Insertion and deletion variation have been shown to associate with many diseases including autoimmune diseases and cancers. Insertions and deletions (indels) are the most common type of structural variation in the human genome and they can be identified using high throughput next generation sequencing techniques. While many computational tools for indel detection from sequencing data are available, the detection accuracy is still considerably lower for indel variation than for single nucleotide variation. The reliable indel calling is desirable in any application field, especially in genetic diagnosis. In order to dissect potential underlying reasons for the shortcomings in detection of indel variants, we studied the impact of the methods as well as the technical and biological features of the sequencing data. We evaluated seven widely used open source indel detection tools (DELLY, Pindel, FermiKit, Platypus, GATK Haplotype caller, VarScan, and Strelka2) with the underlying methodology spanning from assembly-based approaches to machine learning approaches. The impact of the sequencing data on indel detection was evaluated by using real world benchmarking data with varying sequencing coverages spanning from 60X to 5X coverage. Finally, the sequence context of the false positive indel detections was carefully studied. Our results demonstrated that the choice of the algorithm has an impact on the precision and recall of the indel calling, but no systematic bias related to the underlying algorithms was found. The indel detection performance benefited from the higher sequencing coverage compared to the 5X coverage. However, there was only a slight improvement in indel calling between 30X and 60X. The impact of the sequence context had major impact on the indel calling results with the presence of a repeat region being the most problematic sequence context for reliable indel calling. The results provide insights into the key factors influencing indel calling reliability and may be useful in designing of improved solutions for indel detection.

## PgmNr 1747: Pore-C: A method for genome-wide, multi-contact chromosome conformation capture.

### Authors:

---

The DNA within the nucleus of an interphase cell is organised into a complex hierarchy of folds and loops known as the 3D Genome. The development of various chromatin conformation capture methods has enabled the detection of the structures that define each level of this hierarchy e.g. chromosome territories, A/B compartments, topologically associated domains (TADs) and promoter-enhancer loops. This in turn has facilitated functional studies which have uncovered some of the mechanisms behind the formation and maintenance of these structures, as well as their effect on gene expression. However, most of these studies rely on methods that can only capture interactions between two points on the genome, and thus lack the ability to resolve higher-order interactions. We will share our progress on Pore-C, a method to generate genome-wide, multi-contact chromatin conformation maps. Using this technique we were able to resolve misassemblies and join contigs in a *de novo* assembly of the genome of cell line GM12878. This way, we generated an exceptionally contiguous assembly with an N50 of 36 Mb and a longest contig of 129 Mb, which is ~89% of the entire chromosome 8 including the centromere. Furthermore, we will show how we used Pore-C to detect rearrangements and copy number changes and resolve complex structural variants in the human breast cancer cell line HCC1954.

## **PgmNr 1748: lncRNA-peptidome analysis through proteogenomic-approach: Quantifying tissue, cell-line, and plasma lncRNA-peptidome to discover peptide-based cancer biomarkers.**

---

The debate on the translational capacity of lncRNAs to guide the synthesis of polypeptides was ignited with the identification of evolutionary conserved ribosome-binding property of lncRNAs. Proteome-centric studies, although have identified numerous lncRNA-encoded polypeptides, lack differential expression analysis of lncRNA-peptidome across primary tissues, cell lines and cancer states. We developed an integrated proteogenomic pipeline to identify and quantify the polypeptides as the translated products of the lncRNA transcripts in the human genome. In short, we first predicted the hypothetical polypeptide sequence from each lncRNA transcript annotated in the human genome. We then exhaustively searched for these hypothetical polypeptides in the LC-MS/MS data to identify polypeptides that are actually translated in human primary tissues and cell lines. With the aid of the computational-proteogenomic workflow we re-processed publicly available LC-MS/MS data, which facilitated the identification of tissue-specific and universally expressed (UExp) lncRNA-polypeptides across 14 primary human tissues and 11 cell lines. The utility of lncRNA-peptidome as cancer-biomarkers was investigated by re-processing LC-MS/MS data from 92 colon-adenocarcinoma (COAD) and 30 normal colon-epithelium tissues. Intriguingly, a significant upregulation of five lncRNA UExp-polypeptides in COAD tissues was observed. Furthermore, clustering of the UExp-polypeptides led to the classification of COAD patients that coincided with the clinical stratification, underlining the prognostic potential of the UExp-polypeptides. Lastly, we identified differential abundance of the UExp-polypeptides in the plasma of prostate-cancer patients highlighting their potential as plasma-biomarker. The analysis of lncRNA-peptidome may pave the way to identify effective tissue/plasma biomarkers for different cancer types.

## PgmNr 1749: Genomic landscape of conjunctival melanoma.

Conjunctival melanoma (CJM) is extremely rare but potentially lethal and highly recurrent form of cancer of the eye that, similarly to cutaneous melanoma (CM), originates from melanocytes. Contrarily to CM, however, CJM is relatively poorly characterized from a genomic point of view.

A better understanding of genetics of CJM would be beneficial for the improvement of its classification and especially of available treatment options.

To fill this knowledge gap and to gain insight into the genomic nature of CJM, we performed whole-exome (WES) or whole-genome sequencing (WGS) and RNA sequencing (RNA-seq) of tumor-normal tissue pairs in 14 affected individuals.

Our results show that, similarly to CM, CJM is also characterized by a very high somatic mutation load, composed of approximately 500 mutations in exonic regions. This, together with the presence of a clear UV light-induced signature, are signs of the role of sunlight in CJM etiology.

In addition, our analysis showed that the genomic classification of cutaneous melanoma proposed by TCGA seems to be well-applicable to conjunctival melanoma. Specifically, we observe four subclasses, defined on the basis of the most frequently mutated genes: *BRAF*, *NF1*, *RAS* and triple wild-type.

In line with these results, transcriptomic analyses show the presence of immune and keratin signature, again similarly to what has been reported in CM.

Alltogether, our results provide the first unbiased and complete genomic and transcriptomic classification of CJM.

## PgmNr 1750: Mega-analysis of transcriptomic field effect in colorectal cancer reveals novel features.

### Authors:

C. Dampier <sup>1</sup>; M. Devall <sup>2</sup>; V. Moreno <sup>3</sup>; G. Casey <sup>2</sup>

1) Department of Surgery, University of Virginia, Charlottesville, VA; 2) Center for Public Health Genomics, University of Virginia, Charlottesville, VA; 3) Catalan Institute of Oncology, Bellvitge Biomedical Research Institute, and CIBERESP, L'Hospitalet de Llobregat, Barcelona, Spain

---

**Background:** Colorectal cancer is a relatively common malignancy that is curable when detected early but often fatal when diagnosis is delayed. A field effect of cancer in the colon has been reported and could have implications for diagnosis and therapy, but descriptions to date have been limited by small sample sizes and inappropriate tissue comparisons. To address these limitations, we performed a joint analysis of pooled transcriptomic data from all publicly available RNA-seq datasets of healthy and tumor tissue as well as a previously unpublished cohort of our own.

**Methods:** RNA-seq datasets from studies including healthy (HLT), tumor-adjacent but pathologically normal (NAT), and tumor (CRC) samples published in the Genomic Data Commons and Sequence Read Archive as well as our own cohort were systematically screened for inclusion. Samples of bulk sequencing with a depth of at least 10 million quantifiable paired-end reads from flash frozen healthy or tumor colorectal tissue obtained from surgical specimens and biopsies likely to contain a substantial mucosal component were eligible. After converting all available data to FASTQ format, we quantified transcripts using Salmon in GC bias mode for all samples. We aggregated transcripts at the gene level with the tximport R package. We used the SVA package to identify latent batch effects and performed differential expression comparisons across tissue types with DESeq2 using five surrogate variables to control for latent factors.

**Results:** After screening for eligibility and filtering out duplicates, we retained for analysis 924 samples from 11 studies, including 462 HLT samples, 94 NAT samples, and 368 CRC samples. In comparisons across tissue types in which we tested for absolute fold-change of 2 or more at FDR 5%, we found 1,701 differentially expressed genes (DEG) between HLT and NAT, 2,929 DEG between NAT and CRC, and 5,974 DEG between HLT and CRC. Expression of a subset of 43 DEG was found to increase consistently from HLT to NAT and from NAT to CRC, while expression of 18 DEG displayed the opposite pattern. A subset of 128 DEG were overexpressed in NAT compared with both HLT and CRC.

**Conclusion:** In this mega-analysis of the colorectal transcriptome, we leveraged increased power for discovery despite careful tissue selection to identify novel features of the field effect in colorectal cancer. These features may be useful for diagnosis and treatment of colorectal cancer.

## **PgmNr 1751: The enhancer connectome of ovarian cancer refines GWAS loci and identifies target genes of high grade serous ovarian cancer.**

Genome-wide association studies (GWAS) have led to the identification of >30 risk loci for ovarian cancer. GWAS SNPs are annotated to the nearest gene with most fine mapped SNPs lying in non-coding genomic regions suggestive of their distant role on target gene expression. These disease-susceptibility variants frequently lie in cell-type-specific enhancer elements. To identify, interpret, and prioritize such risk variants, and thus identify their target gene, we use H3K27ac HiChIP, an efficient novel protein-mediated chromatin-conformation assay to obtain high-resolution interaction maps. By conducting HiChIP in fallopian tube precursor cells and ovarian cancer cell lines, we can confidently assign enhancer-promoter contacts in a cell-type specific manner and reveal principles that govern these interactions from normal to a cancer state. By establishing this ovarian enhancer interactome, we identify key regulatory elements involved in cancer risk and progression. These connectome maps in normal precursor cells and ovarian cancer cells were combined with summary stats from the Oncoarray to identify enhancer-promoter loops that overlap at GWAS signals (95% credible set). We observe that GWAS variants from ovarian cancer are enriched within the HiChIP interactions consistent within a role of enhancer-promoter interactions in the regulation of gene expression. We further integrate these results with GTEX, eQTL data, and TWAS data to explore the credible SNP-contact genes. This study shows that HiChIP interaction data can be leveraged with GWAS and eQTL to prioritize target genes for ovarian cancer which are supported by physical interactions between regulatory elements (enhancers) and their target genes.

## PgmNr 1752: Gene expression profiling from cervix cancer patients living in Senegal.

---

Cervical cancer (CC) is a multifactorial diseases and the main aetiologic agent is the Human Papillomavirus (HPV). Despite the implementation of cervical uterine Pap smear (HPV) screening and vaccination to treat precancerous lesions , cervical cancer is still a public health problem.

The emergence of novel cervical cancer biomarkers is promising enough to reduce the cost of prevention and improve the specific detection of high-grade cervical lesions and early-stage cervical cancer, implying an improvement in the efficacy of cervical cancer treatment management.

The objective of this study will be to identify gene expression profiles and to investigate potential biomarkers through the analysis of significantly altered signaling pathways from patients with cervical cancer, cervical intraepithelial neoplasia (CIN 1) and healthy control subjects (CTR) using Illumina technology.

The Illumina BeadChips were used for a complete genome-wide transcript profiling of whole blood from 31 CC patients, 27 CIN and 29 CTR. Differentially expressed genes (DEG) were identified by comparing the mean normalized expression for each gene in the different sample groups. A hierarchical clustering was performed on the 3,435 significant genes and DEG at significant level between patients and the clusters generated were analyzed using Gene Ontology (GO) in String protein database to identify biological processes.

Few differences were observed between CIN patients and CTR with only 129 upregulated and 130 downregulated genes in CIN patients. In contrast, 1,569 genes were overexpressed in CC patients including 1,404 and 1,303 genes respectively from the comparisons with CIN patients and CTR. We identified in CC patients compared to CTR a high expression of a spectrum of genes involved in the immunity of CC patients and a weak expression of genes related to metabolism. Microarray data were validated by RT-qPCR in a set of seven genes showing a high degree of correlation.

Conclusion: This enrichment of genes involved in immunity overexpressed in CC patients could be related to their particular immune state regarding cervical cancer and the observation of genes related to metabolism under-expressed in CC patients could reflect the rewiring of the metabolism processes in cancer. Our study highlighted several new genes that could contribute in the identification of innovative clinical biomarkers for diagnostic procedures and therapeutic interventions.

## PgmNr 1753: Examination of whole-genome sequencing using SeqPlus sequencing methodology in esophageal carcinoma formalin-fixed, paraffin-embedded samples stored for more than a decade.

Collection of fresh-frozen tumor samples is often challenging or infeasible. Thus, many studies rely on formalin-fixed, paraffin-embedded (FFPE) tumor tissue samples. Although whole-genome sequencing (WGS) analysis of FFPE samples could enable novel insights from these vast archival sample collections, robust WGS has remained elusive due to poor yields of fragmented DNA, low complexity sequencing libraries, uneven genomic coverage, and sequencing artifacts attributed to FFPE fixation. To examine WGS of stored FFPE samples, we analyzed 20 paired esophageal carcinoma (EC) samples (primary tumors and matched germline samples) that had been stored for 10-16 years using a proprietary extraction and library preparation methodology (SeqPlus). We assessed SeqPlus performance on these older FFPE tissues and measured variant call concordance between WGS and a targeted, high-depth sequencing panel (269 genes, sequenced at >400x mean coverage). At a planned WGS tumor sequencing depth of 70x, 93% of the genome was covered by  $\geq 20$  reads, 99% of bases had 10x coverage; the average duplicate reads were 31%. Importantly, we observed similar transition/transversion ratios and mutational spectra as those reported from The Cancer Genome Atlas (TCGA) fresh-frozen EC specimens. The overall concordance of tumor-specific SNV and indel variant calls derived from WGS and the targeted panel was high at 86%. All 76 targeted panel variants above the WGS lower limit of detection (mutant allele frequency (MAF) >10%) were also detected by WGS, 2 variants in 2 tumors were detected only by WGS, and 12 variants at MAF  $\leq 6\%$  from 9 tumors were exclusively detected with the targeted panel. SeqPlus produced consistent coverage versus the targeted panel that showed uneven coverage across the targeted genes/samples. WGS detected an overall mean of 10.4 putative cancer variants per tumor, like the 12 variants per patient reported from frozen TCGA EC specimens. Copy number variation analysis of the WGS data also identified genomic amplification of *CCND1*, *EGFR*, *TP63*, and *SOX2*, frequent deletion of the *CDKN2A/B* tumor suppressor locus, and additional previously unrecognized genomic aberrations. In conclusion, our study further supports the utility of high-quality, uniform WGS sequencing of archival FFPE cancer samples with SeqPlus and unlocks the potential for massive-scale retrospective genomic analysis of millions of pathology samples with their associated clinical, therapeutic, and outcomes data.

## PgmNr 1754: Two NGS library prep panels for analyzing tumor cells for actionable mutations using a flexible, automated microfluidics platform.

**Affiliation:** Research and Development, Fluidigm Corp, South San Francisco, California.

Genomic analysis of tumor cells is becoming increasingly common as more cancer investigators adopt next-generation sequencing (NGS) and as DNA sequencing costs continue to decrease. Currently, targeted sequencing is the most prevalent strategy for screening large numbers of samples. However, library prep can be expensive and tedious to perform. To provide a solution, we developed two amplicon-based library prep panels targeting actionable variants in cancer cells. The Advanta Solid Tumor NGS Library Prep Assay identifies single nucleotide variants (SNVs), insertions and deletions (indels), and copy number variations (CNVs) in 53 genes. It is comprised of 1,508 amplicons, covering >230 kb of genomic DNA with a bias for protein coding regions, and >18,000 pathogenic COSMIC variants. The complementary Advanta RNA Fusions NGS Library Prep Assay detects gene fusion events from tumor RNA. Its 1,100 amplicons target >1,000 breakpoints in 385 fusion gene pairs reported to be involved in solid tumors and hematologic cancers.

Both panels use a highly multiplexed, nanoliter-scale, PCR-based enrichment method on the Juno system. Libraries can be prepared from 48 samples from one or both panels in a single 9.5-hour run that requires less than 4 hours of hands-on time. Automated assembly of amplification reactions is performed on an integrated microfluidic circuit (IFC). Primer pairs are distributed across eight 270 nL reaction wells, enabling overlapping coverage that reduces amplification of off-target artifacts. As little as 12.5 ng of genomic DNA or cDNA from 10 ng of RNA detects SNVs and indels at a variant allele frequency of  $\geq 5\%$ , CNVs at  $\geq 3.5$  copies, and RNA fusion transcripts at  $\geq 250$  copies of input. Here we compare the performance of these panels using genomic reference standards and formalin-fixed, paraffin-embedded, fresh-frozen, and blood samples employing potential alternative workflows. These new library prep research panels, when integrated with the Juno system, provide valuable content in a flexible and economical platform with convenient workflows for investigators who need comprehensive genomic profiling of tumor samples.

## PgmNr 1755: Understanding genetic variation in cancer using targeted long-read sequencing.

### Authors:

---

Cancer cells acquire varied genetic aberrations through different degrees of genomic instability during tumorigenesis, evolution, and disease progression. Understanding the origin and evolution of tumor complexity by studying tumor heterogeneity in cancer could help reveal new strategies for improved diagnosis and precision therapy. Structural variations (SV), a hallmark of genomic instability in cancer, include insertions, deletions, duplications, inversions, or translocations that can either activate oncogenes or inactivate tumor suppressor genes. While short-read sequencing has aided cancer genomics, it has performed poorly in SV detection, with false positive and false negative rates of 50% or more. Long-read, single-molecule sequencing methods such as Pacific Biosciences single-molecule real-time (SMRT) sequencing and Oxford Nanopore Technologies (ONT) sequencing can address larger variations as they typically generate read lengths of tens of thousands of bases. Long reads can span SV with a single continuous read, giving a clearer idea of the variation, its position, and size. In the recent years, these sequencing strategies have helped identify thousands of genomic features pertinent to cancer that were previously missed by short-read sequencing. However, the throughput and coverage offered by these platforms, coupled with the high cost of whole genome long-read sequencing makes it infeasible to conduct large-scale genomic studies, limiting our understanding of the distribution and frequencies of SVs in the population. Targeted sequencing significantly improves accuracy and coverage by offering the depth necessary to detect rare alleles in a heterogeneous population of cells. However, a lack of efficient long-read compatible targeting techniques makes it difficult to study specific regions of interest on existing long-read platforms. Currently we are evaluating amplicon-based and CRISPR/Cas-based systems for targeted long-read sequencing to enrich for specific regions of the cancer genome (BRCA1, HLA, BRCA2) in two breast cell lines – MCF 10A and SK-BR-3. Our overarching goal is to develop a targeted long-read sequencing strategy to facilitate large population SV analysis, which will help define the landscape of such variants in the population and help identify regions of therapeutic or diagnostic interest.

## PgmNr 1756: Capturing tumor heterogeneity in pre- and post-chemotherapy colorectal cancer ascites using scRNA-Seq.

---

Malignant ascites is the abnormal accumulation of fluid within the peritoneal cavity, caused by metastasis of several cancer types; colorectal cancer included. Cancer cells in ascites reflect poor prognosis and can be a source of recurrence. They also represent a good source of specimen for the study of tumor heterogeneity. Single-cell RNA sequencing has recently emerged as a powerful tool to explore and characterized cellular heterogeneity, and has been applied to different cancers. However, molecular profiles of cancer cells in ascites and their responsiveness to chemotherapy is poorly understood. In this study, we performed, to the best of our knowledge, the first scRNA-Seq analysis of pre- and post-chemotherapy malignant ascites-derived cells from a colorectal cancer patient in order to profile and characterize the cellular heterogeneity and different expression hallmarks within the population. Unbiased clustering of 17,967 cells in total reveals 16 sub-clusters of four major cell types: epithelial cells, myeloid cells, fibroblast, and lymphocytes. We identified distinct epithelial cluster that is mainly seen in pre-treatment samples, as well as another distinct cluster in post-treatment specimens. Interestingly, the percentages of recovered cells from different cell types are not only affected by the chemotherapy treatment, but also appear to be influenced by the single cell preparation protocols, namely enzymatic and mechanical separations. Single cell western blotting was subsequently used to validate the differential amount of recovered cell types between the two single cell preparation methods. Overall, differential expression (DE) analysis between pre- and post-treatment malignant ascites-derived cells reveals several differentially expressed transcription factors and ribosomal genes. Gene Set Enrichment Analysis (GSEA) emphasizes different states of cancer epithelial cells within the patient. In summary, our study underscores cancer heterogeneity within malignant ascites and uncover gene expression profile of ascites-derived colorectal cancer cells in single-cell resolution.

## **PgmNr 1757: Tumor mutational burden analysis: An ultra-multiplex amplicon-based NGS target enrichment approach for accurate, rapid and comprehensive profiling.**

### **Authors:**

L. Lee; K. Pendleton; V. Kapoor; G. Liu; Y.L. Liu; J. Liu; Z. Liu

[View Session](#) [Add to Schedule](#)

**Affiliation:** Paragon Genomics, Inc., Hayward, CA.

---

Assessment of tumor mutational burden (TMB) using NGS methods, with its correlation to patient response to checkpoint inhibitor chemotherapy in the immuno-oncology field, is gaining significant importance. A whole exome sequencing approach has most often been used, although they can be expensive and time consuming. Alternatively, a targeted enrichment strategy using multiplexed PCR can provide better coverage of regions of interest and reduce costs. But, as required for tumor profiling, increasing multiplexity of PCR can lead to problems with non-specificity, primer-primer interactions, decreased uniformity, and increased GC bias. In this study we present a high-quality ultra-multiplex PCR-based strategy for targeting hundreds of genes. We designed a 500 gene TMB panel which uses 27,296 pairs of primers to target them. The lengths of the amplicons were designed to be 105-120bp to allow for target amplification from challenging samples like FFPE DNA and cfDNA. The 27,296 pairs of PCR primers are pooled into two multiplex PCR reactions and cover a total of 1635204bp (1192796 bp of coding sequence). Paragon Genomics' CleanPlex® technology enables a library preparation workflow which includes a multiplex PCR step with the targeted primers in two pools. After the multiplex PCR step, the two pools are combined. A subsequent cleanup step removes by-products, and a final PCR adds sequencer flow cell adapters and sample barcodes. With a read depth of ~2400 reads per amplicon, the TMB panel exhibits ~95% uniformity at 0.2X mean and little to no GC bias despite the highly multiplexed nature of this panel. High mapping and on-target rates of > 90% makes most of the data usable for downstream analysis. The CleanPlex® TMB Panel targets 500 genes using 27,296 amplicons generating ultra-multiplexed libraries with high coverage uniformity (~95%), low GC bias and high mapping and on-target rates. The advanced design of this panel along with the CleanPlex technology enables the rapid interrogation of these genes in a robust assay.

## **PgmNr 1758: Identifying cooperating disease-driving mutations in mutant p53-initiated invasive carcinomas and ductal carcinoma *in situ*.**

### **Authors:**

R. Morrissey <sup>1,2</sup>; J. McDaniel <sup>1</sup>; Y. Zhang <sup>3</sup>; S. Xiong <sup>1</sup>; G. Lozano <sup>1</sup>

---

Ductal carcinoma *in situ* (DCIS) is an early breast tumor confined to the duct by myoepithelial cells. DCIS sometimes progresses to invasion, but does not always do so. Since it is difficult for clinicians to predict whether or not DCIS will become invasive, it is treated with surgical removal and radiation. To prevent overtreatment of patients, a strategy must be devised to stratify tumors that are likely to spread and tumors that will remain localized.

We have generated a somatic mouse model with a conditional wild-type to mutant (WM) R245W p53 mutation only in mammary tissue, conferring predisposition to breast tumorigenesis. Importantly, these mice retain a wild-type stroma and immune system. Pathological analysis indicated that the progression of breast cancer in our mouse model mirrors that in humans, and identified both invasive carcinomas (IC) and DCIS. These IC tumors have long latency (median survival of 1.5 years), thus, we hypothesize that additional mutations are required for DCIS to progress to IC.

DCIS and IC tumors will be identified via pathological examination and immunohistochemical staining. Lesions will be extracted through laser capture microdissection. Exome sequencing will be used to identify recurrent mutations cooperating with mutant p53 to drive breast cancer progression. RNA sequencing will be used to identify genes and pathways that are differentially expressed among DCIS and IC lesions. After identification of recurrent mutations and differentially expressed genes that are exclusive to IC, we will characterize the function of these mutations in driving breast cancer disease progression.

## PgmNr 1759: Molecular signatures of multifocal prostate cancer.

### Authors:

D. Noursome; R. Narayanan; J. Linehan; R. Gentry; K. Tran; S. Hsiang; D. Krasne; J. J alas; M.P. Salomon; D. Hoon; T. Wilson

[View Session](#) [Add to Schedule](#)

**Affiliation:** John Wayne Cancer Institute, Santa Monica, California.

**Background:** Prostate cancer (PCa) usually presents as histologically multifocal lesions (MF), with the potential for differences in aggressiveness among foci. In contrast, single focus (SF) patients are younger with lower Gleason score. Previous studies have attempted to characterize the somatic nature of MF tumors, but additional molecular studies are necessary to identify differences between foci. The goal of this study was to generate a molecular signature between foci in MF PCa, identify differences between MF and SF patients, and to characterize regional metastases to lymph nodes (LN) in patients who have undergone radical prostatectomy.

**Methods:** We performed miRNA sequencing using the HTG EdgeSeq miRNA whole transcriptome next generation sequencing assay for ~2,000 miRNAs on 27 patients (10 MF and 17 SF). The primary and secondary foci of MF patients were determined by MRI. There were 82 samples of LN metastases collected (mean=5.1 LN per patient). We tested differential miRNA expression between primary and secondary foci for each patient. In addition, we assessed differential expression between MF and SF primary foci. Using miRNA markers, we calculated Euclidean distances among foci and LN to assess the degree of relatedness within each patient. For a subset of patients, we performed RNA-seq (6 MF and 3 SF) to characterize cell types enrichment using xCell.

**Results:** For MF patient specimens, two miRNAs (*miR-221-5p* and *miR-378a-3p*) were differentially expressed between the primary and secondary foci. Between MF and SF patients, three miRNAs were differentially expressed (*miR-6515-3p*, *miR-670-5*, and *miR-5571-3p*). In MF patients, the primary lesion was more closely related to LN metastases compared to the secondary focus ( $P<0.001$ ). In MF patients, the primary foci had higher enrichment of T helper 2 cells ( $P=0.005$ ) and dendritic cells ( $P=0.07$ ) compared to the secondary foci. There was less enrichment of CD8+ cells in MF compared to SF patients ( $P=0.02$ ).

**Conclusions:** In this first miRNA expression profiling of MF PCa, we observed that multiple foci harbor distinct molecular signatures. miRNA and RNA signatures may be informative as biomarkers to discriminate MF from SF patients. These signatures indicate the different etiology between primary and secondary foci and also between MF and SF patients. Using molecular profiling to better understand intra-tumor heterogeneity may influence the development of novel surgical approaches in patient management.

## PgmNr 1760: Comprehensive detection of germline and somatic structural mutation in cancer genomes by Bionano genomics optical mapping.

The ability to identify structural variants (SVs) is crucial in cancer genetics. Karyotype and cytogenetics are manually intensive. Microarrays and sequencing cannot detect calls in segmental duplications and repeats, and miss balanced variants and low-frequency mutations.

We describe the Bionano Genomics's Saphyr platform to identify SVs in cancer genomes. DNA >100 kbp is extracted, labelled at specific motifs, and linearized through NanoChannel arrays. Molecule images are digitized and *de novo* assembled, creating chromosomal-arm scale genome maps. Cancer mutations >500 bp are detected by aligning the molecules or the genome maps to the public reference.

