue City Hospital; 5) Department of Gynecology, Cancer Institute Hospital; 6) Department of Medical, AstraZeneca K.K; 7) Department of Basic Pathology, National defense Medical College; 8) Woman's Cancer Center, Takagi Hospital

**Background and objectives:** The CHARLOTTE study showed the prevalence of germline *BRCA1/2* mutations (g*BRCA1/2m*) in Japanese ovarian cancer patients and a slightly higher prevalence of g*BRCAm* in patients with high-grade serous carcinoma and family history of ovarian cancer. In previous report, ovarian cancer cluster region (OCCR) has been attributed to higher ovarian cancer risk and lower breast cancer risk. However, the prevalence of g*BRCA1/2m* within the OCCR has never been evaluated in Japanese ovarian cancer patients. Using the CHARLOTTE study data, we described locations of g*BRCA1/2m* within the OCCR and characteristics of the relevant populations.

**Methods:** The CHARLOTTE study is a collaborative cross-sectional study(NCT03229122)involving numerous study sites throughout Japanwith histologically confirmed FIGO stage I–IV ovarian cancer. g*BRCA*testing was performed using blood samples. Only deleterious or suspected deleterious mutations were defined as g*BRCAm*. Based on previously reported OCCR (g*BRCA1* 1380~4062 bp, g*BRCA2* 3249~7471 bp), distribution of the location of g*BRCA1/2m*were identified and characteristics of these patients were evaluated.

**Results:** A total of 666 patients were enrolled and 634 were evaluated. The overall prevalence of g*BRCA1m* and g*BRCA2m* were 9.9% and 4.7%, respectively. Ovarian cancer patients with g*BRCA1* founder mutation (L63X) were excluded from the subsequent analysis because this founder mutation is known to relate with increases in both breast and ovarian cancer risk. In patients with g*BRCA1m*, 59.6% of ovarian cancer patients were distributed within the OCCR. On the other hand, 31.9% of ovarian cancer patients with g*BRCA1m* were distributed outside of the OCCR. The ovarian cancer patients with g*BRCA2m* were 53.3% within the OCCR, whereas 46.7% of ovarian cancer patients with g*BRCA2m* distributed outside of the OCCR. As for g*BRCA1m*, 39.3% and 32.1% of patients within the OCCR had family history of ovarian cancer and breast cancer, respectively, whereas 13.3% and 60% of patients outside of the OCCR has family history of ovarian cancer and breast cancer, respectively.

**Conclusions:** In Japanese ovarian cancer patients, g*BRCA1/2m* of more than half of study population were distributed within the OCCR and have higher family history of ovarian cancer and lower family

history of breast cancer compared to those outside of the OCCR in g*BRCA1*m. These results suggest future possibility of early detection of ovarian cancer in g*BRC*Am carriers.

## PgmNr 979: Genetic variations in long non-coding RNAs are associated with oral squamous cell carcinoma survival.

**Authors:**

H. Yuan; B. Zhu; Y. Yu; L. Miao

[View Session](#) [Add to Schedule](#)

**Affiliation:** Department of Oral and Maxillofacial Surgery, Affiliated Hospital of Stomatology, Nanjing Medical University, Nanjing, China

---

Oral squamous cell carcinoma (OSCC), the subtype of head and neck cancers, is notorious for its high incidence and death rate. The role of long non-coding RNAs (lncRNAs) is discovered to be significant for the cancerization and cancer progression. lncRNA urothelial carcinoma-associated 1 (UCA1) and nuclear paraspeckle assembly transcript 1 (NEAT1) were identified as a oncogene in multiple carcinomas, but there has been no research on the association of those two lncRNAs with OSCC prognosis. Therefore, we hypothesized that genetic variants of those two lncRNAs might predict the survival of OSCC. We selected six functional SNPs on those two lncRNAs to explore the relationship between the variations in these lncRNAs and the prognosis of OSCC. By using the Kaplan-Meier analyses and Cox proportional hazards regression models, we found that a predictive role of NEAT1 rs3741384 and UCA1 rs7255437 in the prognosis of OSCC. In addition, a remarkable increased risk of death was observed in the patients with an increasing number of unfavorable genotypes (NUG). As a result, our findings indicated that genetic variants in UCA1 and NEAT1 may influence the survival of OSCC patients.

---

To accelerate the rate of discovery in survivorship research we have developed the SJLIFE Portal (<https://survivorship.stjude.cloud>), a data-sharing platform on the St. Jude Cloud. The Portal hosts 3006 clinically-assessed long-term survivors of childhood cancer with whole-genome sequencing (WGS) and detailed demographic, diagnostic, treatment and outcome information. The Portal features the Clinical Dictionary Browser and GenomePaint, a genetic variant browser, for visualizing and analyzing clinical and genetic data integratively. The Clinical Dictionary Browser enables interactive exploration of 1) Cancer-related variables such as diagnosis and treatment; 2) Demographic variables; and 3) Outcomes, including severity-graded chronic health conditions using a modified version of the Common Terminology Classification for Adverse Events, and subsequent cancers. Dictionary terms from these categories are arranged hierarchically from general to specific, allowing a user to traverse the dictionary tree and view patient distributions by user selected terms as customizable barcharts, or perform cross-tabulation between two terms. GenomePaint displays SNV, indel, and copy number variants computed from WGS, allowing to display and filter variants based on a variety of functional annotations and population allele frequencies. Importantly, GenomePaint provides on-the-fly locus-specific association testing on any coding or non-coding locus to identify variants associated with user's choice of clinical terms. For example, by choosing terms from the categories of cancer-related variables in the Clinical Dictionary Browser, a user can compare leukemia and non-leukemia survivors of a specific ethnic group, or survivors diagnosed within a specific age range (e.g.  $\leq 4$  years), against a control population such as gnomAD. The resulting variants can be filtered using  $r^2$  values for nearby variants that are in linkage disequilibrium. Non-coding variants of interest can be further studied for their effect on altering transcription factor binding motifs, thereby providing an in-silico assessment of their potential impact on gene regulation. Participants enrolled in the SJLIFE Study will be followed longitudinally across their lifespan. Therefore, the clinical and genetic information of the SJLIFE Portal will be updated and enriched continuously, providing an increasingly rich resource to facilitate cancer and survivorship research over time.

## PgmNr 981: Characterization of *BRCA1* and *BRCA2* genetic variants in Guatemala population with breast cancer.

### Authors:

The worldwide incidence of breast cancer is increasing. It has become the most common cancer in women in almost all the countries. In Guatemala, it is the second most frequent cancer, only exceeded by cervical cancer. Around 10% of these tumors are hereditary. The hereditary breast-ovarian cancer syndrome is produced in the majority of the cases, by the presence of *BRCA1* and *BRCA2* pathogenic variants.

In Guatemala, there are not previously reports about the variants type of *BRCA1* and *BRCA2* gene. It is important to characterize our population, because our mayan influence.

The main objective of this study was to detect the most frequent *BRCA1* and *BRCA2* variants in Guatemalan population.

To do this, we evaluated 118 patients with hereditary and familial breast-ovarian cancer. We selected patients with breast or ovarian cancer with familial history or/and with age less than 40 years.

We obtained a peripheral blood sample of each patient. And performed DNA extraction. Both genes were evaluated by next generation sequencing (Miniseq, Illumina), and were confirmed by Sanger sequencing.

The mean age in all the positive patients were 41 years old. Twenty-two cases of one hundred eighteen patients, 22/118 (19%) were positive for *BRCA1* or *BRCA2* mutations. Eight cases have *BRCA1* pathogenic variants and fourteen cases have *BRCA2* pathogenic variants.

The most frequent variants in *BRCA1* gene were: c.798\_799delTT (p. Ser267Lysfs) (five cases) and a splice site mutation: c.212+1G>A (four cases). Followed by c.2748delT (p. Asn916Lysfs) found in two cases.

The most frequent variant in *BRCA2* gene was c.9235delG (p. Val3079Phefs) (two cases). In the following table, we showed the pathogenic variants found in our population.

*BRCA1* and *BRCA2* pathogenic variants in guatemalan population

Gene	Nucleotide	protein	N
<i>BRCA1</i>	c.212+1G>A	----	4
	c.798_799delTT	p.Ser267Lysfs	5
	c.2748delT	p.Asn916Lysfs	2
	c.4547G>A	p.Arg1516Lys	1
	c.6436G>T	p.Glu215Ter	1
	c.2596C>T	p.Arg866Cys	1

BRCA2	c.9235delG	p.Val3079Phefs	2
	c.8186delA	p.Lys2729Argfs	1
	c.4936-4939delGAAA	p.Glu1646Glnfs	1
	c.1813delA/c.9097delA	p.Ille605Tyrfs/p.Thr3033Leufs	1
	c.6560C>T	p.Pro2187Leu	1
	c.223G>C	p.Ala75Pro	1
	c.8174_8185delGGTATGCTGTTAinsTT	p.Trp2725Phefs	1

This study showed the most common *BRCA1* and *BRCA2* variants in Guatemalan population, being the first report published in our population. And we demonstrated that our population most frequent variants are different than other countries reports.

## PgmNr 982: BRCA Exchange: Global data sharing and integration for variant interpretation.

### Authors:

---

As genetic testing grows in prevalence, the rate at which new variants are discovered greatly outpaces the rate at which they can be interpreted. To some degree, this is a data sharing problem. Most genetic variants require case-level data for robust interpretation. However, most unclassified variants are rare, such that no single institution may have a sufficient set for variant interpretation, and case-level data is difficult to share for numerous legal, regulatory and ethical reasons. To address this challenge, the Global Alliance for Genomics and Health (GA4GH) launched the BRCA Challenge. The goal of BRCA Challenge is to accelerate and improve clinical interpretation of germline *BRCA1* and *BRCA2* variants in hereditary breast and ovarian cancer, through global data integration and analysis, and to disseminate variant knowledge. Further, the goal of the BRCA Challenge is to analyze what types of approaches prove to be most effective in advancing variant interpretation, given the resources of a focused and active consortium, to serve as a model for other genes, cancers and syndromes.

BRCA Exchange (<https://brcaexchange.org/>), the first work product of the BRCA Challenge, integrates variant-level data from sources including ClinVar, the Leiden Open Variation Database (LOVD), population databases, selected functional assays, and others, in a single point of access. BRCA Exchange is the largest public source on BRCA variation data, with data on close to 25,000 distinct variants. These data are publicly available for analysis on the web portal, for download, and for programmatic access via a GA4GH-compliant API. The BRCA Challenge works closely with the Evidence-based Network for the Interpretation of Germline Mutant Alleles (ENIGMA) consortium and other variant curators to identify and prioritize data resources for variant interpretation.

While BRCA Exchange has integrated data from the major public data sources, most variant data is held in private silos. To integrate these data, BRCA Exchange is developing federated analysis procedures, to 'bring the code to the data' via methods such as Docker, analyze the protected, patient-level data in its secure home repository, and generate aggregated, variant-level statistics that contain no protected health information and can be shared more broadly. BRCA Exchange is working closely with variant curators, regulatory experts and data scientists to ensure that this sharing is safe and informative.

## **PgmNr 983: Deleterious germline mutations in the *BRCA1* gene are associated with increased risk for cancers of the female reproductive system other than breast and ovarian as well as other cancers.**

---

**Introduction:** Mutations within the *BRCA1* gene have been linked to up to an 80% lifetime risk of breast cancer as well as increased risk for ovarian, pancreatic and melanoma cancers. In this study we examined families with known germline mutations in *BRCA1* after long-term follow-up to determine whether carriers experience higher rates of other cancers that have not yet been associated with germline mutations in the *BRCA1* gene.

**Methods:** We studied 127 Hereditary Breast and Ovarian Cancer (HBOC) syndrome families (N = 23,078 individuals who have been followed at Creighton University) in which a causal mutation in the *BRCA1* gene was identified. We performed survival analysis and a mixed effects cox regression with age at follow-up or cancer event as our time variable and presence or absence of *BRCA1*-related or other cancers (separate analyses) as our indicator variable.

**Results:** The survival curves showed a significant age effect with carriers having a younger age at cancer onset for *BRCA1*-related (as expected) as well as other cancers than that of non-carriers. The cox regression models were also highly significant ( $P = 1.77E-37$  and  $P = 1.04E-07$  for the *BRCA1*-related and other cancers, respectively). Of the cancers with enough samples to do stratified analyses, cervix, uterine, skin, lymphoma and colon cancers occurred at higher rates and at earlier ages in mutation carriers.

**Conclusions:** These analyses support the hypothesis that the *BRCA1* mutations carriers of HBOC syndrome have increased risk for early onset of several additional cancer types, especially cancers that arise in estrogen-influenced tissues.

## PgmNr 984: Uterine fibroids in Senegal: Polymorphism of *MED12* gene and correlation with epidemiological factors.

### Authors:

---

**Background:** Mediator complex subunit 12 (*MED12*) is a part of the mediator complex, which is believed to regulate transcription. Our recent study showed that *MED12* is mutated at high frequency and with different mutation frequencies in Senegalese women with uterine fibroids. However, the status of mutations has not been correlated to the epidemiological factors that are implicated in uterine fibroids.

**Methods:** This study aimed to analyze status of *MED12* mutations in Senegalese population. *MED12* was sequenced in tumoral tissues and blood samples of 54 Senegalese women with uterine fibroids. Clinical and pathological data were obtained from the patient's records and other parameters were recorded. Mutation Surveyor software version 5.0.1, DnaSP version 5.10, MEGA version 7.0.26 and Arlequin version 3.5.1.3 were used to determine the level of mutations and genetics parameters. To estimate the genetic variation according to the epidemiological parameters, the index of genetic differentiation (*F<sub>st</sub>*) and the genetic structure like analysis of molecular variance (AMOVA) were determined with Arlequin software version 3.5.1.3. The significance level (P-value) was 0.05.

**Results:** Our results showed that *MED12* is mutated at 88.89% (48/54) only in tumor tissues. The variants frequencies were not similar to those found in the Finnish populations. The Chi2 test indicates a statistically significant difference for the variants c.130G>C, c.130G>A, c.131G>A and for the Intronic Variant Site (*p* < 0.05). This variable expression of the *MED12* gene is further confirmed by the amino acid frequency between blood and tumor tissue with a statistically significant difference for alanine, glutamic acid, lysine, methionine, threonine, valine, tryptophan and tyrosine (*p* < 0.05). In addition, the selection test indicates that codon 44 is under positive selection (*p* = 0.0243) in cases of uterine fibroids. Genetic diversity according to risk factors such as parity and diet was observed in uterine fibroids in Senegal (*p* < 0.05).

**Conclusion:** Significant genetic diversity has been noted in uterine fibroids in Senegal. The codon 44 being under positive selection could be considered as a biomarker in uterine fibroids. Depending on the epidemiological parameters studied, parity and diet seem to be the risk factors most implicated in uterine fibroids in Senegal.

## PgmNr 985: Genome wide copy number variant analysis to identify regions associated with epithelial ovarian risk cancer risk.

---

The genetic risk variants uncovered by GWAS and other genetic studies account for only 30% of the heritability for epithelial ovarian cancer (EOC). To date, no studies have identified germline copy number variants (CNVs; regions of deletion and duplication) that are associated with EOC. Germline CNVs have been associated with risk for several traits (breast and pancreatic cancer) and a single CNV has been reported as associated with survival in ovarian cancer. As germline CNVs are an inherited form of genetic variation, we hypothesized that germline CNVs contribute to EOC risk. Using intensity data from >25,000 EOC cases and >40,000 controls from OCAC genotyped on the OncoArray, we identified CNVs using PennCNV. Subsequent association testing identified CNVs significantly associated with risk for high grade serous ovarian cancer both within previously studied ovarian cancer associated genes (dup:*BRCA1*  $P=9.52 \times 10^{-10}$ , del:*RAD51C*  $P<0.0001$ ) and within several novel loci (dup:*SFI1*  $P=2.0 \times 10^{-5}$ , *GALNT18*  $P=0.0008$ , *CDYL2*  $P=0.0015$ ). We also identified CNVs in high linkage disequilibrium ( $LD \geq 0.8$  in CEU) with tag SNPs on the OncoArray. Four significant loci were identified ( $P<5.0 \times 10^{-8}$ ) in an analysis of all non-mucinous EOC, one of which was also significant in endometrioid and high grade serous histotypes (9p22.2). We then performed annotation of each associated CNV with a large set of epigenomic data generated in >40 ovarian cancer related cell types that includes H3K27Ac, H3K4me1, H3K4me3, RNA-Seq, CTCF, and WGBS, combined to create chromatin state calls. We identified cell type specific enhancers that are disrupted by non-coding CNVs and are validating these with additional genotyping methods and functional experiments. Additionally, we found that regions of H3K27Ac were enriched in a cell-type specific manner for the candidate significant CNVs across the genome, indicating these CNVs may indirectly alter expression of genes via dosage of non-coding regulatory biofeatures. Additionally, deletions and duplications within coding regions of known EOC risk genes such as *BRCA1* and *RAD51C* implicate additional potential pathogenic risk variants not currently included in clinical testing for EOC. Our combination of CNV discovery and annotation analysis has provided functional information about risk variants and identified novel loci not previously found in other ovarian cancer SNP-only GWAS, expanding our knowledge of the heritability of ovarian cancer.