We ran Bionano's cancer workflow on multiple human cancer cell lines. While the number of SVs varies among samples, we typically observe > 3500 calls per genome. In the SK-BR-3 breast cancer genome, we detected a cluster of amplifications, and translocations on chr8, impacting the gene *MYC*. In the CML genome K562, the *BCR-ABL* translocation was detected, while we also detect novel rearrangements, such as insertion and inversion interrupting the gene *NAALADL2* in a prostate cancer cell line LNCaP.

In conclusion, with one platform, Saphyr can discover a broad range of traditionally refractory but relevant SVs, and improves our understanding of cancer.

## PgmNr 1761: Crowdsourced RNA-seq and gene ontology analysis of a human breast tumor in the context of an undergraduate course.

---

Breast cancer's lethality is due, in part, to inherent heterogeneity of breast cancer disease, posing challenges for clinicians to accurately diagnose and subtype tumors. Recently, RNA-seq technology and bioinformatic analysis of gene expression has made it possible to subtype tumors based on molecular classification. In this experiment, our aim was to capture tumor diversity while improving the redundancy and quality of library preparation for transcriptome analysis as a diagnostic tool for breast tumor subtyping. Using a crowdsourcing approach in the context of an undergraduate course, we prepared a whole transcriptome library from a single breast cancer patient, and used multiplex sequencing on twelve uniquely barcoded preparations, which were subsequently pooled and sequenced in a single run on a high-throughput instrument. Datasets obtained from the sequencing were subjected to quality control analysis using the Green Line of DNA Subway (Tuxedo Pipeline, FAST-X, FAST-QC, Tophat, and CuffDiff algorithms). Log-transformed gene expression ratios were subjected to the BiNGO gene ontology algorithm. Significant over-expression of genes for metabolic and cellular process pathways included cell death and cell division ( $p < 0.01$  Binomial). Significantly down-regulated pathways included those in development (e.g. organ development), regulation (stimulus response, inflammatory response, etc), and signaling (cellular communication, etc;  $p < 0.01$  Binomial). Furthermore, using previously established biomarker genes, we subtyped the cells as basal-like, showing little change in expression for Estrogen Receptor (ER), Her2/Neu (HER), or Ki-67 biomarkers, but a significant over-expression of the progesterone receptor ( $q = .0031$ ). Using the Mammprint suite of biomarkers we diagnosed a highly progressed tumor, wherein 60% and 73% of the Mammprint mid-hallmark genes and 38% late hallmarks were differentially expressed. Based on this dataset, we propose the biomarker MELK (maternal embryonic leucine zipper kinase) as a candidate for personalized chemotherapy. Taken together, our findings suggest that crowdsourcing RNA-seq experiments can be a valid approach for improving library preparation toward subtyping and diagnosis of human breast cancers. Furthermore, this can be achieved with undergraduate researchers in the context of coursework, contributing to their learning gains.

## PgmNr 1762: Human papillomavirus and the landscape of secondary genetic alterations in oral cancers.

---

Human papillomavirus (HPV) is a necessary but insufficient cause of a subset of oral squamous cell carcinomas (OSCC) that is increasing markedly in frequency. To identify contributory, secondary genetic alterations in these cancers, we used comprehensive genomics methods to compare 149 HPV-positive and 335 HPV-negative OSCC tumor/normal pairs. Different behavioral risk factors underlying the two OSCC types were reflected in distinctive genomic mutational signatures. In HPV-positive OSCC, the signatures of APOBEC cytosine deaminase editing, associated with anti-viral immunity, were strongly linked to overall mutational burden. By contrast, in HPV-negative OSCC, T>C substitutions in the sequence context 5'-ATN-3' correlated with tobacco exposure. Universal expression of HPV E6\*1 and E7 oncogenes was a sine qua non of HPV-positive OSCC. Significant enrichment of somatic mutations was confirmed or newly identified in *PIK3CA*, *KMT2D*, *FGFR3*, *FBXW7*, *DDX3X*, *PTEN*, *TRAF3*, *RB1*, *CYLD*, *RIPK4*, *ZNF750*, *EP300*, *CASZ1*, *TAF5*, *RBL1*, *IFNGR1* and *NFKBIA*. Of these, many affect host pathways already targeted by HPV oncoproteins, including the p53 and pRB pathways, or disrupt host defenses against viral infections, including interferon and nuclear factor-kB signaling. Frequent copy number changes were associated with concordant changes in gene expression. Chr. 11q (including *CCND1*) and 14q (including *DICER1* and *AKT1*) were recurrently lost in HPV-positive OSCC, in contrast to their gains in HPV-negative OSCC. High-ranking variant allele fractions implicated *ZNF750*, *PIK3CA* and *EP300* mutations as candidate driver events in HPV-positive cancers. We conclude that virus-host interactions cooperatively shape the unique genetic features of these cancers, distinguishing them from their HPV-negative counterparts.

## **PgmNr 1763: Single NGS assay used to evaluate MHC loss of heterozygosity (LOH) and tumor mutational burden (TMB) and determine their impact on response to immunotherapy.**

Many tumor cells survive due to a suppressed immune response that prevents their destruction. This may be overcome during treatment via checkpoint inhibitors. These act via a monoclonal antibody that blocks the interaction of the checkpoint receptors with their cognate ligands. Tumor Mutational Burden (TMB) serves as a surrogate marker of immune response because it provides a readout on altered proteins that should but are not recognized by the immune system. TMB is measured through sampling regions of the cancer genome to estimate the number of mutations/Mb. A high TMB score is associated with better response to immunotherapy because the tumor carries more somatic mutations and has a higher chance of presenting an immunogenic neoepitope. However, not all high TMB tumors are impacted by therapy. One reason can be loss of antigen presentation caused by mutations and loss of heterozygosity (LOH) of the beta-2-microglobulin (B2M) and MHC Class I genes. Consequently, the outcome for high TMB tumors will be dependent on their ability to present antigens with their MHC Class I/B2M complex.

TMB should be considered together with the tumor's ability to present these putative neoantigens. To test this hypothesis, we used the PGDx elio™ tissue complete assay (in development; >500 genes covering 1.3 Mb) to measure TMB and antigen presentation in the same assay. We tested 190 cancer patients and showed that in FFPE tissue samples with ≥20% tumor content, we could detect LOH of the MHC Class I with 88% accuracy. This confirmed our hypothesis that it was possible to measure TMB and evaluate antigen presentation in the same NGS analysis.

We have replicated the combined analysis of TMB and LOH of MHC in a publicly available NSCLC cohort with patient outcome results to checkpoint inhibitor treatment. Patients that were either TMB-low (≤120 mutations per exome) or TMB-high but with predicted LOH of MHC had a poorer outcome and higher hazard ratio (7.9, CI 95% 1.3-49) than patients with high TMB and intact MHC. Thus, our algorithm can be used in the combined evaluation of TMB and the potential for antigen presentation to predict patient outcome. These methods are being used to further evaluate TMB and somatic alterations of the antigen presentation complex in different cancers and to further validate the hypothesis that adding neoantigen presentation capability to TMB scores will significantly improve prediction of response.

## PgmNr 1764: Structurally resolved immune profiling in ovarian carcinoma using whole-transcriptome spatial sequencing.

---

In the United States approximately 22,000 women will receive a new diagnosis and ~14,000 women will die from ovarian cancer (OC) each year, making this disease the fifth most deadly cancer among women. Like many cancers, OC can be genetically heterogeneous making studies difficult to plan, execute, and interpret. Bulk methods such as whole-genome or whole-transcriptome sequencing are limited in their ability to resolve fine grain molecular signatures which hinder their utility in dissecting the underlying biology of individual tumors.

Here we present investigation of 11 subjects, previously diagnosed with OC using whole-transcriptome spatial sequencing on the 10x Genomics Spatial Transcriptomics platform. This system requires no tissue dissociation keeping fragile cell types intact. Using serial sections of solid tumors from each subject we were not only able to profile each section at 100um resolution but also spatially resolve gene expression signatures and cluster regions of tissue based on these signatures. Next, we aggregated the transcriptional profiles of serial sections from each case increasing our power to cluster similar regions and identify differentially expressed genes within these tissues.

Using this information, we went on to conduct a refined analysis of 18 key inflammatory genes that have been previously known to play an important role in the immune response of OC and developed a spatially resolved inflammation score for each section from each subject. Not only did we observe statistically significant regionalized inflammation scores within each subject, we also found intersubject differences which may give insight into response to treatment. Further, we observed clear transcriptional substructure in some tumors, where different tumor regions were defined by molecular pathways that are associated with tumorigenesis (i.e. UV Response, Epithelial to Mesenchymal Transition, and Estrogen Response pathways), regions defined by immune populations (B cells, Macrophages, and CD4+ T cells), and molecular pathways that are associated with immune infiltration (i.e. complement, IL2, and IL6 signaling pathways). These observations highlight the intra-subject heterogeneity of OC in our study. This approach demonstrates the power of using spatial whole-transcriptome sequencing in solid tumor studies to help unravel the complexity of heterogeneous cancers.

## PgmNr 1765: Somatic mutation and copy number alteration profile in chordoma.

Chordoma is a rare bone tumor, which is believed to originate from notochordal remnants and occurs in the axial skeleton at cranial, spinal and sacral sites. Chordomas are considered slow-growing, however, local recurrences are common and treatment options are limited particularly for those with advanced disease, highlighting the need for improving our knowledge of the disease biology to discover novel druggable targets. In this study, we conducted targeted panel sequencing in paired tumor (Formalin-Fixed Paraffin-Embedded) and germline DNA of 57 chordoma patients residing in the United States or Canada. We also evaluated somatic copy number alterations (SCNAs) in a subset of the tumors (n=49) using an Illumina Infinium global screening array. The chordoma site distribution was 49% skull-base, 25% spinal, and 26% sacral, respectively. The most recurrent somatic mutations in this tumor set included *PIK3CA* (n=6), *LYST* (n=5), *SWI/SNF* genes (*PBRM1* [n=2], *SETD2* [n=3], and *SMARCB1* [n=1]), and *USP9X* (n=3). Most *LYST* mutations (4 out of 5) occurred in tumors from females or sacral chordomas, while all 3 mutations in *USP9X* occurred in spinal tumors. Other mutations included *TP53*, *PALB2*, *MAP3K4*, *ATM*, *TSC2*, each in a single tumor. SCNA arm-level profile was consistent with previous reports, including frequent gains of chromosomes 1q, 2, 5, and 7, and deletions of 1p, 3, 4, 9, 10, 13q, 14q, and 18. Gains of chromosomes 1q and 2 and deletions of 13q were more likely to occur in skull-based tumors, whereas deletions of chromosomes 5, 9, and 18 were more prevalent in sacral tumors or chordomas from older patients. GISTIC analysis identified several significant focal SCNA regions, including the deletion peak of the 9p21.3 region containing the *CDKN2A* gene. Homozygous 9p21.3 deletions were seen in 4 tumors. Focal amplification of the *T* gene was seen in 3 tumors (two skull-base, one sacral), which occurred at a much lower frequency compared to the frequency (>20%) reported in a published sacral chordoma sequencing study. In summary, results from our study provide further evidence that mutations in *SWI/SNF* complex genes, *PIK3CA*, and *LYST*, as well as *CDKN2A* homozygous deletions might be driver events in chordoma and some of these genomic events might vary by chordoma sites.

## **PgmNr 1766: Correlation between mutations found in FFPE tumor tissue and paired cfDNA samples.**

Cell free DNA (cfDNA) consists of small (150 – 500 bp) DNA fragments that circulate in the blood. cfDNA levels tend to be low in healthy, non-pregnant patients, and increase in patients with cancer, pregnancy, or extensive damage to tissue. cfDNA is believed to derive mostly from apoptotic cells, and biomarkers for a variety of diseases have been found in cfDNA. As cfDNA is extracted from blood, it is a non-invasive way to detect disease; however, there is some concern that cfDNA does not contain the same biomarkers as tumor tissue. This study measures the efficacy of cfDNA as a biomarker detection medium by comparing mutations found in both FFPE tumor samples and paired cfDNA samples. This study determines whether the same biomarkers are found in each sample type, and which of those can be used as biomarkers in both and which are preferred biomarkers for only a single sample type. Trends in mutation detection with the two different sample types are discussed.

## **PgmNr 1767: Comparison between mutation profiles of paired whole blood and cfDNA samples.**

Liquid biopsies are increasingly becoming a tool of choice for cancer detection and monitoring. NGS of cfDNA is coming into maturity as a non-invasive method to identify mutational profiles in many cancer types . Here we describe a simple method to isolate both gDNA and cfDNA from a patient blood sample and discuss the automation of both extractions. We show the efficacy of cfDNA as reliable biomarker analysis tool by comparing mutations in cfDNA vs whole blood. The study determines if the difference between tumor and germ-line mutations can be established and what are the limitations.

## PgmNr 1768: Functional validation of *RCCD1* as a candidate susceptibility gene for breast and ovarian cancer risk.

### Authors:

---

Breast and ovarian cancers share not only common etiologies and but similar genetics, such as mutations in *BRCA1/2* are responsible for most multi-case breast/ovarian cancer families. These cancers also share common genetic susceptibility variants suggestive of pleiotropic risk for both breast and ovarian cancer. Previous GWA and cis-eQTL analyses identified *RCCD1* as a likely candidate gene for both breast and ovarian cancer risk. To confirm *RCCD1* as the target gene, we utilize chromosome conformation capture assays to identify the physical interactions between this susceptibility gene and risk associated SNPs. We answer the question whether the same risk SNPs have shared interactions with *RCCD1* in their respective cancer or whether different SNPs at this locus act in a cell specific manner with respect to breast and ovarian cancer. Specifically, we use precursor and cancer cell lines for both cancer types to identify interactions between the *RCCD1* promoter and possible candidate causal variants at the 15q26 pleiotropic risk locus. The pleiotropic risk SNPs, rs763280402 and rs570569800 showed 4C interactions with the *RCCD1* promoter in both breast and ovarian cancer cells, hence at this locus the same SNPs appear to contribute to *RCCD1* regulation. Given regulatory elements are the likely functional targets of most risk-associated SNPs, we used regulatory feature annotation (Statehub) to show both SNPs lie in predicted enhancers in their respective cell type. Moreover, normal precursor cells exhibit more interactions (>5-10) compared to their respective cancer cells, demonstrating there are cell type specific interactions from normal to cancer states. Trans interactions were seen between the *RCCD1* promoter and 8q24/*MYC* another pleiotropic risk locus (q value=8.12 e<sup>-48</sup>). In fact, breast and ovarian cancer patients who have high *RCCD1* expression (P<0.004) show prolonged survival curves (KM Plotter). TCGA data shows an increased expression of *RCCD1* expression in ER positive tumors (P value <0.00001). We evaluated the functional role of *RCCD1* in these cancers by perturbing its expression in breast and ovarian cancer precursor cell lines. CRISPR knockdown of *RCCD1* show neoplastic phenotypes consistent with its role in oncogenesis. These findings show that using an integrated functional genomics approach to comprehensively evaluate interactions of a given breast and ovarian cancer risk locus can identify candidate susceptibility genes for both cancer types.

## PgmNr 1769: High throughput high molecular weight DNA extraction from human tissues for long-read sequencing.

---

Structural variants (SVs) such as inversions and translocations are increasingly recognized as drivers of genetic disease. SVs are difficult to detect with traditional short-read sequencing due to their size. However, recent studies using long-read sequencing and optical mapping methods from PacBio, Oxford Nanopore, and Bionano Genomics have found SVs to be 5-10X more prevalent than previously thought.

The ability of these methods to detect SVs is predicated on high purity, high molecular weight (HMW) DNA. Whereas germline SVs are readily detected using blood or saliva, somatic SVs can only be detected using tissues. Tissues present a particular challenge as they contain extracellular material that must be efficiently disrupted without damaging delicate HMW DNA.

The gold-standard for HMW DNA extraction is agarose plug lysis, a tedious two day method that can only process a small handful of samples. In contrast, spin column and magnetic particle methods are fast but fragment HMW DNA, compromising read lengths and SV detection sensitivity. High-throughput methods are needed to enable large scale studies of SVs and to underpin future clinical tests.

We present a high throughput method for HMW DNA extraction. First, Covaris cryoPREP automated dry pulverizer is used to cryofracture frozen tissue samples in tissueTUBEs. Compared to Dounce homogenizer or TissueRuptor, cryoPREP can rapidly process large numbers of samples with high reproducibility. Then, Circulomics Nanobind magnetic disks are used to extract HMW DNA from the cryofractured tissue powder. Each Nanobind disk is covered with micro- and nanostructured silica that protects DNA from shearing to enable higher DNA size, extraction yield, and purity than competing methods. The entire protocol can be completed in only 2 hours.

This method was tested on a comprehensive panel of human tissues including breast, kidney, colon, uterine fibroid, pancreas, and skeletal muscle. DNA size up to 300 kb was obtained across all tissue types with size surpassing 500 kb for some samples. 25 mg of tissue was used in each extraction and resulted in 3-40 µg of DNA. Extraction yields varied across tissue type but were consistent across replicates (11% CV). The DNA were then sequenced on Oxford Nanopore GridION. High read length N50 over 36 kb and throughputs up to 9 Gb were obtained. These high quality DNA samples are suitable for diverse methods including PacBio and 10X Genomics as well as Illumina sequencing.

## PgmNr 1770: Genomic landscape of subependymal giant cell astrocytomas: Unique gene expression profile with few somatic events.

**Background:** Subependymal giant-cell astrocytomas (SEGAs) are rare, slow-growing glioneuronal brain tumors, seen in 10-15% of individuals with Tuberous Sclerosis Complex (TSC). Though histologically benign, SEGAs can cause serious neurological problems and be fatal. SEGAs show *TSC1/TSC2* biallelic loss and distinct gene expression patterns compared to normal brain.

**Aim:** To define other somatic genetic events beyond *TSC1/TSC2* that occur during SEGA development and examine transcriptional differences in comparison to other CNS brain tumors.

**Material and Methods:** Exome sequence analysis was performed in 21 paired resected SEGA tumors (Illumina platform). Whole transcriptome RNA-seq analysis was performed on 16 SEGAs and was compared to TCGA Low Grade Gliomas (LGG; n=530), glioblastoma (GBM; n=171) and gangliogliomas (n=10).

**Results:** Fifteen germline and 5 somatic variants were identified in *TSC2* and 5 germline variants in *TSC1* in 21 SEGAs. Copy neutral Loss of Heterozygosity (CN-LOH; size range: 2.9-46Mb) was seen in 76% (16/21) of SEGAs (35% chr9q and 65% chr16p). Thirty-six somatic non-synonymous variants in

genes other than *TSC1/TSC2* were identified in 12/21 (57%) SEGAs (range:0-6 variants, average of 2.6, median AF 16%), mainly missense changes of uncertain clinical significance. Differential gene expression analysis of SEGAs compared to TCGA LGG, GBM and gangliogliomas RNA-seq data revealed >1500 differentially expressed genes, including several homeobox transcription factors (TFs) with pivotal roles in brain development; *HMX3*, *HMX2*, *IRF6*, *VAX1*, *SIX3*, *TWIST2*, *ZBTB20*, and *EOMES* were all expressed at median >9-fold higher ( $p < 0.003$ ,  $FDR < 0.05$ ) in SEGAs. These TFs were validated by IHC in multiple sections from SEGAs in comparison to normal brain, cortical tuber, GBM, and LGG subtypes including diffuse astrocytoma, oligodendroglioma, ganglioglioma, pleomorphic xanthoastrocytoma and subependymoma. Unsupervised weighted gene co-expression network analysis (WGCNA) identified 24 modules of co-expressed genes, and we found that 6 of the 8 TFs above belonged to the module that showed the most consistent difference between SEGAs and LGG/GBM.

**Conclusions:** SEGAs have one of the lowest somatic mutation rates known for human cancers. *TSC1/TSC2* loss appears to be sufficient, while other somatic variants are likely background. The highly expressed TFs we identified are candidate key drivers of SEGA growth, and serve as novel diagnostic markers and potential therapeutic targets.

Next-generation sequencing (NGS) has revolutionized biomedical research, yet the effective transfer of NGS to the clinical sphere is limited by its per-patient cost, time to construct an assembly, and short-read limitations. Our lab has developed a powerful complement to NGS: a high-speed atomic force microscopy (HSAFM) platform for “nanomapping” the genome. Our HSAFM, the fastest atomic force microscope ever developed, “feels” DNA with a nanoscale tip to yield topography maps with sub-nanometer z-resolution and 15 bp lateral resolution. Enzymes like Cas9 can be easily distinguished from DNA and precisely located in these images. We thus use nuclease-inhibited Cas9 as a programmable biomarker for nanoscale mapping, in which an observed pattern of sgRNA-Cas9 labels is compared to an *in silico* reference to reveal the presence of variants. Our approach is applicable as a programmable assay tuned to any hotspot of genetic mutation and can accommodate DNA fragments sized from <100 bp to >1 Mb. We have demonstrated the method’s efficacy and sensitivity using multiple oncogene targets in blinded cell line and clinical sample experiments, yielding metrics that meet or exceed those of standard assays. Unlike many standard or proposed assays, sample preparation for our technique is cheap and simple, image processing is conducted in near real-time, and the most expensive component of our HSAFM—its optical unit—can be replaced by a commercial DVD optical pickup. Thus, at a fraction of the cost and time of NGS and other comparable techniques, HSAFM nanomapping has the potential to serve as a viable tool for the assessment of genetic disease in the clinical realm.

## **PgmNr 1772: Genome analysis through electric signal detection of nucleotide incorporation using a portable DNA sequencer.**

---

Advancing our ability to produce accurate, high throughput and cost effective sequencing data is the driving force for biomedical discovery and technology innovation. Here, we evaluate a new sequencing platform from Genapsys for its workflow and performance in sequencing quality, output and robustness. The Genapsys technology utilizes a novel sequencing-by-synthesis approach that employs electrical signal detection of nucleotide incorporations on a semiconductor chip, allowing for highly accurate sequence detection. The system adopts standard library preparation followed by DNA template amplification on beads and the sequencing reaction on a scalable and portable format. Using microbial genomes comprised of a wide range of sequence contexts as well as the human reference NA12878 genome, we assess the performance of the Genapsys technology on its accuracy, coverage, error profile, GC bias and alignment ratio in comparison with the Illumina SBS technology. With an early access system, we have demonstrated the high quality of the sequencing data and utility in mutation detections in targeted gene panels. Beyond sequencing of standard control samples for reference benchmarking, we have detected the mutations in genes frequently altered in glioblastoma tumor samples. The quality of data, combined with its highly portable nature and cloud-based data processing workflow, should make this as promising platform for clinical utility.

## **PgmNr 1773: Identification of germline variants for hereditary cancer using the rapid, CleanPlex® multiplexed NGS panel.**

---

The demand for genetic testing for hereditary cancers has been increasing, especially to aid with testing and diagnostics of patients. High quality variant calling and ease of workflow are critical for these assays. We have developed the CleanPlex® Hereditary Cancer Panel V2 for rapid production of NGS libraries with high-quality coverage of relevant hereditary cancer targets. This panel utilizes multiplex PCR of 1445 primer pairs to cover the coding sequence of 37 genes, two SNPs in the BRCA1 3'UTR, and the MSH2 Boland inversion. Here, we present that with as little as 10ng of input and ~1000 reads per amplicon, this panel exhibits a uniformity of ~99% at 0.2X mean bias, little GC bias, a mapping rate of ~96%, and identification of over 95% of SNPs and indels. With the CleanPlex® Hereditary Cancer Panel V2 simple workflow, efficient and economical targeted NGS libraries to investigate inherited cancers can be produced within 3 hours, with high variant calling confidence and excellent coverage uniformity of genomic regions of interest.

## PgmNr 1774: Whole exome sequencing of clinical samples on the GenapSys NGS Platform and performance comparison to industry standard technology.

**Introduction** Advances in Next Generation Sequencing (NGS) technologies and NGS-based diagnostic applications have ushered in a new age of clinical testing. These clinical diagnostic applications include germline and somatic mutation testing, non-invasive prenatal testing etc. Clinical testing is typically performed at centralized laboratories, partly due to the large capital costs of NGS platforms and high run costs, which necessitates pooling of large numbers of samples. There is a strong need for decentralized NGS-based clinical testing, e.g. at hospitals, enabling cheaper and faster results for doctors and patients. The GenapSys NGS platform offers an accurate solution with low capital equipment and run costs, making it ideal for point-of-care testing. In this study, the GenapSys system performance was characterized by sequencing clinical samples from Novogene and compared to industry standard Illumina technology.

**Methods** GenapSys NGS libraries were generated from patient samples, and sequencing metrics, as well as germline and somatic mutation calling, were compared with Illumina sequencing. Genomic DNA was extracted by Novogene from patient FFPE and blood samples, and genomic libraries were generated following mechanical fragmentation, adapter ligation, size selection and PCR. Hybrid capture-based enrichment on GenapSys libraries was done using the IDT Exome Research panel, which targets a 39 Mb region (19,396 genes), to generate a Whole Exome Sequencing (WES) library. WES was performed for both FFPE and blood sample libraries on the GenapSys and Illumina systems, with typical coverage >100x. Sequencing reads were aligned to the hg38 reference genome using BWA-MEM. Variant calling analysis involved additional training of the Google DeepVariant model based on GenapSys sequencing data.

**Results** Comparison of GenapSys and Illumina sequencing demonstrated high concordance, with the F1 score of ~95% on SNV detection in high confidence regions. Average read length of GenapSys sequencing was > 125 bp, and the library on-target rate was > 85%.

**Conclusions** This study demonstrated that the GenapSys NGS platform generated comparable sequencing performance to the industry standard NGS technology. It identified germline and somatic mutations in clinically relevant WES libraries generated from patient FFPE and blood samples, thereby showing promise for use in decentralized clinical testing applications.

## PgmNr 1775: Compositional and functional analysis of the microbiome in tissue and saliva of oral squamous cell carcinoma.

### Authors:

Z. Zhang <sup>1,2</sup>; C. Wantao <sup>1,2</sup>

[View Session](#) [Add to Schedule](#)

---

Oral squamous cell carcinoma (OSCC) is affected by the interaction between oral pathogen and holobionts, or the combination of the host and its microbial communities. Studies have indicated the structure and feature of the microbiome in OSCC tissue and saliva, the relationships between microbiota and OSCC sites, stages remain unclear. In the present study, OSCC tissue (T), saliva (S) and mouthwash (W) samples were collected from the same subjects, and carried out the microbiome study by 16S sequencing. The results showed the T group was significantly different from the S and W groups with the character of lower richness and diversity. Proteobacteria were most enriched in the T group at the phylum level, while Firmicutes were predominant in groups S and W. At the genus level, the predominant taxa of group T were *Acinetobacter* and *Fusobacterium*, and for group S and W, the predominant taxa were *Streptococcus* and *Prevotella*. The genera related to late stage tumours were *Acinetobacter* and *Fusobacterium*, suggesting microbiota may be implicated in OSCC developing. Both compositional and functional analyses indicated that microbes in tumour tissue were potential indicator for the initiation and development of OSCC.

## PgmNr 1776: Low allele fraction variant discovery via electrical detection of nucleotide incorporations.

Among the problems in human genomics research is that of successfully discovering allelic variants that occur at low frequencies. Germline sequencing allows robust claims to be made for variation from a reference even at low sequencing depth, because the true proportions for an allelic variant are *a priori* known to be 50% or 100%. Tumor samples, however, owing to stromal contamination, heterogeneity, or polyploidy, may have allelic fractions ranging from nearly 0% to nearly 100%. The discovery of low-frequency variants is particularly important from the clinical perspective because if such variants occur in coding or regulatory DNA, they may be indications of subclonal elements of the tumor that can take over and cause recurrence, should the primary clone(s) be successfully treated. Thus, methods for confidently discovering and validating low-frequency variations are crucial for improving the quality of cancer genomics research, particularly because of the rising importance of liquid biopsies and the analysis of cell-free DNA.

We have begun testing a new DNA sequencer (Genapsys) that uses a sequencing-by-synthesis approach. This sequencing technology employs electrical detection of nucleotide incorporations. The solid state instrument detects a steady-state signal allowing for highly accurate sequence detection. Prior to loading on the sequencer, a library of DNA fragments is clonally amplified with DNA primers conjugated to beads. Amplified beads are loaded into a Complementary Metal-Oxide Semiconductor (CMOS) sequencing chip containing a scalable number of sensors. Nucleotides are injected one base at a time and incorporations are measured as electrical signals from each sensor that collect on the instrument's solid-state drive. The incorporation data files are transferred in real time to a secure cloud-hosted server and storage environment. At the end of the run, a FASTQ file becomes available.

Via a number of admixture experiments, we have tested the ability of this sequencer to produce data that allows detection of low-frequency variants in important genetic regions, ranging to a proportion of coverage of less than .1%. Even given very low coverage proportions, we have found that the Genius sequencer allows detection, giving results similar to a comparison ddPCR assay. As a low-footprint, highly sensitive sequencing technology, the use of solid state sequencing should expand the space for effective targeted testing of important variants.

## **PgmNr 1777: Simultaneous capture of short and long RNA subtypes from liquid biopsy substrates and FFPE tissue samples by a novel RNA-Seq library preparation method accelerates biomarker discovery.**

Technological advances in recent years have accelerated the study of biological markers as diagnostic, prognostic, or predictive indicators of a physiological state. Through the use of RNA sequencing (RNA-Seq) technology, researchers are querying the differential expression of messenger RNA (mRNA) transcripts and non-coding RNAs (lncRNA) as potential biomarkers of disease. One limitation that impedes discovery is the inability to query all RNA subtypes in a sample simultaneously. Most commercially available RNA-Seq library preparation methods are limited in their ability to capture only long or short RNAs. Here, we describe a new library preparation kit that utilizes a novel enzyme to capture all RNA subtypes at great sensitivity and independently of their size, enabling the simultaneous differential expression analysis of mRNA, lncRNA, miRNA, snoRNA, and other subtypes. Furthermore, we demonstrate the robustness of the enzyme and its ability to capture RNA from complex and highly degraded biological samples, such as liquid biopsies substrates and FFPE tissue samples.

## **PgmNr 1778: Anatomical and transcriptional characterization of breast tumor heterogeneity using spatial RNA sequencing.**

The tumor microenvironment is consisted of highly heterogeneous cellular components that interact and communicate with each other dynamically. Significant advancement in single-cell RNA sequencing allowed capturing thousands of cells and has revealed many subpopulations of cells in tumor tissues. However, dissociation of the tissue into single cells results in the loss of its important architectural information. The recently introduced spatial transcriptomics technology resolves localization of cells within a tissue section. Here we present an improved version of this spatial technology with increased tissue coverage, higher spatial resolution, and significantly improved sensitivity. We applied our improved technology to tumor tissue sections from human breast tumors and analyzed tissue-wide transcriptomics profiles to locate cancer related genes and infiltrating immune cells within spatial context and revealed intra-tumor heterogeneity within a tissue section. Elucidation of the spatial heterogeneity of tumor cells can shed light into understanding the disease states and progression, thus possibly aiding treatment decisions.

## **PgmNr 1779: An automated high-throughput custom single-cell targeted DNA sequencing platform to reveal rare clones and clonal evolution in cancer and characterize mutation profiles in CRISPR-edited cells.**

A great challenge in precision medicine is the understanding of cancer heterogeneity and clonal evolution, which has major implications in targeted therapy selection and disease monitoring. Single-cell DNA sequencing has the potential to provide unique insights on the cellular and genetic composition, drivers, and signatures of cancer at unparalleled sensitivity. Previously we have developed an automated high-throughput single-cell DNA analysis platform (Tapestri™) that leverages droplet microfluidics and a multiplex-PCR based targeted DNA sequencing approach. Here we present a new generation of Tapestri™ system which features a new instrument with simpler workflow and a cartridge with new microfluidic design, coupled with optimized and updated chemistry, resulting in drastically higher cell throughput, higher genomic coverage, better precision, and robust performance. The system now take input from 5,000 to 100,000 cells and generate genotypes of 1500 to 30000 cells in one run. The employment of AI (artificial intelligence) engine during panel design improves amplicon performance resulting in >90% panel uniformity and coverage of amplicons with high GC content (65-72%) across panels. Catalog panels such as AML, Myeloid, CLL and Tumor Hotspot are readily available for direct use or adaptation. We also have developed a web-based custom panel design portal for all human or mouse exome targets. Custom panels from 20-2000 amplicons can be easily built with a turn-around time of 4-6 weeks from design to validation and delivery. The new biochemistry allows maximum flexibility for panel optimization, enabling easy addition of new targets into existing panels for improved coverage or updated study design. The new analysis pipeline and software also employ AI-based algorithms resulting in better sensitivity and specificity for rare mutation detection and de novo discovery. We have validated the system with fresh, frozen and fixed cells, including cell lines, blood cancer samples, and solid tumor tissues, demonstrated detection of rare subclones of <0.1% prevalence, identified cancer mutation co-occurrence, and constructed clonal phylogenetic trees during disease progression and drug treatment. Additionally, the system enables unprecedented throughput and insights in mutational profiling of CRISPR-edited single cells, enables distinction of individual mutation zygosity and multi-mutational co-occurrence, further advancing research into cell therapies.

## PgmNr 1780: Spatial nucleus barcoding integrates cellular genomics and tissue architecture in normal and malignant breast tissues.

---

The expression programs of cell types in tissues and their spatial organization are critical for understanding homeostatic functions of normal tissues and the progression of diseases such as cancer. However, current single cell RNA-seq methods inherently lose all spatial information on cellular localization. To overcome this technical obstacle, we developed a spatial nucleus barcoding (SNUBAR) technology that delivers spatial barcodes into tissue regions, after which barcoded nuclei are used for high-throughput single nucleus RNA-seq. We validated this method by sample barcoding and intermixing experiments with cell lines, which showed a high efficiency of barcode delivery and doublets identification. We applied SNUBAR to 36 spatial regions of a normal breast tissue which identified 9 major cell types and 3 distinct spatial regions (fatty, fibroblast and epithelial). The fatty region was mainly composed of adipocytes that colocalized with a distinct lipo-fibroblast cell expression state, while the fibroblast region contained matrix-producing fibroblasts that colocalized with pro-angiogenic macrophages and vascular endothelial cells. The epithelial areas were composed of three distinct epithelial cell types that colocalized with lymphatic endothelial cells, and another fibroblast expression program. We further applied SNUBAR to 15 spatial regions of an invasive breast tumor, which identified 4 cell types in the microenvironment in addition to the tumor cells. While most immune and stromal cells were uniformly distributed across the 15 spatial regions, the tumor cells consisted of two distinct expression programs that were spatially segregated and harbored distinct copy number alterations. The two tumor clones exhibited differences in gene signatures associated with epithelial-to-mesenchymal transition, MYC targets, hypoxia and the expression of several cancer genes (eg. *VEGFA*, *AKT1*, *AKT2*). Additionally, we found two distinct macrophages expression states that colocalized with different tumor sub-clones. These data demonstrate the utility of applying SNUBAR to delineate the spatial organization of cell types and their expression programs in normal and malignant tissues to understand how spatial localization influences gene expression programs. This new technology is expected to have numerous applications in broad fields where the spatial organization of cell types is key to understand biological functions and the progression of diseased states.

## PgmNr 1781: A new sample extraction method for multiomics profiling and signaling pathway analysis.

### Authors:

A multiomics approach to translational and clinical research aims to create more comprehensive molecular profiles to elucidate both molecular phenotype and mechanism of disease. One of the challenges in creating multiomic molecular profiles is the limited amount of relevant clinical material provided by FFPE and small surgical biopsy tissue. Often, one must choose between obtaining only genetic or proteomic information from the sample. Even when the sample source is plentiful, as with cells and large tissue, variation in cell populations or tissue subsections can create discordance between genetic and proteomic results when processed separately to extract nucleic acid and protein. We have developed a procedure to extract both NGS ready DNA and RNA and mass spec compatible peptides from the same FFPE section, cell pellet or tissue sample without the need to split the lysate. The entire workflow takes less than five hours. We applied our multiomic sample prep workflow to two applications; molecular profiling in FFPE cancer tissue and targeted signaling pathway analysis in human cells. DNA and RNA extracted from FFPE tissue were screened for clinically relevant DNA mutations and RNA fusions through targeted sequencing on the Ion Torrent GeneStudio S5 platform; these variants were then functionally verified by analyzing the extracted peptides on a Thermo Scientific Orbitrap Fusion Lumos mass spectrometer. Both mutation and fusion detection through the multiomic sample prep workflow was on-par with results from standard FFPE DNA/RNA extraction methods, but with the added benefit of verification of mutated protein presence. For signaling pathway analysis, we applied the multiomic extraction procedure to IGF treated human cancer cells to compare both RNA transcription and protein expression levels of key genes in the *AKT/mTOR* pathway. Using both targeted NGS and mass spec, we were able to determine the mechanism by which IGF treatment dysregulated the *AKT/mTOR* pathway within the cells. Our new sample extraction workflow enables genetic, transcriptomic and proteomic profiling from even limited sample sources while eliminating potential variabilities introduced by subsampling. This multiomics approach allows for DNA variant, RNA fusion and transcription detection, in addition to functional validation through proteomics.

## PgmNr 1782: Single-cell RNA sequencing of B16 melanoma model reveal the trajectory of distant metastasis of melanoma.

### Authors:

**Background:** Understanding the mechanism for distant metastasis is one of the fundamental issues in controlling metastatic melanoma. The purpose of our study was to elucidate the trajectory for distant metastasis of melanoma using single-cell RNA sequencing (scRNAseq) of B16 melanoma model.

**Methods:** We performed scRNAseq of murine melanoma cell line (B16F0) and its highly pulmonary metastatic variant (B16F10). The transcriptomic data of 2,884 and 1,827 cells were generated and analyzed from B16F0 and B16F10, respectively. The Seurat package was used to identify the subpopulation, differentially expressed genes between clusters, and cellular heterogeneity in genetic signatures. Copy number alternations between subpopulations were inferred by the InferCNV package. Pseudo-temporal ordering and RNA velocity analyses were performed by the Monocle package and the Velocyto package, respectively.

**Results:** Unbiased clustering of single-cell transcriptomes found two major populations according to the cell type, in which known cancer driver genes and additional putative genes were differentially expressed. Further finer clustering revealed five subpopulation, among which putative intermediate clusters with mingled B16F0 and B16F10 cells showed higher proliferative signature and lower invasive melanoma signature of melanoma, and putative highly metastatic cluster showed high expression of cancer driver genes. Inferred copy number alternation profiles suggested genetic aberrations between subpopulations. Pseudo-time trajectory and RNA velocity analyses supported the trajectory from putative intermediate subpopulation to putative highly metastatic subpopulation.

**Conclusions:** We identified transcriptional heterogeneity of melanoma cells during the metastasis progression using scRNAseq.

## PgmNr 1783: QIAseq FastSelect -rRNA and -Globin: One-step, rapid removal of rRNA and/or globin mRNA during whole transcriptome NGS library prep.

### Authors:

---

Whole transcriptome next-generation sequencing (NGS) enables the characterization of both mRNA and long noncoding RNAs (lncRNAs) from biological samples. For optimal results, significantly overrepresented RNAs, such as ribosomal RNA (rRNA) and globin mRNA must be removed. Elimination of these contaminating RNAs simultaneously increases sensitivity and decreases the sequencing budget required per sample.

Various methodologies exist to deplete rRNA and globin, including hybridization/capture methods employed both as a sample pre-treatment or during post-library construction and methods which utilize enzymatic digestion in combination with target specific probes. However, these methods do not efficiently remove rRNA and globin, distort transcriptomic profiles, are ill-suited for damaged samples, are time consuming and potentially cause sample loss.

To remedy these shortcomings associated with rRNA and globin depletion, we have developed QIAseq FastSelect -rRNA HMR and -Globin. The FastSelect technology utilizes a novel, one-step rRNA depletion method that prevents cDNA synthesis of unwanted RNAs in cell, tissue, and whole blood RNA, whether the molecules are intact or degraded. Furthermore, FastSelect is compatible with virtually all stranded RNAseq library methods, and works with human, mouse and rat samples, as well as other model organisms. Custom kits are also available for any species or RNA.

Here we present examples of utilizing QIAseq FastSelect -rRNA HMR and -Globin with strand-specific RNAseq to analyze the whole transcriptome of matched normal and tumor lung cancer FFPE samples as well as whole blood samples. Such resulting differentially expressed RNA signatures are typically being utilized for pathway analysis, biomarker discovery, or for sample stratification. QIAseq FastSelect -rRNA HMR and -Globin rapidly eliminates rRNA and globin to enable the discovery of novel gene signatures. FastSelect is more efficient, tolerant of degraded samples, faster, and more cost effective than existing solutions.

## PgmNr 1784: Lotus DNA Library Prep Kit: A single flexible workflow with endless applications.

### Authors:

H. Huang; M. Hong; R. Lopez; A. Royall; K. Lai; L. Lewis; U. Das Chakravarty; Y. Zheng; S. Henck

[View Session](#) [Add to Schedule](#)

**Affiliation:** Integrated DNA Technologies, Redwood City, CA.

Recent advances in NGS technology provides unprecedented value to the scientific community in understanding how genomic diversities translate to complexities in biological processes. As NGS is increasingly adopted in clinical and diagnostic settings, high throughput laboratories would benefit from a streamlined workflow that seamlessly transitions from library preparation to target enrichment, and enables multiple applications using a single library prep kit. We present the Lotus DNA library preparation kit that employs a combination of enzymatic fragmentation and unique end repair mechanisms in a single-tube with efficient adapter ligation strategy to generate high-quality NGS libraries in approximately 2 hours. The flexibility in the chemistry allows the users to pair any TA-ligation compatible adapter (full-length or stubby) with a sample indexing strategy of their choice for PCR-free, PCR-amplified, and targeted sequencing applications on Illumina platforms. This library prep kit is compatible with multiple custom IDT NGS adapters, including TruSeq<sup>TM</sup>-Compatible Full-length Adapters and TruSeq<sup>TM</sup>-Compatible Stubby Adapter and Indexing Primers, as well as xGen suite of reagents for hybridization capture. This workflow can be used with bacterial or eukaryotic genomic DNA (gDNA) as well as FFPE DNA samples.

To assess the performance of the Lotus workflow, libraries were prepared using full-length adapters from a range of human gDNA and FFPE DNA inputs (1-250 ng). Whole genome sequencing (WGS) analysis showed highly uniform GC coverage and low bias from PCR-free and PCR-amplified samples. As exome sequencing of coding regions within the human genome reduces sequencing costs and increases sample throughput, we evaluated our workflow in targeted sequencing using the TruSeq<sup>TM</sup>-Compatible Stubby Adapter and Indexing Primers and xGen Lockdown Exome hybridization capture panel. We observed high on-target mapping and uniform sequence coverage across the entire human exome, including GC-rich exons. To evaluate sensitivity and specificity in low frequency somatic variant detection, libraries were generated using full-length xGen Dual Index UMI adapters from mixtures of genome in a bottle gDNA (NA12878 and NA24385) and captured using a 75 kb custom panel targeting single nucleotide and copy number variants. In summary, the Lotus workflow provides a fast and reliable strategy for preparing libraries to address a wide variety of applications.

## PgmNr 1785: Imputation of plasma metabolites using whole exome sequencing data.

**Introduction.** Metabolomic profiling is a powerful tool for identification of novel disease biomarkers and mechanisms. For example, we have described two discrete metabolic clusters that are associated with obesity, insulin resistance, type 2 diabetes and cardiovascular disease (CVD): branched chain amino acids and short-chain dicarboxylacylcarnitines. However, many large cohort studies do not have metabolomic profiling; or they may have metabolic data that do not include the metabolites of interest, but which otherwise would serve as important studies of these cardiometabolic diseases. Many of these cohorts, including the UK Biobank and Trans-Omics for Precision Medicine (TOPMed), have existing deep genomic data that could be leveraged to understand relationships between metabolites and disease. This study sought to evaluate using whole exome sequence (WES) data to impute plasma metabolite levels using metabolomic quantitative trait loci (mQTL).

**Results.** WES with 20X coverage and data on 66 targeted mass-spectrometry profiled amino acids and acylcarnitines were generated on individuals enrolled in the CATHGEN cardiovascular study. The cohort was split into a training set (N=3,441) and a validation set (N=860). Genetic variants were filtered based on minor allele count ( $\geq 10$ ) and significance of GWAS association with individual metabolite ( $p < 5e-5$ ); indels and non-autosomes were removed. Machine learning models controlling for age and sex fit in the training set included between 2 and 874 genetic variants; they were evaluated for efficiency in the validation set using two methods. (1)  $R^2$  between directly measured and imputed metabolites were measured and ranged from 0.01 to 0.38. (2) Associations between metabolites and Homeostatic Model Assessment of Insulin Resistance (HOMA-IR), were evaluated to see that the clinical value of these metabolites remained after imputation. For example, propionylcarnitine is strongly associated with HOMA-IR ( $p < 3e-30$ ) and had only a slight attenuation of effect size within the validation set after imputation (0.74 vs 0.24, measured vs imputed) indicating the imputed version of this metabolite has some value.

**Conclusions.** This method shows promise for extracting additional understanding of obesity and CVD by enabling the many large cohorts with genomic data on their participants to engage in metabolomic profiling studies. Further work will be needed to refine our machine learning models from these preliminary results.

## PgmNr 1786: A genome-scale Crispr screen identifies modulators of doxorubicin-induced cardiotoxicity.

**Authors:**

C. McDermott-Roe; W. Lv; K. Musunuru

[View Session](#) [Add to Schedule](#)

**Affiliation:** University of Pennsylvania, Philadelphia, PA.

---

Doxorubicin is a potent chemotherapeutic used to treat various cancers. Despite efficacy, doxorubicin can cause severe and irreversible cardiotoxicity. We carried out a genome-scale CRISPR-Cas9 screen in HL1 mouse cardiomyocytes to identify genes which when disrupted, either protect against or worsen doxorubicin toxicity. Validating our approach, *Top2a* (the doxorubicin target) and *P-glycoprotein* (the doxorubicin efflux pump) were amongst the very top desensitizers and sensitizers, respectively. The screen also uncovered hundreds of other genes which significantly influenced toxicity as well as multiple over-represented gene sets. Our study provides an unbiased, forward genetics-based insight into doxorubicin-induced cardiotoxicity and a springboard to define novel toxicity mechanisms and susceptibility alleles.

## PgmNr 1787: Reducing the sample quality barriers between short and long read platforms to achieve genome comprehensiveness.

---

Comprehensive whole genome sequencing (WGS) requires more than standard Illumina short-read sequencing. We have tested alternative DNA sequencing platforms, including Pacific Biosciences (PacBio) or Oxford Nanopore (ONT) (long reads), 10x Genomics (short linked-reads) along with improved bioinformatics solutions, and demonstrated impressive phasing lengths (N50 of 67 Mbp). In a pilot study, we 'upgraded' 18 samples selected from a Cardio Vascular Disease (CVD) cohort set of 4,425 samples, based upon predicted Structural variations (SV) representation, by generating ~10x PacBio long read coverage of each. This demonstrated that long read data identifies new SVs and confirms SVs identified in short-read data and illustrated the ready need to establish production readiness for the new platforms.

Each method has particular sample requirements that must be balanced with performance attributes – for example, 10x Genomics platform is susceptible to low DNA quality but needs only ~1ng as library input. ONT provides the longest reads and PacBio platform generates CCS reads of highest read quality, however each require long molecular length DNA as for routine use. To introduce the procedures to a production environment, these DNA quality and DNA quantity demands must be met and balanced with the desired sequence output.

Using the 10x genomics platform for development, we improved both the DNA quality and quantity in the sample preparation workflow. For DNA QC, instead of the Pippin Pulse technology, that can QC 12 samples per run, Bio-Rad Pulse field gel electrophoresis was employed to QC 2x more samples and also provide better size resolution for >50 Kb DNA fragments. A follow-up electro-elution protocol for isolating DNA fragments >50Kb from fragmented DNA samples is under development. A new QC step to accesses the linked molecule length in 10x Chromium libraries through low coverage (~8x) sequencing is in production. These methods are also easily adaptable to PacBio and Nanopore platforms and will collectively reduce the DNA quality barriers between the short and long or linked read platforms and facilitate use of existing DNA for achieving genome comprehensiveness.

## **PgmNr 1788: Using genetic information for the reconstruction of metabolic processes underlying coronary heart disease: An example of the use of metabolomics in systems epidemiology of lipids.**

**Authors:**

F. Drenos

[View Session](#)[Add to Schedule](#)**Affiliation:** Brunel University London, London, United Kingdom

---

Lipids and the particles carrying them in circulation play a crucial role on the development and progression of changes leading to coronary artery disease (CAD). Studying the relationships between these particles and other CAD relevant molecular measures can provide valuable information for the metabolic processes involved and their functional organisation.

I used 230 metabolic measures from a targeted metabolomics approach together with genetic information from two samples of an established European cohort, totalling more than 9,400 individuals. I tested the phenotypic and genetic correlations between the metabolic measure identifying extensive correlations present and an almost identical correlation structure between the phenotypes and their underlying genetic factors. After Mendelian randomisation, I identified causal connections between 9,496 pairs of metabolic measures, though the direction of the effect was not always easy to infer.

Using the data to generate causal correlation networks showed that we could reconstruct well known metabolic processes using very little prior information. Even with no additional information, the causal correlations clearly showed the heterogeneity of function between high density lipoprotein (HDL) particles that can impact their role on CAD risk. I also found that the observed associations of lipoproteins levels with conjugated linoleic acid and glycolysis markers, such as glucose and citrate, are probably not due to an underlying biological mechanism. In contrast, the acute phase a1-acid glycoprotein is likely able to modify the larger triglyceride rich lipoproteins.

The results suggest that the use of genetics in the system epidemiology of lipids is possible but establishing the direction of effect will require additional information. The approach can improve our understanding of interactions between metabolic processes and, in this case, help us to elucidate the role of HDL particles in CAD.

## PgmNr 1789: Determination of expression level of miRNAs circulating plasma in patients with acute myocardial infarction (AMI) early onset.

### Authors:

### Introduction

MiRNAs are important players in cardiovascular physiology, as some balance control the differentiation and proliferation during cardiogenesis, and the aberrant expression of certain miRNAs has been related to cardiac diseases, including myocardial ischemia, because they act by limiting the expression of some proteins or increasing their expression according to the cellular requirement.

### Aim of the study

To determine the level of expression of miR1, miR16.2, miR21, miR107, miR130, miR133, miR143, miR155 and miR221 in patients with AMI and compare their expression in subjects without AMI.

### Material and methods

In 37 patients with AMI and 32 patients without AMI The extraction was done performed miRNAs circulating plasma with the exoRNeasy kit SerumPlasma. The synthesis of cDNA was done with the miScript kit II RT and the validation of expression of the 9 miRNAs by real-time PCR using the miScript matrix miRNA PCR Arrays. Comparative analysis of expression of miRNAs between patients and control is performed carried off by the algorithm  $2^{-DDCt}$  in RT<sup>2</sup>Profiler™ PCR Array Data Analysis (QIAGEN) software.

### Results

The average age of presentation of the AMI in the patients was 63.56 years. Of the patients studied, 81% were men, 70% had DM2 and 70% had hypertension. The comparison of the level of expression of miRNAs showed a differential expression profile in patients with AMI compared to the group without AMI, since a significant pattern of subexpression was observed in miR16 ( $p = 0.02$ ), miR21 ( $p = 0.023$ ) and miR155 ( $p = 0.0001$ ), with level greater than 2 times of change to the downside.

### Conclusions

The results suggest that there is an expression profile of miRNAs that distinguish patients with AMI

from healthy subjects, highlighting the possible involvement of miR16, miR21, and miR155 in the physio pathology of AMI in the Mexican population and its possible use as molecular biomarkers .

## PgmNr 1790: Genotype correlates with clinical severity in *PIK3CA*-associated lymphatic malformations.

Lymphatic malformations (LMs) are congenital, non-neoplastic vascular malformations associated with post-zygotic activating *PIK3CA* mutations. The mutation spectrum within LMs is narrow, with the majority having one of three “hotspot” mutations. Despite this relative genetic homogeneity, clinical presentations differ dramatically. We used molecular inversion probes and droplet digital polymerase chain reaction to perform deep, targeted sequencing of *PIK3CA* in 271 affected and unaffected tissue samples from 81 individuals with isolated LMs and retrospectively collected clinical data. Pathogenic *PIK3CA* mutations were identified in affected LM tissue in 64 individuals (79%) with isolated LMs, with variant allele fractions (VAFs) ranging from 0.1 to 13%. Initial analyses revealed no correlation between VAF and phenotype variables. Recognizing that different mutations activate PI3K to varying degrees, we developed a metric to reflect differences in mutation strength, which we called the **genotype-adjusted VAF (GVAF)**, and found significantly higher GVAFs in LMs with more severe clinical characteristics including orofacial location or microcystic structure. In addition to providing insight into LM pathogenesis, we believe GVAF may have broad applicability for genotype-phenotype analyses in mosaic disorders.

## PgmNr 1791: Profiling of transcriptome and chromatin accessibility dynamics during iPSC-cardiovascular progenitor cell differentiation identifies novel cardiac fate-determining marker genes.

---

The origin of many diseases are rooted in development, rather than in adults, underscoring the importance of identifying and characterizing genes driving cell differentiation. To identify genes underlying differentiation into cardiomyocytes (CMs), it is possible to leverage induced pluripotent stem cell (iPSCs) as there are known experimental protocols for differentiating iPSCs into CMs. However, while the importance of modulating WNT signaling is well established, the set of genes whose expression drives differentiation at each step of the protocol remain unknown. Thus, elucidating which genes are key drivers of the cardiac differentiation protocol could provide insight into cardiac disease etiology.

To identify the genes underlying CM differentiation, we characterized the dynamics of gene expression and chromatin accessibility throughout differentiation. We examined temporal changes in RNA-seq and ATAC-seq profiles at various stages of CM differentiations (day 0, 2, 5, 9, 15) in three iPSC lines (L1, L2, L3) from three subjects in triplicate (45 total samples). We observed a substantial divergence of global gene expression and chromatin accessibility at D5 and beyond in one line (L1) compared to the other two lines, suggesting the samples have different cell fates. We thus examined scRNA-seq data and found that while L1 was primarily comprised of epicardium-derived cells (EPDCs), L2 and L3 were primarily CMs. We leveraged these two different cell types to distinguish the driver from neutral genes that happen to have similar expression patterns. First, we identified genes with A-shaped spikes in their expression patterns at day 5, 9, or 15 in CMs and not in EPDCs. Next, we intersected these genes with the signature CM genes from the scRNA-seq, and utilized a machine learning approach to identify the genes at each time point which explained a large proportion of variation in final cell fate. This process resulted in the identification of 23 putative driver genes across the three time points. The genes from D9 and D15 were functionally enriched for cardiac muscle contraction and CM membrane potential regulation, respectively, and also included known cardiac trait-associated genes (*PRKAG2* and *FBN2*). Of note, 17 are eGenes regulated by cardiac eQTLs. Our results provide a list of driver genes that underlie key time points of cardiac cell differentiation and whose differential expression may contribute to the fetal origin of heart disease.