## PgmNr 986: Germline deleterious rare variants and their association with lung cancer.

### Authors:

Y. Liu <sup>1</sup>; J. McKay <sup>2</sup>; S. Tsavachidis <sup>1</sup>; X. Xiao <sup>1</sup>; Y. Li <sup>1</sup>; C. Cheng <sup>1</sup>; J. Field <sup>3</sup>; M. Davies <sup>3</sup>; P. Brennan <sup>2</sup>; G. Liu <sup>4</sup>; R. Hung <sup>5</sup>; D. Christiani <sup>6</sup>; C. Amos <sup>1</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Baylor College Medicine, Houston, Texas.; 2) International Agency for Research on Cancer, Lyon, France; 3) The University of Liverpool, Liverpool, UK; 4) Princess Margaret Cancer Center, Toronto, ON, M5G 2M9, Canada; 5) Lunenfeld-Tanenbaum Research Institute, Sinai Health System, Toronto, ON, M5G 1X5 Canada; 6) Harvard University School of Public Health, Boston, MA 02115, USA

**Background:** Despite previous family-based linkage studies and intensive population-based genome-wide association studies analyses, a large proportion of the heritability of lung cancer remains unexplained. Recent studies suggest that rare variants exhibit stronger effect sizes than common variants, and could account for missing heritability unexplained by common variants.

**Methods:** Germline DNA from 1045 lung cancer cases and 885 controls from the Transdisciplinary Research in Cancer of the Lung and International Lung Cancer Consortium studies were sequenced, utilizing the Agilent SureSelect<sup>XT</sup> Custom ELID and Whole Exome v5 captures. To identify rare (minor allele frequencies <1%) variants, including single nucleotide variants (SNVs) and insertion/deletions (Indels), we focused on frameshift, nonsense, stop-gain/loss, and splice donor/acceptor variants. To further prioritized candidates that are highly enriched in cases (risk-conferring) or controls (protective), we conducted allelic association analyses of single variant and gene-based collapsing tests of multiple variants.

**Results:** We identified 78 candidate variants of which 28 were SNVs and 50 were Indels, including 18 reported to be pathogenic in ClinVar database (i.e., *ATM* missense p.V2716A and *CHEK2* p.S471F frameshift). The top five risk-conferring candidates (allelic association  $P < 0.005$ ), including the p.P173R frameshift in *CRIPAK*, in-frame deletion p.A324del in *NOVA2*, in-frame deletion p.R85del in *RBM10*, p.G629R frameshift in *SYCP1*, stop gain p.Q7971\* in *NEB*; whereas the top five protective candidates (allelic association  $P < 0.005$ ), including the transcription factor binding site (rs1252601936) in *KYAT1*, frameshift p.N295K in *MED8*, p.L94H frameshift in *FAM111A*, p.E9G frameshift in *TXNDC15*, and transcription end site (8:69699853) in *C8orf34*. We also identified candidates mapped to known lung cancer susceptibility genes, i.e., *HLA*, *GPC*, *TP63*, *CDKN2A/B*, *CHRNA6*, and *LAMC1*. Among the candidate genes with multiple rare deleterious variants, the top five genes with strong association ( $P < 0.001$  from the Combined Multivariate and Collapsing test and the Kernel-Based Adaptive Cluster test) are *CYP24A1*, *KYAT1*, *C8orf34*, *CDKN2B*, and *SYCP1*.

**Conclusion:** Our whole exome sequencing analyses led to identification of 78 rare and deleterious inherited variants associated with lung cancer susceptibility. Further in-depth functional follow-up studies are needed to evaluate the pathogenicity of the candidates.

## PgmNr 987: Highly aggregated lung cancer families show significant linkage to chromosome 12q23.3 for cancer risk.

Lung cancer (LC) kills more people than any other cancer in the United States. It is known that lung cancer is a complex trait caused by both environmental and genetic factors, yet the genetic etiology of lung cancer remains poorly understood. In this study, we have performed whole exome sequencing (WES) on 262 individuals from 28 extended families that have a strong history of LC and are highly aggregated for the phenotype. The WES was recalled with PICARD/GATK and standard quality controls were performed, leaving approximately 500,000 SNVs and indels for analysis.

Parametric genetic linkage analysis was performed on these families using two distinct models – the lung cancer only (LCO) model, where only lung cancer patients were coded as affected, and the all inherited cancers (AIC) model, where other inherited cancers were coded as affected as well (pedigrees averaged 1-2 additional non-lung cancer patients). All unaffected individuals were given an “unknown” phenotype. Both models assumed an autosomal dominant mode of inheritance with a disease allele frequency of 1% and a penetrance of 80% for carriers and 1% for non-carriers. The AIC model yielded a genome-wide significant result (HLOD = 3.3) at rs61943670 in the RNA polymerase III gene *POLR3B* at 12q23.3. *POLR3B* has been implicated somatically in lung cancer but this germline finding is novel. Interesting genome-wide suggestive haplotypes were also found within individual families, particularly near *SSPO* at 7p36.1 and a large haplotype spanning 4q21.3-28.3. The 4q haplotype contains potential causal rare variants *DSPP* at 4q22.1 and *PTPN13* at 4q21.3. *PTPN13* is a known tumor suppressor in lung cancer. Functional work on *POLR3B* and several of the best candidates for the individual family signals (such as *SSPO*, *DSPP*, and *PTPN13*) is planned for future work.

## PgmNr 988: Sex differences in genetic associations with Barrett's esophagus and esophageal adenocarcinoma.

### Authors:

J. Dong <sup>1</sup>; C. Maj <sup>2</sup>; A. Thrift <sup>1</sup>

[View Session](#) [Add to Schedule](#)

1) Medicine, Baylor College of Medicine, Houston, TX.; 2) University of Bonn, Germany

---

**Background and Aims:** Esophageal adenocarcinoma (EA) is characterized by a strong and yet unexplained male predominance (with a male-to-female ratio in the incidence of up to 9:1). Genome-wide association studies (GWAS) have identified more than 20 susceptibility loci for EA and its premalignant lesion, Barrett's esophagus (BE). However, the sex differences in genetic associations with BE/EA remain largely unknown.

**Methods:** Given the strong genetic overlap, BE and EA cases were combined into a single case group for analysis and compared cases with population-based controls. We performed a sex-specific GWAS of BE/EA in two separately study datasets and then meta-analyzed using fixed-effects inverse variance-weighting approach. We further conducted a genome-wide single nucleotide polymorphism (SNP)-by-sex interaction analysis of BE/EA. To correct for multiple testing, we used  $P < 5 \times 10^{-8}$  for statistical significance.

**Results:** There were 6,758 male cases, 3,488 male controls, 1,670 female cases and 2,226 female controls. Genome-wide meta-analysis of SNP-by-sex interaction identified three novel variants at chromosome 11q13.2 not previously associated with the risk of BE/EA: rs1626067 (*CARNS1*,  $P_{\text{meta}} = 1.16 \times 10^{-8}$ ), rs12789119 (*PITPNM1*,  $P_{\text{meta}} = 2.35 \times 10^{-8}$ ) and rs2276120 (*PITPNM1*,  $P_{\text{meta}} = 2.91 \times 10^{-8}$ ). These three SNPs exhibited stronger associations in males than in females. Although meta-analysis of sex-specific GWAS did not identify any association reached genome-wide significance ( $P < 5 \times 10^{-8}$ ), top-ranked SNPs at  $P_{\text{meta}} < 1.0 \times 10^{-6}$  appeared to be sex-specific.

**Conclusions:** We identified novel variants association with BE/EA. These identified differences could improve our understanding of the genetic architecture of the disease. Further studies are needed to elucidate the biological processes through which this risk is conferred.

## PgmNr 989: GWAS and fine mapping analysis identifies 16 new epithelial ovarian cancer risk loci.

### Authors:

---

Genome-wide association studies have identified approximately 40 epithelial ovarian cancer (EOC) susceptibility risk loci in women of European ancestry. A large fraction of the genetic contribution to EOC risk remains unexplained. In this analysis, we imputed genotype data from 26,151 EOC cases and 64,783 controls to the Haplotype Reference Consortium panel and assessed the association of 31,995,530 genetic variants with risk of six EOC histotypes: non-mucinous (all cases of invasive EOC excluding mucinous), high-grade serous (HGSOC), low-grade serous (LGSOC), endometrioid (ENOC), clear cell (CCOC) and mucinous (MOC). We identified five new susceptibility loci for EOC risk at  $P < 5 \times 10^{-8}$ : two for HGSOC - 4q13.3 (rs4149419,  $P = 2.7 \times 10^{-8}$ ), 9p22.1 (rs7851336,  $P = 2.9 \times 10^{-10}$ ); two for non-mucinous - 5q11.2 (rs336126,  $P = 6.4 \times 10^{-11}$ ), 21q22.12 (rs2070368,  $P = 1.1 \times 10^{-8}$ ); and one for MOC - 2q14.2 (rs72827480,  $P = 2.7 \times 10^{-8}$ ). We then performed fine mapping analysis in each region that had a signal at genome wide threshold, adjusting for the most significant SNP in the region. These identified an additional 11 independent signals at a threshold of  $P < 10^{-5}$ , four of which were genome wide significant. Five of these signals were associated with HGSOC - 2q13 (rs895412,  $P = 1.3 \times 10^{-7}$ ), 5p15.33 (rs10069690,  $P = 2.1 \times 10^{-6}$ ), 8q24.21 (rs7833298,  $P = 1.2 \times 10^{-9}$ ), 9p22.1 (rs10810671,  $P = 6.5 \times 10^{-10}$ ) and 19p13.11 (rs12982058,  $P = 4.1 \times 10^{-6}$ ); two with MOC - 2q31.1 (rs2594950,  $P = 6.5 \times 10^{-6}$ ), 8q24.21 (rs6470494,  $P = 5.7 \times 10^{-6}$ ); two with non-mucinous - 5p15.33 (rs2853669,  $P = 4.9 \times 10^{-8}$ ), 8q24.21 (rs77235147,  $P = 7.2 \times 10^{-6}$ ); and two with LGSOC - 2q13 (rs1470053,  $P = 2.6 \times 10^{-6}$ ), 5p15.33 (rs2853677,  $P = 7.8 \times 10^{-10}$ ). We calculated the Bayesian False Discovery Probability (BFDP) for each of the loci identified in our analysis to assess noteworthiness of our findings, with low BFDP scores ( $< 10\%$ ) indicating true associations. We used a prior probability association of 0.0001 for regions with one signal, 0.001 for regions with more than one signal and a plausible per allele odds ratio of 1.2. Of the five loci identified in the primary GWAS analysis, the BFDP was  $< 1\%$  for three loci, and between 1% to 10% for the other two loci. For the 11 loci identified in conditional analysis, the BFDP was  $< 1\%$  for five loci, between 1% to 10% for one locus, and  $> 10\%$  for five loci. Our findings have the potential to improve EOC risk prediction and provide insight into the underlying genetic architecture of EOC.

## PgmNr 990: Leveraging tumor characteristics to predict germline variant pathogenicity in mismatch repair genes.

Pathogenic variants (PV) in mismatch repair (MMR) genes (*MLH1*, *MSH2*, *MSH6*, *PMS2*) increase cancer risks. Microsatellite instability (MSI) and protein immunohistochemical (IHC) changes due to MMR deficiency are often assessed to clinically evaluate cancer risk. It has been shown that these tumor characteristics may be useful in predicting germline MMR variant pathogenicity. In a large cohort of patients who underwent germline panel testing (GPT; n=4827) or paired germline/somatic testing (GST; n=1429), we derived likelihood ratios (LR=%PV carriers/%non-carriers) for those with abnormal vs. normal MSI/IHC status. For each variant, we computed the tumor characteristic LR (TCLR) as the product of carriers' MSI/IHC LRs. For GST samples, we additionally estimated *MLH1*-hypermethylation (hm)<sup>+/-</sup> LRs among samples with abnormal MSI/IHC (n=583). The MSI/IHC LRs were combined with *MLH1*-hm<sup>+/-</sup> LRs to compute overall and tumor-specific (colorectal, endometrial, ovarian, breast) TCLRs. We then compared the prediction performance of 3 approaches: TCLR alone, *in silico* priors with TCLR, and integrating TCLR evidence with *in silico* and other evidence into a Bayesian multifactorial model. Comparing carriers of germline PV vs. non-carriers, GPT samples had LRs of 2.98 for abnormal and 0.10 for normal MSI/IHC, while GST LRs were 1.57 and 0.04 for abnormal and normal MSI/IHC, respectively. The LR in favor of pathogenicity for samples with abnormal MSI/IHC was 4.47 for *MLH1*-hm<sup>-</sup> and 0.03 for *MLH1*-hm<sup>+</sup>. MSI/IHC LRs also varied by cancer type; LRs were highest in colorectal, whereas *MLH1*-hm<sup>-</sup> LRs were significantly higher in endometrial than colorectal cancers. TCLR alone accurately predicted 67.2% of 177 classified germline missense variants. Combining TCLR with *in silico* priors accurately classified >73.4% variants, depending on the *in silico* scores used for analysis. Integrating TCLR into a multifactorial model increased the proportion of accurately classified variants to 97.2%. Applying these models to the prediction of 221 variants of unknown significance (VUS), TCLR alone predicted 73% as (likely) pathogenic or (likely) benign, while the multifactorial model with TCLR reclassified 64%. However, TCLR alone yielded 5 false positives/negatives, while the multifactorial model resulted in 0 false predictions. These data highlight the importance of incorporating somatic sequencing in germline variant assessment and demonstrate the utility of TCLR evidence for VUS reclassification.

---

Known rare ovarian cancer susceptibility alleles target DNA coding sequences whereas most common risk alleles are in the non-coding genome; however, the functional role of non-coding variation is not well understood.

Statistical power limits the detection of individual rare susceptibility variants; power is increased by using burden testing, which has been used to identify several ovarian cancer risk genes. We hypothesize that germline non-coding variants associated with ovarian cancer risk might target important regulatory elements, such as binding sites of key transcription factors. Therefore, the aim of this study is to find rare, non-coding ovarian cancer susceptibility alleles on regulatory elements (specifically PAX8 binding sites in active chromatin regions) using burden testing.

High-grade serous ovarian cancer, the most common ovarian cancer histological subtype, is characterized by PAX8 overexpression. PAX8 is a transcription factor, also expressed in normal ovarian and fallopian tube surface epithelial cells (FTSECs), which are the putative precursor cells of high-grade serous ovarian cancer.

We used disease-specific epigenetic marks; active chromatin annotation (H3K27ac ChIP-seq) from 5 primary HGSOCS and PAX8 binding sites (PAX8 ChIP-seq) from 5 cell lines, two FTSEC (FT194, FT246) and three ovarian cancer cell lines (JHSO4, Kuramochi, OVSAHO). We selected PAX8 binding sites present in all 5 cell lines that overlap the consensus set (3 out of 5 H3K27ac ChIP-seq HGSOCS) of active chromatin regions.

We called variants in these regions in germline genomes of a partial dataset of 247 ovarian cancer patients and 1102 non-cancer controls sequenced for the main programme version 4 of the UK 100k Genomes Project. Variants with a frequency > 0.01 in the gnomAD dataset and in our dataset were excluded. Variants were manually filtered for quality using IGV. In a preliminary analysis, we found 56 cases and 173 controls with at least one rare variant at PAX8 binding sites.

We suggest that burden testing across non-contiguous regions of the non-coding genome is a promising approach to the identification for uncommon and rare disease susceptibility alleles.

The relationship between germline genetic variation and breast cancer survival is largely unknown, especially in understudied minority populations. Genome-wide association studies (GWAS) have interrogated survival associations but are often underpowered to find small effect sizes due to subtype heterogeneity in breast cancer and a wide range of clinical covariates. GWAS also tend to detect loci in non-coding regions, which require follow-up studies or colocalization analyses to interpret functionally. Recent work in transcriptome-wide association studies (TWAS) has shown increased power in detecting functionally-relevant, trait-associated loci by leveraging information from expression quantitative trait loci (eQTLs) in external reference panels in relevant tissues. However, race-specific reference panels for TWAS may be needed to draw correct inference in large, racially-heterogeneous cohorts, and such panels for breast cancer are lacking.

Here, we provide a framework for TWAS for breast cancer in diverse populations, using data from the Carolina Breast Cancer Study (CBCS), a population-based cohort that oversampled for women self-identifying as African American. Using Nanostring expression data from CBCS, we perform an eQTL analysis for 417 breast cancer-related genes to train race-stratified predictive models of tumor expression from germline genotypes. We use these models to impute expression in held-out samples from the CBCS and in TCGA, using a permutation method to assess predictive performance accounting for sampling variability. We find that these race-stratified expression models are not always applicable across race, depending on the imputation cohort. Furthermore, their predictive performance varies by breast cancer subtypes. Lastly, we conduct a small-scale TWAS for breast cancer mortality in CBCS (N = 3,828), controlling for covariates used in previous GWAS for breast cancer survival. At an FDR-adjusted *P* value less than 0.1, we find hazardous associations near *CAPN13* (2p23.1), *VAV3* (1p13.3), and *BLK* (8p23.1) and a protective association near *SERPINB5* (18q21.33) in TWAS that are underpowered in GWAS. This approach shows increased power for detection of survival-associated genomic loci, demonstrating the relative strength of TWAS over GWAS.

A carefully implemented TWAS is an efficient alternative to GWAS for understanding the genetics underpinning breast cancer outcomes in diverse human populations and across biologically distinct

tumor types.

---

GWAS have identified a locus at 2q33.1 as associated with melanoma (rs10931936-T,  $P=2.12 \times 10^{-12}$ ) and multiple other cancers, including breast cancer. In order to identify potential causal genes mediating melanoma risk at this locus, we generated an eQTL resource from primary human melanocytes ( $n=106$ ) and assessed candidate genes by both eQTL colocalization (HyPrColoc) and TWAS (FUSION). *CASP8* was the only gene identified by both TWAS and colocalization for this locus, where lower *CASP8* levels are associated with risk (TWAS  $P=5.57 \times 10^{-12}$ ; rs3769821 eQTL  $P=6.14 \times 10^{-12}$ ; colocalization posterior probability=0.98). *CASP8* was also a significant TWAS gene for 29 GTEx tissues, 23 of which showed the same direction of effect as melanocytes. *ALS2CR12* was also a colocalizing eQTL in melanocytes (rs3769821, eQTL  $P=2.42 \times 10^{-5}$ ; colocalization PP=0.37) and TWAS gene in 37 GTEx tissues (marginal TWAS significance in melanocytes), with the risk allele associated with higher *ALS2CR12* expression in all tissues. To identify functional risk-associated variants, we performed a multi-locus massively parallel reporter assay (MPRA) in melanoma cells. Seven high-LD

variants at this locus located within promoter/enhancer-relevant annotations in melanocytes or melanoma cells (Roadmap Epigenomics) were tested. Two variants showed significant allele-specific transcriptional activity (rs3769823, MPRA FDR=1.86x10<sup>-12</sup>, PAINTOR PP=0.76; rs3769821, FDR=0.04, PAINTOR PP=0.04), with the risk allele of rs3769823 demonstrating higher reporter activity (consistent with the *ALS2CR12* eQTL), but the risk allele of rs3769821 showing lower reporter expression. Individual reporter assays revealed that rs3769823 exhibited the strongest and most consistent effect on reporter expression, and appeared to play the largest role on transcriptional activity when tested as a part of common haplotypes for a region including rs3769823 and rs3769821. Quantitative mass spectrometry for rs3769823 using melanoma and breast cancer nuclear extract identified E4F1 and IRF2 as binding preferentially to risk-associated rs3769823-A. Promoter-focused capture-C in primary melanocytes revealed an interaction between rs3769823 and the *ALS2CR12* promoter, a finding we are presently validating via 3C. Our data suggest that the top credible causal set variant rs3769823 likely influences expression of both *CASP8* and *ALS2CR12* in melanocytes, and may be a relevant functional variant for other cancers associated with this locus.

## PgmNr 994: Integrative analysis of epistasis involving oncogenesis-related genes in lung cancer risk development.

### Authors:

**Background** Epistasis plays important role in cancer development. Our previous study identified significant genetic interactions within oncogenesis-related genes in lung cancer risk development. More genetic interactions may exist between oncogenesis-related genes and outside regions in the genome. An integrative genetic, eQTL gene expression and functional annotation analysis will help us identify the functional epistasis and provide insights about the complicated mechanism in lung cancer.

**Method** The genotypes from two independent lung cancer GWAS studies including a total of 23,351 lung cancer patients and 19,657 health controls with European ancestry were collected for the analysis. Pairwise epistasis was conducted between 27,722 SNPs, from 2,027 oncogenesis-related genes, and 317,624 SNPs from the rest of the genome. Additional genotyping and gene expression data from 409 independent individuals with European ancestry were used to evaluate the effect of identified epistasis on gene expression levels in lung tissues. The epistasis-involved genes, were submitted to DAVID and Reactome for gene functional annotation and pathway analysis.

**Result** Significant genetic interactions were identified between SNPs in gene pairs ATR-GALNT18 (Interaction OR=0.76, p value=7.98x10<sup>-13</sup>) and MET-DPF3 (Interaction OR=0.76, p value=1.62x10<sup>-12</sup>) in lung adenocarcinoma; and PICALM-PDZRN4 (Interaction OR=1.47, p value=1.67x10<sup>-12</sup>) in lung squamous carcinoma. None of these genes have been identified from previous main effect association studies in lung cancer. Further lung eQTL gene expression analysis revealed the significant association in expression levels between joint genotypes at rs637304:rs285581 and the PICALM gene expression (p=0.009). A total of 12 unique genes were submitted to functional annotation and pathway analysis. Three of them (ATR, MET and FHIT) are shown to be related with lung cancer, and six of them (RAD51B, FHIT, CALNT18, RGL1, SYNE1 and TSPAN8) are involved in tobacco-use disorders. The top 10 pathways include TP53 regulates transcription of DNA repair genes (FDR=1.67x10<sup>-2</sup>), homologous DNA pairing and strand exchange (FDR=2.57x10<sup>-2</sup>), and Meiotic synapsis (3.08x10<sup>-2</sup>).

**Conclusion** We identified novel genes in lung cancer risk development by interacting with other genetic variants. The study provides evidence that epistasis explains part of the missing heritability in lung cancer; and complex gene network and pathways contribute to lung carcinogenesis.

## PgmNr 995: Combining multiethnic data improves polygenic risk prediction for breast cancer in East Asians.

### Authors:

Y. Ji<sup>1,2</sup>; R. Tao<sup>1,2</sup>; Y. Yang<sup>4</sup>; J. Long<sup>4</sup>; W. Zheng<sup>4</sup>; B. Li<sup>1,3</sup>

### Affiliations:

1) Vanderbilt Genetics Institute, Nashville, TN; 2) Vanderbilt Biostatistics Department, Nashville, TN; 3) Department of Molecular Physiology & Biophysics, Vanderbilt University, Nashville, TN, USA; 4) Division of Epidemiology, Department of Medicine, Vanderbilt Epidemiology Center, Vanderbilt-Ingram Cancer Center, Vanderbilt University School of Medicine, Nashville, TN, USA

**INTRODUCTION:** Both European and East Asian studies have shown that polygenic risk score (PRS) is an important predictor for breast cancer risk. However, it was observed in various traits that PRS predict individual risk more accurately in Europeans than non-Europeans due to much larger sample size and better statistical power. How to best construct PRS for non-European population is still an open question. As many SNP associations should be generalized across populations, we reason incorporating information from higher-powered European study may help increase accuracy in non-Europeans.

**OBJECTIVES:** The aim of this study is to evaluate whether we can improve breast cancer PRS prediction in East Asians through incorporating European information.

**METHODS:** We use the largest GWAS to date for breast cancer in European (n=228,951) and East Asian (n=44,835). A simple approach incorporating European information is to use fixed effect meta analysis for European and Asian GWAS (**FE-META**). However, FE-META approach couldn't take into account linkage disequilibrium (LD) differences between populations. Therefore we proposed a meta analysis approach that leverage LD scores to adjust for effect size differences and tailor the resulting effect size estimate closer to target East Asian population (**ADJ-META**). We construct PRSs using the single population summary (European only, East Asian only), FE-META and ADJ-META by commonly used methods: LD-clumping and pvalue thresholding (P+T) and LDpred. We evaluate prediction performance by area under ROC curve (AUC) in an independent East Asian sample (n=4646).

**RESULTS:** In the East Asian test sample, we observe the AUC of prediction to be 0.608 (European), 0.599 (East Asian), 0.619 (FE-META) and 0.620 (ADJ-META). We also assess the correlation of causal variant effect sizes between European and East Asian in GWAS and observe highly similar effects ( $r_g=0.81$  by POPCORN), supporting the use of joint analysis.

**CONCLUSION:** We have shown that combining European and East Asian data improved prediction accuracy for breast cancer in East Asian than using training data from a single population. These relative improvements help reduce the gap compared to documented risk prediction accuracy in European (0.63-0.68). However, the purposed ADJ-META show negligible improvement over FE-META, potentially related to highly similar LD score estimates and large sample size discrepancies between the two populations.

Mendelian randomization (MR) offers an attractive approach to test hypotheses of causality of breast cancer survival and assumed breast cancer risk factors. In this study, we provide an overview of causal relationships between breast cancer survival and 15 factors for which genetic variants have been identified: breast density, telomere length, chronotype, body mass index, age at menarche, age at menopause, age at onset of alcohol consumption, ever/never smoked, years of education, celiac disease, depression, schizophrenia and type 2 diabetes mellitus (T2DM).

We performed a two-sample MR using 15-year survival summary estimates of 88,793 patients of European origin with 7,189 breast cancer-specific and 13,962 all-cause mortality events of the BCAC cohort. As instrumental variables for the risk factors, we used genome-wide significant variants from the GWAS catalog. We ran the analyses for overall, breast cancer-specific mortality and for estrogen receptor (ER)-status specific subgroups. We estimated the causal relationships between each of the factors and outcome using an inverse-variance weighted (IVW) method. To test for horizontal pleiotropy effects, we used MR-Egger regression. For those exposures with a significant causal association (FDR < 0.05) we run further sensitivity analyses and applied other MR methods (simple mode, weighted median and weighted mode) to explore the effect under different assumptions.

Genetically increased risk of T2DM (Hazard Ratio [HR] = 1.07, 95% Confidence Interval [CI] = 1.02-1.12, P value [P] = 0.006) and fewer years of education attainment ([HR] = 0.69, [CI] = 0.52-0.91, [P] = 0.010) were significantly associated with worse breast cancer-specific survival. For all-cause mortality, later age at onset for alcohol consumption was associated with better survival ([HR] = 0.96, [CI] = 0.93- 0.99, [P] = 0.011). There were no significant effects for any of the risk

factors in the ER-status subgroups. For all significant associations the sensitivity analyses did not show evidence for violation of the assumptions.

The strongest risk factors for prognosis after a diagnosis of breast cancer relate to the tumor characteristics and the extent of disease at the time of diagnosis. Our data suggest that other patient and lifestyle characteristics may also contribute to variation in outcomes. Such predictors could be included in prognostic models aimed at identifying women most likely to benefit from adjuvant therapies.

## PgmNr 997: TP53 R249S mutation in circulating tumor DNA predicts prognosis of hepatocellular carcinoma patients with or without hepatectomy.

### Authors:

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Department of Infectious Diseases and Hepatology Unit, Nanfang Hospital, Southern Medical University, Guangzhou, Guangdong Province, China.; 2) Institute of Cancer, Affiliated Hospital of Jiangnan University, Wuxi, Jiangsu Province, China.; 3) State Key Laboratory of Genetic Engineering, School of Life Sciences, Fudan University, Shanghai, China.; 4) School of public health, Fudan University, Shanghai, China.; 5) Qidong Liver Cancer Institute, Qidong people's hospital, Qidong, China.

**Purpose:** Hepatocellular carcinoma (HCC) accounts for 80%-90% primary liver cancer, which is the second most lethal tumor worldwide. Due to the lack of effective biomarkers for early diagnosis, the majority of HCC patients are diagnosed at advanced stage, and can only receive conservative treatment rather than surgical resection. In HCC, the tumor suppressor gene *TP53* is frequently mutated with a hotspot mutation at codon 249 (R249S) accounting for >50% of all *TP53* mutations. For HCC patients with hepatectomy, previous studies have indicated that *TP53* mutations detected in tissue specimens were associated with worse clinical outcomes, though the prognostic significance of specific individual *TP53* mutations remains to be clarified. For HCC patients without hepatectomy, however, no study has been conducted to investigate the association of *TP53* mutations with HCC prognosis. In the present study, we aimed to assess the relationship between *TP53* R249S mutation in circulating tumor DNA (ctDNA) and prognosis of HCC patients with or without hepatectomy.

**Methods:** We analyzed 895 HCC patients included in three cohorts. The mutation spectrum of *TP53* was examined by direct sequencing of tissue specimens in HCC patients with hepatectomy (Cohort 1, n=260). R249S or other recurrent mutations were assessed for their associations with overall survival (OS) and progression free survival (PRS) of HCC patients in Cohort 1. R249S harbored in ctDNA was detected through droplet digital polymerase chain reaction (ddPCR) and its association with OS and PRS was analyzed in HCC patients with (Cohort 2, n=275) or without (Cohort 3, n=360) hepatectomy.

**Results:** In Cohort 1, R249S occupied 60.28% of all *TP53* mutations. In addition, three other missense mutations, i.e., R110L, V157F and A159P also occurred in more than two HCC patients. R249S, but not other three recurrent mutations or other *TP53* missense mutations in combination, was significantly associated with both worse OS ( $P=0.006$ ) and PRS ( $P=0.01$ ) of HCC patients. Consistent with the results in Cohort 1, HCC patients in Cohort 2 and 3 with R249S mutation bore worse OS ( $P=8.291 \times 10^{-7}$  and  $2.608 \times 10^{-7}$  in Cohort 2 and 3, respectively) and PRS ( $P=5.115 \times 10^{-7}$  and  $5.900 \times 10^{-13}$  in Cohort 2 and 3, respectively) compared to those without this *TP53* defect.

**Conclusion:** We provided an evidence for the first time that *TP53* R249S mutation in ctDNA may serve as a promising prognosis biomarker for HCC patients regardless of receiving hepatectomy.

# PgmNr 998: Screening of cervical smears, prevalence of hr-HPV sub-types in cervical pathologies and promoter methylation of RAR $\beta$ 2 gene.

## Authors:

S. Thumaju <sup>1,2</sup>; V. Mohan <sup>1</sup>; Y.R. Ahuja <sup>1</sup>

## Affiliations:

1) Vasavi Medical and Research Centre, Dept of Genetics and Molecular Medicine, Hyderabad, India. 040-23210251, Hyderabad, Telangana, India; 2) Osmania University, Dept of Genetics, Hyderabad, India

## Introduction:

Though persistent infection with oncogenic Human Papillomavirus (HPV) types is considered the most important risk factor for cervical cancer development, less than 5% of women with HPV will eventually develop cervical cancer supporting that other molecular event, like gene methylation may co-contribute to cervical carcinogenesis. In India, due to lack of awareness of screening and non-availability of appropriate infrastructure, cervical cancers are detected at advanced stages where cure is difficult.

Identifying women who are sexually active for more than 3 years, with an abnormal papanicolaou (Pap) smear or cervical lesions seen on visual inspection.

Testing PAP DNA samples for the presence of high-risk (12) HPV subtypes to see their prevalence in the population.

Evaluate promoter methylation status of RAR $\beta$ 2 gene to establish the association of epigenetic changes with pathologies of the cervix.

## Method:

Organized screening programs were conducted in different rural and urban areas to identify women with abnormal PAP cytology. Complete information about the screening program was given to the women participants. Pap samples were collected along with the personal and medical history.

## Results:

Pap smears of 530 women were obtained *via* screening programs. 66% of cases were found to show an abnormal Pap cytology, mostly inflammatory smears. Upon exclusion of inflammatory smears, 32% were found to be abnormal smears. Of all abnormal cases 31.8% cases showed RAR $\beta$ 2 methylation. Of the cases detected with presence of HPV, 14.1% showed HR-HPV subtypes. Of these 81.8%, 54.5% cases showed hMLH1 & RAR $\beta$ 2 methylation respectively.

## Conclusion:

RAR $\beta$ 2 gene product inhibits transcription of viral oncogenes (E6 & E7) in HR-HPV immortalized cells. RAR $\beta$ 2 promoter methylation, resulting in loss of expression, may affect this function, giving scope for viral oncogene transcription & carcinogenesis. RAR $\beta$ 2 methylation testing along with screening for HR-HPV subtypes could prove to be biomarkers for potential cancer risk in these patients. It is also important that the prevalence of specific HR-HPV subtypes has to determine in our population before we go ahead with administering the cervical vaccines.

## **PgmNr 999: An empirical comparison of approaches to discovering novel cancer predisposition genes by rare variant analysis using public available summary counts or full genotype data.**

### **Authors:**

---

Childhood brain tumors are the second commonest pediatric cancer after leukemia, but they are still rare, with an incidence rate of 0.53% in United States. Therefore, finding novel germline cancer predisposition genes in pediatric brain tumors is challenging. Most published datasets involved a simple Fisher exact enrichment analysis using public summary counts from “healthy” individuals (e.g. gnomAD databases) as a control cohort. The advantage is the large number of the controls. However, the heterogeneity of the sequencing platforms, capture designs and coverage variations will inevitably introduce false-positive and false-negative findings. Moreover, without properly adjusting for the genetic background, the results from a simple Fisher’s exact test are unreliable. A more formal approach is to use raw sequencing data through the same pipeline for the analysis, progressing through mapping, variant calling, variant QC to generate the full genotype data. By rigorously controlling the analytical approach, systematic errors can be avoided and standard rare variant analysis can be applied.

In this study, we compare the two approaches described above. We downloaded whole exome sequencing data for ~5,700 healthy individuals from the Alzheimer's disease Sequencing Project and ~2,600 individuals from the 1000 Genomes Project. We performed rigorous QC to remove regions without good coverage, false variants due to paralogous mapping or sequencing artifacts. Top principal components were included to adjust for population stratification in the rare variant analysis. For the “summary count” approach we contrast the quality controlled genotype counts from cases with those from gnomAD. We also evaluated different population frequency thresholds to define rare variants, as well as different *in silico* functional impact measurements. Using previously classified pathogenic and likely pathogenic variants in Clinvar, we chose REVEL score as the most informative feature.

We chose ~150 brain cancer patients from the Pediatric Cancer Genome Project (PCGP) as study cases. In our analysis, when properly quality controlled, we observed no obvious inflation in QQ plot for both approaches using samples from European ancestry. Some genes are consistently ranked top in both approaches. However, some genes show large discrepancies. We validated *NF1* as a cancer predisposition gene. We also identified a few candidate ‘brain tumor risk’ genes (e.g. *PTPN11*) for further investigation.

# PgmNr 1000: Application of two joint model methods to the CSP380 longitudinal colorectal cancer screening cohort in SNP discovery for advanced neoplasia.

---

Cohort studies following participants over time and making multiple phenotypic measurements may provide information about the presence of germline susceptibility variants for complex traits, however, such studies also suffer from loss to follow-up and death of participants. Two R packages, JMBayes and rstanarm, join the mixed model for longitudinal binary outcomes and the survival model to address repeated measurements and censored data, respectively. Our goal in this work is to evaluate these two packages in the setting of genetic variant discovery. The Department of Veteran Affairs (VA) Cooperative Study 380 is a longitudinal study of 3121 asymptomatic and otherwise healthy participants aged 50-75 from 13 VA Medical Centers who had a screening colonoscopy between 1994-1997. Participants were followed over 10 years capturing the histopathological outcomes for all colonoscopies or other colon-related procedures along with ascertainment of vital status from the National Death Index and the VA Electronic Medical Record (EMR). Advanced neoplasia (AN) at each colonoscopy was defined using pathology reports indicating at least one polyp with tubular adenoma  $\geq 10$  mm, adenoma with villous histology, adenoma with high-grade dysplasia or invasive cancer. Time to death from all causes or time to last visit was recorded. A total of 612 individuals were genotyped on the Illumina Infinium Omni2.5-8 v1.3 Beadchip. We analyzed the 500 European American participants, randomly selected 150 SNPs to evaluate the results under the null hypothesis and compared the 50 top SNPs from logistic regression of AN to check consistency. We fit a random effects model to all colonoscopies including an additive genetic term, age and two genetic principal components (PCs). We also fit a Cox proportional hazards model to time to death including baseline screening outcomes along with age, comorbidity, and follow-up group. The models are linked by the random effect. We fit the same model to both packages (JMBayes and rstanarm): 127 random SNPs ran successfully with rstanarm and the QQ plot gave a  $\lambda=0.92$ ; 84 random SNPs ran successfully with JMBayes and the QQ plot gave a  $\lambda=2.3$ . Of the 50 top SNPs, 36 ran successfully in both packages, the correlation coefficient is 0.498,  $p$ -value= 0.0019. From these comparisons we conclude that JMBayes will require adjustment of  $p$ -values if used in a GWAS context. Both packages require substantial tuning to run large numbers of SNPs.