## **PgmNr 1792: Longitudinal multi-omics profiling in response to acute exercise in healthy and prediabetic individuals.**

---

Exercise training has been widely recognized to have multiple benefits including cardiac effects and systemic factors. Insulin resistance (IR) is linked to the development of prediabetes and type 2 diabetes (T2D), all of which are further associated with increased risk for cardiovascular disease and altered immune function. Exercise training is also commonly recommended to control IR and T2D. However, the main molecular mechanism of its cardioprotection and prevention against T2D development is still poorly understood. In this context, we present an integrative multi-omics profiling study, including transcriptomics, proteomics, metabolomics, and lipidomics, on blood-based analytes in response to exercise in healthy and prediabetic individuals at a longitudinal fashion. The acute bout of exercise was associated with a wealth of bio-molecular changes (10,235 molecules at FDR < 0.05) spanning all omic layers. The integrative omic analysis revealed a complex network of molecular associations highlighting expected and novel connections related to energy metabolism, inflammation, oxidative stress, and coagulation/homeostasis. This longitudinal multi-omics study not only provides integrative insights into the mechanisms underlying exercise effects with molecular pathways, but also enables detection of personalized responses to exercise between healthy and prediabetic individuals, further facilitates precision exercise interventions against the development of prediabetes and T2D.

## PgmNr 1793: RNA-based mutation detection approaches identify a novel *PKP1* mutation with unusual splicing pattern in a family with ectodermal dysplasia-skin fragility syndrome.

---

Ectodermal dysplasia-skin fragility syndrome (ED-SFS), an ultra-rare autosomal recessive form of epidermolysis bullosa, manifests with blistering and erosions of the skin and palmoplantar keratoderma, variably associated with abnormal ectodermal development, including hypotrichosis, hypohidrosis, nail dystrophy, and abnormal dentition. Here, we examined a consanguineous family with two siblings with ED-SFS, for mutations by phenotype- and homozygosity mapping (HM)-assisted transcriptome profiling by RNA-Seq. HM reduced the number of candidate genes to 29, and transcriptome profiling identified *PKP1* with reduced expression. In addition, *PKP1* was the most downregulated gene among 94 candidate genes previously associated with the range of phenotypes observed in our cases. *PKP1*, encoding plakophilin 1, an integral component of the epidermal cell adhesion complexes, desmosomes, harbored a sequence variant at the end of the intron 10, *PKP1*: IVS10: c.1835-1G>C. As a result, the canonical acceptor splice site at the intron 10/exon 11 borders was inactivated, and instead, a cryptic splice site eight bp upstream within the exon 11 was activated. Sashimi plot revealed splicing aberrations, including retention of intron 13 sequences. Thus, our results support the hypothesis that whole-transcriptome sequencing assisted by HM and clinical phenotype can be utilized as a first-tier diagnostic approach for finding mutations in patients with Mendelian skin disorders.

## PgmNr 1794: Clinical, genetic and biochemical findings in a cohort of >1,000 patients with Gaucher disease.

### Authors:

C. Beetz; C. Cozma; L. Demuth; M. Werber; G. Oprea; V. Weckesser; A. Rolfs

[View Session](#) [Add to Schedule](#)

**Affiliation:** Centogene AG, Rostock, Germany

Gaucher disease (GD) is a lysosomal storage disorder that is caused by bi-allelic pathogenic variants in *GBA*. It may manifest with organomegaly, bone pain, thrombocytopenia and/or other symptoms, and is clinically very heterogeneous. Genotype-phenotype correlations have been suggested for the two outstandingly frequent mutations c.1226A>G (p.Asn409Ser, “N370S” in old nomenclature and representing a ‘milder’ allele) and c.1448T>C (p.Leu483Pro, “P444L”; ‘sever’ allele). While the activity of the *GBA*-encoded enzyme glucocerebrosidase has classically been determined as a biochemical diagnostic parameter, we recently suggested the sphingolipid Lyso-Gb1 to represent an even more sensitive and potentially dynamic biomarker. We now present Lyso-Gb1 determination as well as clinical and genetic findings in a cohort of >1,000 confirmed GD patients from 52 countries.

We identified a total of 157 pathogenic alleles, 68 (43%) of which are novel. Homozygosity was approximately as frequent as compound heterozygosity, and there were similar numbers of males and females. The clinical records were translated into 170 distinct HPO terms; there were an average of 4.1 terms per patient. Consistent with the cardinal symptoms of the disease, the most frequent terms were *thrombocytopenia* (in 53% of patients), *anemia* (48%), *splenomegaly* (41%), *hepatomegaly* (40%), *hepatosplenomegaly* (34%) and *bone pain* (34%). Plasma Lyso-Gb1 concentrations ranged from 18.7 to 1,600 ng/μl (pathological cutoff at >10 ng/μl), and showed an exponential distribution. Notably, Lyso-Gb1 values correlated with the numbers of HPO terms per patient, and were higher in more severely affected patients (e.g. *thrombocytopenia* + *excessive bleeding* vs. *thrombocytopenia*). Homozygous c.1226A>G patients had lower Lyso-Gb1 levels than homozygous c.1448C>T patients, while c.[1226A>G];[1448C>T] compound heterozygous patients were intermediate. Many additional genotypes differed significantly from each other as regards the associated Lyso-Gb1 values.

Our study widens the mutational spectrum in Gaucher disease, and reveals novel insights into clinical-genetic associations. It also characterizes Lyso-Gb1 as a highly valid biomarker for assessing disease severity and, potentially, monitoring of progression and response to therapy.

## PgmNr 1795: Characterization of heterogeneity in adipogenesis by single-cell RNA-seq.

### Authors:

J. Li <sup>1,2,3</sup>; S. Gustafsson <sup>4</sup>; A. Rao <sup>5</sup>; C. Park <sup>1,2,3</sup>; E. Ingelsson <sup>1,2,3</sup>

---

Significant cell-to-cell variability in morphology and function has long been observed in differentiating adipocytes, which cannot be discerned by population-averaged measurements, such as bulk RNA-seq. It is also unclear to what extent the observed variability reflects the presence of phenotypically distinct subpopulations or asynchronous cellular responses to differentiation stimuli. To better characterize the heterogeneity in adipogenesis, we performed single-cell RNA-seq on human Simpson-Golabi-Behmel syndrome (SGBS) cells - a non-immortalized and non-transformed preadipocyte model - before and after 7 days of adipogenic differentiation. By using droplet-based single cell capture which enabled the gentle handling of large and rupture-prone adipocytes, we successfully mapped a single-cell profile including 5,662 cells from day 0 and 3,643 cells from day 7, validated by the correlated transcriptomic profiles of matching bulk samples. Next, by applying K-means clustering on the aggregated and normalized single-cell data of both timepoints, followed by t-SNE visualization, we defined 3 major clusters with distinctive gene expression patterns. Cells in Cluster 1 showed strong enrichment in genes featuring a preadipocyte phenotype, including those involved in proliferation (*TGFB1*, *CCND1*), extracellular matrix remodeling (*CLDN11*, *SERPINE1*) and negative regulation of adipogenesis (*GREM1*, *ID3*). Cells in Cluster 2 and 3 were enriched in genes positively associated with adipogenesis (*FABP4*, *ADH1B*, *CFD*), indicating a cell commitment to adipogenic trajectory. Among these, cells in Cluster 3 were further enriched in genes characteristic of a mature adipocyte function, such as adipokine synthesis (*ADIPOQ*), lipolysis (*PLIN1*, *LIPE*, *GOS2*, *PNPLA2*), fatty acid biosynthesis and desaturation (*FASN*, *SCD*, *FADS1*), representing a subpopulation of lipid-rich and metabolically active adipocytes further along into differentiation. Our single-cell transcriptomic catalog thus serves as a valuable resource to uncover novel molecular events underlying the intrapopulation heterogeneity both within and between timepoints of adipogenesis. Future studies combining single-cell profiling with genetic and metabolic perturbations in human primary (pre)adipocytes can pave a way for deeper understanding of subject-, depot-, and cell-specific regulation of adipocyte formation and function in health and disease.

## PgmNr 1796: Metagenomics of gallbladder stone and bile in Han Chinese in Taiwan.

---

**Background and Goal:** Gallstone disease (GSD) confer as common gastrointestinal disease worldwide. Cholesterol-, mixed- and pigmented-stone are major types in GSD. This complex disorder most resulting from interactions between genetics and environmental factors. The incidence of GSD is about 5-14.3% in adult and correlated with age positively in Taiwan. It costs lots of clinical and surgical treatment. Genetic factors are also affecting in pathogenesis of gallstone. Many evidences for bacteria playing a role in the pathogenesis and formation of pigmented gallstones from human. However, the relationship between microbiota and GSD are not well discussed in Taiwan. In this study, we try to find the possible risk factors in bacteria affect in GSD.

**Methods:** We enrolled 78 GSD samples by laparoscopic cholecystectomy which include pigmented-bile, pigmented-stone, cholesterol-bile, and cholesterol-stone. Gallbladder bile and stone total DNA extracted by ZymoBIOMICS DNA miniprep kit. Bacteria V3, V4 region amplified by PCR and sequencing by Illumina Miseq. Sequence data trimmed, alignment and analysis by CLC Bio software.

**Results:** All the GSD sample in microbiota analysis merely bacteria-free. We found that microbiota diversity of pigmented-bile, -stone are far more than cholesterol-bile, -stone. For example, *Proteobacteria*, *Gammaproteobacteria*, *Enterobacteriales*, *Enterobacteriaceae*, and *Klebsiella*. The percentage of bacteria between male and female are different significantly under the same type of stone or bile. Such as *Firmicutes*, *Bacilli*, *Lactobacillales*, *Enterococcaceae*, *Enterococcus* are significant in male than female.

**Summary:** Our study provides a framework to study microbial profiling that predict a potential role in gallstone formation across different types of stones and patient backgrounds. We hope that will provide to clinical use in the future.

## PgmNr 1797: Identification of differentially expressed genes from kidney transplant recipients in Northern Ireland.

### Authors:

K. Kerr; L.J. Smyth; J. Kilner; A.P. Maxwell; H. McAneney; I. Young; B. McGuinness; F. Kee; A.J. McKnight; The Northern Ireland Cohort for the Longitudinal Ageing collaborative group.

[View Session](#) [Add to Schedule](#)

**Affiliation:** Centre for Public Health, Queens University Belfast, Belfast, United Kingdom

Belfast City Hospital is a kidney transplantation centre with the highest living donor transplant rate per million population in Europe. Kidney transplantation is a gold standard treatment for end stage renal disease, however there are significant complications associated with immunosuppression, such as an increased risk of diabetes and cancer. To date there have been limited transcriptomic analyses of patients following kidney transplantation. We aimed to identify differentially expressed genes (DEGs) and pathways associated with kidney disease and those that may be indicative of complications associated with kidney transplantation.

Targeted RNA sequencing was conducted using the Ion AmpliSeq™ Human Gene Expression Core Panel from peripheral blood mononuclear cells, to identify DEGs in kidney transplant recipients (n=37, median age = 54 yrs) compared to individuals with no evidence of renal disease (n=21 controls, median age = 56 yrs). In the kidney transplant group, 15 had a previous cancer diagnoses, one participant had unknown cancer status and three participants had new onset diabetes after transplantation (NODAT).

Analyses comparing transplant recipients to controls, identified 1089 significant DEGs with a 2 fold +/- change in expression ( $P \leq 0.1 \times 10^{-8}$ ). The pancreatic cancer pathway was significantly enriched with identification of six significant DEG in this pathway previously associated with several cancer types and/or diabetes (*RALA*, *JAK1*, *PIK3CA*, *MAPK8*, *JNK*, *SMAD2*). Outside of the pancreatic cancer pathway, *BAP1*, a gene previously associated with renal tumorigenesis, was identified to have significantly increased expression ( $p=7.3 \times 10^{-13}$ ) in kidney transplant recipients compared to controls. Gene ontology analysis identified enrichment in metabolic process, cellular process and biogenesis.

Our analyses have illustrated a significant enrichment in the pancreatic cancer pathway, as well as genes associated with several non-pancreatic cancers and diabetes, in kidney transplant patients approximately 20 years post-transplantation. RNA-seq and additional multi-omic analysis, in a larger case-control study, will help determine if exploration of a transplant recipient's molecular profile can predict risk of developing certain cancers and NODAT following transplant.

## PgmNr 1798: Expression profiling of allograft inflammatory factor-1(AIF-1) in association with cold/warm preservation time and the outcome of kidney graft function.

### Authors:

D. McDaniel <sup>1,2</sup>; J. Neill <sup>1,2</sup>; M. Roseburgh <sup>1,2</sup>; A. Bangale <sup>1,2</sup>; C. Anderson <sup>1,2</sup>; L. McDaniel <sup>2,3</sup>

### Affiliations:

1) Department of Surgery, Univ Mississippi Med Ctr, Jackson, Mississippi.; 2) School of Medicine; 3) Department of Microbiology and Immunology

---

**Background:** Gene expression profiling of kidney with end stage disease (ESRD) revealed that allograft inflammatory factor-1 (AIF-1) was a highly expressed gene associated with pathologic glomerular nephritis at post allograft transplantation. The mRNA expression pattern of AIF-1 in kidney tissue and plasma protein were elevated in associated with rejection episodes. Our goal was to explore the significance of this genomic marker in early rejection vs. late rejection episodes in association with cold/warm preservation time that may trigger the release of inflammatory signals causing early host response of rejection. Extended cold or warm preservation time during organ procurement has been associated with increased risk of long term graft failure. To elucidate the early state of rejection and establish its therapeutic strategy, it is important to clarify the factors that are influential in the initiation of inflammation.

**Methods:** Clinical data were stratified, including delayed graft function (DGF), in which the patient required kidney dialysis after transplantation, stable graft function (SGF), or rejection episode (RE). The data were analyzed on the basis of cellular and antibody mediated rejection and time points (<6 months, 6-12 months, 13-36 months and >36 months) that rejection occurred. Blood samples from each patient at different time intervals (pre-transplantation, day 3 and day 6 after transplantation) were tested by q-RT-PCR. The impact of cold and warm preservation time were assessed.

**Results:** A total of 400 patients who received kidney transplant between 2007 and 2014 at the UMMC were subject of this study. A rate of 22/66 (5.6%) for rejection episodes within <6 months and 9/66 (2.3%) within >36 months were observed. Patients who received a kidney within a  $\leq 10$  hr. cold ischemia time (CIT) had superior clinical outcome and low AIF-1 expression, indicating that prolongation of CIT causes a delay in graft function. AIF-1 was expressed in podocytes and infiltrating inflammatory cells specifically increased in patient's samples that experienced cellular rejection within the < 6 month after transplantation. An undirected intersection network genes/protein analysis revealed interaction between AIF-1 and multiple immunologic signals involved in both inflammation and rejection.

**Conclusion:** The mRNA profiles of inflammatory markers observed in this study appeared to be predictive of early and long term allograft status after transplantation.

## PgmNr 1799: Applications of immuno-omics strategies to identify molecular features in infectious diseases caused by unknown pathogens.

---

Infection source clearance is the most effective way to prevent the progression of sepsis. However, identifying the source of infection in patients with sepsis is a major challenge. Although typical laboratory methods could expand certain microbes for further investigation, many microbes are still difficult to culture. We combined advanced omics platforms to obtain comprehensive data on the diversity of microbes and immunoglobulin (BCR receptor, BCR) that can interact directly with pathogens. We found that 8 patients with acute sepsis also expand the selected strain as in the general infection pattern. In addition, we also observed a dominant clonal expansion of these patients. The clonal expansion of IgM supported that although sepsis patients may not have sufficient immune defenses to combat these sources of infection, B cells in these patients still have the ability to screen for pathogens and expand effector B cells. Interestingly, we also found the consensus motifs of expanded immunoglobulin clonotypes between different patients, which implied that some patients with sepsis may be caused by the same source of infection. Our data suggested that patients with sepsis still have the ability to produce antibodies against pathogens, and applying immuno-omics strategies will be beneficial for identifying sources of infection.

## **PgmNr 1800: Somatic hypermutation (SHM) in the human heavy chain immunoglobulin receptor: Regions of low and high mutational burden.**

---

The immune system is equipped to fight a multitude of antigens thanks to the diversity of its immune cell receptors. In the heavy chain of the B cell receptor, diversity stems from the antigen independent process called VDJ gene rearrangement, which occurs in Pro B cells. The heavy chain diversity is furthered through antigen-dependent processes during B cell maturation: Naïve B cells undergo maturation in the dark zone of the germinal center, where they are activated through antigens and proliferate into centroblasts. Single point mutations in the variable region are introduced at a high rate by activation-induced cytidine deaminase in this stage of maturation. Some centroblasts will have improved affinity to antigens due to introduced mutations in the variable region while other mutations lead to an inability to bind to antigens. The latter will undergo apoptosis. Centrocyte affinity is tested in the light zone of the germinal center through antigen exposure, which induces class switching. After class switching a subset of formerly naïve B cell leave the germinal center as memory B cells.

The process of SHM on a molecular level is not well understood. For example, it is unknown whether specific regions of the heavy chain are more or less prone to SHM. For this study, regions of high and low SHM were mapped through heavy chain DNA sequencing of naïve and memory B cells. In detail, cells from a leukopheresis blood product were magnetically sorted into memory and naïve B cells. Each pool of cells (naïve or memory) underwent RNA extraction. cDNA was synthesized from RNA using the SMARTer® PCR cDNA Synthesis Kit utilizing oligo dT primer on the 3'end and SMARTer oligonucleotide on the 5'end. Nested PCR resulted in amplicons of 530-550 basepair size, which were sequenced on Illumina DNA sequencing instruments in a paired-end approach. Naïve and memory B cells were sequenced from the same donors and DNA sequences in naïve and memory B cells compared to identify region of low versus high SHM activity.

## PgmNr 1801: Single-cell transcriptomics identifies effector capacity as a critical determinant of human CD4+ T cell responses to cytokines and activation.

**Background:** Immune-mediated diseases are caused by the dysfunction of immune cells and the interactions between them. In particular, risk loci for immune-mediated diseases are enriched in genes specifically expressed in CD4+ T cells. However, CD4+ T cells are a heterogeneous cell population, with different subsets of naïve and effector memory cells. These effector subsets are shaped by the cytokine signals present in the environment. Thus, to disentangle the molecular mechanisms of disease it is crucial to understand how cytokines modulate T cell function.

**Methods:** We exposed naïve and memory CD4+ T cells from healthy individuals to different cytokine cocktails and profiled RNA (RNA-seq) and protein (LC-MS/MS) expression. For a subset of cytokines, we also profiled gene expression at the single-cell level (scRNA-seq).

**Results:** We observed that, in contrast to naïve T cells, memory cells did not respond to Th2-polarising cytokines and did not acquire a regulatory phenotype in response to TGF- $\beta$ . This suggested that naïve and memory cells activate different pathways in response to cytokines. We investigated this at the single-cell level and found that CD4+ T cells form a continuous spectrum, spanning from naïve to effector memory T cells. The position of cells in this spectrum reflects their effector capacity. We observed that the effector capacity of a T cell shapes its response to activation and to cytokines. For instance, Th17 cytokines induced the expression of IL9 and CCL17 only in the cells with higher effector capacity. In contrast, only cells with lower effector capacity responded to Th2-stimulation. In the context of T cell activation, cytokine and chemokine genes were also upregulated in a manner proportional to the effector capacity. To assess the disease relevance of these findings, we generated a time course of CD4+ T cell activation with single-cell resolution and integrated it with risk loci for immune diseases to identify the stages of activation most relevant to disease.

**Conclusions:** In this study we created a reference map of T cell responses to activation and cytokine stimulation with single-cell resolution. Our results shed light on the heterogeneity of CD4+ T cells and suggest that T cells respond to cytokines in a manner dictated by their effector capacity. This study

will serve as a valuable resource for studying the role of cytokines in human health and disease.

## PgmNr 1802: Adaptive immune receptor repertoire determination through probe capture of genomic DNA followed by next-generation sequencing.

---

The collection of B cell receptor (BCR) and T cell receptor (TCR) form the adaptive immune receptor repertoire (AIRR). The antigen binding sites of BCR and TCR are composed of variable (V), diversity (D) and joining (J) segments. When V(D)J recombination occurs, one segment is chosen from each V(D)J types in genomic DNA, which causes the extreme diversity of adaptive immunity. Human leukocyte antigen (HLA) genes have long been implicated in many diseases. *ATD*-induced agranulocytosis (TiA) was found associated with *HLA-B\*38:02* and *HLA-DRB1\*08:03*; anti-IFN- $\gamma$  autoantibodies in adults with disseminated nontuberculous mycobacterial (dNTM) infections were found associated with *HLA-DRB1\*16:02* and *HLA-DQB1\*05:02*. However, only a proportion of people carrying the risk HLA genotypes developed the phenotypes. Here we propose a hypothesis that the development of certain immune related diseases (such as TiA or dNTM) is determined by the combined effect of genomic profile of AIRR and HLA genes. In this study, we established a probe captured-based next-generation sequencing (NGS) method of genomic DNA to determine the AIRR profiles. We first designed probes for every known V alleles of BCR and TCR based on the ImMunoGeneTics (IMGT) database. Each probe was continuous 60 bps sequence by customized service from Roche/NimbleGen, and each V allele was covered by three probes. We verified this method by testing seven reference materials (RMs) from genome in a bottle (GIAB) (<https://jimb.stanford.edu/giab/>), as well as several Taiwanese participants with newly retrieved primary peripheral blood mononuclear cells (PBMCs). We built bioinformatics pipelines for analyzing the NGS data of genomic AIRR genes. In the future, we will apply this method to the genomic DNA samples from clinical TiA and dNTM patients. Through combined analysis of the AIRR and HLA genotypes, we will test the digenic/oligogenic hypothesis of genetic susceptibility of TiA and dNTM.

## PgmNr 1803: TotalSeq™ antibodies standardized antibody-oligo conjugates for CITE-Seq™, or single-cell proteogenomics.

High-throughput single cell RNA-seq techniques have transformed our understanding of complex cell populations and processes, however, these don't allow additional phenotypic analysis of the same cells. Stoeckius *et al.* (Nature 2017) described the use of antibodies coupled with oligonucleotides to simultaneously study protein and RNA expression at the single cell level. This method, termed Cellular Indexing of Transcriptomes and Epitopes by sequencing (CITE-seq), combines highly multiplexed protein marker detection with unbiased transcriptome profiling and is compatible with scRNA-seq platforms based on a poly-A capture system. A collaboration between CITE-seq developers and BioLegend generated antibody-oligonucleotide conjugates under the brand name TotalSeq™.

As new technologies are developed, it is imperative to demonstrate that reagents deliver reproducible results, and that manufacturing complies with the highest standards possible. Here we demonstrate that our conjugates comply with BioLegend's quality standards, and the results are comparable with traditional flow cytometry. We also demonstrate the utility of CITE-seq using TotalSeq™ conjugates to improve cluster resolution as compared to samples analysed via RNA-seq alone. We also show that the technology can produce equivalent data when compared to CyTOF. Finally we show how TotalSeq™ "Hashtags" are used to efficiently multiplex single cell samples, analyse multiple TotalSeq antibody dilutions simultaneously, or optimize the CITE-seq protocol and reagents.

In summary, we establish the utility of analysing proteins and transcriptomic in the same cell in a highly multiplexed fashion, and show a completely new way to approach biomedical research.

## PgmNr 1804: Unique RNA profiles in different fractions of plasma.

### Authors:

J. Jia; L. Wang

**Affiliation:** Pathology, Medical college of Wisconsin, Milwaukee, WI.

---

Circulating extracellular RNAs (exRNAs) have great potential to serve as biomarkers for a wide range of diagnostic, therapeutic and prognostic medical conditions. Current research has been focusing on the characteristics of the RNA content in extracellular vesicles and its delivery process in various human biofluids. However, exRNAs are also present in other plasma fractions including cell debris, platelets, nucleosomes or free circulating condition. So far, knowledge of the difference or association between these different sources of exRNAs is very limited. To address this issue, we collected 10 plasma samples and performed a sequential physical and biochemical precipitation to receive 4 plasma fractions (cell debris, Thrombin-associated fraction, exosomes and supernatant) from each sample. From total RNAs of 40 fractionated plasma fractions, we made ligation-free libraries and performed RNA-seq in an Illumina HiSeq sequencer. To evaluate full spectrum RNA abundance, we included all RNAs during library preparation without size selection. Due to complicated RNA composition in these libraries, we utilized a successive stepwise alignment strategy to map the RNA sequences to different RNA categories, including mature miRNAs, premature miRNAs, piwi-interacting RNAs, tRNAs, other types of ncRNAs, cDNAs, circRNAs, and exogenous RNAs. We found that each plasma fraction had its own unique distribution of RNA species. Hierarchical cluster analysis showed similarity in samples with the same fraction and significant differences between different fractions. As expected, exosome fraction showed the highest percentage (~4.9% of all mappable reads) of mature miRNAs with average detectable miRNA=398, while premature miRNAs, other types of ncRNAs and cDNAs were predominant in cell debris fraction with the percentage of all mappable reads at ~1.3%, ~61.9%, and ~8.1%, respectively. Interestingly, the supernatant fraction showed the lowest percentage of most small RNAs but relatively higher percentage of premature miRNAs and circRNAs (~2.1% and ~12.6% respectively). In addition, we also observed abundance difference in each unique transcripts. miR-1246 ranked the highest abundance in exosome fraction while miR-3123 ranked the highest in the cell debris fraction. Furthermore, we observed a considerable proportion of exogenous RNAs in all plasma fractions. These results demonstrate that thorough inspection of all plasma fractions is necessary for exRNA-based biomarker study.

## PgmNr 1805: Validating age-associated sex-specific DNA methylation sites in a Bangladeshi population.

---

For epigenome-wide association analyses, replication of CpG associations with human traits is critical for identifying robust evidence for associations. In this study, we used an independent validation set consisting of 399 Bangladeshi individuals (167 males) participating in the Health Effects of Arsenic Longitudinal Study (HEALS) to replicate age-associated CpGs identified in a previous study of 400 (189 males) individuals from the Bangladesh Vitamin E and Selenium Trial (BEST). Prevalence of never smoking was 90% and 48% among females and 26% and 4% among males in HEALS and BEST, respectively. All BEST but no HEALS participants had arsenical skin lesions. The mean age in HEALS was 41 (SD=10) for males and 34 (SD=9) for females compared to 43 (SD=9) and 44 (SD=11), respectively, in the BEST sample. DNA was extracted from whole blood in both studies. The Illumina HumanMethylation 450K Beadchip was used for BEST and the Illumina EPIC array (850K) Beadchip was used for HEALS which meant 47780/423604 (11%) 450K CpGs were not present on the 850K chip. Using the HEALS validation set, we conducted a genome-wide search for age-associated CpG sites (among 375,824 overlapping sites) using a reference-free approach for cell type proportion adjustment (R package: RefFreeEWAS) and model adjustment for ever/never smoked. Among the 3,294 overlapping age-associated CpGs ( $P < 5 \times 10^{-8}$ ) observed among females in BEST, 1162 (35% at  $P < 5 \times 10^{-8}$ ) were also associated with age in HEALS in a consistent direction. Likewise for males, among the 716 age-associated CpGs ( $P < 5 \times 10^{-8}$ ) observed in BEST, 316 (44% at  $P < 5 \times 10^{-8}$ ) were also associated with age in HEALS in a consistent direction. Similar to the BEST analysis, in HEALS there is a higher proportion of hypomethylation across individual genome regions (shore, shelf, open sea) and higher proportion of hypermethylation (islands) based on Fisher exact tests among the age-associated CpGs for both sexes. Again consistent with the BEST analysis, hypermethylation enrichment among the age-associated CpGs across individual relationship to gene categories (i.e., TSS1500, TSS200, 5'UTR, First Exon, Body, 3'UTR, and Intergenic) compared to all CpGs tested, only intergenic was not significant. Our results indicate that age-associated methylation tends to be highly consistent across both study samples for both sexes even with different sample age distributions, smoking status, and lesion status.