## PgmNr 1001: Variable selection for SNP-SNP interaction models: AA9Lasso approach.

**Authors:**

H. Tung; H. Lin

[View Session](#) [Add to Schedule](#)**Affiliation:** Biostatistics, LSUHSC New Orleans, New Orleans, LA.

---

The ideal goal of genetic association studies is to improve the prediction of clinical outcomes. It has been shown that SNP-SNP interactions can explain complex diseases better than individual SNP effects. The AA9int method is a powerful method to test SNP-SNP interactions associated with an outcome by considering the non-hierarchical structure. It is beneficial to build a prediction model using AA9int SNP interaction findings. For SNP interaction analyses, the number of predictors increases dramatically due to consider all possible pairwise interactions. An effective preliminary selection can help on selecting a subset of SNP pairs for building a multivariable model. For a small sample size, SNP pairs with the main effect term(s) are often neglected during the selection process. We proposed AA9Lasso, a modified Group Lasso approach with proper weights of the penalty terms used for variable selection for AA9int identified SNP pairs. The goal of the new method is to increase detection rates for the pairs with complex interaction structures, such as Full and One-Main structure. We conducted a simulation study to compare AA9Lasso with univariate approaches and regular Group Lasso. We observed AA9Lasso outperformed other testing methods. Its detection rates of all the designed pairs were higher than 90% under a large sample size of 5000. For  $>0.2$  effect size and 0.45 of the minor allele frequency (MAF) for both SNPs, AA9Lasso had almost 100% detection rate with a sample size of 5000. AA9Lasso achieved the goal to increase detection rates of SNP pairs with a complexed structure; meanwhile, the pairs with the interaction only structure also had excellent detection rates. When the sample size reduced to 3000 and 1000, the proposed method still performed better than others. Both MAF and effect size impacted the performances of selection, but the proposed method maintained its advance. This study demonstrates that AA9Lasso can effectively select a subset of SNP pairs associated with the outcome. Although the proposed AA9Lasso already ruled out  $> 97\%$  of the false positive findings, it remained thousands of predictors. Thus, another variable selection may be needed to build the final prediction model.

## PgmNr 1002: DOT: Gene-set analysis by combining decorrelated association statistics.

---

Historically, the majority of statistical association methods have been designed assuming availability of SNP-level information. However, modern genetic and sequencing data present new challenges to access and sharing of genotype-phenotype datasets, including cost management, difficulties in consolidation of records across research groups, etc. These issues make methods based on SNP-level summary statistics for a joint analysis of variants in a group particularly appealing. The most common form of combining statistics is a sum of SNP-level squared scores, possibly weighted, as in burden tests for rare variants. The overall significance of the resulting statistic is evaluated using its distribution under the null hypothesis. Here, we demonstrate that this basic approach can be substantially improved by decorrelating scores prior to their addition, resulting in remarkable power gains in situations that are most commonly encountered in practice; namely, under heterogeneity of effect sizes and diversity between pairwise LD. In these situations, the power of the traditional test, based on the added squared scores, quickly reaches a ceiling, as the number of variants increases. Thus, the traditional approach does not benefit from information potentially contained in any additional SNPs, while our decorrelation by orthogonal transformation (DOT) method yields steady gain in power. We present theoretical and computational analyses of both approaches, and reveal causes behind sometimes dramatic difference in their respective powers. We showcase DOT by analyzing breast cancer data, in which our method strengthened levels of previously reported associations and implied the possibility of multiple new alleles that jointly confer breast cancer risk.

## PgmNr 1003: Search for additional high-risk genes for familial cutaneous malignant melanoma using unified linkage and association analyses of whole exome sequencing data.

Approximately 10% of cutaneous malignant melanoma (CMM) cases occur in a familial setting but known high-risk CMM genes account for melanoma risk in less than 40% of melanoma-prone families. Even with the advance of sequencing technologies, finding novel high-risk CMM genes has been challenging, largely due to genetic heterogeneity, variable penetrance, and difficulty in variant interpretation. New analytical approaches with the design of integrating multiple sources of data may have the potential to address some of these challenges. Here, we performed Whole Exome Sequencing in germline DNA of 89 CMM patients from 28 families without known mutations to identify novel high-risk genes for familial CMM. We used pedigree-Variant Annotation Analysis and Search Tool (pVAAST), which uses a composite likelihood ratio test incorporating linkage signal in families, external controls, and functional prediction of variants to identify rare variants that are statistically associated with disease. pVAAST analysis identified 20 genes with statistical significance (p-value < 0.05 after  $1.0^6$  permutations) that were recurrently altered in  $\geq 3$  families. Among them, ASAP3, SRCAP, DDX60, GORASP1, MC1R and ATM showed high quality reads and had variants that were rare or absent in public databases. MC1R and ATM have been previously described as CMM susceptibility genes. GORASP1 encodes a protein required for the maintenance of the Golgi apparatus integrity. In addition to GORASP1, variants in several other genes associated with Golgi apparatus, including the previously described CMM high-risk gene GOLM1, were found cosegregating in six families, further supporting the role of Golgi complex genes in CMM susceptibility. Several families carried variants in more than one candidate gene, highlighting some of the complexities in disease gene discovery. In future work, we plan to investigate additional approaches including Rare Variant Sharing (RSV), a test to assess association and linkage between rare genetic variants and disease phenotype in pedigrees, rare variant burden test, and outlier test using gene expression data. We will compare the results from the analysis using pVAAST with results from the other complementary approaches to increase opportunities for identifying high-risk genes for CMM.

## PgmNr 1004: Transcriptome-wide association study of endometrial cancer.

### Authors:

P.F. Kho; A.B. Spurdle; T.A. O'Mara; D.M. Glubb; Endometrial Cancer Association Consortium

[View Session](#) [Add to Schedule](#)

---

Endometrial cancer is the most commonly diagnosed gynaecological cancer. We have recently performed a meta-analysis of endometrial cancer genome-wide association studies (GWAS; total 12,906 cases and 108,979 controls) and identified 16 genetic loci that robustly associate with endometrial cancer. However, 99% of endometrial cancer risk-associated variants are located in non-coding regions. Further, because of enhancer-promoter chromatin looping, the genes involved in disease aetiology are not necessarily the most proximal genes to the GWAS variants. Thus, elucidating the causal genes underlying GWAS association remains challenging. To address this issue, we have used transcriptome-wide association study (TWAS) techniques to identify genes whose expression levels associate with endometrial cancer. Using findings from the largest eQTL reference panel for blood (N = 31,684) and the endometrial cancer GWAS meta-analysis, Summary data-based Mendelian Randomization (SMR) analysis prioritised *EVI2A* as a candidate gene for endometrial cancer. We also conducted a TWAS using Fine-mapping of CaUsal gene Sets (FOCUS) on the same GWAS of endometrial cancer to prioritise credible genes by fine-mapping TWAS associations identified from the GTEx Project eQTL reference panel. FOCUS analysis prioritised *BHLHE41* (Posterior Inclusion Probability; PIP 0.99), *SRCIN1* (PIP 0.99), *SNX11* (PIP 0.92), and *RNF217* (PIP 0.85) as candidate genes. Notably, chromatin looping data from endometrial cell lines supports the targeting of *BHLHE41*, *SRCIN1* and *SNX11* by endometrial cancer risk-associated variants. Notably, *BHLHE41* and *SRCIN1* play a role in the epithelial-mesenchymal transition in cancer and *BHLHE41* is upregulated in endometrial tumours. *SNX11* is involved in intracellular trafficking but has not been previously related to cancer. However, reporter gene analysis of a *SNX11* promoter endometrial cancer risk-associated variant was consistent with the TWAS finding that increased *SNX11* expression was associated with increased risk. In summary, using TWAS and supportive functional genetic evidence, we have prioritised several candidate genes for assessment of their effects in cellular studies of endometrial cancer.

## PgmNr 1005: Deconstructing myeloma tumor heterogeneity: Transcriptome dimension signatures.

### Authors:

**Affiliation:** University of Utah School of Medicine

---

Multiple Myeloma (MM), the 2nd most common hematologic malignancy, is a complex cancer of plasma cells with 32,110 new cases expected in 2019 and poor prognosis (52.2% survive 5 years). Tumor heterogeneity hinders MM clinical management and research. A standard approach is to partition tumors into mutually exclusive, categorical subtypes. However, categorical subtypes are unidimensional and may fail to capture important variation.

An alternate approach is quantitative expression dimensions. Tumor heterogeneity is deconstructed using principal component analysis (PCA) to establish tumor traits that capture important global transcriptome variation. Each dimension is an independent tumor characteristic – a unique weighted average of key genes – which alone could uncover associations with clinically-relevant endpoints. In addition, together multi-dimension signatures may uncover biologically relevant characteristics and reflect specific molecular liabilities or therapeutic vulnerabilities.

MM tumor dimensions were derived from RNA sequencing on treatment-naïve, CD138 sorted, tumor cells on 768 patients in the Clinical Outcomes on MM Genetic Profiles Assessment (CoMMpass) study. Gene-based SALMON expression counts were normalized for gene length, library size, and RNA composition. Multi-stage PCA was performed on the normalized counts to derive orthogonal, quantitative tumor dimensions. Distinct dimensions and multi-dimension signatures were investigated for associations with demographic, clinical, and genetic characteristics using penalized linear regression modeling.

We identified 28 dimensions of interest in the MM tumors and characterized multi-dimension signatures for each of the 768 patients. After correcting for multiple testing, 29 associations between a dimension and a clinical variable were significant. Dimensions 1-8 were associated with one or more somatic alterations, known to correlate with myeloma prognosis, including t(11;14), t(14;16), t(4;14) and amp(1q) (max  $p = 8.22 \times 10^{-5}$ , min  $p = 1.61 \times 10^{-23}$ ). Interestingly, dimensions 11 and 24 were significantly associated with African heritage ( $p = 2.86 \times 10^{-7}$  and  $8.04 \times 10^{-7}$ ), indicating the possibility of molecular disparities by race.

We present a new quantitative framework to represent transcriptome variability in MM tumors that provides more flexibility for statistical modeling with clinically relevant endpoints and ultimately, the potential to improve precision cancer care.

## PgmNr 1006: Investigation of novel transcript splicing in multiple myeloma reveals an ultra-high risk subgroup and potential novel therapeutic targets.

### Authors:

M.A. Bauer <sup>1,2</sup>; A. Ashby <sup>1,2</sup>; C. Wardell <sup>1,2</sup>; E. Boyle <sup>3</sup>; G. Morgan <sup>3</sup>; B. Walker <sup>2</sup>

Disruption of the normal splicing patterns of RNA is a major factor in the pathogenesis of a number of cancers. Increasingly research has shown the strong influence that splicing patterns can have on cancer progression. Multiple Myeloma is a molecularly heterogeneous disease classified by the presence of key translocations, gene expression profiles and mutations. The role of alternative splicing in MM remains largely unexplored.

Working with RNA-Seq data from the CoMMpass dataset, we split the newly diagnosed MM samples ( $n=598$ ) into three groups. The initial groups consisted of the top and bottom 20% (both  $n=120$ ) and middle 60% ( $n=358$ ) in number of novel splice loci. There was a significant difference in progression free survival (PFS) and overall survival (OS) between the low novel splice group and the high splice group ( $p=0.03$  and  $0.013$ ). Surprisingly, a comparison of the groups with known MM genomic characteristics revealed significantly less novel splicing in the  $t(4;14)$  group ( $p\text{-value} = 0.002$ ), a poor prognosis MM subgroup and an increase in the  $t(11;14)$  group ( $p\text{-value} < 0.001$ ), a better prognosis subgroup. Survival analysis for just the  $t(4;14)$  subgroup showed a significant adverse survival in the high splice group within  $t(4;14)$  versus  $t(4;14)$  with low number of novel splice groups (PFS:  $p=0.003$  and OS:  $p<0.001$ ). This finding suggests that there is a previously undescribed ultra-high risk group of  $t(4;14)$ .

Differential gene expression analysis identified 619 upregulated genes and 697 down regulated genes ( $\log_2$  fold-change  $> 2.0$  and adjusted  $p\text{-value} < 0.05$ ). A number of MAGE genes were over expressed in the high splice group. Gene set enrichment analysis revealed an enrichment in genes involved in the G2/M checkpoint and E2F (family of transcription factors) target pathways and a decrease of the p53 DNA repair and unfolded protein response pathways. Protein-protein analysis resulted in a highly connected network with significant enrichment for several protein domains including MAGE family, GAGE protein, and SSXRD motif. These present potential therapeutic targets with fewer side effects due to their limited expression in somatic tissue.

Alternative splicing is an important pathogenic disease mechanism in MM that affects important pathways. In this study, we show that a high number of novel splice loci is associated with adverse survival and an ultra-high risk group. We also identify a number of genes that may represent novel therapeutic targets.

## PgmNr 1007: An enhanced genetic model of colorectal cancer progression history.

**Authors:**

L. Yang

[View Session](#) [Add to Schedule](#)**Affiliation:** Ben May Department for Cancer Research, Univ Chicago, Chicago, Illinois.

---

The classical genetic model of colorectal cancer presents somatic *APC* mutations as the earliest genomic alterations, followed by *KRAS* and *TP53* mutations. However, the timing and relative order of clonal expansion and other types of somatic genome alterations such as genomic rearrangements are still unclear. Here, we performed detailed analysis of somatic genetic alterations, including point mutations, copy number alterations and genomic rearrangements, in 63 whole-genome sequenced colorectal cancers from the Cancer Genome Atlas Research Network. The relative order of these alterations occurring during tumorigenesis was inferred from variant allele fractions. We found that driver point mutations, gene fusions, and arm level copy losses typically arise early. Copy-neutral loss of heterozygosity is often a two-step event: a deletion followed by a duplication. Different mechanisms act in different genomic regions to optimize the DNA dosage. Chromothripsis, clustered genomic rearrangements previously thought to occur as a single catastrophic event, is frequent and may occur multiple times independently in the same tumor through different mechanisms. In contrast to recent studies reporting neutral growth of tumors, selection is often present on subclones. Our results suggest that different evolutionary models can operate in a single tumor at different stages. Combining these results, we present a refined tumor progression model for human colorectal cancer. Our enhanced genetic model significantly expands our understanding of tumorigenesis process.

## PgmNr 1008: Comprehensive assessment of gene fusion detection, prioritization, annotation, and characterization.

### Authors:

V. Chakraborty; S. Ramachandrula

[View Session](#) [Add to Schedule](#)

**Affiliation:** Strand Life Sciences Private Limited, Bengaluru, Karnataka, India

---

Fusion events are commonly observed in cancer and are prevalent in both hematological and solid tumors. Though these events seem to be random but they show classic non-random behavior both structurally and functionally. For example, hematological tumors mostly results in juxtaposition of a normal gene under the regulation of a new gene, resulting in abnormal expression of the normal gene. In case of solid tumors most of the known gene fusions are either Transcription control genes or Tyrosine kinases, which are potential targets for drug development. Hence, to understand the behavior of both the groups of tumors, as well as the tissue and lineage specificity of the events, we chose targeted RNA-Seq data in addition to whole transcriptome data from various types of blood, lung and prostate cancers from publicly available datasets: PRJNA484669 and GSE80126.

In this study, we used Strand NGS to perform an end to end analysis starting from aligning the raw data, filtering reads based on quality, perform gene fusion detection, filter the fusion events to remove false positives, annotate against already known fusion events, quantify the data to understand the change in expression levels caused due to these events and lastly link the biological effect of the fused genes.

We utilized the ability of Strand NGS to align raw reads from RNA data to the exonic (known transcriptome) as well as intronic parts of the genome. Apart from gene fusions, we also looked for any co-occurrence of other significant mutational events like SNP or MNP.

Usually, the trickiest part after mutational detection is to assess these events; this was readily possible by viewing the fusion events in the elastic genome browser of Strand NGS which is unique in its nature as among other properties it gives a one shot view of even the inter-chromosomal gene fusion events up to nucleotide level resolution. Finally, we tie all the sequence changes in the data with expression level changes and their functional significance via GO and Pathway analysis.

Testing for the gene fusion events helps in disease diagnosis, identifying therapeutic treatment, prognosis information and works as a guide to take targeted therapy decisions. A comprehensive GUI-based tool like Strand NGS allows biologists to analyze gene fusion events and also correlate it with the biological effects caused by these events.

## PgmNr 1009: Optimized computational genotyping of known structural variation for clinical diagnoses.

Structural Variation (SV) is a major contributor to genomic variation and associated with many genetic diseases. Despite the importance of this class of variation, there are shortcomings in the usual *de novo* methods for their assessment using short DNA sequencing. The short reads alone provide low sensitivity and a high false discovery rate, significantly hindering applications for routine SV screening and limiting their proper characterization for clinical diagnoses. These shortcomings can be partially ameliorated with the use of long-reads, however, the current cost, DNA requirements and time-intensive nature preclude their routine application for clinical diagnostics.

We investigated SV genotyping as a cost-effective diagnostic tool in the clinic. SV genotyping enables computational detection of known annotated SVs directly from short read DNA sequence data in patient samples, which dramatically reduces the false discovery rate and thus, the potential misdiagnosis of patients. Further, the validation of methods for detection of known events provides an easier challenge for regulatory and compliance purposes than *de novo* detection.

We assessed five state-of-the-art SV genotyping software methods (Delly, Genome STRiP, STIX, SVtyper, SV2) based on short-read sequence data and investigated their potential applicability for clinical diagnosis. These methods were characterized based on their ability to genotype SV types across a range of simulated and real data. We determined which genotype software optimally performs for each type and influence of size of SVs on sensitivity. Optimal tuning of calling parameters markedly improved sensitivity and reduced initial false discovery calls. Among the SV genotypers, STIX performed best on both simulated and GiaB based SVs calls, demonstrating a good balance of high sensitivity versus reduced false discovery. In aggregate, our results indicate SV genotypers have better performance than SV callers. Our approach can be integrated to routinely scan for known pathogenic SVs into existing analysis pipelines, thereby representing a computationally efficient and rapid way to diagnose SVs in clinical diagnostic settings.

## PgmNr 1010: TACCO, a database, connects transcriptome alterations, pathway alterations, and clinical outcomes in cancers.

---

While numerous cancer sequencing data is already publicly available, to systematically dig out meaningful correlations from those data is still challenging for cancer biologists who do not possess related computer skills. Previously, we have downloaded all the expression levels of miRNA and mRNAs from firehose and build a database, Transcriptome Alteration in CanCer Omnibus (TACCO), which aims to link the transcription alterations and transcriptome regulatory network with downstream pathway alterations and clinical outcomes in 22 cancer types. TACCO provides: 1. Volcano plots for selection of significantly differentially expressed miRNA or mRNA (DEGs) 2. Correlations between the expression levels of miRNA and their targets 3. Gene Set Enrichment Analysis for significantly altered pathways 4. KEGG pathway enrichment analysis for selected or uploaded gene list 5. Gene Ontology (GO) enrichment analysis for selected or uploaded gene list 6. Survival-related signature selection from transcriptome. DEGs selected on TACCO or a gene list uploaded by user can be used for the pathway analysis and survival prediction model construction. These signatures have great potentialities for patient stratification and treatment decisions in later clinical applications. Based on TACCO, we include extra genomic features in the prediction models and found further improvement. As an integrated transcriptome database, our tool comes with a user-friendly query interface will be invaluable for cancer biologist to investigate the transcriptome regulatory networks alterations and the following clinical outcome in cancers systematically.

## PgmNr 1011: Representing cancer-relevant variants in variation graphs.

Variation graphs provide a single data structure that can represent both a reference genome and reference-relative variation. Compared to a linear reference, graphs improve read mapping and reduce reference bias when mapping against common population variation from sources such as the 1000 Genomes project. This has been shown to improve genotyping of single-base variants and indels. Graphs have also been shown to benefit structural variant calling and genotyping.

Tumors possess both a germline background and somatic variation. Nearly 200 genes have been implicated as contributing to cancer predisposition, and these genes may each have many specific predisposition variants. There are over 4,000 known germline predisposition variants among nearly 25,000 total catalogued mutations in the BRCA1 and BRCA2 genes for instance. There is significant interest in quickly and accurately detecting such variants in whole-genome sequencing data. We demonstrate a pipeline for building graphs of many thousands of predisposition variants, implemented using the variation graph toolkit (vg), and show that reads can be directly mapped to these variants.

We also build graphs of somatic variants from the Catalog of Somatic Mutations in Cancer: one containing more than 4 million coding mutations and one with tens of thousands of structural variants. Somatic calling is often confounded by low tumor purity, alternative ploidies, and tumor subclonality, making improved read mappings especially valuable as a small amount of additional evidence for a variant. However, one must carefully choose the variants included in such a graph and their representation, especially when incorporating structural variation. We discuss specific decisions that must be made when selecting variants to include and their representation, as well as how these factors impact the performance of downstream analyses. Lastly, we demonstrate that mapping reads from a sample with known somatic variants (such as BRAF V600E) is feasible with vg and compare our results to traditional variant callers.

## PgmNr 1012: A combinatorial approach for single-cell variant detection via phylogenetic inference.

Single-cell sequencing provides a powerful approach for elucidating intratumor heterogeneity by resolving cell-to-cell variability. However, it also poses additional challenges including elevated error rates, allelic dropout, and non-uniform coverage. A recently introduced single-cell-specific mutation detection algorithm leverages the evolutionary relationship between cells for denoising the data. However, due to its probabilistic nature, this method does not scale well with the number of cells. Here, we report on a novel combinatorial approach for utilizing the genealogical relationship of cells in detecting mutations from noisy single-cell sequencing data. Our method, called scVILP, jointly detects mutations in individual cells and reconstructs a perfect phylogeny among these cells. The method employs a novel Integer Linear Program algorithm for deterministically and efficiently solving the joint inference problem. scVILP achieves similar or better accuracy but significantly better runtime over existing methods on simulated data. We also applied scVILP to an empirical human cancer dataset from a high grade serous ovarian cancer patient.

## PgmNr 1013: Benchmarking copy number aberration detection tools on single-cell DNA sequencing data.

Copy number aberrations (CNA) have been shown to cause genetic diseases such as cancer. Accurate detection of CNAs can help with diagnosis, prognosis and treatment of cancer. Different from bulk sequencing, single-cell DNA sequencing provides a way of looking into the CNAs one cell at a time, making it possible to detect CNAs occurring to small clones and understand the heterogeneity of cancer. However, most CNA detection methods that have been applied to single-cell DNA sequencing data are not specifically designed for single cells. While single-cell DNA sequencing has its unique error profile such as low and uneven coverage, a benchmark study on the performance of these methods when applied to single cell DNA data is currently lacking. We designed experiments on both simulated and real data to measure the recall and precision of three methods that have been used to detect CNAs in single-cell DNA sequencing data--Ginkgo, HMMcopy and CopyNumber. Specifically, we designed a single-cell DNA simulator on which the CNA rate, CNA size and read coverages are all stochastically sampled from their corresponding distributions that are estimated from and thus consistent with the real data. We looked into four aspects of the three methods in the simulation experiments: the scalability and the affect of ploidy, coverage and doublets. Furthermore, using real data, we investigated the consistency among the three methods, and analyzing their inferences with respect to the evolution of copy numbers. The study highlights the strengths and weaknesses of the existing methods, and identifies areas of improvement.

## PgmNr 1014: Imputation of the *GSTM1* deletion in the 1000 Genomes Project populations to develop a reference dataset for epidemiological studies.

### Authors:

**Affiliation:** Division of Cancer Epidemiology and Genetics, National Cancer Institute, Bethesda, Maryland.

---

The deletion of the *GSTM1* gene on chromosome 1p13.3 is a common germline polymorphism. The homozygous loss of *GSTM1* (*GSTM1*-null) is likely to be functional because *GSTM1* detoxifies various environmental carcinogens and toxins and multiple associations have been reported for susceptibility to inflammatory and metabolic pathologies and cancer risk in carriers of this genotype. Large-scale genotyping of this deletion is challenging due to the complex genomic structure of the region. Using a custom assay, we genotyped *GSTM1* deletion in 1840 individuals representing 19 populations from the 1000 Genomes Project (1KGP). *GSTM1*-null status was found in 39.5% samples, with strong inter-population differences ( $p < 0.001$ ). The *GSTM1* deletion was most strongly linked with rs36209093 ( $r^2=0.43$ ,  $D'=0.81$  in the whole set). However, we found that rs36209093 is a pseudo-SNP that results from a near-complete similarity within two duplicated regions. Considering that *GSTM1* deletion is not tagged by any easy-to-genotype proxies, we aimed to explore whether it can be imputed to facilitate its association analysis with relevant outcomes in GWAS.

We randomly partitioned the 1840 *GSTM1*-genotyped 1KGP samples into a reference panel ( $n=846$ ) and a test panel ( $n=852$ ), with each panel containing ~50% of samples from each population. Haplotype phasing within a 2-Mb window around *GSTM1* deletion was done with ShapeIT software, and *GSTM1* deletion imputation was done with IMPUTE2 software with and without pre-phasing of the test panel. *GSTM1* deletion was scored in samples with a post-probability dosage of more than 0.6. Post-imputation quality parameters were calculated based on genotyped vs. imputed *GSTM1* deletion. We observed lower concordance rate (85% vs. 90%) and imputation quality score (0.76 vs. 0.84) but a higher rate of imputable samples (96.7% vs. 93.1) and shorter computation time (4 vs. 16 hrs) for imputation with vs. without pre-phasing of the test panel. In conclusion, our results demonstrate that to explore its associations with relevant phenotypes, *GSTM1* deletion can be imputed with reasonable quality in existing GWAS datasets using the modified 1KGP or custom reference panels.

## PgmNr 1015: Identification of synthetic cytotoxic gene pairs associated with a therapeutic response for the anticancer drug etoposide based on cell line-drug database.

### Authors:

J. Goh <sup>1,2</sup>; Y.J. Kim <sup>3</sup>; K. Kim <sup>4</sup>; K. Lee <sup>3</sup>

In cancer genomics profiling, the most important clinical question was whether the patients show treatment responsiveness as well as low toxicity. Although traditional chemotherapeutic agents form the basis of treatment for many cancers at different stages, resistance and toxicity often result in therapeutic failure. In order to evaluate the genomic signature associated with the chemotherapeutic response, the synthetic cytotoxic interaction (SCI) of the anticancer drug etoposide was analyzed based on the cell line-drug database, GDSC. To find SCI gene pairs for etoposide, we defined significantly damaging mutations if a gene have a more than one loss of function mutations and/or nonsynonymous mutations with SIFT score<0.05 and/or copy number deletion. IC50 value of etoposide for each cell line was used as drug responsiveness marker to decide whether cell line showed greater sensitivity to etoposide when both genes were damaged compared with when one or none of the genes have a damaging mutation. There were 871 cell lines having etoposide IC50 values as well as whole exome sequencing data in GDSC database. To compare the SCI effect for etoposide, we grouped cell lines into 4 groups according to mutation profile for each gene pair: PP, PN, NN and NP, and P represent gene have damaged mutation and N represent no mutation, respectively. There were 3,804 genes have at least 5 damaging mutations (7,233,306 gene-gene pairs), and Student's t-test was used to identify gene pair showed significantly lower IC50 of PP group compare to other three groups adjusting multiple testing correction.

Total of 14 gene pairs containing 24 genes were identified to have significant SCI for etoposide (p value<0.05). After functional enrichment using GO terms, five genes (*CRB2*, *RYR2*, *LRP1B*, *CACNA1E*, and *DNAH7*) were enriched to calcium ion binding (GO:0005509). We analyzed correlation between the number of mutations in five calcium ion binding genes and IC50 values for all cell lines and identified mild but significant decreasing correlation (p value<0.05).

We identified that cancer cell lines showed interactive gene-gene paired synergistic effect to etoposide especially enriched in calcium ion binding which was biologically related to a well-known etoposide side effect, cardiac toxicity, and this method have great potential which could be broadly applied to other drugs and genes as well to identify sensitive genomic profiles in cancer cell.

# PgmNr 1016: Interpretable deep learning model to integrate genomic profiles and histopathological images for cancer survival prediction.

---

Integration of heterogeneous types of biological data promises an improvement in predicting cancer survival. Specifically, the integration of genomic data and histopathological images enhances survival predictions and personalized treatments in cancer study, while providing an in-depth understanding of genetic mechanisms and phenotypic patterns of cancer. Histopathology, as a clinical gold-standard tool in diagnosis and prognosis for many cancers, allows clinicians to make a better decision on therapies. Whereas, the genetic mechanism of cancer can be unveiled with high-throughput genomic data. We propose a biologically interpretable deep learning model that integrates genomic data and pathological images, not only for improving survival predictive performance but also identifying genetic and pathological patterns that cause different survival of patients. Our model consists of genome/pathology/demography-specific layers, each of which provides biological interpretability. In particular, we adapt our previous pathway-based sparse deep neural network, named Cox-PASNet, for the genome-specific layers. We propose a novel patch-wise texture-based convolutional neural network with a patch aggregation strategy to extract survival-discriminative features without manual annotation for pathology-specific layers. Survival-discriminative features are extracted from a pre-trained deep learning model with uncensored data, and the features are aggregated from multiple patches of a whole slide image. Finally, the high-level representations of genomic and pathological data along with age are introduced to a shared layer that estimates Prognostic Index (PI) in a Cox proportional-hazards regression model. We examined gene expression data and pathological images of Glioblastoma Multiforme (GBM), downloaded from The Cancer Genome Atlas (TCGA) and The Cancer Imaging Archive (TCIA), to assess our proposed model. The proposed model achieved 0.67 of C-index, which is higher than the results of recent reports with only pathological images of TCGA GBM data (0.64 of C-index) and Cox-PASNet (0.63 of C-index). More importantly, our proposed integrative deep learning model can identify genetic and pathological prognostic factors simultaneously associated with patients' survival. We will demonstrate how our integrative model can represent a complex biological system with multiple types of data and discuss a new finding of genetic and pathological patterns inferred from our model.

## PgmNr 1017: The Reactome Pathway Knowledgebase and ReactomeFIViz app.

Reactome (<https://reactome.org>) is an open-access, open-source, open-data, open-graphics, curated and peer-reviewed knowledgebase that stores full descriptions of pathways and biological processes. Geneticists, clinicians, molecular biologists, bioinformaticians and systems biologists use Reactome to interpret high-throughput experimental datasets, develop novel algorithms for data mining and visualization, and build predictive models of normal and abnormal pathways. Recent extensions of our data model accommodate the annotation of drug interactions and their function in disease processes. Reactome pathways currently cover over half of the translated portion of the genome, and are available through our web site for browsing, downloading, and manipulation by in-house and third-party analysis tools.

The ReactomeFIViz Cytoscape app provides several analytical tools built upon the Reactome Functional Interaction network. A recent extension of the Reactome FI network, with updated protein-protein interactions and other pair-wise protein or gene relationships, has increased the FI network to covering just over 13,000 human proteins and over 431,000 interactions. We have expanded our current Probabilistic Graphical Models (PGM) for Reactome pathways to support an inference of pathway impacts of somatic mutations affecting protein structures in tumours. Moreover, we have established an approach to convert Reactome pathways into Boolean networks (BN) and have adapted a fuzzy logic model to perform pathway simulation to infer drug and somatic mutation impact. Both PGM- and BN-based pathway modeling approaches have been incorporated into the ReactomeFIViz app. to help users to perform PGM- and BN-based pathway impact analysis.

## **PgmNr 1018: iCOALAA-lite: An R-Shiny application for interactive correlation and liquid association analysis of multi-omics pan-cancer data.**

In recent years, pan-cancer analysis has demonstrated its powerful use in identifying the commonality and dissimilarities among the alternation in the key biological processes across tumor types. The Cancer Genome Atlas (TCGA) and Pan-Cancer Atlas have generated a rich resource of multi-omics data processed by the standardized procedure with batch corrections. Due to the substantial case-to-case heterogeneity, some associations between molecular features and clinical features are expected to be preserved only in a subgroup of cases. An interactive analysis and visualization tool guided by real-time/precomputed statistics, and biological knowledgebases will help investigators better explore and interpret the complex association in massive multi-omics pan-cancer databases. We have developed the R-shiny application iCOALAA-lite to serve this purpose. This application allows users to select subgroups of cases of their interest based on the clinical and molecular features for the subsequent analysis. Precomputed statistics within each tumor type are provided for the preliminary screening of molecular features and the signatures derived from Pan-Cancer Atlas. Liquid association, a general statistical notion depicting the change in the covariation of two variables as a third variable varies, together with the conventional correlation will be computed in real-time for the second-stage feature selection. It allows users to perform modern visualization methods to visualize the case-to-case and feature-to-feature similarities in an interactive manner. This R-Shiny application and the precomputed statistics will be hosted as a web-based application. The R-Shiny application will also be released individually as a package for users to analysis their in-house data locally.

## PgmNr 1019: Cross-gene interactions of somatic mutations in transcriptomic system of cancer pathways.

**Authors:**

S. Jang; B. Han

[View Session](#) [Add to Schedule](#)**Affiliation:** Department of Biomedical Sciences, Seoul National University, Korea

---

Genetic mutations are known to affect gene expressions of downstream genes in the cancer pathways. However, the comprehensive view of regulatory systems of cancers is still yet to be uncovered. Recently, there were efforts to interpret the interplays between the cancer somatic mutations and the expression levels of genes in cancer pathways. These studies showed that somatic mutations can affect the gene expressions of the gene itself (cis) and other genes (trans), constructing a graph of regulatory effects which describe genomic effects on the transcriptome. Here, we found there exist strong cross-gene interactions in the transcriptomic system of cancer pathways. Specifically, we found that, if we consider two genes connected in the pathway (signal-sending gene and signal-receiving gene), there were interplays between the trans-effects of somatic mutations of signal-sending gene and the cis mutations of the signal-receiving genes. We analyzed key signaling pathways of cancer using the TCGA data to show the existence of cross-gene interactions. Our observations suggested that the regulatory systems of cancers can hardly be explained by the standard additive model.

# PgmNr 1020: An integrative pathway activity inference method using directed random walks for predicting survival in bladder cancer.