## PgmNr 1806: The utility of WGS-derived telomere length in population health studies: A proof-of-concept using consumer wearable sleep metrics.

---

Premature telomere attrition is associated with adverse health outcomes, including cardiovascular disease and all-cause mortality. The measurement of leukocyte telomere length (LTL) in population health studies have in the past been carried out using quantitative PCR. However, the growing adoption of whole-genome sequencing (WGS) in population health studies presents an opportunity to estimate LTL using WGS data. To validate the utility of WGS-derived LTL in population health studies, we used a computational tool called telomerecat to estimate LTL in 175 healthy volunteers. We first showed that WGS-derived LTL is significantly correlated with both qPCR-derived LTL as well as volunteer chronological age. We then examined the relationship between WGS-derived LTL and habitual sleep duration obtained from consumer-grade wearables. There was a significant positive association between habitual sleep duration and WGS-derived LTL after adjusting for age, gender and ethnicity. Volunteers that had sufficient sleep (> 7 hrs) had significantly longer WGS-derived LTL compared to those that had insufficient sleep (< 5 hrs). We were able to replicate these associations in a separate validation cohort of 300 individuals, for whom LTL was measured using qPCR. Our findings demonstrate the utility of WGS data in population health studies to estimate LTL, and thus provide insights into lifestyle and clinical factors associated with biological aging.

## **PgmNr 1807: Isolation and characterization of exosomes from mixed cortical neurons derived from Induced Pluripotent Stem Cells (iPSC) from patients with type 2 Gaucher disease and controls.**

### **Authors:**

---

Exosomes, intracellular vesicles ranging in size between 30-100 nm, originate from many cell types. Originally, thought to contain cellular debris; they are now recognized to contain proteins/RNAs captured from the cytoplasm. Exosomes transduce cell-to-cell signals to adjacent cells and to distant cells by entering the bloodstream and being captured in other locations. Although their physiologic roles remain unclear, exosomes function in intracellular communications and, perhaps, deliver critical proteins to other cellular locations. There is increasing evidence that delivered exosome cargo may mediate neurodegenerative disease progression.

Type 2 Gaucher disease (GD2), a lysosomal storage disorder, has a severe neurodegenerative course resulting in early death. We used patient and control neonatal fibroblasts to derive iPSC lines that were then used to generate neural progenitor cells (NPCs) and then differentiated to mixed cortical neurons. The NPCs stain with Neurofluor Cdr3, a fluorescent probe for early neuron differentiation. The mixed cortical neurons stain with Neurofluor NeuO, a live stain that detects neurons. Both stains identified >90% of the cells in a 10 cm plate. Further characterization of the cortical neurons by PCR showed expression of MAP2, NeuN, Nestin, NSE and ChaT. Some cultures also showed low expression of TH (dopaminergic) and GFAP (astrocytes).

Neurons were grown in serum free Brainphysy medium for >30 days. Exosomes were isolated from culture plate medium collected over 48-72 h. Two methods were used to capture exosomes, ExoQuick and Captur'em columns. Nanosight analyses showed a peak of vesicles in the 50-200 nm size range. The best yields were from ExoQuick preparations. Western blots identified flotillin-1, a marker protein for exosomes. Dot blots showed other exosome markers. GCase protein and a potential tetrameric form of synuclein were found in both control and GD2 samples.

The exosomes will be analyzed by transmission electron microscopy and be evaluated for additional neuronal markers. Proteome analysis will be performed on exosome cargo from controls vs. GD2. Transcriptome analysis for miRNAs will be evaluated. It has been suggested that since exosomes circulate in the blood and cross the blood-brain barrier, they may represent a therapeutic modality to carry drugs to neurons. Our exosomes will be labelled fluorescently and tested for entry into both control and GD2 neural cells.

## **PgmNr 1808: Connect the dots: A method for interpreting multi-metabolite perturbations for the diagnosis of metabolic disease using disease-specific metabolomics networks.**

Untargeted metabolomics profiling captures a global view of the metabolic state of an individual, and diagnosis using untargeted metabolomics is data-driven and unbiased. One prominent practice in diagnosing Inborn Errors of Metabolism (IEM) is to follow a targeted approach, where a diagnosis is nominated based on clinical symptoms observed, and targeted biochemical testing is performed to either confirm or rule out the nominated diagnosis. Problems with this targeted approach to diagnosis occur when clinical symptoms are undifferentiated across multiple IEM. In these circumstances, untargeted metabolomics profiling has shown to be useful. The challenge with diagnosis using untargeted profiling, however, is quantifying the significance of multi-metabolite perturbations observed in individual profiles using a standardized, automatic and transparent methodology. Currently, interpretation of untargeted metabolomics data is performed manually, where clinicians use their biochemical knowledge to reason about the patterns observed. In effect, metabolite perturbations can be examined by superimposing those perturbations onto biochemical pathway maps, and searching for bottlenecks where metabolite perturbations around an affected enzyme show opposite directionality.

To improve accuracy and transparency and to automate this subjective and manual diagnostic process, we develop CTD, a computational diagnostic method that “**connects the dots**” between metabolite perturbations observed in patient’s metabolomics profiles with patterns observed in disease-specific networks. In this work, we show that disease-specific metabolomics perturbation networks lead to more accurate detection of disease-specific metabolite perturbation patterns when compared to general biochemical pathways. Furthermore, using disease networks for 16 different IEM (e.g., 4 organic acidemia disorders, 2 Zellweger spectrum disorders, 4 urea cycle disorders, 3 nucleotide metabolism disorders, and 3 others), we show that CTD reproduces expert performance in diagnosing IEM disorders.

## PgmNr 1809: Diagnosis of guanidinoacetate methyltransferase (GAMT) deficiency by untargeted metabolomic analysis in plasma.

### Authors:

L. Lizcano-Gil <sup>1</sup>; K. Pappan <sup>2</sup>; D. Toal <sup>2</sup>; B. Wittmann <sup>2</sup>

---

**BACKGROUND:** Guanidinoacetate methyltransferase (GAMT) deficiency causes neurological and muscular alterations, which, being nonspecific and of varying severity, make clinical diagnosis difficult.

**METHODS:** To describe the usefulness of metabolomic analysis in cases of patients with suspected neurometabolic disease, we present the case of a 6 years old patient, with symptoms of ataxia and epilepsy. Features of the autistic spectrum were observed, seizure control had not been achieved, and there was no improvement of his neurodevelopmental process through intervention by therapies. Previously, Angelman syndrome and other chromosomal conditions were ruled out, using FISH, methylation testing and arrCGH. Plasma amino acid profile, urine, qualitative organic acids, and brain MRI spectroscopy were normal. Given the possibility of neurometabolic disease, analysis by non-targeted metabolomics in plasma was performed.

**RESULTS:** We documented reduced creatinine levels and extremely elevated levels of guanidinoacetate, a pattern consistent with a blockage of the creatine synthesis pathway. These findings reflect the deficiency of GAMT. There was also a decrease in molecules in different metabolic pathways that have, in common, pyridoxal phosphate-dependent reactions. Several metabolites of the glutamate and DOPA pathways were decreased. All those changes can contribute to the phenotype. Sequence analysis of *GAMT* gene revealed two variants: Probable pathogenic variant c.64del and a variant of uncertain significance, c.521G>T. Three bioinformatics predictors estimate that the resulting changes in the protein would be pathogenic. We designed a treatment with creatine, restriction of arginine, L-Ornithine, pyridoxine and increase in the dietary contribution of taurine. Crisis control was achieved, normalization of the walking pattern and noticeable improvement in the interaction with the environment and with third parties were observed.

**DISCUSSION:** It is demonstrated that metabolomic analysis is useful for the diagnosis of GAMT deficiency and that also it is a very valuable tool for the study of patients with suspected neurometabolic disease.

## PgmNr 1810: Untargeted metabolomic analysis in plasma for the diagnosis of 3-methylglutaconic aciduria (MGA).

### Authors:

S. Ospina Lagos <sup>1</sup>; L. Lizcano-Gil <sup>2</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

*Introduction:* MGA includes a heterogeneous group of metabolic disorders which main biochemical characteristic is the increased levels of 3-Methylglutaconic Acid. Up to date, seven of MGA are recognized based on the gene involved.

*Objective:* To describe the usefulness of metabolomic analysis in cases of patients with suspected neurometabolic disease, but with nonspecific manifestations and normal DNA analysis.

*Materials and methods:* We present the case of a 9-year-old Colombian patient, who was referred to the neurogenetic clinic with cognitive disability, global neurodevelopment delay, hypotonia and complex seizures. Previously, clinical exome sequence was done with normal results (there were no pathogenic variants or variants of uncertain significance), plasma and urine amino acids profiles were also normal. Given the possibility of neurometabolic disease, analysis by non-targeted metabolomics in plasma was performed, which demonstrated a biochemical signature consistent with the diagnosis of MGA, mainly, characterized by elevation of 3-methylglutaconate and 3-methylglutaryl carnitine. We performed sequence and deletion/duplication analysis for genes AUH, TAZ, SERAC1, OPA3, TMEM70 and DNAJC19, with normal results. Based on these findings, diagnosis of 3-methylglutaconic aciduria type 4 was established (NOS 3-MGA-uria).

*Conclusion:* It is demonstrated that metabolomic analysis is useful for the diagnosis of 3-methylglutaconic aciduria and that it also is a very valuable tool for the study of patients with suspected neurometabolic disease.

## PgmNr 1811: Deciphering the role of non-coding genome in mitochondrial function: From long non-coding RNAs to hidden micropeptides.

Advances in computational biology and large-scale OMICS approaches reveal that a larger fraction of the genome than previously recognized is transcribed and translated. Most of these novel transcripts are long-noncoding RNAs (lncRNAs). Though mostly functionally uncharacterized, they are emerging as important players in cellular processes during normal development and physiology, but also disease. Noteworthy, genes coding for small peptides (<100 amino acids in length) have been frequently missannotated as lncRNA genes due to their small open reading frame, overlooked by automatic gene annotation. Micropeptides are known to have important roles in fundamental biological processes. In addition, the mammalian mitochondrial proteome is surprisingly enriched in micropeptides, accounting for 5% of its proteins. To gain insight into the role of lncRNAs in mitochondria, we have integrated GTEx data, performed RNA-Sequencing (RNA-seq) and measured oxygen consumption rate of >300 fibroblasts derived from mitochondrial disorder patients. We performed logistic regression on samples from GTEx dataset using MITOCARTA genes as the positive class and all other protein coding genes as the negative class, correlated gene expression of mitochondrial-disease genes and lncRNAs, and correlated lncRNA expression and cellular respiration. By performing these three strategies, we were able to identify several lncRNAs as new candidate genes to be associated with mitochondria. To explore whether these lncRNAs encode micropeptides with a possible role in mitochondria, we analysed their coding potential by looking at possible open reading frames, evolutionary conserved regions and RNA-seq and ribosomal profiling data. As additional supportive evidence of a novel micropeptide discovery, we have applied mass spectrometry (MS)-proteomics on patient-derived fibroblasts. Next to computational approaches, knockout studies are currently ongoing in order to elucidate the function and biological relevance of these genes and overall highlight the importance of small peptides in cellular processes.

## PgmNr 1812: Transcriptional changes in circulating immune cells of patients with Gulf War Illness.

---

**Background:** Gulf War Illness (GWI) is a severely debilitating condition with a cluster of chronic symptoms affecting up to 30% of the veterans deployed to the 1990-91 Persian Gulf War. The symptoms associated with GWI include fatigue, headaches, musculoskeletal/joint pain and disturbances of multiple organ systems. The causes and mechanisms of GWI are unknown, although the spectrum of symptoms and organ systems involved suggest that GWI is most likely caused by a combination of genetic predisposition and its interaction with environmental factors such as exposure to toxic chemicals and/or pathogens.

**Objectives:** The main objective of this research proposal is to identify novel mechanisms of transcriptional regulation in GWI, which will help to better understand GWI pathobiology.

**Methods:** We used RNA-seq to evaluate gene expression and alternative splicing in the peripheral blood mononuclear cells (PBMC) of 20 GWI patients and 20 matched healthy controls at T0 (baseline), T1 (VO2max, exercise challenge) and T2 (4 hours of rest after T1). After alignment using STAR and counting exons using HTSeq, we used DESeq2 to evaluate differences in gene expression and DEXSeq to evaluate differences in splicing. We compared the gene expression and splicing events between individuals with GWI and healthy controls at each time point, as well as difference in responses to the exercise challenge (between time points for the same group). Results of RNA-seq analysis were validated using NanoString technology.

**Results:** An increased abundance of differentially expressed genes related to immune disorders, small GTPase mediated signal transduction, protein binding and nucleotide binding was observed. Additionally, the observed changes in gene expression and alternative splicing between time points (in response to exercise challenge) were smaller in individuals with GWI as compared to healthy controls.

**Conclusion:** Our findings provide novel insights into the molecular changes associated with GWI onset and progression enhancing the current understanding of the pathophysiological mechanisms of the disease.

---

Dementia is an age-associated neurodegenerative disease marked by diminishing cognitive function. There are multiple types of dementia, with Alzheimer's disease being the most common. Alzheimer's disease and related dementias (ADRD) are a major worldwide public health problem. ADRD affects individuals of all ethnicities, but Hispanic individuals show a 1.5-fold higher risk when compared to non-Hispanic whites. ADRD is a complex phenotype with both genetic and environmental causal components. Additionally, precise diagnosis often requires invasive measures. The identification of ADRD biomarkers is a research topic of growing importance. We propose to identify novel non-invasive endophenotypes (a particular type of biomarker that specifically indexes genetic risk) using high dimensional multiomic data in an existing cohort of Mexican American individuals. The participants are members of large Mexican American families of the GOBS (Genetics of Brain Structure and Function Study) project. Extensive multiomic data is available for approximately 2,000 subjects. We applied a mean-based endophenotype discovery method tailored for relatively rare diseases when extended pedigree are available. A set of 70 GOBS subjects were diagnosed as suffering from ADRD. The estimated heritability of ADRD is high ( $h^2 = 0.75$ ) in this population, supporting a major role of genes influencing risk. The ADRD cases have 363 1<sup>st</sup>, 2<sup>nd</sup>, 3<sup>rd</sup>, and 4<sup>th</sup> degree relatives currently not suffering from dementia. We contrasted this group of ADRD relatives with a set of 839 unaffected individuals lacking relatives with no ADRD. This approach detects genetic correlation between endophenotypes and disease risk and eliminates the problem of disease state effects. We tested the validity of our proposal by testing a set of 113 genes associated to Alzheimer's disease. We observed a clear enrichment for significant effects over that expected under the null hypothesis ( $p = 3.3 \times 10^{-10}$ ). Several cytokine genes (*TNF*, *IL1B*, and *IL1A*) exhibited reduced expression in relatives of cases versus controls. Notably, the *APBB1* gene showed increased expression in case relatives. This gene regulates the transcription of the amyloid precursor protein that is central for ADRD development. The efficient selection of relevant transcriptomic endophenotypes can aid the identification genes involved in ADRD risk. Quantitative non-invasive endophenotype identification may ultimately aid early detection of increased ADRD risk.

# PgmNr 1814: ‘Dark’ and ‘camouflaged’ genes may harbor disease-relevant variants that long-read sequencing can resolve.

**Background.** Researchers have known for years that many genomic regions remain ‘dark’ because short-read sequencing read lengths are inadequate; the extent of the problem has largely remained uncharacterized, however. Here, we systematically characterize ‘dark’ regions, and regions we term ‘camouflaged’—dark regions arising from low mapping quality due to genomic duplications. We assess how well long-read sequencing technologies resolve these challenging regions, and we present a method to rescue variants from camouflaged genes. We applied our method to >10000 whole-exomes and genomes from the Alzheimer’s Disease Sequencing Project (ADSP), rescuing 4200 variants from protein-coding exons, including a rare 10bp frameshift deletion in *CR1*—a top Alzheimer’s disease gene.

**Methods and Results.** We identified 6054 gene bodies containing at least one dark region ( $\geq 10$ bp), many known to drive human disease. Regions are dark for two reasons: (1) low read depth ( $\leq 5$  reads); or (2)  $\geq 90\%$  of reads have a mapping quality  $< 10$ . Dark regions are based on an average across whole-genomes from 10 unrelated individuals, aligned to hg38 by BWA (median 37x coverage). 527 gene bodies are 100% dark and 2128 are  $\geq 5\%$  dark. Nearly 4000 are protein-coding genes, where most dark regions are intronic, followed by exons. 117 protein-coding genes are 100% dark in coding exons while 592 are  $\geq 5\%$  dark. Most dark regions are specifically camouflaged. Oxford Nanopore Technologies best resolves these regions (90%), compared to 10x Genomics (50%) and PacBio (64%).

Many disease-relevant genes are camouflaged, including *CR1* (26% camouflaged), *C4B* (83%), *SMN1* and *SMN2* (95%; spinal muscular atrophy), and *NEB* (10%; associated with 24 diseases). We also determined long-read alignment may not properly represent an individual’s *CR1* structure where Bionano Genomics’ optical mapping succeeds.

To rescue variants, we identified sets of genomic regions with  $\geq 98\%$  similarity (BLAT), masked all but one region, and aligned all reads previously aligned within the set to the unmasked region. We cannot determine upfront from which region in a set the mutation originated, but we can determine it exists within the set. The rare *CR1* 10bp frameshift was found in 5 ADSP cases and 0 controls (confirmed by Sanger). We identified a 6<sup>th</sup> case in a separate dataset.

**Conclusion.** Thousands of genes remain dark, potentially hiding important disease variants. Long-

read sequencing technologies are critical to resolving them.

## PgmNr 1815: Somatic mosaicism and mono-allelic expression across six brain cell types from single-cell RNA-seq in 48 AD individuals.

Due to discovery power, most genetic variants reported to be associated with complex disorders are common with weak effect sizes, though few cases of rare mendelian events have also been described. For Alzheimer's disease (AD) in particular, the spectrum of causal variation spans common variants in 29 loci and rare familial mutations in three genes. In addition to the heritable genetic mechanisms underlying disease, somatic mosaicism may also account for a fraction of cases that remain with no molecular genetic diagnosis. Here, we seek to interrogate whether mosaicism in cell types that can still differentiate and propagate through the brain, such as astrocytes, oligodendrocytes and/or glial cells, can create focal areas of dysfunction leading to the manifestation of disease-relevant symptoms.

Here, we develop a new method for using single-cell RNA-seq technology to infer exonic mutations across brain cell types and characterize the identity of each cell harboring these mutations. We applied our method to Smart-seq2 data from post-mortem brain samples in a cohort of 24 Alzheimer's and 24 control patients from the ROS/MAP project. We aligned single-cell RNA-seq reads, inferred called genotypes, QC filtered, and rejected germline hits using whole-genome-sequencing. We validated called mutations both through targeted higher depth re-sequencing and by computational methods including linked-read analysis and comparison to low allelic balance calls in brain WGS, resulting in a cell-type specific map of mosaic events per individual.

We next assessed differential mutational burden across healthy and affected individuals, and detected several potential clonal events in glial populations, that further cluster in discrete pathways differing by cell-type. Our mutational and burden analysis uncovered multiple significantly differentially mutated or altered genes for oligodendrocytes, microglia, and excitatory neurons, many of which have been previously implicated in AD. Finally, we observed that 80% of germline heterozygous variation is expressed in a mono-allelic manner in single cells.

Our results show that single cell RNA-seq enables systematic cell type-specific survey of mosaicism in the aging brain, shedding light on the role of clonality and differential allelic expression. We also demonstrate how these observations can be used for relative pathway burden analysis in different cell types and prioritizing mutations, genes and pathways, for functional validation.

## **PgmNr 1816: Investigating oxidative damage: Implications in cognitive and metabolic phenotypes of Alzheimer's disease in the Mexican American population.**

---

As the elderly population expands, it is predicted that many age-related diseases, such as cardiovascular disease, metabolic disorders, cancer, and neurodegenerative diseases will burden the healthcare system. The Texas Alzheimer's Research and Care Consortium (TARCC) is a collaborative research effort to identify factors in the development and progression of Alzheimer's Disease (AD) in the Mexican American population compared to non-Hispanic whites, and to better understand the role of these factors. In the Mexican American population diabetes, depression, stroke, and obesity are common risk factors for developing cognitive impairment. The reasons for the association between cognitive decline and comorbidities remain unclear. Some studies have shown correlation between common pathological changes that are observed in AD and those that are a result of DNA damage. The mitochondrial genome specifically is particularly vulnerable to DNA damage. Age-associated decrease in mitochondrial function results in accumulation of reactive oxygen species which are capable of damaging DNA and other vital biomolecules. Oxidative damage to DNA takes many forms, but oxidation of guanine (G) to 8-oxoG is one of the most prevalent lesions. Currently, the methods for detection of 8-oxoG are limited and lack reproducibility. We propose nanopore sequencing technology as an improved alternative to the current methods. Here we describe preliminary proof of concept results and discuss the future application of this method for analysis of mtDNA damage in the TARCC cohort. We will investigate if oxidative DNA damage may be implicated in cognitive and metabolic phenotypes observed in Mexican Americans as compared to non-Hispanic whites.

## PgmNr 1817: Enabling precision genomics diagnosis: Accelerating diagnosis of rare diseases in clinical setting by reporting and re-interpreting VUS variants in genes of unknown clinical significance.

---

Next-generation sequencing (NGS) has resulted in an exponential number of new gene-disease associations. Assessing the level of evidence available for these assertions is necessary as part of quality variant interpretation for clinical diagnosis. The standards and guidelines for the interpretation of variants developed by the ACMG and the AMP promote consistency of variant interpretation; however these guidelines do not apply to genes of unknown significance (GUS). *De novo* variants are heavily weighted, given their overall rarity in the genome and their contribution to human diseases. Other compelling genotypes include loss of function variants in genes with high pLi scores or compound heterozygous variants in a gene with biological relevance. In our center, such variants in GUS are only included in the report if there is human genetic evidence. Other GUS are not reported, but are submitted to Matchmaker Exchange. As such, inconclusive results for clinical exomes are frequent, particularly for ultra-rare conditions where the phenotypic spectrum is ill-defined. To further the knowledge base for new gene disease associations and phenotypic spectrum of emerging genes, we report our current experience in the diagnosis of rare disease in a clinical laboratory setting by evaluating variants in GUS, particularly *de novo* variants, as well as patients with novel phenotypes associated with known genes. **Methods:** Of ~2000 trio clinical NGS tests performed in a three year period, over 170 novel candidate genes or novel-expanded phenotypes were submitted to GeneMatcher. **Results:** 38% (65/171) candidate genes had more than 5 matches; of these 80% (52/65) had more than 10 GeneMatcher hits, which suggests an eminent publication implicating the gene in human disease. *De novo* variants were detected in 28% (48/171) candidate genes of which 90% (43/48) were clinically reported as GUS. Of these, many have only been previously reported in large autism cohorts where limited phenotypic information is available, albeit with *de novo* variants in some. **Conclusion:** The use of tools such as GeneMatcher, is an essential step for assembling the evidence necessary for a strong gene-disease association in humans, with identification of multiple affected individuals and functional studies being the ultimate goal. Data sharing is imperative for fostering multi-center collaboration for gene-disease relationships. Lastly, the reporting and re-interpretation of VUS and GUS is highly important.

## PgmNr 1818: Concordance of germline and non-germline genotypes in glioblastoma multiforme patients.

### Authors:

---

**Introduction:** Glioblastoma multiforme (GBM) is an aggressive brain tumor with expected mortality within 2 years of initial diagnosis with median survival as low as 12.61 months. Germline and non-germline DNA sources have been historically used for varying purposes for studies in patients with GBM. The objective of this study was to compare genotype results between two sources of DNA – germline and non-germline – in patients with GBM to improve the usefulness of collected data in retrospective studies. **Methods:** We analyzed data from 143 patients included in a cooperative group front-line therapy trial who had been genotyped using both DNA sources – blood (germline) and tumor tissue (non-germline). Samples were genotyped using the Illumina chips, according to manufacturer's protocol. The genotypes were analyzed using GenomeStudio. The concordance was analyzed by two methods: 1) percent concordance per chromosome - calculated by dividing the number of concordant SNPs by total number of SNPs in the germline DNA in a given chromosome; and 2) Kappa coefficient with 95% CI - calculated with two-sided significance level of 0.05. **Results:** After standard quality control measures, germline and non-germline genotypes were determined from 141 patients and for 937,203 SNPs from somatic chromosomes. The mean concordance among germline genotypes compared to non-germline genotypes for autosomal chromosomes in individual samples was 91.78% (range: 88.99 – 93.93). The lowest kappa coefficient was seen in chromosome 22 (0.9152) followed by chromosome 10 (0.9172). We also found that the kappa coefficient and concordance are proportional to the call frequency in germline DNA source. The lowest germline call frequency was seen in chromosome 10. **Conclusion:** For most chromosomes, no significant discordance between germline and non-germline genotypes was found, suggesting either could be used for retrospective studies as a good source of DNA for most SNPs. However, concordance was especially low for chromosome 10. This is of interest for GBM as the MGMT gene is located on chromosome 10, which has been associated with poorer therapy-related outcomes among GBM patients. Methylation of the MGMT promoter region regulates MGMT expression which is correlated with GBM survival. This indicates that tumor tissue derived genotypes may not be suitable for all types of retrospective genomic studies, e.g., those examining factors in areas of known genomic disturbance in the tumor tissue.

## PgmNr 1819: Omic-analysis to discovery genetic biomarker of extreme CNS forms of Incontinentia pigmenti by using IPGB biobank.

The phenotypic heterogeneity of Incontinentia Pigmenti (IP, MIM308300), a rare X-linked dominant disorder affecting neuroectoderm, suggests to search for molecular genetic markers to aim personalized therapeutic strategies.

Although significant progress has been made over the last few years in the diagnosis of this rare condition, the genetic defect and underlying pathological abnormality remain unknown. Moreover, to date no definitive cure is available for IP, nor are there sufficiently reliable and specific biomarkers to predict the disease severity. This is in part due to the rarity and genetic and phenotypic heterogeneity of IP disease and the lack of access to patient samples.

The availability of the genetic Biobank for IP has addressed this bottleneck and supported IP research. The Incontinentia Pigmenti Genetic BioBank Project (IPGB, <http://www.igb.cnr.it/ipgb>) was launched in 2015 with the aim of providing evidence for the implementation of personalized medicine by constructing a large, patient-based biobank and to enhance research on IP, related to pathophysiology, biomarkers and therapeutic approaches.

The cohort includes 0-60 years old, encompassing 436 clinically-confirmed IP cases (IP female and IP male) and 7 EDA-ID male from 200 cooperative medical institutes worldwide including USA. The Biobank contains blood samples, peripheral blood mononuclear cells (PBMC), red blood cells/granulocyte pellet (totaling 1370 samples).

We will describe the IPGB infrastructure and we will present preliminary results of the project to identify what variations/genes/pathways may affect the severity of IP, we used an OMIC-strategy: Target Exome Sequencing of Metabolic Pathway in 80 IP cases (40 IP-severe, 40IP-mild); Whole Exome and Transcriptome Sequencing in 3 IP-severe. More than 30,000 high quality variants were found across the haloplex samples, with an average of 430 variants/sample, and more than 300,000 across the exome samples, with an average of 40,900 variants/sample. Statistical analysis and gene validation are in progress. All IP patients belonged to our historical collection and to IPGB biobank.

## PgmNr 1820: Impact of exercise rehabilitation on skeletal muscle transcriptional programs in Parkinson's disease.

---

Parkinson's disease (PD) is the most common motor neurodegenerative disease, and neuromuscular function deficits associated with PD contribute to disability. Targeting these symptoms, our laboratory has successfully used 16-wk high-intensity resistance exercise as rehabilitative training (RT) in individuals with PD. We observed significant improvements in muscle mass, strength, power, motor unit activation and total score on the 39-item PD Questionnaire (PDQ-39), providing encouraging evidence of potential symptom reversal through RT. In order to characterize the transcriptome-wide transducers of this intervention in PD, we generated RNA-seq data from skeletal muscle of a subset of these individuals [4M/1W, 67±2yr, Hoehn & Yahr stages 2 (n=3) and 3 (n=2)] before and after 16-wk high intensity RT. Following RT, 302 genes were significantly upregulated, notably related to remodeling and nervous system/ muscle development. Additionally, 404 genes, primarily negative regulators of muscle adaptation, were downregulated. Next, we used Pathway-Level Information Extractor (PLIER) to reveal coordinated gene programs (as latent variables, LV) that differed in skeletal muscle among young (YA), old (OA) healthy adult muscle (n=12 per cohort), and PD subjects pre- vs post-RT. Notably, the LV4 gene program was significantly lower at baseline in PD than YA, tended to be lower in OA, and was significantly increased by exercise. LV4 genes are associated with angiogenesis, axon guidance, and muscle remodeling. The LV16 program was higher in both PD and OA than YA and was reduced by 16-wk RT in PD; functional annotations suggest involvement in denervation, autophagy, and cell death. In summary, this approach enabled identification of two novel skeletal muscle transcriptional programs that are dysregulated by PD and aging, respectively. Encouragingly, RT has a normalizing effect on both programs in individuals with PD. Findings provide direction towards elucidating the molecular mechanisms responsible for RT-induced improvements in symptom severity and optimizing exercise regimens for individuals with PD.

## PgmNr 1821: Elucidating iPSC-derived neuronal phenotypes of Smith-Magenis syndrome.

### Authors:

J. Cross; J. Russ; F.J. Gordovez; S. Detera-Wadleigh; F. McMahon

[View Session](#) [Add to Schedule](#)

**Affiliation:** National Institute of Mental Health, National Institutes of Health, Bethesda, Maryland.

Retinoic Acid Induced I (*RAI1*) is highly expressed in the brain and is thought to encode a transcriptional regulator. Smith-Magenis Syndrome (SMS) is caused by a ~3.7 MB deletion on chromosome 17p11.2, which includes *RAI1*, but ~10% of cases have mutations in *RAI1* alone. Clinical features of SMS include obesity, craniofacial abnormalities, sleep cycle disturbance, and intellectual disability. Although several studies have investigated *RAI1* deletions in mice, very few have examined the functional effects in patient-derived cells.

We have generated induced pluripotent stem cells (iPSCs) from SMS patients with mutations in *RAI1* to study the impact at the cellular level. Genes co-expressed with *RAI1* were established using RNAseq data sets from post-mortem brains, and evaluation of these genes indicated that *RAI1* could have an important function at neuronal synapses. Specifically, *SYT5* (calcium-dependent vesicle fusion) and *PHACTR1* (synaptic plasticity) were present. Therefore, we first differentiated iPSCs from three SMS patients and unaffected controls into neuronal precursor cells (NPCs).

RNAseq data from these cells provided 293 differentially expressed genes (122 up-regulated, 171 down-regulated). The up-regulated genes were associated with terms relating to neuropsychiatric disorders, such as schizophrenia and depression, suggesting that *RAI1* may have a broad role in neuropathology. The down-regulated genes provided strong evidence of defects in the extra-cellular matrix (ECM), including genes such as asporin and decorin which are implicated in axonal development. Interestingly, *BICDL1* is the only gene found in both the co-expression and NPC RNAseq data sets, and has a role in vesicle secretion and neurite outgrowth.

As such, it is critical to differentiate our iPSCs into neurons. As transcription of *RAI1* can be influenced by retinoic acid, I am utilizing a direct differentiation approach, in which the human transcription factor, neurogenin-2, is transfected into the desired iPSC lines. Once stable transfection has occurred, doxycycline can induce differentiation directly into excitatory cortical neurons in a matter of weeks. I then aim to ascertain differences in neurite and dendritic growth, with particular focus on proteins involved in the ECM and synaptic vesicle transmission. Such knowledge will provide insights into mechanisms involved in SMS and other neuropsychiatric disorders, ultimately leading us to novel treatments.

## PgmNr 1822: Low coverage RNA sequencing increases power for eQTL studies.

---

Expression quantitative trait studies (eQTL) have proven to be a powerful approach to identify common genetic variants contributing to regulation of gene expression, and subsequently to complex traits and diseases. Here, we show that low-coverage RNA-seq across an increased number of individuals attains more power for eQTL discovery than high-coverage RNA-seq with a limited amount of individuals, under a fixed budget. We propose a framework to improve gene expression estimation in low-coverage bulk RNA-Seq datasets, by leveraging correlation structure across genes as well as patterns across individuals to correct low confidence gene expression estimates. We show via simulations that reducing coverage while increasing the number of individuals in an eQTL study can boost power to discover eQTLs. This is quantified by effective sample size, or the amount of individuals that would have needed to be sequenced at high-coverage to discover the same number of eQTLs. We find that RNA-Seq data at 5-fold reduction in coverage captures upwards of 40% of the variation of high-coverage RNA-sequencing, on average. Within the context of reducing experimental costs, our results suggest that low-coverage RNA-sequencing in many individuals can yield increased effective sample size of eQTL studies based on high-coverage RNA-seq. We explore an empirical demonstration, by assuming a fixed budget and accounting for all costs, and show that instead of sequencing 690 individuals at 50 million reads per sample, we can achieve an effective sample size of over 800 individuals by sequencing 2000 individuals at 10 million reads per sample. Applying our approach for low-coverage gene expression measurement can further improve these estimates, which provides an additional boost to the effective sample size.

## PgmNr 1823: Identifying and validating cell type specific driver genes in autism-associated copy number loci using cerebral organoids.

---

Neuropsychiatric disorders have been particularly challenging to study using model organisms, and recently, human-derived cerebral organoids demonstrate great promise for discovering molecular processes that are important in these disorders. However, several challenges remain in achieving robust phenotyping of cerebral organoids to discover cell type specific genes. We perform RNA sequencing on 1,420 cerebral organoids from 25 donors, and describe a framework (Orgo-Seq) to identify cell type specific driver genes, for two major risk loci associated with autism, by leveraging on bulk and single-cell RNA sequence data. We identify stem cells and neuroepithelial cells as critical cell types for 15q11-13 duplications and 16p11.2 deletions respectively, and discover novel and previously reported cell type specific driver genes.

Finally, we describe a CRISPR/Cas9-based framework to differentiate 'mosaic' cerebral organoids harboring synthetic mutations in *KCTD13*, followed by single-cell dissociation for fluorescence activated cell sorting (FACS) and targeted MiSeq sequencing. We validated the observations from our transcriptomics analyses, that deleterious mutations in *KCTD13* in the 16p11.2 locus are significantly enriched in Nestin+ neuroepithelial cells (Wilcoxon  $P=4.6 \times 10^{-3}$ ), depleted in TRA-1-60+ stem cells (Wilcoxon  $P=3.5 \times 10^{-3}$ ), but do not affect the proportion of NeuN+ neurons in the cerebral organoids (Wilcoxon  $P=0.47$ ). Our work presents a quantitative discovery and validation framework for identifying cell type specific driver genes in complex neurological diseases using cerebral organoids.

## PgmNr 1824: Proteomics of addiction: Postmortem brain analyses of cocaine and opioid use disorder.

### Authors:

Substance use disorders (SUD) are a significant global health problem, with drug overdoses being the leading cause of death for Americans under the age of 50, killing more than guns, car accidents, or breast cancer. Drug use leads to changes in the structure and function of the brain by causing alterations in brain proteins. However, the assessment of protein modifications in human brain has been limited by the difficulty in obtaining brain tissue. Here we present preliminary data in our investigation of brain proteome alterations in the dorsolateral prefrontal cortex (BA9) of subjects with cocaine use disorder (CUD, n=10), opioid use disorder (OUD, n=20) and controls (n=12) from the UTHealth brain collection. Importantly, all CUD and OUD subjects died of a cocaine or opioid overdose, respectively.

Approximately 50 mg of tissue was lysed in RIPA buffer and extracted proteins were reduced, alkylated, de-lipidated and digested. NanoLC MS/MS was performed using a nano-LC chromatography system, coupled on-line to a mass spectrometer through a nanospray ion source. Data were acquired using XCalibur and the raw mass spectrometry data files were processed using MaxQuant. Peptide identifications were accepted if they could be established at greater than 95.0% probability. MS/MS spectra were searched against the Swiss-Prot human database. In total, 4584 unique proteins were identified in all the samples. Data was normalized and differential expression analyses were performed in CUD and OUD vs. controls respectively using the protein-wise linear models combined with empirical Bayes statistics implemented in the DEP (Differential Enrichment analysis of Proteomics data) R package and the *limma* R package.

We identified 49 proteins differentially expressed between the CUD and control groups and 40 proteins between the OUD and control groups ( $p.val < 0.05$  and  $|\log FC| > \log_2(1.5)$ ), of which 10 were found in both CUD and OUD. Pathway enrichment analyses identified protein localization to synapse and myelination pathways to be enriched in CUD, and acute inflammatory response and astrocyte development as the main enriched pathways in OUD.

Our results point to unique brain protein alterations induced by cocaine and opioids, suggesting distinct mechanisms of action and neurotoxicity. These results could shed light on the neurobiological mechanisms of SUDs and could lead to development of novel therapeutic approaches to minimize damage induced by these drugs of abuse.

## PgmNr 1825: Approaches to transcriptome analysis of human induced neurons in co-culture with murine glia to model functional synapses.

Neurons derived *in vitro* from human iPS cells carrying known genetic variants are an increasingly important model for studying the molecular mechanisms and neurophysiological consequences of neurogenetic disorders. To make use of the full potential of this approach, the neurons have to reach maturity and display functional synaptic properties. Achieving neuronal maturity often requires co-culture with glial cells derived from mouse brains. This is a robust and well-established procedure for neurophysiological analyses, but it creates cell cultures that contain both mixed cell types and from mixed species. Therefore functional genomics analyses of these cultures require either experimental or computational separation of cells, but the cultures contain dense and inter-connected networks and are difficult to dissociate.

We developed a dissociation protocol that generates intact single cells from cultures of human induced neurons (iNs) that had matured on mouse glia.

Using this dissociation protocol we carried out droplet-based single-cell (sc) RNA-Seq analyses of mature human iN cultures. We accompanied this with comparative analyses between scRNA-Seq, bulk RNA-Seq (i.e. of RNA extracted from the neural cultures without dissociation and separation of cells), and bulk RNA-Seq after dissociation and separation of cell types by immunopanning (i.e. of RNA extracted separately from neurons and glia).

Bulk RNA-Seq analysis that includes computational separation of murine and human reads, using a Bowtie2+RSEM pipeline, already performed unexpectedly well in distinguishing between the two species. This was confirmed by RNA-Seq of immunopanned cells. For scRNA-Seq where single cells are analyzed, the co-culture of murine and human cells does not interfere with the analysis. Both the bulk and scRNA-Seq detected very similar levels of human versus murine sequencing read distributions. However, unlike bulk RNA-Seq, the scRNA-Seq approach revealed varying degrees of cellular heterogeneity within cell types from the two species. The single-cell approach also provides an increased ability to gauge variability between biological replicates and enables functional genomics studies of, for example, the molecular basis of neuron induction and maturation and reciprocal signalling effects on heterogeneous cell types. Taken together, we present a comprehensive comparative overview of approaches to transcriptomic analysis of heterogeneous human stem cell

based neuronal cultures.

## PgmNr 1826: Using a novel “audiomic” approach to understand hearing loss of unknown etiology.

### Authors:

---

Whole exome strategies are now the mainstay for genomic diagnoses in patients who have multisystem disorders and lack a unifying reason for their condition. The Mayo Clinic Genomic Odyssey Board has performed analysis for 1451 patients who have undergone whole exome sequencing. Of this group 88 patients were identified to be deaf or hard of hearing of unknown etiology as part of their systemic condition. In order to find the cause of their condition, we are developing novel strategies in this subset of patients. Previous tiered strategies evaluated target genes for 1) *de novo* variants, 2) homozygous recessive variants, and 3) compound heterozygous gene variants. Our novel strategy utilizes the evaluation of the transcriptome of zebrafish and mouse inner ear hair cells in order to identify novel genes that could be implicated in hearing loss that would have otherwise been ignored through previous strategies. We used a large dataset of known inner ear hair cell and supporting cell transcripts obtained from published literature (Barta et al. 2018, Elkon et al. 2015) and performed what we call an “audiomics” analysis. Using the publically available adult zebrafish RNAseq data from Barta et al., of the 442 uniquely expressed genes in the sensory hair cells and 2152 uniquely expressed genes in the non-sensory hair cells 1273 genes had human orthologues. Using publically available P0 mouse microarray expression data from Elkon et al. 2015 human orthologues for 1185 genes were identified. Between the zebrafish and mouse data only 95 duplicates between species were noted. This “audiomics” analysis includes referencing these two lists (zebrafish and mouse) to a gene list created from phenolyzer using the term “hearing loss”. Phenolyzer returned a list that includes 711 putative genes with various degrees of association to the term “hearing loss”. Therefore, of the 2393 genes uniquely expressed in zebrafish sensory and non-sensory supporting cells and mouse hair cells, 2262 were not captured by the current phenolyzer gene list. This strategy demonstrates our unique approach to identifying novel gene-disease associations for hearing loss and could possibly identify the cause of disease in this subset of patients.

## PgmNr 1827: Identification of novel limbal stem and progenitor cell types in human corneal epithelium using single-cell transcriptomics.

### Authors:

---

Limbal stem cells (LSCs), also known as corneal epithelial stem cells, are located at the basal epithelial layer of the corneal limbus and serve an important function in maintaining the homeostasis of the corneal epithelium. The inherent regenerative properties of LSCs, therefore, hold the promise for treating various degenerative eye diseases and LSC-based cornea transplantation. Several putative molecular markers of LSCs have been previously identified. Nonetheless, the specificity of these markers remains largely controversial. To address this gap in the current understanding of LSCs, we performed a transcriptome profiling of heterogeneous corneal limbal population using single-cell transcriptomics technology to identify LSCs and their exclusive markers. Using the 10x Genomics platform, we obtained the transcriptome of about 18,000 individual single-cells. Furthermore, principal component analysis (PCA) was used to reduce the dimensionality of the dataset, followed by clustering unique cell types through the graph-based visualization method Uniform Manifold Approximation and Projection (UMAP). A total of 11 unique clusters of cells were identified and each cluster was assigned to a putative cell type based on previously published biomarkers. As a result, 5 differentiated cell clusters, 3 progenitor clusters, 2 melanocyte clusters, and 1 putative stem cell cluster were identified. Differentiated cell clusters were defined by well-known differentiation markers such as *KRT12* and *GJA1*. Interestingly, the differentiated cell clusters were divided into two main subtypes as characterized by presence of *KRT3* gene expression. Two subtypes of differentiated cells likely represent different stages of differentiation or spatial location they reside. Progenitor clusters were defined by known basal limbal markers such as *KRT14* and *KRT19*. One progenitor cluster was characterized by the increased expression of cell cycle related genes and, therefore, has been assigned as transient amplifying cells (TACs). Two melanocyte clusters were defined by many melanocyte related genes and likely represent different stages of cell maturation. Lastly, one putative stem cell cluster was defined based on the expression of several novel stem-cell related markers. To further validate each cell cluster and determine their location in human corneal limbus tissue, a combination of tissue RNA in situ hybridization (ISH) assay using RNAscope and antibody staining is currently underway.

## PgmNr 1828: Best approaches and methods for saliva-derived genomic DNA extractions.

### Authors:

---

Technological advancements have led to the development of minimally invasive and easily accessed (e.g. clinic, home, field) biospecimen collection methods and specimen stability for DNA. Saliva is a popular alternative to whole blood for sequencing of germline DNA, due in part to the ease, portability, and lower cost. This is of particular importance when conducting large-scale population genetics studies, especially in challenging field settings where human subjects risks associated with venipuncture and access to appropriate infrastructure for the collection, processing and storage of whole blood may be burdensome or impossible. With the increased demand for saliva biospecimens there has been an influx of genomic DNA extraction kit options from various commercial entities; however, there is a dearth of unbiased, peer-reviewed literature for objectively assessing which collection method and extraction kit should be used, balancing the considerations of cost and time. In the absence of these resources, investigators may compromise sample collections for a more expensive kit both in time and money, at the expense of under-powering the study. As part of the Consortium on Asthma among African-ancestry Populations the Americas (CAAPA), for which a major goal is to study the genetics of asthma in populations of African ancestry where prevalence is disproportionately high, we have identified the following logistical questions: 1) Which extraction kit is the most-efficient and yields high quality results; and 2) Are DNA extracted from saliva and whole blood comparable for variant calling?

Thirty participants with saliva and whole blood specimens were recruited into a pilot study to address these questions. Four different saliva extraction kits were used and the following four metrics were assessed: DNA quality, DNA yield, time for extraction, and cost. Because time is a significant factor for large-scale studies, we also considered using a kit that can be automated versus kits that require labor intensive, hands-on extraction processes. Quality was assessed by assessing A260/280 readings, DNA fragmentation levels, and bacterial contamination ratios. A TaqMan 16S rRNA gene expression kit was used to measure bacterial contamination and a TaqMan RNaseP probe was used to measure human control DNA. Paired sample collections of whole blood and saliva were extracted and genotyped on a custom-build of Illumina's MEGA chip where concordance was assessed across ~2M SNPs.

## **PgmNr 1829: Primate brain retinal ganglion cell (RGC) topographic map revealed by ultra high DSI 2D hexagonal pattern (Polyak, 1953) translates faithfully from optic nerve to 3D thalamic arrays.**

---

The complex circuitry of the primate visual system is an elegant testament to the central role of light processing in survival throughout the past 550 my of evolution. Organized as the integration of the evolutionarily older “primary” visual system, that then maps on to the visual cortex, a striking feature is the general “retinotopic” organization that is found in most target regions of both systems. How this organization arises from the planar organization (Polyak 1953) seen as a plane of hexagons for retinal ganglion cells (RGC) is known for only a few basic rules. The fundamental need has been for a technology capable of tracing multiple neighboring axonal bundles from the retina or optic nerve through the complex crossings of the optic chiasm, to target regions. Diffusion spectrum imaging (DSI) provides a theoretical framework to do this but has needed internal systems of known biological structures to be able to evaluate its validity. We report the creation of a heretofore unprecedented dataset of the macaque fascicularis brain that utilized >500 directions, multiple b values of up to 40,000, and 140 h of acquisition in a Bruker 7T with a 20 cm coil. Using the DSI Studio algorithm (Yeh), we generated a series of tests that required successful navigation of multiple DSI challenges including closely spaced crossing fibers in the primate visual system. Further to dimensionally decrease the complex patterns, we developed novel approaches using subvoxel seeding equivalent to micro-voxels of 16-32 micron cubed regions. To align these with high resolution neuroanatomic architecture, we used diffeomorphic transformations to integrate the tracks with a 3D atlas generated from the same animal using block face acquisitions of the complete brain (2300 slices) sectioned at 30microns. We report here two major findings. Axon patterns, presumably represented by the diffusivity of multiple clustered axons, correctly tracked from the right versus the left optic nerve, to reveal a closely apposed pattern of more than 1,000 red versus green signals in the left visual cortex. Second, the findings revealed a pattern of hexagonally arranged planes that could be followed from each of the optic nerves, through the chiasm and to the lateral geniculate nucleus where the patterns were maintained. These results strongly suggest that DSI combined with histological data, may be suitable for tracing the micro and mesocircuitry of the primate brain.

## PgmNr 1830: Gene Curator: A multi-source, data-driven approach to disease-based gene ranking.

### Authors:

P. Singh; L. McAuliffe; M. Fasnacht; S. Ng; J. Delaney; J. Hakenberg; M. Jung

[View Session](#) [Add to Schedule](#)

**Affiliation:** Illumina Inc, 5200 Illumina Way, San Diego, CA 92122.

Targeted sequencing based on data-driven disease content strategies is a powerful and cost-effective application of high throughput sequencing technologies. However, the data supporting evidence for correlations between genes and diseases are spread across several isolated databases with no single tool currently available that integrates the information for the purpose of assay design, thus necessitating better integration models.

Here we present Gene Curator, a tool that optimizes gene content for disease phenotypes using a multi-omics data driven approach where each type of information encompasses a separate module. Currently, four different modules are implemented namely, gene expression, GWAS catalog, scientific literature, and curated databases. The **gene expression** module is based on the data in Illumina Correlation Engine with more than 22K studies and over 500K individual experiments based on RNA-seq and microarrays. It embraces experimental heterogeneity by analyzing multiple cohorts that are diverse in their population, sample type, assays used and other factors. Our robust statistical pipeline allows us to find reproducible and tissue-specific gene expression signals in the “noise” of multiple studies. The **GWAS module** extracts data from the GWAS catalog and combines across multiple studies to bump up p-values based on study sizes. It then maps the SNPs to genes and derives gene p-values using a simulation approach that takes the length of the gene and linkage disequilibrium into consideration to rank genes with SNPs that have the lowest p-values for that gene. The **curated databases** module is Illumina’s gene panel app that starts with a phenotype supported by ontology backbone (e.g. Omim, SNOMED, MedGen), generating a list of disease-associated genes. The **scientific literature** module utilizes 30 million articles in PubMed with scores reflecting the number of text pieces supporting the gene-disease relation.

Gene Curator results can be utilized to tailor gene panels for a disease of interest, enhance current targeted content, understand the implications of sequencing results by intersecting with disease-gene correlations or to identify new biomarkers for complex disease models. Taken together, our modular approach enables streamlined design procedures for each gene panel application, simplifying the selection from CNV panels over tissue specific RNA expression screenings to genotyping panels.

## PgmNr 1831: Differential gene expression between the Turner and Klinefelter syndromes.

### Authors:

A. Rojas <sup>1</sup>; M. Manotas <sup>1</sup>; J. Calderon <sup>2</sup>; O. Moreno <sup>1</sup>; F. Suarez <sup>1</sup>; L. Lopez <sup>2</sup>

[View Session](#) [Add to Schedule](#)

---

**Background:** Analysis of patients with chromosomal abnormalities, including Turner syndrome (45,X) and Klinefelter syndrome (47,XXY), has highlighted the importance of X-linked gene dosage as a contributing factor for disease susceptibility. Escape from X-inactivation and X-linked imprinting can result in transcriptional differences between normal men and women as well as in patients with sex chromosome abnormalities

**Objective:** identify differentially expressed genes among patients with Turner and Klinefelter syndrome.

**Methodology:** Two sets of gene expression data of Turner and Klinefelter syndrome were obtained from the Gene Omnibus Expression (GEO) database of the National Center for Biotechnology Information (NCBI) with accession number GSE46687 and GSE42331. The statistical analysis of the data was performed using the R software, the data processing was done using different Bioconductor libraries. Differentially expressed genes were determined using significance analysis of microarray (SAM), for the data corresponding to Turner syndrome a critical value of  $d_i = 3.0649$  was selected and for the data of Klinefelter syndrome a value  $d_i = 0.9579$  was selected, corresponding respectively to a false positive percentage that approaches zero (FDR - False Discovery Rate). The functional annotation was performed in DAVID v6.8 (The Database for Annotation, Visualization and Integrated Discovery)

**Results:** There are no genes over expressed simultaneously in both diseases. When crossing the list of repressed genes for Turner syndrome and the list of over expressed genes for Klinefelter syndrome, there was a coincidence in 16 genes: *SLC25A6*, *AKAP17A*, *ASMTL*, *KDM5C*, *KDM6A*, *ATRX*, *CSF2RA*, *DHRX*, *CD99*, *ZBED1*, *EIF1AX*, *MVB12B*, *SMC1A*, *P2RY8*, *DOCK7*, *DDX3X*, of which eight genes encode to regulators of gene expression through epigenetic mechanisms.

**Conclusion:** our results suggest that global epigenetic and RNA expression changes play a central role for the Turner and Klinefelter phenotype.

## PgmNr 1832: Resonance tunneling integrated omics sequencing.

**Authors:**

V. Vatannia; S. Vatannia; M. Yavi

[View Session](#) [Add to Schedule](#)

**Affiliation:** Resonance HRT, Palo Alto, California.

---

Resonance HRT has developed a novel approach utilizing resonant tunneling (RT) to achieve identification of biopolymers, DNA, RNA, proteins and metabolites on the same device. This technology enables single molecule long reads, which has not yet been fully achieved by the currently available platforms. In addition, Resonance tunneling-based sequencing approach is inherently preserving the secondary modifications on molecule. Lastly, this process spares the multi-step sample preparation and is independent of PCR-based sequencing technology.

The Resonance HRT device utilizes coupling between energy states of a custom designed quantum well structure (Chip) with the electronic state (HOMO and LUMO) of individual molecule components (e.g. nucleotides, peptides, methylations, sugars, etc.). The system (emitter, insulator, base, molecules and collector) is designed such that when the energy levels of the Emitter and Quantum Well are aligned, the electrons will pass through the insulator layer by way of resonance tunneling effect to the Base. These electrons are highly coherent in energy spectrum and will travel through the Base and will be collected by the Collector, only if the energy level of the molecules (in this case the DNA bases) align with the eigen energy of Quantum Well and Fermi level of the Emitter.

Results show a sharp Lorentzian Peak around -1.7V, which is indicative of RT in solution at room temperature over large distances. We have ruled out electrochemical reactions since the voltage is kept constant at -0.5V, below the level of electrochemical reactions for Pt in an aqueous. The current stops after withdrawing the tip more than 5nm from the original setpoint (for a total of 7nm between electrodes), within the range of electrochemical reactions but beyond the range of RT.

Our current projections indicate orders of magnitude improvement in standard measures over the current state of the art sequencing (e.g. Q40 raw accuracy, 1 base/ms/channel speed, and much lower total cost of sequencing) and entirely new possibilities for direct sequencing RNA, precise methylations mapping, non-destructive, single-molecule protein sequencing, and ultra-precise metabolomic sensing. Enabling multi-omics sequencing will broadly advance biomedical research, with commensurate impacts on a variety of applications such as displays and sensors.

## PgmNr 1833: A 12 minute, single tube, nanogram input library prep for WGS, FFPE, WES, and RNAseq.

---

Next Generation Sequencing (NGS) library construction is a workflow bottleneck. The processes of library construction for DNA and RNA sequencing are complex, error prone, costly, and in general are time consuming. Current commercial products offer multistep, multi-hour sample processing that can be cost and labor prohibitive. These issues have created a demand for a simple, rapid, and cost-effective library construction product that offers users application flexibility while minimizing construction complexity for low to ultra-high throughput sample processing. SeqOnce has developed a novel library technology that is rapid and minimizes sample processing complexity. The five tube kit is comprised of formatted master mixes for a simple and stable user workflow. The 12 minute library construction for Human WGS, FFPE, and WES, uses a single master-mix that when combined with fragmentation and PCR steps produces libraries in less than 50 minutes. A single size selection step occurs after PCR and the PCR free protocol is less than 20 minutes. The kit contains three master mixes and includes adapters, which maximally promotes product flexibility across multiple applications. With master-mixes that are stable for multiple days at ambient temperatures, automation on liquid handling platforms is effortless due to the simple workflow. The technology has been validated on human samples for shallow and deep whole genome sequencing, FFPE, WES, and RNAseq with input ranges of 10ng - 200ng. The sequencing data is either equivalent or superior to other competing library products, with high mapping rates and excellent performance across variable GC content. The technology is currently optimized for the Illumina platform and alternative NGS platforms are under evaluation for future development.

## PgmNr 1834: Best practices for handling genomic DNA during NGS library preparation.

Superior NGS library preparation and sequencing results start with quality genomic DNA (gDNA). Quality control analysis provides a great deal of information that is required before beginning NGS library preparation including size, smear distribution, and concentration. Quality of the gDNA starting material can be modified by the dynamic environment and handling processes it encounters. To determine how common laboratory practices such as pipetting, vortexing, and freeze-thaw cycling impact gDNA quality, commercially available gDNA samples were analyzed using the Agilent 5200 Fragment Analyzer system. Both the Agilent Genomic DNA 50 kb kit and HS Genomic DNA 50 kb kit were used to determine the average size, smear distribution pattern, concentration, and percent of degradation of the gDNA sample. It was found that different sample handling practices have varied impact on gDNA sizing, with some, such as high-speed vortexing having a greater effect on sample integrity compared to gentler handling practices, such as slow pipetting with a wide-bore pipet tip. From this study, we have developed a set of best practices for handling gDNA. Quality control analysis of gDNA and gentle handling practices ensure gDNA integrity and build confidence in the success of downstream applications such as NGS library preparation.

## PgmNr 1835: IFN- $\gamma$ -dependent transcriptome altered by human cytomegalovirus-encoding UL23 protein on human foreskin fibroblast cells(HFF) using RNA-seq.

### Authors:

H. Li; S. Wu; L. Feng; H. Chai; X. Yang; Z. Deng

[View Session](#) [Add to Schedule](#)

**Affiliation:** College of Life Science and Technology, Jinan University, Guangzhou, Guangdong, China

Human cytomegalovirus (HCMV) is a human pathogenic herpesvirus belonging to the subfamily of beta-herpesvirus, which causes global epidemics and complications in AIDS patients and organ transplant recipients, and is a major factor of birth defects. HCMV infection is also associated with inflammatory and proliferative diseases such as certain cardiovascular diseases and cancers. Interferons (IFNs) are pleiotropic cytokines produced and secreted upon pathogen encounter to induce a remarkable change of the cellular gene expression profile, leading to an enforcement of intrinsic immunity, the induction of innate immunity and the stimulation and recruitment of adaptive immunity. Interferon responses are vital for a host to combat infections of many human viruses including human herpesviruses. HCMV has a large dsDNA genome of approximately 230 kb, encoding a multitude of proteins mediating immune evasive properties, targeting both innate and adaptive immune responses.

HCMV-encoding UL23 is a virion protein found in the tegument and is expressed in the cytoplasm in HCMV-infected cells. UL23 was found to facilitate viral immune escape from IFN- $\gamma$  responses and enhancing viral resistance to IFN antiviral effects in our previous studies. Here, we profiled the expression of mRNAs in UL23-ectopic expressing HFF cells using the RNA-seq to investigate the transcriptional changes during IFN- $\gamma$  treatment. At 12 hours IFN- $\gamma$  incubation, a total of 84,709,994 sequence reads was obtained. 18,585 protein-coding genes were observed in Refseq database. Differential gene expression analysis identified 257 differentially expressed genes (DEGs) between HCMV-infected and mock-infected HFF cells, including 28 up-regulated genes and 229 down-regulated genes. These regulated genes were involved in chemokine signaling pathway and NF-kappa B signaling pathway, all of which may be implicated in host defence against HCMV infection. These findings have provided a dynamic scenario of differentially expressed candidate genes at the virus-host interface and clearly warrant further experimental investigation associated with HCMV infection.

NGS is commonly used for amplicon sequencing in clinical applications, to study genetic disorders and detect clinically actionable mutations. But this approach can be plagued by limited ability to phase sequence variants and makes interpretation of sequence data difficult when pseudogenes are present. Long read high fidelity (HiFi) amplicon sequencing can provide very accurate, efficient, high throughput (through multiplexing) sequences from single molecules, with read lengths largely limited by PCR. The data is much easier to interpret; phased variants and breakpoints are present within high fidelity individual reads.

Here we demonstrate SMRT sequencing of the *PMS2* and *OPN1MW* genes. In both cases there is a second very similar gene, *PMS2CL* and *OPN1LW*, which can make NGS and MLPA results very difficult to interpret. For *PMS2*, 8 amplicons ranging in size from 3.2 kb to 8.2 kb were designed using primers unique to this gene, covering the entire 38 kb. SMRT sequencing produced HiFi reads with coverage ranged from 200x to 1500x; data clearly indicated 2 deletions >1000kb with precise breakpoint mapping.

For *OPN1MW*, two 14 kb amplicons can be generated covering the regions of interest; *OPN1LW* produces one 15.5kb amplicon. These amplicons can be sequenced in their full length or digested with a restriction endonuclease to produce to two fragments, each about half the original length. We show results of sequencing these genes from 3 patient samples with different mutations, including sequencing the full-length amplicons. In 2 of the 3 cases, the mutations were confirmed by orthogonal technologies.

These results demonstrate several areas of added value from long amplicon sequencing:

- Efficiency
- Less PCR, no nesting
- No added tests (like MLPA)
- Multiplexing for high throughput
- Easier data interpretation and analysis; improved results
- Ability to distinguish between genes and pseudogenes
- Variant phasing within long reads
- Precise breakpoint detection

## PgmNr 1837: Highly scalable linked read library technology enables single tube whole genome sequencing for haplotype phasing and *de novo* sequencing.

---

Genome scale haplotype phasing and structural variant detection, and *de novo* assembly of novel genomes are major hurdles for short read based next generation sequencing (NGS) platforms. Long sequence reads are essential to overcome the significant sequence homology on many regions of the genomes. Several NGS library technology breakthroughs recently have demonstrated barcode linked-read sequencing method can effectively generate long read like information and successfully applied for human genome phasing, structural variation detection or *de novo* assembly of other genomes. However, they either require expensive capital expenditure on specialized instruments or are not scalable for commercial adoption yet due to sophisticated barcode generation. We have developed a simple and scalable NGS library technology, Transposase Enzyme Linked Long-read Sequencing (TELL-Seq<sup>TM</sup>), to use short NGS reads for genome scale haplotype phasing and/or *de novo* genome assembly. Millions of uniquely barcoded beads are used to generate linked reads, which could be linked as long as a hundred kilobases, by strand transfer reactions using transposase in a PCR tube in a standard NGS laboratory setting without any specialized instruments. TELL-Seq library procedure takes approximately 3 hours and multiple samples can be easily processed parallelly in a 96-well format when needed. The library protocol can be adjusted and used for various sizes of genomes from bacteria to human. Using TELL-Seq technology we are able to generate comparable and excellent haplotype phasing results on GIAB human samples, and successfully *de novo* assembly on microbial genomes with various GC content. In addition, *de novo* assembly for human size genome is expected to become achievable routinely soon with improvement on assembly algorithm to overcome the dependency on supercomputing capacity. More applications and analysis solutions are being developed for TELL-Seq library technology.

## PgmNr 1838: Bionano Genomics “Sample to Answer” workflow for single molecule analysis of variation in genome structure.

Complex structural changes are often observed in cancer and other diseases. Bionano optical mapping of very long single DNA molecules provides critical structural information for comprehensive genome analysis. The extracted DNA molecules are labeled at specific motifs and analyzed in massively parallel nanochannels. The single-molecule maps can be assembled into chromosome arm-length maps. The maps can be used for structural variation (SV) detection and elucidation of complex rearrangements.

Bionano presents an optimized workflow for cancer and constitutional disorders that includes DNA isolation and labeling, DNA imaging, and genomic data analysis. The workflow starts with the isolation of ultra-high molecular weight (UHMW) genomic DNA using Bionano Prep SP. This couples solution-based lysis with a purification step that leverages a novel process to bind, wash and elute UHMW genomic DNA. This entire protocol can be conducted with 3 hours of hands-on time on a batch of 6 samples, allowing 12 samples to be processed in one day. The eluted material is ready to label by day 2 and contains high quality UHMW DNA, that includes Mbp-sized molecules. After DNA isolation, an enzymatic labeling approach, Bionano Prep DLS (Direct Label and Stain), preserves the integrity of the DNA while labeling sequence motifs across the whole genome. The labeled DNA molecules flow through the Saphyr Chip and are imaged by the Saphyr system. Up to 3.9 Tbp of coverage can be collected per Saphyr Chip, allowing for the processing of multiple samples and/or very high depth for cancer analysis. The data analysis tools provided with Bionano Access take advantage of this data for genome assembly and SV analysis applications. At standard coverage, we provide unprecedented sensitivity to heterozygous SVs. At high coverage, the single molecule pipeline also uncovers SVs that occur at a 5% allelic frequency. These analyses can be performed on local resources or on Bionano Compute On Demand, an economical hosted offering. Combining all these elements, allows cancer researchers, for example, to get whole genome low allelic SVs from multiple samples, in less than 5 days, sample-to-SVs.

## **PgmNr 1839: Single enzymatic DNA fragmentation workflow simplifies library preparation from FF/FFPE samples of varying quality.**

Mechanical fragmentation of DNA is the most commonly-used method for library construction. Current protocols for mechanical shearing are labor intensive, time consuming, expensive, and therefore unsuitable for clinical customers. Because of these drawbacks, enzymatic shearing methods are becoming more popular. However, these methods also require additional optimization for different input amounts or when used with samples of varying quality. Furthermore, the enzymes are sensitive to commonly-used buffers for DNA storage such as TE because of EDTA presence, and/or generate more false SNPs or fusions compared to mechanical shearing. Here, we address these challenges by developing an endonuclease-based enzymatic double stranded-DNA fragmentation method which generates random DNA fragments from a variety of fresh frozen tissue, and FFPE samples of varying quality and input (in the range of 10-200ng) with a single protocol (i.e., no optimization other than adjusting the PCR cycles). Furthermore, the enzyme is not sensitive to commonly-used high/low TE DNA storage buffers.

The DNA fragments generated have 5'-phosphate and 3'-hydroxyl termini and can be directly used in end-repair/dA tailing without further modification/purification. Unlike transposase shearing, it is suitable for library preparation from any FFPE tissue derived DNA including highly-damaged FFPE samples. As we will demonstrate, fragmentation and library preparation experiments using three bacteria of varying GC content (30%-67%) and human DNA shows high coverage uniformity and minimal bias across all GC content. The correlation of coverage (Rs<sub>q</sub>) by targeted region is >0.9 (between enzymatic and Covaris replicates), and similar percentages of known and unknown variants are called by both methods. Furthermore, we observe more complex libraries (~50%) across samples of medium to high quality (TapeStation DIN >3) compared to mechanical shearing. This is likely due to lower loss of DNA since it is a single-tube process, and/or the presence of more DNA ends that are repairable (as opposed to mechanical shearing).

## **PgmNr 1840: Rapid and accurate quantification of Illumina NGS libraries using sparQ Fast Library Quant Kit on the Q real-time qPCR instrument.**

Accurate quantification of the number of amplifiable library molecules is a critical factor for obtaining high quality read data with NGS technologies. The high sensitivity, broad dynamic range, and specificity of qPCR to quantify library molecules that are suitable for bridge amplification provide significant advantages over methods for total DNA quantification. However, these advantages are often offset by the time to result, complexity of execution, and costs associated with qPCR run. Here we describe application of the sparQ Fast Library Quant Kit and Q real-time qPCR system to simplify accurate and reproducible library quantification with 50% shorter run times compared to traditional protocols.

The sparQ Fast Library Quant Kit consists of a set of six prediluted standards, an optimized library dilution buffer, and a ready-to-use master mix containing Illumina P5 and P7 primers that is optimized for fast cycling on the Q qPCR system. The Q qPCR instrument is a compact and portable system that exploits a novel magnetic induction technology to rapidly heat reactions held in a unique spinning aluminum rotor. This provides superior temperature uniformity of  $\pm 0.05^{\circ}\text{C}$  that eliminates well position effects and cross-instrument variability associated with traditional peltier block-based real-time cyclers. Robust optics with rapid data acquisition times are coupled to an intuitive data analysis interface to deliver highly accurate and reproducible qPCR results.

To test the efficacy of this new library quantification kit and novel qPCR instrument we measured libraries of various fragment sizes and GC contents over multiple trials using a universal fast cycling protocol. Results for sparQ on the Q were highly correlated to those obtained with a leading library quant kit following the manufacturer's recommended protocol. These data demonstrate highly precise measurements across multiple trials and production lots of reagents and standards, high and consistent amplification efficiencies for libraries of varying GC content and fragment sizes, with completed run times in under 40 minutes. Consequently, in addition to simplifying and streamlining reaction assembly and providing faster time to result, the Q and sparQ Fast Library Quant Kit offer the potential to reduce costs and improve operational efficiencies for both independent investigators and moderate throughput NGS labs.

## **PgmNr 1841: Consistent nucleic acid extraction is the key to reliable genomic data - and the Fluent® NAP workstation is the ideal tool to support your efforts.**

### **Authors:**

B. Marg-Haufe

[View Session](#) [Add to Schedule](#)

Having the right samples is crucial to the success of any genetic research and testing workflow. Reliable and unbiased processing ensures clean nucleic acid samples and the best possible results, generating data you can trust without the need to repeat experiments. Converting from manual to automated extraction is the best way to relieve the common bottlenecks and pain points in sample preparation, helping to improve performance and consistency – from run to run, operator to operator, and lab to lab. This provides higher quality samples for downstream applications, ranging from qPCR to various types of arrays or NGS.

The Fluent NAP workstation offers reliable processing of up to 96 individual samples, with full tracking throughout the process, plus optional quantification and normalization ready for downstream processes. The system's universal set-up allows you to perform a variety of magnetic bead-based extraction workflows without rearranging the worktable, while the intuitive interface provides on-screen prompts to guide user interactions and allow straightforward process customization. All of these features seamlessly work together to help give you consistent results, while easing the time and energy required to transition your lab to an automated workflow.

## **PgmNr 1842: A highly multiplexed target enrichment approach for sample identification and tracking using the NEBNext Direct Genotyping Solution.**

Next-generation sequencing is increasingly being adopted for genetic screening and clinical diagnostics. To prevent false reporting of results, it is imperative that patient samples are tracked throughout sample processing and data analysis. A reliable method to track sample identity throughout a workflow is to monitor single nucleotide polymorphisms (SNPs) that are highly discriminatory across individuals. In order to incorporate a routine sample tracking method into diagnostic workflows, the method should be reliable, high-throughput, and cost-effective.

To address the need for high-throughput genotyping assays, we developed the NEBNext Direct Genotyping Solution. This approach enables multiplexing of up to 96 samples in a single hybridization reaction that targets between 100 to 5000 SNPs. Here we demonstrate the power of this approach to distinguish 24 unique human samples from each other using a sample identification panel of highly discriminatory SNP targets. Using this approach, minimal sequencing reads were required per sample to obtain sufficient data for germline variant calling. With a one day target enrichment and library preparation protocol and an approximately 12 hour sequencing strategy, we went from DNA samples to data in less than 24 hours. Our approach offers a convenient and reliable method to ensure that data integrity is maintained in a diagnostic workflow.

## PgmNr 1843: Comparative purification methodologies and synthetic long-read sequencing for fecal microbiome identification.

Study of the human microbiome is rapidly expanding as we further our understanding of the relationship between human health and gut microbiota. Thus, there is an increased need for protocol optimization to more accurately see what organisms are present. Here, we study two aspects of the protocol: comparison of purification methods and the use of a synthetic long-read sequencing library prep method for improved species level identification.

DNA was purified via three extraction methods from replicate fecal samples and a control sample. Samples were prepared for 16S microbiome sequencing using a novel library prep method that provides comprehensive profiling of all 9 variable regions while incorporating barcode-based molecular counting designed to algorithmically combine short reads into a full-length molecule using linked-read de novo assembly. Two separate chemistries for size-selection of libraries were also compared. Illumina sequencing was performed and results across methods were compared.

In fecal samples, variation in microbiome levels were virtually indistinguishable between size-selective purification chemistry, but showed moderate distinction depending on purification method, with two methods (fecal protocols from Promega Maxwell® RSC PureFood GMO and Authentication kit and ReliaPrep™ gDNA Tissue Miniprep System) in close agreement but diverging from the Qiagen QIAmp PowerFecal purification kit. When comparing results utilizing a microbial community standard, the various purification methods were indistinguishable, but all three methods deviated significantly from the theoretical mix as reported by the manufacturer. These results were likely due to the control being comprised of pre-lysed organisms, negating differences in pre-processing between methods. All methods produced synthetic read lengths approaching the full length 16S maximum of 1500bp when combined with the novel library prep method on standard sequencing platforms, with most organisms identified at the species or strain level.

Divergence from theoretical mixes in a community standard demonstrates the need for careful selection of proper controls when evaluating purification methods. High prevalence microbes are easily detectable in all methods, but rare organisms can be potentially lost depending on purification methods. Full length 16S sequences can be achieved without the need for long-read sequencing platforms, providing greater detail and discrimination within a microbiome.

---

Inflammation is a key host response to infection or injury. However, pathological chronic inflammatory responses occur in immune-mediated diseases, such as rheumatoid arthritis or inflammatory bowel disease (IBD). In addition, there is growing recognition of the role of chronic inflammation in disorders not classically considered autoimmune, such as cardiovascular disease. Understanding the effects of genetic variation on inflammation-related proteins will therefore provide valuable insights into disease aetiology and inform development of novel therapies. In addition, there is now a growing armamentarium of biological therapies capable of targeting specific inflammatory proteins, providing opportunities for drug repurposing.

Knowledge of the genetic determinants of the human plasma proteome has until recently been limited by lack of suitable high-throughput proteomic assays, but technological advances now allow protein measurement at population scale. Here, we report data from the SCALLOP consortium, a multi-national collaboration which seeks to combine genomic and proteomic information. We performed genome-wide protein quantitative trait locus (pQTL) mapping for 91 inflammation-related plasma proteins measured using Olink immunoassays in a meta-analysis of 15,335 individuals. We identify at least 1 pQTL for 71 out of 91 proteins; 12 had *cis* pQTLs only, 14 *trans* only, and 45 both *cis* and *trans* ( $P < 5 \times 10^{-10}$ ). The majority of the 20 proteins with no detectable pQTLs had low abundance in

plasma. We identified up to 8 pQTL regions per protein, with conditional analysis revealing multiple additional independent variants. We use colocalisation and Mendelian randomisation techniques to integrate these data with disease susceptibility information from genome-wide association studies to provide new insights into disease aetiology. For example, we found 1 *cis* and 6 *trans* pQTLs for IL12B, including at IBD- and psoriasis-associated variants, mirroring the clinical efficacy of IL12/23 blockade (ustekinumab) in these conditions. This study provides a resource for understanding complex disease traits and an example of the application of novel bioassay technologies to population-scale cohorts.

## PgmNr 1845: Improving transcriptome analysis by incorporating unique molecular identifiers in RNA-sequencing.

RNA-sequencing is a powerful tool for the study of gene regulation and function. Over the years, applications of RNA-sequencing (i.e. single-cell, rare cell type characterization) have vastly expanded by improving library preparation methods that require lower RNA inputs. Although analyzing samples with low RNA inputs allows for a more diverse probe of biological questions, generating these libraries can also introduce greater biases. Generating sequencing libraries with sufficient yields also requires a greater number of PCR amplification cycles after adaptor ligation. During this process, however, transcripts are not amplified equally, leading to an over-representation of certain transcripts.

To resolve true transcript abundance, unique molecular identifiers (UMIs) can be used to detect bias that is introduced during the amplification process. UMIs are molecular tags typically of 8-12 random base pairs that allow researchers to distinguish transcript duplicates that originate from a single molecule. Here we introduce UMI-containing barcoded adaptors optimized across various inputs (10 ng - 1 mg) for the NEBNext Ultra II Directional RNA Library Prep for Illumina. Ligation of these adaptors followed by subsequent PCR enrichment produced high-quality library yields and metrics (i.e. insert size, 5'-3' coverage, and GC bias) consistent with established protocols. In addition to these metrics, use of the newly developed UMI-containing adaptors allowed for detection of duplication rates and correction of differential amplification artifacts. This workflow enables a more quantitative transcript level assessment that can be applied across various studies and applications for a more biologically meaningful quantification of transcripts.

## PgmNr 1846: Effect of RNA editing on molecular phenotypes through a multi-omics analysis.

RNA editing (RNAe) is a post-transcriptional process consisting in the enzymatic modification of one nucleotide encoded by the genomic sequence resulting in another nucleotide in the transcriptomic sequence. Hundreds of thousands of RNAe sites are well established in humans and other species. It has been proposed that the function of RNAe in vertebrates is to edit endogenous long double stranded RNAs to prevent the innate immune from misidentifying them as viral RNA. We used a bioinformatics approach to detect RNAe sites and estimated RNAe levels in two independent RNA-seq datasets: the Geuvadis dataset composed of 421 Europeans and Africans and original data from the QMDiab study, composed of 320 participants of Arab, Filipino and Indian ethnicities. We conducted a *cis*-association study with RNAe levels in Geuvadis and replicated 534 associations (RNAe-QTLs) in QMDiab. We observed a clear allele-specific editing associated with the two alleles of an RNAe-QTL. Moreover, the RNA structure prediction shows the potential of RNAe-QTL in generating a hairpin loop in the double stranded RNA structure. A total of 83 RNAe-QTLs overlapped with QTLs for immune cell count of eosinophils, neutrophils and lymphocytes, and also with risk of inflammatory diseases including Asthma, Crohn's disease and inflammatory bowel diseases. We investigated the correlation of RNAe with the levels of over 1,100 blood circulating proteins and discovered that the most correlated proteins were related to the immune response. We then assessed the correlation between the RNAe and the white blood cell count. We found that RNAe was positively correlated with neutrophil count and negatively correlated with lymphocyte count. We further tested for association of RNAe level with the DNA-methylation derived estimates of Natural killer cells (NK), T helper cells (CD4), Cytotoxic T cells (CD8) and B cells. We found that most of RNAe positively correlated with NK and B-cells and negatively correlated with CD4 and CD8, or inversely. We finally assessed the correlation of RNAe level for RNAe belonging to an editing enriched region and detected the presence of negatively correlated RNAe sites. We explored these cases in detail and found that they were controlled by either the same RNAe-QTL with opposite Beta or a potential CpG site. Our study is the first to study the RNAe-QTL in two independent datasets and to shed light on the correlation between RNAe and other phenotypes in a multi-omics approach.

## PgmNr 1847: Semi-automated RNA extraction from platelets for disease panel expression profiling.

Platelets are anucleate cell fragments in blood, which have long been recognized for their importance in blood clotting and wound healing. Beyond these curative roles, platelets also function in disease pathology. As a result of interactions with stimuli encountered during their circulation, the RNA expression patterns in platelets are altered in ways that are characteristic of certain diseases, including inflammatory diseases, like Alzheimer's disease and cardiovascular disease, sickle cell anemia, and cancer. Additionally, by taking up vesicular RNA from solid tumors, platelets have also been shown to become "tumor-educated," carrying cancer-derived RNA biomarkers. There is growing interest in using platelet biomarkers and expression patterns for liquid biopsy rather than more invasive surgical biopsy procedures for disease diagnosis and monitoring. With this in mind, we developed a semi-automated protocol for total RNA extraction from platelets on a unique robotic platform utilizing single-use cartridges. We analyzed RNA expression by RNA-sequencing with a custom-designed panel of RNA targets whose expression is implicated in disease pathology. We compared expression profiles for RNA extracted from platelets and white blood cells collected from two healthy individuals. Clear differences in RNA expression profiles of white blood cells and platelets demonstrate that the platelet expression profile in our study is not masked by that of the RNA-rich white blood cells. While the platelet RNA expression generally looked similar between the two healthy individuals, there are some notable differences for specific genes. This work demonstrates that an RNA-sequencing workflow for platelet expression studies can be simplified by automation of upfront RNA extraction.

## PgmNr 1848: High-throughput encapsulation of single cells in agarose microdroplets for 3D culture.

**Authors:**

T. Ayers; N. Shakir

[View Session](#) [Add to Schedule](#)

**Affiliation:** Dolomite Bio, Royston, Hertfordshire, United Kingdom

---

Hydrogel droplets are picolitre-volume spherical scaffolds. They represent a potent solution for many single cell applications owing to their properties which allow the diffusion of nutrients and dissolved gases to circulate and reach encased cells. Encapsulating biological material within hydrogels allows cells to be grown within three-dimensional scaffolds, closely mimicking their native physiological environment, whereas conventional plate-based cell culture methods grow cells in a two-dimensional plane with relatively low throughput. This property of hydrogels is useful in the field of 3D *in vitro* cell and tissue culture. Cells can be grown in individual hydrogel beads or seeded onto 3D scaffolds for larger scale tissue synthesis. Importantly, 3D *in vitro* tissue culture requires monodisperse hydrogel beads to enforce their predictable stacking into a geometric tetrahedral 3D structure. The ability of the Dolomite Bio Nadia product family to generate highly monodisperse aqueous droplets in an oil phase makes this platform ideal for this application.

Experiments were carried out to, firstly, define run conditions such as pressures, stirrer speeds and temperatures that allowed for stable encapsulation of agarose taking advantage of the versatility of the Nadia Innovate platform. Secondly, we aimed to demonstrate the high-throughput encapsulation of live cells in agarose and the recovery of agarose beads from the resultant emulsion produced on both the Nadia Innovate and the Nadia Instrument.

Agarose hydrogels were successfully produced after adjusting pressures to accommodate the viscosity of a 1.5% agarose solution. The Nadia Innovate Temperature Control Unit enabled the system to be kept at 37°C during droplet formation to ensure that agarose remained molten and could flow freely into the Nadia Innovate microfluidic chip. Following optimisation of the run conditions, live cells were encapsulated in agarose and recovered from the generated emulsion. In conclusion, the Nadia Innovate and Nadia Instrument were used to produce solid agarose beads containing cells that were subsequently recovered and imaged. The beads were monodisperse and their diameter could be changed by altering pressures to ensure compatibility with cells of different sizes. The flexibility afforded by the Nadia product range therefore enhances the potential of hydrogel cell encapsulation in the field of tissue engineering.

## PgmNr 1849: Targeted interrogation of genetic variants in *CFTR* with NEBNext Direct.

---

The screening and detection of variants in the cystic fibrosis transmembrane conductance regulator (CFTR) are critical for the effective management of cystic fibrosis. More than 2,000 *CFTR* mutations have been reported worldwide and refined sequencing technologies may provide improved genotype-phenotype correlations and better-informed genetic counseling.

Here, we introduce an NEBNext Direct target enrichment panel for the interrogation of genetic variants in the *CFTR* gene. The NEBNext Direct technology uses a novel approach to selectively enrich nucleic acid targets directly from genomic DNA. The approach rapidly hybridizes both strands of genomic DNA to biotinylated baits, captures the targets on streptavidin beads, enzymatically removes off-target sequence, and directly converts captured molecules into Illumina-compatible sequencing libraries in a single day protocol.

The NEBNext Direct CFTR Panel consists of a single pool of baits targeting both strands of DNA across 27 exons (including padding to detect splice mutations) and 7 intronic sites, for a total captured territory of 6.751 kilobases. The panel covers all 346 CF-causing variants listed in the March 11, 2019 release of CFTR2. Here we demonstrate the utility of this panel to detect germline variants in the *CFTR* gene in clinical samples with documented mutations.

Library construction for Next Generation Sequencing (NGS) using formalin-fixed paraffin-embedded (FFPE) samples offers unique challenges in acquiring high-quality sequencing data due to wide distribution of sample quality. Specifically, differences in formalin fixation methods often lead to crosslinked and/or degraded nucleic acid and inconsistent extraction yields. Hence, FFPE extraction and library construction methods must be carefully considered for target enrichment applications. In collaboration, Covaris and Twist Bioscience demonstrate a complete library preparation and target enrichment solution that generates ready-to-sequence multiplexed libraries directly from FFPE tissue.