---

Urologic cancers include prostate, kidney, testicular, and bladder cancer with common genetic architecture in different types. To better understand the molecular features of urologic cancers, a comprehensive analysis using multi-omics data has been conducted. Additionally, a pathway activity inference method has been developed to facilitate the integrative effects of multiple genes. However, one of the limitations of the existing pathway activity inference approaches is to target a single genomic profile alone. In this respect, we have recently proposed a novel integrative analysis approach using directed random walk-based pathway activity inference method and demonstrated that it not only contributed to a higher survival group classification performance and also successfully reflected the combined effect of genes. In this study, we integrated multi-omics data to infer pathway activities for predicting survival outcome in bladder cancer. To reflect the interaction effects of genes, we designed a directed gene-gene graph using pathway information by assigning interactions between genes in multiple layers of networks. The proposed method selects cooperative driver pathways and predicts survival outcome using Lasso-Cox model. As a proof-of-concept study, multi-omics datasets, including RNA-Seq, DNA methylation, and copy number data, for bladder cancer were obtained from the Cancer Genome Atlas (TCGA) data. In the experiments, the proposed integrative method on three genomic profiles was evaluated with respect to the survival outcome prediction performance and the prioritized genes and pathways for survival of bladder cancer patients. In the results, the proposed integrative approach achieved average 7.7% improvements (C-index) of survival prediction performance than that of a single genomic profile. The integrative approach also identified 13 pathways as predictive prognostic features in bladder cancer, which are not found from a single genomic profile. They include 4 amino acid metabolism related pathways, 3 DNA repair pathways, and 6 cell proliferation, and growth related pathways. Our results showed that the integrative approach guided by pathway information not only improves survival outcome prediction performance, but also provides better biological insights into the pathways and genes prioritized by the model in an integrated view. This study warrants further exploration in other urologic cancer types to identify common/cancer-specific driver pathways.

## PgmNr 1021: Enabling big data analysis through cloud-based tools in the Cancer Research Data Commons.

**Authors:**

E. Kim; T. Davidsen; J. Klemm; A. Dearry; T. Kerlavage

[View Session](#) [Add to Schedule](#)

**Affiliation:** Cancer Informatics Branch, CBIIT/NCI/NIH, Rockville, Maryland.

---

Basic and clinical research in human disease is increasingly being focused on generation of rich datasets to identify molecular underpinnings of disease. NIH and NCI have supported numerous programs including The Cancer Genome Atlas (TCGA) and Clinical Proteomic Tumor Atlas Consortium (CPTAC) to generate a wealth of data to be leveraged by the research and clinical communities to better understand diseases and ultimately inform development of better treatments and prevention tools. However, we are still limited in our ability to draw insights and meaningful interpretations from these rich datasets, which include multi-omics, imaging, and clinical data, by challenges in integration across disparate datasets.

To progress towards this goal, the research community will need to access, integrate, and analyze multi-modal data, including genomics, proteomics, imaging data, clinical treatment/outcomes, and population-based data. Investment in the informatics infrastructure to fully leverage these diverse data types is imperative and was called out as a priority by the Cancer Moonshot<sup>SM</sup> Blue Ribbon Panel. To this end, NCI has initiated development of a Cancer Research Data Commons (CRDC) to provide access to interoperable data repositories, analysis tools, and workspaces. The vision for the CRDC is a virtual, expandable infrastructure that provides secure access to diverse data types, allowing users to analyze, share, and store results, leveraging the storage and elastic compute of the cloud. The CRDC is built upon Data Commons Framework (DCF) which provides a core set of modular, reusable components to rapidly develop data nodes for the CRDC. Currently the CRDC hosts the Genomics Data Commons (GDC) and the Proteomics Data Commons (PDC), while additional nodes (e.g., Imaging Data Commons, Integrated Canine Data Commons) are in development. In addition, the CRDC offers three NCI Cloud Resources that provide innovative methods to query, visualize, and analyze data by making best practice tools and pipelines readily available. These cloud-based systems eliminate the need for researchers to download and store large-scale datasets by allowing them to bring bioinformatics tools to the data either by integrating with CRs or by connecting via DCF. They also offer the computational capacity to enable big data analysis. The NCI CRDC nodes, DCF, and Cloud Resources are currently available to the scientific community to accelerate research and promote new discoveries.

## PgmNr 1022: An investigation of germline variants as the determinants of somatic mutations' patterns on cancers.

---

With advances of sequencing technologies, in-depth studies of the somatic mutations for various cancers have been realized and identified some germline mutations that are related to the somatic mutations. However, a detailed study on such relations needs to overcome their sparsity and insufficient effect.

Here, we conducted an extensive study of the large-scale cancer dataset with both somatic and germline mutations, using two concepts to overcome the limitations: the mutational signature and novel pathway-based method that integrates biological information and statistical model. Using the mutational signatures from the somatic mutations and their corresponding germline mutations from 2,588 whole genomes, we conducted association studies between those mutational signatures and germline mutations.

Based on cancer-wise and signature-wise approaches, our association studies identified statistically significant signals between five genes and multiple signatures. Literature searches support their relationship of the corresponding cancer types.

Additional studies on those genes identified strong functional relationship on epigenetic regulation, which suggests the potential evidence on the mutational signatures with no proposed etiology.

In summary, we successfully conducted our preliminary study by identifying associations between germline and somatic mutations, with the novel methods that can overcome the current limitations.

## PgmNr 1023: QC measurements of exome chip sequence data in a family-based study.

---

Quality control (QC) is an important step in sequence data analysis. In VCF files, many genotype calling quality measurements are reported at the variant level and the variant-and-sample level. Common practice is to drop variants based on pre-set thresholds of several key QC measurements, including QD, MQ, FS, SOR, MQRankSum, and ReadPosRankSum at the variant level. In addition, genotypes at specific loci should be set to missing if the variant-and-sample level measurements are poor. Pedigree information can be used as the third step of data cleaning, eliminating genotypes causing Mendelian inconsistencies.

In a linkage analysis of small intestinal carcinoid tumors, we performed QC on exome sequence data from a pedigree of 34 individuals. In this work, we reported the summary statistics on the genotype calling QC measurements of 219,742 variants. We found that the QC measurements have a wide range of variation across different chromosomes. Using hard-filtering based on recommended thresholds, 182,132 (~83%) variants were kept. We found that the current QC thresholds cannot remove all the poorly typed genotypes. Among the retained variants, 21% incurred at least one Mendelian error. Given the 18 informative child-parent trios in the pedigree and the 28,114 variants, this is a rate of ~1.9% per trio, per variant. Extensive and iterative cleaning of Mendelian errors are needed after data filtering by QC measures alone. In conclusion, the current hard filtering thresholds are inadequate and are improved by Mendelian inconsistency checks.

## PgmNr 1024: *Ab initio* spillover compensation in CyTOF data.

### Authors:

---

The mass cytometry (CyTOF) technology, which employs metal-isotope-tagged monoclonal antibodies to measure proteomic marker expressions in single cells, has been widely used to characterize cellular heterogeneity. Due to technological limitation, the intensity measured in a channel can be affected by neighboring channels. Although generally minor, such spillover effects can substantially limit the accuracy of clustering and lineage tracing. The CATALYST approach (PMID:29605184) can reduce spillover, but it requires the use of additional control beads, which increases the cost.

Here, we present a novel computational method that autonomously compensates the spillover effects in a CyTOF dataset without using any control beads. Our method utilizes knowledge-guided modeling and statistical techniques such as finite mixture modeling and sequential quadratic programming to infer the optimal compensation matrix and perform the correction.

We evaluated our method using four CyTOF datasets obtained from C57BL/6J mouse bone marrow, healthy human bone marrow, human peripheral blood, and chronic lymphocytic leukemia patient samples, respectively. In two datasets, our method resulted in improved clustering consistency with manual gating results. In the other two datasets, our method led to the discovery of novel subpopulations expressing functionally meaningful, cluster-specific markers.

The tool we developed in R will greatly facilitate large-scale cellular profiling of tumor immune microenvironment and development of novel immunotherapy.

# PgmNr 1025: A comparison of eVai, CADD and VVP variant prediction results on the ICR639 hereditary cancer dataset.

**Authors:**

G. Nicora <sup>1</sup>; I. Limongelli <sup>2</sup>; S. Zucca <sup>2</sup>; R. Santolisier <sup>1</sup>; P. Magni <sup>1</sup>; R. Bellazzi <sup>1</sup>

[View Session](#) [Add to Schedule](#)

**Affiliations:**

1) University of Pavia, Via Ferrata 5, 27100 Pavia, Italy; 2) enGenome S.r.l., Via Ferrata 5, 27100 Pavia, Italy

---

**Background**

Genomic variant interpretation for the diagnosis of hereditary diseases is a complex process and several bioinformatics software to support geneticists have been developed in the last few years. Strategies generally include variant filtering algorithms based on information from reference populations and other omics databases, computation of a score of deleteriousness assigned to each variant, or a combination of them.

The Expert VARIant Interpreter (eVai.engenome.com, PMID: 30298955) classifies variants based on ACMG/AMP guidelines and assigns each variant a score for pathogenicity prioritization. Performances in variant prioritization have been compared to two currently available hypothesis-free tools: CADD (PMID: 30371827) and VVP (PMID:29463208). Benchmark analysis was performed exploiting ICR639 validation set of cancer predisposition (PMID:30175241).

**Methods**

ICR639 hereditary cancer dataset was downloaded from European Genome-phenome Archive. It includes 639 VCF files from individuals tested for cancer predisposition genes (Illumina TruSight Cancer panel); 645 pathogenic variants in total (339 indels, including 16 complex indels and 24 indels longer than 5 bps), 232 SNVs and 74 exon copy number variants (excluded from this study). VCF files of each samples were analyzed with eVai, CADD and VVP tools as suggested by the guidelines and manuals. For each tool, a threshold was established according to specific tools guidelines to consider a variant as pathogenic (eVai score >3, CADD score >20, VVP score > 57). Commonly classification metrics were then applied for each tool to test classification performances with respect to known pathogenic variants such as accuracy (ACC), F1, ROC and PRC. Moreover, the Normalized Discounted Cumulative Gain (NDCG) ratio was used to identify the most performing tool in prioritizing pathogenic variants in the top 20 variant list: the more this score tends to one, the better the prioritization is among the first 20 positions.

**Results**

eVai resulted to be the best performing tool, with classification metrics higher than CADD and VVP. Classification accuracy and F1 score were higher for eVai (ACC=0.998, F1=0.416) respect to VAAST (ACC=0.988, F1=0.065) and VVP (ACC=0.860, F1=0.006). ROC and PRC AUCs were higher for eVai (ROC-AUC=0.999, PRC-AUC=0.803) compared with CADD (ROC-AUC=0.996, PRC-AUC=0.266) and VVP (ROC-AUC=0.985, PRC-AUC=0.334). Finally, NDCG-20 value was 0.956 for eVai, 0.619 for CADD and 0.436 for VVP.

## PgmNr 1026: Allelic-imbalance in DNA inferred from RNA-seq data using a haplotype-based method.

---

There is a growing interest in using RNA-seq data to identify somatic DNA mutations, particularly for scenarios when analyses of DNA are not feasible. Recently, this approach was used to characterize somatic mutations in The Genotype-Tissue Expression (GTEx) data for a comprehensive view of mosaicism across human tissues, primarily focusing on point mutations. Mutation detection in such settings is challenging due to the non-random distribution of expressed genes across tissues, and differential expression rates resulting in uneven coverage. In this work we sought to overcome some of these challenges for inference of acquired chromosomal alterations (allelic imbalance; AI) from RNA-seq by using a haplotype-based approach.

We obtained SNP-array, whole-exome sequencing (WES), and RNA-seq data from 279 lung adenocarcinoma (LUAD) participants in The Cancer Genome Atlas (TCGA). For AI detection, we applied hapLOHseq to WES and RNA-seq data, and hapLOH to SNP arrays. We considered AI events detected in the SNP array data as a gold standard, for the purposes of scoring our approach. Overall, our method tailored to RNA-seq data performed nearly as well as inference of AI from WES. Evaluating concordance at each SNP marker, we achieve sensitivity estimates of 86% and 83% in WES and RNA-seq, respectively, and corresponding specificity estimates of 87% and 77%.

AI calls in the RNA set that are not present in the gold standard set ("RNA-only events") could be false positive calls in the RNA, false negative calls in the gold standard set, or could represent AI patterns exclusive to RNA. To more confidently identify RNA-only AI candidates, we explicitly tested these specific regions for AI in the WES and SNP array data using a binomial test and excluding any segments with p-values < .10. After this filter, RNA-only events comprised 8% of the RNA-seq derived calls. We observed an apparent enrichment of these, in absolute counts and by application of GRIN ( $q < 1e-9$ ), on chromosomes 2, 7, and 10.

Our results suggest that detection of AI in RNA-seq may constitute a useful surrogate for detection of DNA-level AI in resource-limited settings. Currently, we are benchmarking AI detection in WES and RNA-seq in additional cancer sites from the TCGA, and further investigating technical and biological factors underlying the inferred RNA-only events, as these may offer insights into mechanisms of long-range epigenetic regulation.

## PgmNr 1027: Development of a new microsatellite instability defining tool using whole exome sequencing data.

### Authors:

---

**Background:** Microsatellite instability (MSI) is an important marker estimating the prognosis and determining the direction of therapy in gastrointestinal cancer patients. Polymerase chain reaction (PCR) is currently a gold standard to define MSI, but it takes time and has a possibility of misreading. We intended to develop a new tool to define MSI using next-generation sequencing (NGS) data.

**Methods:** To develop the MSI defining tool, we used whole exome sequencing data of 517 colorectal cancers in The Cancer Genome Atlas (TCGA) with MSI information as a training set. Through the analysis of diverse features such as single variant and copy number variants called from the colorectal cancer data set, we developed a NGS-based MSI defining tool based on the decision tree, one of the machine learning methods.

**Results:** When we applied our system to the 517 TCGA colorectal cancers (94 MSI and 423 MSS), the performances of defining MSI are as follows: sensitivity: 0.947, specificity: 0.991, accuracy: 0.983. We validated this tool with 23 colorectal cancer whole exome sequencing data generated in our lab, and their MSI status was confirmed by pentaplex PCR (8 MSI and 15 MSS). As a result, our tool discriminated the 8 MSI and 15 MSS cases exactly as the pentaplex PCR results.

**Conclusions:** Our NGS-based MSI defining tool is possible to execute by a simple command in the Linux OS. This tool showed good performance to discriminate MSI and MSS in both TCGA and our colorectal cancer data. Considering that NGS analysis became an ordinary test in the clinical field for gastrointestinal cancer diagnosis, this system would be a useful tool for defining MSI status without PCR analysis.

## PgmNr 1028: Detecting and refining low frequency somatic variants from gene panel-based next-generation sequencing.

---

Targeted cancer gene panel sequencing is the most prevalent NGS implementation in clinic. Despite its significance, major challenges exist in accurate detection of somatic mutations, especially of those with low allele frequency (LAF). As LAF variants often occur in a small proportion of the measured cells, the allele frequency can't be theatrically modelled. Also, cancer gene panel sequencing usually lacks matched normal in practice, which increases the error rate in defining variants as somatic origin. To improve the detection accuracy, we systematically evaluated four open source somatic SNV callers in both pair- and tumor-only mode and another two in either mode; multiple filtering strategies were further assessed to refine variants. We first computationally assembled benchmarking gene panels from AML31 sequencing data (dbGAP phs00159) with 268 cancer genes, including a primary tumor, its subsequent relapse, and a matched normal sample. The gold standard mutations (PMID: 26645048) were used as the reference set, including 25 somatic mutations in primary tumor (VAF: 0.08-49.5%) and 18 in relapse tumor (VAF: 0.16-22.4%). Using pair-mode in primary tumors, Varscan identified ten (MAF  $\geq$  0.39%), vardict identified seven (MAF  $\geq$  1.49%), and Lofreq, mutect2 and bassovar each identified six (MAF  $\geq$  11.8%) mutations, which all dropped to six after applying the common filters based on variant quality and MAF in public germline databases (1000G, ExAC and ESP). In relapse tumor that has lower sequencing depth, Varscan identified ten (MAF  $\geq$  0.24%), vardict identified five (MAF  $\geq$  2.84%), and the other three each identified 3-4 (MAF  $\geq$  6.8%) mutations, which were reduced to four for Varscan, verdict and lofreq (MAF  $\geq$  6.8%) and 2-3 for other two (MAF  $\geq$  14.3%) after filtering. Using single-mode in primary tumors, where bassovar was replaced with GATK UnifiedGenotyper, all five callers identified six mutations (VAF: 11.8-50.43%) and missed LAF variants. In relapse tumors, the five callers identified 4-5 mutations; mutect2 missed two and verdict missed one variant after the filtering. However, mutect2 reported less total variants than other callers. We further checked the possible source of false positives and found that over 60% and 20% of them were located in genes with certain characteristics of domains or having homologous events, respectively. Our analysis argues for the need to develop a more optimal strategy to reduce false calls, such as machine learning approach.

## PgmNr 1029: BioMethyl: An R package for biological interpretation of DNA methylation data.

---

**Background:** The accumulation of publicly available DNA methylation data sets has resulted in the need for tools to interpret the specific cellular phenotypes in bulk tissue data. Current approaches use either single differentially methylated CpG sites or differentially methylated regions that map to genes. However, these approaches may introduce biases in downstream analyses of biological interpretation, because of the variability in gene length. There is a lack of approaches to interpret DNA methylation effectively. Therefore, we have developed computational models to provide biological interpretation of DNA methylation (BioMethyl) in the context of The Cancer Genome Atlas (TCGA).

**Method:** We downloaded RNA-seq and DNA methylation data for all 37 TCGA cancer types from Firehose (<https://gdac.broadinstitute.org/>, Nov, 2016). We fit models to the cancer types that contained more than 50 samples with both RNA-seq and DNA methylation profiles. We trained each BioMethyl model using linear regression to capture the association between gene expression and DNA methylation for each cancer types. To automatically identify enriched pathways, GSEA R script method “GSEA.1.0.R” was deployed in BioMethyl package to perform enrichment analysis with default settings

**Results:** Using breast cancer as an example, BioMethyl shows high consistency in the identification of enriched biological pathways from DNA methylation data compared to the results calculated from RNA sequencing data. We find that 12 out of 14 pathways identified by BioMethyl are shared with those by using RNA-seq data, with a Jaccard score 0.8 for estrogen receptor (ER) positive samples. For ER negative samples, three pathways are shared in the two enrichments with a slight lower similarity (Jaccard score=0.6). Using BioMethyl, we can successfully identify those hidden biological pathways in DNA methylation data when gene expression profile is lacking. We also shown that BioMethyl is able to apply to non-cancer diseases.

**Conclusion:** We illustrate that BioMethyl utilizes the complete DNA methylation data for a given cancer type to reflect corresponding gene expression profiles and performs pathway enrichment analyses, providing unique biological insight. BioMethyl R package is freely available in the GitHub repository (<https://github.com/yuewangpanda/BioMethyl>).

## PgmNr 1030: Transcriptomic profiling and deconvolution for biomarker identification and immune cell infiltration estimation in colon mucosa of Lynch syndrome patients from a phase Ib chemo-preventive trial of naproxen.

---

**Background** Lynch Syndrome (LS) is one of the most prevalent cancer-prone hereditary conditions. It is characterized by predisposition to a wide spectrum of cancers, primarily colorectal cancer (CRC) and endometrial cancer (EC). Patients with LS are more likely to be diagnosed with cancer in a young age and have up to 70-80% risk of developing CRC during their life time. Naproxen is a non-steroidal anti-inflammatory drugs (NSAID) that is widely used for treatment of pain and has an excellent safety profile. Preclinical study using a genetically engineered LS mouse model (VC-MSH2-LoxP) has shown that Naproxen is the most effective agent among a selected panel of NSAIDs in preventing colorectal tumors. The present phase Ib clinical trial was designed to assess the safety profile and tolerability of long-term chemo-preventive usage of Naproxen, as well as to identify noncanonical molecular biomarkers and their associated possible functions via transcriptomic profiling and immune deconvolution. **Methods** Patients were randomly assigned to Naproxen 220 mg qd (LD), 440 mg qd (HD) or placebo (PL) once daily administered for 6 months. Biopsy of colon mucosa was obtained at the time of enrollment (pretreatment) and after 6 months of Naproxen administration (posttreatment). RNA was extracted and sequenced at Sequencing and Microarray Facility (SMF) at MD Anderson. Sequencing reads was aligned to UCSC hg19 reference genome using spliced aligner STAR. Whole transcriptome was quantified using *rsem-calculate-expression*. Differential expression, pathway analysis and immune deconvolution were performed using R. **Results** From 80 enrolled patients, 23/28 in placebo group, 18/27 in LD Naproxen group, and 17/25 in HD Naproxen group completed the study, and their RNASeq data were used for bioinformatics analyses. 0, 70 and 120 differentially expressed genes were found in PL, LD and HD posttreatment vs pretreatment at FDR=0.1 respectively. Pathway analysis revealed significant enrichment of immune/chemokine related pathways in both LD and HD Naproxen groups. Differential infiltration fractions of various immune cell types were found in LD and HD posttreatment groups. **Conclusion** Long-term

Chemoprevention with Naproxen for a total of 6 months was generally well-tolerated. Naproxen may exert chemo-preventive effect by modulating infiltration of certain immune cell types into colon mucosa.

## PgmNr 1031: gcMECM: Graph-based clustering of mutual exclusivity of cancer mutations.

Advancement of next-generation sequencing technology has transformed the study of cancer genome. Whole-genome or whole-exome measurements of somatic mutations in large numbers of cancer genomes are now a reality. With the comprehensive mutation landscape, tremendous progress has been made to identify cancer driver genes through detection of highly recurrent mutations called “significantly mutated genes”, which are limited to the highly mutated genes. To provide therapeutic options for most patients, it will, therefore, be critical to identify and understand the pathway-level implications of all genes mutated at low frequencies. The reason is that cancer genes tend to be altered in a limited number of pathways related to cell division, differentiation, survival, and genome maintenance. Here we present a novel tool that combines Louvain Method for community detection, mutation association, and gene interaction to identify the mutually exclusively mutated gene sub-networks. The sub-networks reveal crucial genes in the canonical pathway and discover new cancer-relevant genes, which are used to build better prediction models of response and survival. We analyzed mutation data in thirty-three cancer types from The Cancer Genome Atlas (TCGA) and identified sub-networks common in multiple cancer types with improved survival prediction comparing to the single gene method. gcMECM also provides informative visualization functionality of mutual exclusivity and networks.

## PgmNr 1032: Reducing false positive somatic variant calls arising from breakpoint-associated alignment artifacts.

Somatic variant calling in cancer samples is routinely done using short read next generation sequencing (NGS) technologies. False positive somatic variant calls from tumor samples can arise from a wide range of artifacts in NGS reads and read alignments. These include spurious calls from homopolymer regions, low-complexity regions, microsatellite, regions with pseudogene counterparts, reads with extreme strand bias. Of particular interest in tumor sample analysis are the false positive caused by breakpoint-associated short read alignment artifacts when a duplicated sequence is inserted or deleted with respect to the reference genome. In these cases, if the end of a read does not have enough flanking sequence from the neighboring non-duplicated region, the read ends can be incorrectly aligned to the reference genome, leading to spurious somatic variant calls.

In tumor sample analysis, FMS-like tyrosine kinase 3 (FLT3, a proto-oncogene) internal tandem duplications (ITDs) are detected in a quarter of the patients with acute myeloid leukemia (AML). FLT3 ITDs are strongly linked to bad prognosis, higher risk of relapse and lower survival rate. In samples with FLT3 ITDs, the reads ending with a short sequence stretch in the ITDs often aligns with the nearby genomic region, leading to false positive calls. False positives can also arise for several other tumor-associated genes with duplicated segments (e.g., CEBPA, CALR), where reads with the deletion of one of the duplicated segments often align incorrectly. A computational protocol has been developed to address this issue, resulting in significantly reduced the false positive calls due to breakpoint-associated artifacts in NGS-based somatic variant calls.

This approach performs multiple iterations of read realignment by the ABRA tool in regions with INDELs, DUPs and structural variants ((e.g., for FLT3 ITDs), where imperfect read alignment is more likely to happen. Use of the re-aligned BAM files not only reduces the false positive calls due to misalignment near the ends of the reads, but also improves sensitivity for detection of true somatic mutations since more reads harboring the duplicated region are correctly aligned. The protocol for tumor sample analysis has been implemented and it has eliminated almost all false positives due to breakpoint-associated false positive calls.

## PgmNr 1033: Construction of circRNA-miRNA-mRNA networks in the pathology of gastric cancer based on integrated bioinformatics strategy.

---

Gastric cancer (GC) is a prevalence malignant neoplasm of the digestive system. The aim of the present study was to identify key genes, micro RNAs (miRNA) and circular RNAs (circRNAs) in GC and understanding the potential molecular mechanism of GC by constructing a circRNA-miRNA-mRNA network. With the threshold of the adjusted false discovery rate (FDR) P-value of  $<0.01$  and a log fold-change ( $\log FC$ )  $>1$ , 751, 481 and 3,340 mRNAs from GSE63089, GSE27342 and STAD (from TCGA), 111, 233 and 130 miRNAs from GSE63089, GSE27342 and STAD and with predefined criteria (a log fold-change ( $\log FC$ )  $>2$ ), 33 circRNAs from GSE78092 were differentially expressed in GC. By intersecting the 51 overlapping miRNA target genes and the 233 overlapping DE mRNA between GSE63089, GSE27342 and STAD and 12 target genes of miRNA sponged by DE circRNAs, we acquired 290 overlapped genes. Using the DAVID database (v. 6.8), it demonstrates that the 290 genes were mainly enriched in the extracellular space and proteinaceous extracellular matrix and were involved in the mitotic nuclear division, collagen catabolic process, and participated in the regulation of the Cell cycle pathway. Interactions between differentially expressed miRNAs, mRNAs and circRNA were predicted via miRWalk3.0 and CircInteractome. Co-expression of miRNAs, circRNA, and mRNAs was selected to construct circRNA-miRNA-mRNA interaction networks. A protein-protein interaction network based on the 290 genes was established, 12 hub genes (*CDK1*, *CCNA2*, *CCNB1*, *ESR1*, *BUB1*, *IGF1*, *KIF11*, *TOP2A*, *CHEK1*, *PLK1*, *AURKA*, *MKI67*, *KIF20A*, and *CDC6*) determined from the network. The results were visualized in Cytoscape software (v. 3.7.1). DGIdb database predicted 39 small molecules as the possible drugs for treating GC, the identified target network was visualized using STITCH (version 5.0). In summary, we identified key genes, pathways, and constructed circRNA-miRNA-mRNA networks in GC by integrated bioinformatics analysis. These data may provide new insights into GC pathogenesis and useful information for the utility of personalized therapy in the future.

## PgmNr 1034: Paired DNA and RNA sequencing illuminates the extent of allele-specific expression in multiple myeloma and identifies impacted pathways.

In the human genome, allele-specific expression (ASE) is the differential expression of two alleles. Further, it has been shown that when ASE occurs in cancer it is often linked to driver genes. However, very little work has been performed in this area as they relate to certain specific cancer types. In multiple myeloma (MM), a hematological malignancy, ASE has not been fully investigated. In this work, we look at a large dataset of MM samples with paired DNA and RNA data to characterize the ASE present.

The dataset was composed of 589 newly diagnosed MM samples from the Multiple Myeloma Research Foundation CoMMpass study. Each sample had paired whole-exome sequencing and RNA-Seq expression data. Strelka2 was used to identify mutations. We used cisASE to identify somatic allele-specific expression at the gene level. Read positions were kept based on default cisASE recommendations. We identified a median of 67 (range 18-1937) genes containing at least one mutation per sample. Using a significance level of  $p < 0.01$  identified a median of 33 (range 4-633) genes with ASE per sample.

All major translocation subgroups in MM were identified as having some degree of ASE and were significantly associated (Fisher's exact;  $P < 0.01$ ) with the genes impacted by the translocation events in those samples. These include *FGFR3* in t(4;14) (100%,  $n=27/27$ ), *CCND1* in t(11;14) (80%,  $n=16/20$ ), *CCND3* in t(6;14) (66%,  $n=2/3$ ), *MAF* in t(14;16) (90%,  $n=9/10$ ) and *MAFB* in t(14;20) (100%,  $n=4/4$ ).

We observed 169 genes with overexpressed mutated alleles (significant and RNA variant frequency  $> 75\%$ ) that were recurrently present in two or more samples. These genes were significantly implicated in a wide variety of pathways including many cancer types and key pathways, such as the p53 and PI3K-Akt signaling pathway. Next, using published results of 63 MM driver genes, we identified overexpressed mutated alleles in 33 of them including: *CCND1* 80% ( $n=16/20$ ), *DIS3* 52% ( $n=15/29$ ), *FGFR3* 37% ( $n=10/27$ ), *NRAS* 18% ( $n=9/49$ ), *TP53* 56% ( $n=9/16$ ), *TRAF3* 64% ( $n=9/14$ ), *MAF* 80% ( $n=8/10$ ), *TENT5C* 24% ( $n=7/29$ ), *TGDS* 100% ( $n=7/7$ ), *MAX* 50% ( $n=5/10$ ), *MAFB* 100% ( $n=4/4$ ), *ATM* 27% ( $n=3/11$ ), *SAMHD1* 27% ( $n=3/11$ ), and *XBP1* 23% ( $n=3/13$ ).

Our results show that ASE is a frequent event in MM and has the potential to further increase our

understanding and identify novel therapeutic targets of this malignancy.

## PgmNr 1035: Transcriptomic deconvolution reveals cell-type specific signals across cancer types.

---

Most tumors consist of a variable proportion of malignant and nonmalignant cells including epithelial cells, fibroblasts, and infiltrating immune cells, which confounds biomarker studies of response to treatment. Deconvolution approaches have been developed for transcriptomes to address this heterogeneity in tumor samples.

We developed a new deconvolution framework, *DeMixT*, (Bioconductor R package) for the more accurate and efficient transcriptome deconvolution of high dimensional data from mixtures of more than two components. Besides estimating mixing proportions, *DeMixT* uniquely provides per-gene per-sample expression levels of each mixture component. To address multiple sources of variations observed in real data, we proposed a novel profile likelihood-based (PL) method to adaptively select a gene set, with a high signal-to-noise ratio, for the proportion estimation. This adaptive gene set selection substantially improves the estimation accuracy of both proportions and cell-type specific gene expression levels for the entire transcriptome.

We applied the PL-enabled *DeMixT* in two component modes (tumor and stroma) to 16 solid tumor types from The Cancer Genome Atlas (TCGA) database: BLCA, BRCA, COAD, HNSC, KICH, KIRC, KIRP, LIHC, LUAD, LUSC, PAAD, PRAD, READ, STAD, THCA, UCEC. We compared results of pathway and survival analyses from the original mixed expression data with the deconvolved expression data. We also performed three-component deconvolution (tumor, stroma and immune) for 5 cancer types (BLCA, COAD, PRAD, HNSC, KIRC) without requiring data from the immune profiles. For these 16 cancer types, we obtained tumor purities, immune proportions (if available) and the deconvolved individual-level gene expression. The mean number of genes (per cancer type) recovered was 13,239 (sd=886), and the mean number of tumor deconvolved samples was 371 (sd=201). Downstream analyses were performed and biological findings from previous literature were validated using deconvolved expressions but not the original mixed expressions. Novel cell-type specific pathway activities were identified. Immune proportions were shown to be highly predictive and of good prognosis in multiple cancer types.

We provide comprehensive transcriptome deconvolution outputs for the TCGA datasets which will enable investigation of the tumor-stroma-immune microenvironment and elucidate new biological mechanisms for cancer.

## PgmNr 1036: Chromosomal allelic imbalances in lymph nodes of lung cancer patients.

---

The lymphatic system is a component of cancer metastasis, serving as a gateway to organs distant to a primary malignancy. To attempt to understand genomic mechanisms associated with metastasis, we sought to study the DNA alterations present in lymph nodes (LNs) derived from patients with early stage lung cancer. Traditional challenges to such an endeavour include access to tissues and the low mutant cell fraction expected to be exhibited in such samples.

We obtained samples from 141 lymph nodes and 27 corresponding primary tumors from 34 non-small-cell lung cancer (NSCLC) patients from a retrospective collection of specimens at MD Anderson. The LN samples were either from surgical resection or needle aspiration during endobronchial ultrasound (EBUS), a non-surgical procedure supporting assessment of the extent of tumor involvement in LN samples. Samples were genotyped via DNA microarrays (Global Screening Array, Illumina). To overcome low aberrant cell content, we applied our haplotype-based algorithm to study somatic copy number alterations (sCNAs).

We detected 317 sCNAs in LNs with tumors cells detected by cytopathology review (LN+) and 81 alterations in LNs without tumor detected (LN-). Chromosomes 2 and 12 demonstrated the most sCNAs in LN+ samples, while chromosome 3 and 8 were most prevalent among LN-. 19 of the 42 LN+ samples had sCNAs that were shared with the corresponding primary tumors. However, only 12 of the 99 LN- samples had shared sCNAs. Additionally, we identified “mirrored” alterations in 7 patients by statistically testing whether the over-represented parental haplotypes matched between overlapping alterations in LN and tumors, indicating independent, convergent mutational events.

Our findings demonstrate a potential to discover chromosomal alterations in histopathologically confirmed LN- tissues; further, some of these sCNAs were found in the corresponding primary tumor. Further analyses of our data may help understand molecular alterations associated with, or critical for, metastasis. In the longer-term, our approach may offer the potential to advance or complement traditional forms of detection and diagnosis of NSCLC and LN metastasis.

## PgmNr 1037: Adaptive immune responses associated with the progression of premalignant lesions to colorectal cancer.

### Authors:

---

Colorectal cancer (CRC) progresses by the accumulation of molecular alterations, from normal epithelium to adenoma to cancer. It has been increasingly recognized that immune responses, measured by the abundance of tumor-infiltrating lymphocytes (TILs), may play a critical role in CRC etiology and prognosis and treatment response. However, immune responses in the progression of premalignant lesions to CRC is still unclear. Analyses of gene expression data can comprehensively characterize immune responses in tumor tissues. Here we systematically collected publicly available gene expression data from the Cancer Genome Atlas (TCGA) and previous literature, including the data from 118 normal colon mucosa, 243 adenoma and 2,608 cancer tissue samples. We performed bioinformatic analyses to normalize the gene expression data combining from all these tissue samples. We estimated the ImmuneScore (quantified by overall local immune activities, including B-cells, CD4+ cytotoxic T-cells, CD8+ cytotoxic T-cells and other TILs) and the abundance of each type of TIL using the xCell tool. Our results showed that the ImmuneScore consistently decreased along the continuum of carcinogenesis from the normal mucosa, to adenoma, to cancer. We also observed the same trend for B cells, CD8+ cytotoxic T-cells, CD4+ effector memory T-cells and overall T-cell densities. To explore the biological processes underlying these alterations of immune responses, we analyzed the differences of gene expression among normal colon mucosa, adenoma and cancer. Using a threshold fold change > 2 and a False Discovery Rate (FDR) < 0.05, we identified a total of 1,984 and 1,708 differentially expressed genes (DEGs) between normal mucosa and adenoma, and between adenoma and cancer, respectively. Of them, 469 genes were commonly observed in both comparisons. We further performed gene-set enrichment analysis for the above two sets of DEGs, respectively. Our results showed that immune-related signature IFN $\gamma$  response and MYC targets were significantly enriched in both gene sets, while Wnt/beta-catenin signaling and oxidative phosphorylation were specifically enriched in the former gene set, and KRAS signaling, inflammatory response and TNF- $\alpha$  signaling were significantly enriched in the latter gene set. These findings provide novel insight into the alterations of immune responses and the related biological mechanisms in the progression of premalignant lesions to CRC.

## PgmNr 1038: Modeling aneuploidy evolution in tumor single cells reveals genetic divergence and functional convergence.