This workflow leverages the Covaris truXTRAC FFPE total Nucleic Acid Plus Kit and Adaptive Focused Acoustics (AFA) technology with the world-class performance of Twist Bioscience's Target Enrichment Solutions. In this FFPE-specific application, the Covaris truXTRAC FFPE total Nucleic Acid Plus Kit and shearing in AFA-TUBE consumables enable full emulsification of paraffin and disaggregation of tissue for highly efficient nucleic acid extraction and generation of size specific DNA libraries. With the Twist Bioscience Human Core Exome kit, the resulting libraries are indexed, pooled, and target enriched with uniquely optimized DNA probes to generate ready-to-sequence high quality multiplexed libraries.

Using the aforementioned workflow, results from processing FFPE tissue types with a wide distribution of quality (Q305/Q41 ratios ranging from 0.06 to 0.35) are presented. Sequencing results demonstrate substantial improvements in general Picard metrics that include uniformity (Fold<sub>80</sub> < 1.8), sequencing depth (30X coverage >85% with 150X downsampling), and duplication rates (<10%) when compared to similar published studies. These results demonstrate a validated solution for library preparation and targeted exome sequencing of FFPE samples that can be integrated into automated workflows. The truXTRAC kit and AFA technology from Covaris generate size specific DNA libraries from FFPE samples which, when paired with Twist Bioscience's superior target enrichment workflow, deliver multiplexed libraries for high performance targeted sequencing.

# PgmNr 1851: Resolution of a highly complex rearrangement of an SV40 insertion in an immortalized cell line using a combination of short and long read sequencing technologies.

## Authors:

16HBE14o- cells are an immortalized human bronchial epithelial cell line that was first described by Cozens and colleagues (AJRCMB, 1994). This cell line is widely used in CF research as it expresses *CFTR* mRNA and protein, possesses essential epithelial morphology, and is suitable for electrophysiological studies in Ussing chambers or similar systems.

Recently, in house deep sequencing of the *CFTR* locus of the parental 16HBE14o- cells revealed an insertion of SV40 sequence in intron 6 of one *CFTR* allele. The cell line was originally immortalized by transformation with SV40 and whole genome sequencing showed that in fact the only insertion of SV40 sequence is in the *CFTR* allele. All isogenic cell lines created by CRISPR/Cas9 gene editing of the parental cells also contain the same SV40 insertion, suggesting that the insertion is stable and required to maintain the 16HBE14o- immortalization. Given the widespread use of the parental and gene-edited 16HBE cell lines, a complete characterization of the genomic locus and quantification of the mRNA isoforms induced by the SV40 insertion was needed.

To elucidate the full sequence of the insertion, two novel target enrichment strategies were employed: (1) capture of SV40/*CFTR* using biotinylated baits and (2) Cas9 digestion ~500bp up and downstream of the SV40 insertion followed by Oxford Nanopore Minion long read sequencing. Additionally, RNAseq using Illumina-based short read sequencing, as well as a *CFTR* strand switching isoform assay followed by long read sequencing were used to fully characterize the expressed mRNA isoforms.

Initial analysis relying on available automated hybrid assembly tools using short and long reads failed to completely resolve the insertion and resulted in a stuffed gap assembly. We completed the assembly manually utilizing the information provided by paired end and long reads and determined the inserted sequence to be 16 kB and to contain highly rearranged and repeated SV40 viral genome and vector backbone sequences. Using short read RNAseq data, normal *CFTR* mRNA and fusion products of *CFTR* intronic/coding and SV40 sequence were identified. We are currently using long read data to quantify expressed isoforms. However, allelic discrimination analysis and western blot analysis of a gene-edited heterozygous 16HBE cell line suggest that the allele carrying the SV40 insertion is non-functional and therefore the 16HBE14o- parental and derived cell lines are functionally monoallelic for *CFTR*.

## PgmNr 1852: Clariom™ GO Screen Assay: Transcriptional profiling from direct cellular lysates using 384-well array plates.

---

Genome wide profiling of cellular transcription can currently be done with a variety of lab methods. However challenges still exist for cost effective, high throughput workflows. Here an overview of recent advances related to the Clariom GO Screen Assay is presented.

The Human Clariom™ GO Screen array is a 384-well array plate with ~60,000 probes used to measure ~20,000 genes associated with GO (Gene Ontology Consortium). There are in addition array processing controls, housekeeping genes, gender linked genes and human viral content. The array targets the most constitutively expressed exons which are least affected by alternative splicing. Each gene is assayed with three probes selected for specificity and uniqueness, as well as performance across empirical data. The assay is configured to use cellular lysates or total RNA, precluding the need for RNA extraction but allowing the flexibility for both sample types. GO Screen data can be analyzed in a streamlined fashion utilizing Transcriptional Analysis Console (TAC) Software which allows a user to perform exploratory grouping analysis to find gene expression differences between clusters and underlying structures in data sets.

Following target amplification and labeling, sample hybridization to the 384-array plate, and subsequent wash/stain steps are performed on the Gene Titan Multichannel instrument minimizing hands-on time. Array performance characterized using cell line lysates demonstrates that lysates ranging from 10-1000 cells perform in a comparable manner to total RNA. Furthermore, lysate samples are stable at 4°C for at least eight hours which is useful in applications where sample collection may take course over time (e.g. Fluorescence Activated Cell Sorting). For larger studies where multiple 96- or 384- cell culture plates may be needed, lysates can be stored at -80°C for greater than two months with no measurable decrease in performance.

In summary, the Clariom™ GO Screen Assay provides a complete workflow from sample to answer for high-throughput interrogation of gene-level expression, precluding the need for RNA extraction and the reliance on imputation from a limited number of transcriptional events. Results presented here suggest utility in a large range of applications including, but not limited to, secondary compound library screening to prioritize candidates for lead optimization.

---

Solve-RD – “solving the unsolved rare diseases” – aims to solve a large number of rare diseases with unknown molecular cause and improve diagnostics of patients. The project, funded by the European Commission, is applying a sophisticated combination of ‘omics approaches coupled with shared knowledge about genes, genomic variants and phenotypes. As a first milestone, Solve-RD has already collated over 5,000 exomes and genomes from undiagnosed families across Europe through contributions from the four “core” European Reference Networks (RND, EURO-NMD, ITHACA, GENTURIS) and other associated networks, such as UDPs from Italy and Spain. Collation of clinical and phenotypic information is done with a PhenoTips instance linked to the RD-Connect Genome-Phenome Analysis Platform (GPAP) using standards such as HPO, ORDO and OMIM. Standard processing and analysis of the genomic data is done with the GPAP, while custom and innovative approaches are

being setup on the Solve-RD Sandbox, an HPC-like cloud environment enabling collaboration between project partners. Each of the ERNs has setup a Data Interpretation Task Force (DITF), and has proposed several Use Cases for analysing the data. The prioritised Use Cases for exome re-analysis have been distributed across 5 Working Groups within the Data Analysis Task Force (DATF), dealing with individual's relatedness, runs of homozygosity, consanguinity, SNVs, InDels, CNVs, *de-novo* mutations, mosaicism and mutational burden. In the first screening of the data we are prioritising specificity to "solve" the easier cases. We leverage on all the genotypes being annotated and indexed in the GPAP, allowing for real-time queries to a high number of samples. We have tested several combinations of filters on 147 individuals with confirmed causative variants. The filters tested include, amongst other, ClinVar classification, gnomAD frequency, internal GPAP frequency, SNPeff classification and association with HPO terms linked to the specific case. We have settled on a combination with a specificity of 39% and a sensitivity of 35%. The same combination of filters applied to the undiagnosed cases from Solve-RD has yielded a similar number of variants per case as in the test group. The outcome of this approach will be presented at the ASHG meeting. Generation of novel 'omics data from selected cohorts and cases is expected to start at the end of 2019, enabling more comprehensive and innovative approaches.

## PgmNr 1854: Comparing whole exome sequencing probes at the sample and exon level for the human genome.

---

**Introduction:** The ample use of next generation sequencing across laboratories has pushed this technology to become a normality in most research and clinically-based applications today. Due to the higher cost of whole genome sequencing, whole exome sequencing has been a good alternative to still generate the detailed data that sequencing can provide, but at a lower expense. A sufficient capture must be comprehensive, while keeping the overall capture size low enough to keep sequencing costs low. In addition, the capture must produce high on target results, with low duplication rates, and coverage uniformity throughout the targeted region.

**Materials/Methods:** In our study, we tested a total of twenty unique samples against six different captures from three vendors. Amongst the cohort, there were HapMap, positive controls, and FFPE samples. The samples were processed using vendor-specific library preparation kits and were prepared manually or by automation. All samples were sequenced on the Illumina HiSeq 2500 or the NovaSeq. To reduce bias amongst sequencing data, all alignment files were down-sampled between the range of 50-65X mean sample coverage. To compare the captures, we focused on the percent of target bases at 20X across three different interval sets. These sets included the intersected region between all captures in the study, HGMD variants, and an in-house curated gene list. We analyzed further by comparing the per sample statistics including percent on target, duplication rates, and capture uniformity. Tools used to generate the data include Illumina DRAGEN Bio-IT Platform, GATK, and BEDTools.

**Results:** Of the six captures, the Twist Human Core Exome probes performed the most efficient in all aspects of the study. Specifically, we calculated this capture to produce the lowest number of regions below 100% at 20X for all three interval sets (less than 6% for all data sets). In addition, the Twist Human Core Exome kit displayed the highest percent on target values at >70%, lowest duplication rates below 10%, and greatest uniformity across the target region.

**Conclusion:** The Twist Human Core Exome probes offer a versatile capture that can be used for multiple applications. The sequencing data shows promising results at all levels of the gene, especially for on-target, duplication rates, and capture uniformity.

## **PgmNr 1855: BCH Connect: Supporting patient diagnoses with a streamlined CLIA-compliant research sequencing pipeline.**

Though researchers and clinicians both generate and analyze whole exome and whole genome sequencing data for the purposes of understanding patient disease, there exists an iron curtain between research and clinical pools of genomic data. Research sequencing is generally not done to clinical standards and raw sequencing data remains siloed to the research environment where it might be shared with other researchers, but not clinicians. Findings from research sequencing must be confirmed and cannot contribute directly to clinical reports, and patients rarely, if ever, are returned results or raw research sequencing data.

Clinical sequencing data is paradoxically both more and less accessible. As clinical findings are collected in compliance with Clinical Laboratory Improvement Amendments (CLIA), they are regularly used in the process of generating clinical reports that are returned to the electronic health record and can inform precision medicine. Though the clinical reports are readily available, raw clinical sequencing data is only available for re-analysis (outside of the sequencing company) when approved by the patient. Thus, re-analysis of clinical sequencing data by clinicians or researchers occurs rarely.

Here we describe mechanisms, processes, and technologies implemented at our institution, Boston Children's Hospital (BCH), to enable researchers and clinicians to accelerate rates of discovery and patient diagnoses. Through strategic investment in clinical-grade research sequencing of disease specific cohorts, we have harmonized the sample collection, ordering, and data return processes for research groups across our institution with a prudent, CLIA-compliant workflow. We have integrated research sequencing with clinical follow up; aligned, refined, and operationalized our earlier patient consenting approaches; and streamlined processes for migrating clinically collected genomic data into repositories where BCH clinical and research staff can re-analyze patient data.

By merging research data, electronic health records, and genomic data into repositories with cutting edge technologies, we are empowering researchers and clinicians to access highly curated candidate variants and collaborate with one another more rapidly to discover genes and diagnose patients.

---

Whole-exome and whole-genome sequencing technologies have revolutionized human genomics research and clinical diagnosis, leading to identification of hundreds of new disease causing genes and pathogenic variants. At the same time, these assays are revealing thousands of variants of uncertain significance (VUS) in known disease genes that require functional assessment. Moreover, variants in genes of unknown significance (GUS) are uninterpretable due to lack of gene function information in human.

To facilitate functional annotation of human genes and variants, we are generating a large collection of UAS constructs and transgenic *Drosophila melanogaster* (fruit fly) strains based on sequence validated full length human cDNAs using the  $\phi$ C31 transgenesis system. So far, we have generated >3,000 constructs and established >1,000 transgenic lines that are available from the *Drosophila* Genomics Resource Center (DGRC) and Bloomington (BDSC)/Kyoto (DGGR) Stock Centers, respectively. These reagents can be used to study the function of a genetic variant linked to a human disease by "humanizing" the fly ortholog through the *T2A-GAL4* gene trap system, or through tissue specific over-expression of reference and variant human cDNAs. By further probing the *in vivo* function of these genes in flies and translating these findings to mammalian systems, *Drosophila* studies can facilitate the understanding of biological mechanisms underlying genetic disorders in human to develop effective therapies.

---

## Background

Whole blood is currently the most common DNA source for whole-genome sequencing (WGS), but for studies requiring non-invasive collection, self-collection, greater sample stability, or additional tissue references, saliva or buccal samples may be preferred. However, the relative quality of sequencing data and accuracy of genetic variant detection from blood-, saliva-, or buccal-derived DNA need to be thoroughly investigated.

## Methods

Matched blood, saliva, and buccal samples from four unrelated individuals were used to compare sequencing metrics and variant-detection accuracy among these DNA sources.

## Results

We observed significant differences among DNA sources for sequencing quality metrics such as percentage of reads aligned and mean read depth (P-value < 0.05). Differences were negligible in the accuracy of detecting short insertions and deletions; however, the false positive rate for single nucleotide variation detection was slightly higher in some saliva and buccal samples. Sensitivity for copy number variation (CNV) detection was up to 25% higher from blood samples, depending on CNV size and type, and appeared to be worse in saliva or buccal samples with high bacterial concentration. We also show that methylation-based enrichment for eukaryotic DNA in saliva and buccal samples increased alignment rates, but also reduced read-depth uniformity, hampering CNV detection.

## Conclusion

For WGS, we recommend using DNA extracted from blood rather than saliva or buccal swabs; if saliva or buccal samples are used, we recommend against using methylation-based eukaryotic DNA enrichment. The data used in this study are fully available for further open-science investigation.

## PgmNr 1858: Turbolase: A rapid, high-throughput sample prep to sequencing workflow for targeted and whole-genome sequencing.

Streamlined NGS library preparation saves time and reduces errors allowing for cost-efficient, high-throughput sample processing. We have developed a workflow that combines a rapid library prep, a novel library normalization methodology, and optimized hybridization capture panels for an efficient targeted sequencing library prep solution. Swift 2S Turbo kits comprise two enzymatic steps and a single purification to complete DNA fragmentation, end repair, and adapter ligation. This is followed by standard library amplification using Normalase PCR primers followed by a single purification and two 15-minute Normalase incubation steps that enzymatically select the desired amount of each library and normalize each library to an equimolar concentration within a single pool. Normalase is an enzymatic library normalization method that eliminates manual concentration adjustment of each sample prior to library pooling. When combined with Swift 2S Turbo library kits, a highly streamlined 'Turbolase' workflow is created that is readily automated, where simple bulk processing improves throughput and reduces cost. The pools can then be target-enriched using Swift Hybridization Capture panels or directly sequenced without further purification. Swift offers a 39Mb Exome Panel, a 0.8Mb Pan-Cancer panel covering 127 oncology-related genes, and a 11.1Mb Inherited Disease panel covering genes and SNPs associated with inherited diseases for targeted sequencing. Use of Normalase in this workflow allows for greater than 10-fold variation in input quantity while generating less than 10% variation in sample representation within a pool resulting in optimal sample balance for multiplexed target enrichment or whole-genome sequencing. Together this workflow simplifies NGS library prep minimizing clean-ups and pipetting steps for a rapid, cost-efficient workflow from library generation to sequencing.

# PgmNr 1859: NGS target enrichment: Automation of IDT xGen hybridization capture of DNA libraries on Beckman Coulter i7 Hybrid Genomics Workstation with KAPA libraries and exome panel.

## Introduction:

Next Generation Sequencing (NGS) has enabled collection of exome-wide information faster than any previous technology. Hybridization capture is an enrichment method that can provide disease specific information tuned to the user needs. From small target spaces used to detect rare variants to exome-wide data, the IDT hybridization system can confidently provide the flexibility needed by researchers. This workflow is compatible with NGS libraries prepared using ligation-based techniques, such as TruSeq<sup>®</sup> library kits, KAPA library kits and tagmentation-based library kits such as Nextera<sup>®</sup>. Automated library preparation allows for higher throughput and less hands-on time for complex NGS assays.

## Method:

The xGen Hybridization Capture automated protocol on Biomek i7 NGS workstation has a throughput of 96 samples and can perform concentration via bead based or dry down method. The deck configuration provides components for plate processing, incubation and thermocycling that enable efficiency and minimal hands-on time. The automated method is written in modular design with safe stop points that enable labs to customize how they work. The method provides flexibility to run any number of samples, ease of setup including reagent calculation and decreased costly setup errors using DeckOptix Final Check software.

## Experiment and Result:

Libraries were prepared with 1ug Coriell NA12878 input into KAPA Hyperprep. Eight libraries were captured using IDT's xGen Hybridization and Wash Kit and xGen Exome Research Panel. 500ng of each library was dried down per *xGen Hybridization Capture of DNA Libraries for NGS Target Enrichment* with an overnight hybridization. Captured libraries were quantified with Qubit<sup>™</sup> ds HS DNA Kit, analyzed on TapeStation HS D1000 tape, and sequenced by IDT on a NextSeq 500 (Illumina). 2x150bp, paired end reads were generated. The flanked-on target percentage was 94 % with a mean insert size of 295 bp. The duplicate percentage was <3% and GC skew 60/40 was 1.2.

## Conclusion:

Automation of xGen Hyb Capture of DNA libraries on the Biomek i7 Hybrid Genomics Workstation is a fast and efficient process that delivers quality results, providing a flexible and scalable solution for any size lab.

## **PgmNr 1860: *Whole exome sequencing is “still” a valuable platform for variant detection in research: A 2019 overview of capture methods and improvements.***

**Introduction:** A decade has passed since Next Generation Sequencing (NGS) technologies emerged and became powerful to the research field and later to the clinics. New approaches permitted whole-exome sequencing (WES) or targeted panels to be sequenced faster leading to a higher sensitivity and significant decrease in costs making the technology feasible for a diverse areas in research. The WES has evolved through the years, and the captures have improved exponentially in terms of content (better gene annotations) and chemistry. The ideal capture nowadays must be cost-effective, but also versatile in terms of DNA input, offer better on target and representations of relevant genes with great uniformity.

**Materials/Methods:** We tested a total of twenty unique samples against 6 different captures from three vendors. Amongst the cohort, there were HapMap, positive controls, and FFPE samples. The samples were processed using vendor-specific library preparation kits and were prepared using Perkin Elmer Sciclone automation. All samples were sequenced on the Illumina HiSeq 2500 or the NovaSeq. We aimed for specific metrics for quality control (QC) purposes: capture yield after PCR, traces distribution and molarity. Bioinformatics analysis was performed using DRAGEN (Illumina) and GATK. These sets included the intersected region between all captures in the study, HGMD variants, and an in-house generated curated gene list.

**Results:** We found that of the 6 captures, the Twist Human Core Exome probes performed the most efficient in all aspects of the study when compared to other vendors. Precisely, we calculated this capture to produce the lowest number of regions below 100% at 20X for all three interval sets (less than 6% for all data sets). In addition, the Twist Human Core Exome exhibited the highest percent on target values at >70%, lowest duplication rates below 10%, and greatest uniformity across the target region. Additionally, the time for the capture was significantly reduced and the entire protocol was completed within 2 days.

**Conclusion:** The sequencing data demonstrated significant improvements in uniformity, on-target, duplication rates, and flexibility with DNA yield in comparison with other platforms. The Center for Applied Genomics (CAG) has expanded the sample evaluation for other research areas and we continue to work on the most cost-effective and highest quality capture methods for the WES data generation offered by the center.

## PgmNr 1861: Sample identity quality control in Next Generation Sequencing (NGS) routine diagnostics using KASP.

NGS applications comprise complex protocols with parallel processing of multiple samples. Thus, consideration of possible sample swaps is part of the laboratory best practices as they can occur at every step of the process. We present a quality control approach based on the genotyping of single nucleotide polymorphisms (SNPs) with Kompetitive Allele Specific PCR (KASP) technology and the comparison to NGS data for the verification of sample identities. Based on genotypic frequencies and KASP assay performance, 16 SNPs covered in our NGS capture kit (Agilent SureSelectXT) were selected. To reliably detect sample swaps two criteria have to be fulfilled: first, haplotype overlaps between samples need to be excluded, i.e. no sample has been pooled twice (uniqueness); second, the identity of each sample needs to be confirmed based on the comparison of KASP and NGS data per sample (identity). Due to possible dropouts or erroneous KASP results, some comparisons might not always be possible. Therefore, cutoffs were defined based on a risk-benefit assessment to minimize the probability of missed sample swaps and simultaneously the frequency of unnecessarily rejected samples. The minimal number of successful comparisons and maximum number of mismatches for a reliable confirmation of uniqueness and identity was determined by statistic calculations, taking into account the average dropout and error rate of KASP signals. To address the question of uniqueness, the probability of encountering two samples with the same haplotype over a certain number of SNPs in a certain number of samples was calculated; the cutoffs for identity confirmation are based on the probability of a sample showing one specific haplotype over a certain number of SNPs. Results showed that at least two differing SNPs in all pairwise comparisons of the samples exclude overlaps with >99% certainty. Further, with a cutoff of maximally four dropouts of SNPs or three dropouts and one mismatch in the identity confirmation step the correct sample assignment can be verified with a probability of >99%. The identity confirmation is integrated in our NGS analysis pipeline. Samples failing the criteria are automatically identified and held back from further processing (variant calling, annotation and assessment) until the case is resolved. Performance of SNPs in KASP is continuously tracked for quality management and the list of SNPs can easily be adapted, making the method flexible and highly scalable.

## PgmNr 1862: Photodamage of single dye-stained DNA during in vitro fluorescent imaging.

**Authors:**

J. Chen

[View Session](#) [Add to Schedule](#)**Affiliation:** Department of Chemistry & Biochemistry, Ohio Univ, Athens, Ohio.

---

Under illumination, dye-stained DNA generate reactive oxygen species (ROS) that cause photodamage of DNA molecules. ROS are a class of oxygen-containing molecules that, as the name suggests, are highly reactive and have been the focus of many studies. Common ROS are superoxide, singlet oxygen, hydroxyl radicals, and hydrogen peroxide. ROS are believed as a cause of ailments and cancer. The photocleavage of DNA by ROS is a problem for DNA imaging when DNA is cut into smaller pieces. It is particularly problematic for single-molecule DNA imaging such as in a genome optical mapping measurement. Thus, monitoring the generation of ROS and measure its ability of photocleavage is an important step towards finding a solution to this problem. In this report, measure the photodamage of dye-stained DNA molecules, and we use a commercial group of ROS sensing dye CellRox to in situ monitor the ROS generation near single DNA molecules that have been stained with the YOYO and POPO dyes. We observed the correlation between the photobleaching of the DNA staining dyes and the generation of the ROS. This opens an opportunity to directly test ROS suppression reagent at the single-molecule level.

## **PgmNr 1863: A versatile microfluidic platform for NGS library preparation enables multi-omics studies for a broad range of research samples and laboratory settings.**

---

Advances in sequencing technologies have made NGS available to a broad range of researchers, yet the number of labs with dedicated assay development and automation teams remains limited. Here we describe a novel microfluidic platform, the Miró Canvas™ system, for the deployment, optimization and standardization of new and existing NGS workflows such as library construction for whole genome, exome/targeted panels and RNA sequencing.

Library construction was performed on a simple, disposable cartridge, utilizing proprietary Miró technology to automatically drive samples and reagents through the workflow. Miró technology utilizes electromechanical forces for manipulating (i.e., move, merge, mix and dispense microliter volumes) fluids across a surface of patterned electrodes in an automated fashion. To demonstrate the platform's versatility across different workflows and reagent types, Miró technology was used to automate: 1) the KAPA Hyper Prep kit for PCR-Free Human Whole Genome Sequencing (WGS), 2) the Twist library preparation and Fast Hybridization target enrichment kit of Human Core Exome for Exome Sequencing (WES) and 3) the NEBNext Ultra II Directional RNA Library Prep Kit for RNA-Seq. All sample manipulation steps including reagent mixing, incubations, thermocycling and magnetic bead-based clean ups were done on-chip with the output being a sequence-ready library.

We constructed DNA libraries with varied inputs (75-200ng sheared gDNA for WGS, 50-200ng unsharded gDNA for WES) using reference gDNA (NA12878) and DNA from varied, limited and degraded samples. For RNA-Seq, we used 5-50ng of Poly(A) enriched mRNA from different human tissues as input. Libraries made using Miró technology are equivalent or better in terms of turnaround time, reproducibility, yield, and data quality than current manual or plate-based automated methods. Miró technology improves the stoichiometry of reactions by introducing active mixing steps during incubations and shrinking reaction volumes, leading to higher adapter ligation conversion rates. This enables lower input, lower cost and improved sequencing quality across different sample types.

We believe the Miró Canvas can empower labs lacking sophisticated infrastructure to seamlessly tackle genomics and transcriptomics focused research projects. It combines the advantages of automated, hands-off library construction (alleviating user error and increasing reproducibility) while reducing sequencing costs and improving results.

## PgmNr 1864: Automation of the Twist exome library preparation and capture on the PerkinElmer Sciclone liquid handler for high-throughput, scalable NGS application.

**Introduction:** Advances in next-generation sequencing technologies involving sequencer instruments have allowed for faster processing of libraries via reduced on-instrument sequencing time. Updated bioinformatics pipelines have also decreased the analysis time of whole exome libraries from hours to minutes. However A potential limiting factor in any approach is the processing time required to generate libraries from the source and capture the desired regions of the DNA for sequencing. Liquid handler-based automation allows for the simultaneous processing of large sets of samples (up to 96) while limiting manual pipetting mistakes or sample to sample variation that can result. To optimize and expedite processing, liquid handler automation paired with Twist library preparation allow for the simultaneous processing of large sets of samples (up to 96) while limiting manual pipetting mistakes and sample to sample variation.

**Methods:** The Twist core exome kit was used for library preparation of 24 HapMap DNA samples with an input of 50ng. Samples were fragmented enzymatically on the PerkinElmer Sciclone instrument and proceeded immediately into library preparation. Libraries were examined for sizing and yield then normalized-pooled into 4 "capture pools." The hybridization preparation for capture was performed using two methods: on the instrument deck and utilizing a vacuum centrifuge. Capture pools were hybridized overnight in a thermal cycler and then returned to the Sciclone for the automated capture washes. Libraries were assessed for QC, then proceeded to Illumina-based sequencing.

**Results:** Our results indicated that the automated version of the library prep produced similar library sizes, yields, and general sequencing QC metrics when compared with the manual version of the preparation and at a multifold higher throughput. There was a minor drop in the percent on target statistic upon a comparison between the two approaches, which required optimization for improved performance. Results between the on deck hybridization preparation and the vacuum centrifuge based approach were comparable and did not indicate that either method was preferred.

**Conclusion:** The automation capacity of the Sciclone and rapid, high-scalability aspects of the Twist core exome kit allow for minimal processing times of NGS exomes. This leads to decreased turn-around times, and higher overall throughput of samples while maintaining high quality libraries and subsequent NGS data.

## PgmNr 1865: The Library Kit comparison in whole genome sequencing.

**Authors:**

K. Park; S. Lee; D. Seo

[View Session](#) [