Aneuploidy is one of the major mechanisms for tumor clonal evolution. It can lead to a burst of diverse genomic profiles, enabling rapid adaption and evolution. Although studies based primarily on multi-regional bulk-seq samples have yield valuable insights, how aneuploidy evolves amongst single cells remains elusive due partly to technological and analytical challenges. Particularly, single-cell analytical methods available to construct tumor cellular phylogenies cannot accurately represent the lineage, timing, diversity, scope and types of CNAs underlying the evolution.

We developed a novel single-cell evolutionary modeling method that can efficiently construct a rooted direct minimal aneuploidy event tree (MAET), from a population of thousands of tumor cells undergone single-cell DNA or RNA sequencing. Our algorithm dynamically infers the minimal set of CNA events required to evolve one genome to the next, providing an unbiased estimate on the CNA rate at various stages and lineages of the evolution. Evaluating our method using data simulated under various CNA rates, evolution dynamics and CNA mechanisms such as whole-genome doubling, breakage-fusion-bridge, etc. confirmed the superior applicability of our method over conventional phylogenetics methods on available single-cell data.

We examined longitudinal scDNA-seq data obtained from tens of chemoresistant triple-negative breast cancer patients and scRNA-seq data from a set of relapsed multiple myeloma patients. The MAETs constructed using our method indicated branching evolution in all the cases, with CNAs often accelerated in cells sampled from late stage samples and from lineages with alterations in DNA damage repair genes. Despite the increased genetic divergence, we found that CNAs tend to affect genes in the PI3K, TGFb, Nrfs, Hippo, and/or MYC pathways in an evolving tumor, indicating both convergent and competing evolution amongst the lineages.

Our study revealed structural, functional characteristics of aneuploidy evolution at single-cell resolution, implicated combinational therapeutics for treating aneuploid tumors, and provided a first-of-its-kind method that supports accurate evolutionary modeling in tumor single-cell data, which are becoming widely available.

## PgmNr 1039: Metagenomic bioinformatics tools for the study of microbial associations in human cancers and other human disease.

Increasingly, relationships between microbiome composition, human disease, host immune response, and genomic characterization are being studied. Metagenomics and microbial functional genomics contributes to an understanding of how different microbiomes (e.g., oral, gut, and skin) contribute to or correlate with specific cancers or disease states. Current studies include the association between the human oral microbiome and pancreatic cancer risk, as well as changes in the microbiome observed in human cancer cases including oral squamous cell carcinoma (saliva), esophageal cancer (saliva, biopsied tissue), gallbladder cancer (bile culture), colorectal cancer (feces, biopsied tissue). In addition, many human cancers are known to be driven by microorganisms such as *Helicobacter pylori*, Human papillomavirus, Epstein-Barr virus, Human immunodeficiency virus, Hepatitis B, C viruses, Human T-cell lymphotropic virus type 1, and Human herpesvirus 8. A perpetuating bottleneck is the ability to perform the analysis of microbiome data in a seamless way without the need for large computational infrastructures. Bioinformatics tools are needed to provide comprehensive microbiome analysis that reports subspecies or strain level microbial identification, antimicrobial resistance and virulence information, and comparative microbiome analysis of samples among different geographic locations, cohorts, cases, or time series.

To address these needs, CosmosID has developed a cloud-based metagenomics bioinformatics platform based on microbial and gene databases with >150,000 reference sequences. CosmosID has also analyzed tens of thousands of biological samples. The databases have been cleaned of human and other DNA contamination commonly found in public repositories and human host DNA has no effect on microbial identification. Microbiome sequencing data can simply be uploaded to the CosmosID web application where CosmosID identifies all microorganisms (bacteria, viruses, fungi, and protists) and characterizes their attributes (e.g., antibiotic resistance, virulence) in a single, universal, rapid analysis in a secure platform with version control, periodic updates, frequent addition of new features, and the ability to do both whole genome metagenomics and amplicon analysis. Both metagenomic and amplicon analysis can also be performed with command line API access. In addition to the web application, CosmosID provides bioinformatics support for customized study needs.

## PgmNr 1040: Robust foreground detection in cancer genomic read depth data.

Somatic copy number alterations (SCNAs) can drive cancer and provide therapeutic, diagnostic, and prognostic value in precision oncology. The key challenge to sensitive and precise detection of SCNAs in cancer sequencing data is “waviness” and “noise” in read depth data, which has been previously attributed to technical and biological biases introduced during library preparation and sequencing. To overcome this challenge, we present dryclean, a signal processing algorithm to optimize SCNA detection in whole genome sequencing (WGS) and targeted sequencing platforms through the modeling and subtraction of a complex background. Application of dryclean to WGS demonstrates that the primary contributor to WGS background is replication timing and the intensity of this waviness correlates with biomarkers of proliferation. Through rigorous benchmarking utilizing numerous primary tumor samples, we show that the dryclean foreground signal improves the detection of biologically significant and clinically actionable SCNAs relative to state-of-the-art algorithms across multiple sequencing assays. Applying dryclean to *in silico* dilutions simulating cell-free tumor DNA detected with WGS, WES, and targeted panel (TP), we demonstrate more than 10-fold improvement in liquid biopsy residual disease detection for breast cancer and glioblastoma compared with existing methods. Dryclean’s ability to detect subtle, yet clinically actionable signals in genomic read depth data suggest this algorithm has the potential to become a vital component of the oncologist’s armamentarium.

## PgmNr 1041: *Oncogene.iobio*: A web app for real-time, integrative examination and functional prioritization of tumor mutations.

Genetic testing and clinical tumor sequencing are rapidly becoming part of the standard of care for a large subset of cancers. At present, a scattered framework of resources, often requiring expensive hardware and heavy computational skills, exists to aid clinicians and researchers in the bioinformatic analysis process. To assist in addressing the need for a comprehensive tool that operates intuitively, and at the pace of critical therapeutic timelines, we have developed *oncogene.iobio*. Utilizing our novel *iobio* analysis ecosystem (<https://iobio.io>), *oncogene.iobio* visualizes genomic, transcriptomic, and epigenetic data to aid in the discovery of variants with the highest potential for association with the patient's cancer.

*Oncogene.iobio* consumes primary sequencing data (in bam, vcf, fasta/fastq formats) sourced from local, or cloud-based repositories. In real-time, variants are identified and annotated on a gene-by-gene basis, and prioritized using functional annotations (sourced from SNPEFF, VEP, SIFT, PolyPhen) and cancer databases (COSMIC, cBioPortal). Uniquely, *oncogene.iobio* identifies compound heterozygotes between inherited cancer-implicated variants and somatically-acquired tumor mutations, dynamically filters mutations by allele frequency, and analyzes somatic variants within areas of chromosomal CNVs or LOH. Areas with large transcriptional change or allele-specific expression are highlighted when RNAseq data is present, along with hypo- or hyper-methylated sites given bisulfate-treated DNA sequencing reads. Ranked, candidate gene lists, cancer-associated variants, and subtype-associated metadata (sourced from ICGC, cBioPortal) are provided by *oncogene.iobio* to guide users in the analysis process, and to quickly elucidate suspect loci.

With extensive integration and immediate feedback, *oncogene.iobio* aims to aid the discovery of impactful variants in oncological research and diagnostic care.

## PgmNr 1042: The landscape of *BRCA1* and *BRCA2* putative protein-truncating variants from a UK Biobank population sampling.

### Authors:

Z. Ghazoui; A. Matakidou; S. Petrovski

[View Session](#) [Add to Schedule](#)

**Affiliation:** Centre for Genomics Research, Discovery Sciences, BioPharmaceuticals R&D, AstraZeneca. Cambridge Road, Royston SG8 6EH. England

Prior prevalence estimates of *BRCA1* and *BRCA2* protein-truncating variants (PTVs) have been generally limited to studies that have ascertained for cancer patients or individuals with a family history of cancer. As a community, access to a large population-based sampling of exome sequences linked to rich phenotypic data has not been available to perform a more real-world assessment. The aim of this study is to utilise one of the largest sequenced Biobank population to investigate the prevalence of *BRCA1* and *BRCA2* PTVs in the UK. We analysed whole-exome sequence data (WES) from an initial 100,000 UK Biobank participants (<https://www.ukbiobank.ac.uk/>), which is a prospective cohort study of 500,000 individuals that is linked to a wide variety of phenotypic data.

Among the 100K exome sequences, we identified a collection of 2,236 carriers of a predicted PTVs in *BRCA1/2*. Applying a panel of PTV *in silico* filtering to these variants, 1780 (79.6%) carriers were withdrawn based on the PTV affecting the final 5% of the gene (driven by two common SNPs that accounted for 1769 of these exclusions), 28 (1.3%) carried a PTV with a ClinVar Benign or Uncertain Significance classification, and 12 (0.5%) were restricted to a *BRCA1/2* transcript that is not among the consensus coding sequence (CCDS). The remaining 416 (18.6%) individuals are carriers of high-confidence rare protein-truncating variants (PTV) in *BRCA1* (124 PTV carriers) or *BRCA2* genes (292 PTV carriers). Of the total 416 individuals, 202 (48.6%) have been diagnosed with cancer, 125 (30%) have a reported family history of cancer but are not diagnosed with cancer in the UK Biobank self-report, doctor-diagnosed, or ICD10 cancer registry information, and approximately 89 (21.4%) have no reported history (or family history) of cancer. We also evaluated the distribution of cancer incidence in the UK Biobank among these 416 *BRCA1/BRCA2* PTV carriers and identified that ovarian (5.2% of reported), breast (1.9% of reported) and prostate (1% of reported) cancers are amongst the most commonly enriched types of cancers in this cohort.

This study provides a summary of the oncology landscape among *BRCA1/2* germline PTV carriers. Of further interest are the 21.4% of individuals with a germline *BRCA1/2* PTV that currently have no reported family history of cancer. This study further highlights the value derived from adopting a simple *in silico* screening of PTV annotated variants to reduce noise in interpretation of effects.

## PgmNr 1043: Germline associations with response to immune-oncology and adverse events in a large patient cohort.

### Authors:

---

### Background:

Immuno-oncology (IO) has led to an unprecedented improvement in durable responses in cancer therapy but only a fraction of patients derive lasting benefit, motivating research into IO response mechanisms and biomarkers. Current studies have primarily focused on rare somatic mutations or nonspecific features such as total tumor mutational burden. In contrast, only few studies have focused on germline factors.

### Methods:

Using a large cohort of IO patients in a clinical setting (N=600 non-small-cell lung cancer (NSCLC); N=1200 pan-cancer), we probe the influence of germline genetic factors on clinical outcomes of IO, including overall & progression free survival (OS/PFS), as well as multi-event progression trajectories abstracted from medical imaging reports with deep neural networks. We impute common SNP genotypes, germline HLA alleles, genetic ancestry, and GWAS polygenic risk scores (PRS) from panel sequenced tumors in addition to traditional somatic and clinical features. We perform multivariate survival analysis, considering covariates representing the heterogeneity of our data and ascertainment of patients. Using competing risk models we investigate germline and somatic influences on adverse events. We integrate published datasets to replicate and meta-analyze our findings in a combined pan-cancer cohort of ~2500 IO patients.

### Results:

We study the reproducibility of known biomarkers and look for novel associations to germline factors. In the NSCLC cohort we find significant associations between OS and a PRS for pan-cancer risk ( $q < 0.05$ ) and nominal associations between OS and PRS's for specific cancers, and auto-immune-related phenotypes (both  $q < 0.1$ ). We perform an association scan across common HLA alleles and identify nominal associations ( $p < 0.05$ ) in the NSCLC patient cohort.

### Conclusions:

We are continuing to investigate associations to complex IO outcomes and toxicities with the aim of developing clinical predictors. Our initial results suggest that multiple germline factors significantly influence progression and OS.

## PgmNr 1044: A powerful method to estimate cell-type specific QTLs from bulk expression by leveraging allelic imbalance.

### Authors:

C. Kalita; A. Gusev

[View Session](#) [Add to Schedule](#)

**Affiliation:** Medical Oncology, Dana-Farber Cancer Institute, Boston, MA.

Quantitative trait loci (QTLs) have been crucial in providing an understanding of how genetic variants in regulatory sequences can affect gene expression levels that lead to cancer and influence progression. However, tumor and normal tissues are not a pure cell type, and disease related variants have been found to exert their effects in a cell type specific manner. Existing approaches to identify cell type specific QTLs are infeasible for large scale analysis of multiple tumor types and are currently underpowered. While methods exist to identify genotype-by-cell-type interactions from deconvoluted bulk RNA sequencing data, they require massive sample sizes to achieve adequate power (particularly for cell types present at low frequency), and have largely been unexplored. However, by measuring allelic imbalance (AI) within-individuals, additional power can be leveraged from read coverage as well as sample size. eQTL-interaction and AI tests are independent, and can thus be combined to further increase power to detect cell-type specific QTLs.

We developed a new method, DeCAF (DEconvoluted Cell type Allele specific Function), to identify cell-type specific QTL effects in tumors by leveraging both allelic and total expression information. We simulated allelic read counts modeling a variety of real life conditions and real cell proportion data from The Cancer Genome Atlas (TCGA) to investigate test performance. At a sample size of N=600, our combined test achieved >50% power to detect a cell-type specific eQTL with a low allelic fraction of 0.6. In contrast, the conventional eQTL interaction test required 1,000 individuals to achieve >50% power for the same effect size. As most TCGA sites have <600 individuals, our method thus empowers many new cell-type specific discoveries. Using real immune cell proportion data estimated from gene expression signatures in kidney cancer, only the combined test was well-powered (>75%) to detect allelic effects in CD8 T cells and Dendritic cells for low eQTL effect sizes. When effects were high (allelic fraction of 0.9 and MAF=0.5), the number of individuals required to reach >75% power was, on average, 1.8x lower than the conventional eQTL interaction test. Our method could lead to a better understanding of germline mechanisms underlying the anticancer immune response as well as identify the relevant cell types and QTLs contributing to cancer risk. We are now applying our methodology to real gene expression data from TCGA.

## **PgmNr 1045: Dealing with change, the only constant: Evaluation of a novel approach to rapidly develop and deploy optimized cancer hotspot panels for clinical research.**

**Authors:**

A. Kothandaraman; D. Fox; C. Clear; J. Stewart; K. Kushiro

[View Session](#)[Add to Schedule](#)

**Affiliation:** PerkinElmer, Inc., Austin, TX

---

The interrogation of mutation hotspots in oncogenes or tumor suppressors using genetic sequencing platforms such as Next Generation Sequencing is critical for the advancement of clinical oncology research. New hotspots are being discovered at a rapid pace and opinions on clinical relevance of these hotspots has varied among experts. Laboratories have the desire to adapt their targeted sequencing panel to the constantly evolving genomic landscape but do not have ready access to the necessary development and deployment tools. To address this challenge, we developed an automated design pipeline that provides flexibility to add and/or remove hotspot targets using a core panel as the backbone. The automated design pipeline's machine learning capability allows rapid development of new panels with optimized primer designs. A universal reagent formulation was used such that new designs are tied to a previously validated library prep chemistry. The poster describes the automated design pipeline and performance metrics associated with this novel approach.

For Research Use Only. Not for Use in diagnostic procedures.

## PgmNr 1046: Expression of folate-mediated one-carbon metabolism-related genes in cancer cells is associated with response to chemotherapy.

### Authors:

J. Krushkal; S. Vural; D.-J. Min

[View Session](#) [Add to Schedule](#)

**Affiliation:** Division of Cancer Treatment and Diagnosis, National Cancer Institute, National Institutes of Health, Rockville, Maryland.

---

Folate-mediated one-carbon metabolism (OCM) is important for cell growth and survival. Malignant cells are dependent on OCM reactions, and folate cycle genes have been associated with cancer risk and progression. We investigated whether the response of cancer cells to chemotherapy may be partially influenced by pre-treatment expression levels of OCM genes. We used drug response data for 251 antitumor agents, OCM gene expression information, and additional data on genome sequence variants, gene amplification, and gene fusions in 635 cancer cell lines with matching information from the Cancer Cell Line Encyclopedia and the Genomics of Drug Sensitivity in Cancer resources. We examined whether pre-treatment expression of 34 OCM-related genes was associated with drug response. Selected association results were validated in the NCI-60 cancer cell line panel. Expression of *GART*, *TYMS*, *SHMT2*, *MTR*, *ALDH2*, *BHMT*, *MAT2B*, *MTHFD2*, *NNMT*, and *SLC46A1* showed modest correlations with response to a variety of antitumor agents. Higher expression levels of *SLC46A1* were associated with resistance to multiple drugs, whereas elevated expression of *GART*, *TYMS*, *SHMT2*, *MTR*, *BHMT*, and *MAT2B* was associated with chemosensitivity to multiple agents. *NNMT* expression was bimodally distributed and showed different directions of association with various agents. Expression of *MAT2B*, *MTR*, *SHMT2*, and *SLC46A1* was associated with response to crizotinib, and these associations remained significant after accounting for the presence of genome alterations (*ALK* fusions, *ROS1* fusions, *MET* amplification, or *MET* exon 14 skipping mutations) known to affect crizotinib sensitivity. Expression of several OCM genes was strongly associated with expression of components of drug target pathways. For example, expression of *TYMS* and *GART* was strongly positively correlated with *BRCA1* expression, *NNMT* expression was associated with *EGFR* and *ABL2*, and expression of *TYMS*, *DHFR*, and *SHMT1* was positively correlated with *AURKB*. Pre-treatment expression levels of *DHFR*, *TYMS*, *ATIC*, *GART*, *AHCY*, *MTHFD1*, *SLC19A1*, and other genes were positively correlated with each other, suggesting their co-regulation, whereas *NNMT* expression was negatively correlated with expression of several OCM genes. Correlations of expression of OCM genes with drug response could be related to metabolic roles of these genes, or they may be associated with the increase in the rate of cancer cell growth and proliferation and with tumor progression.
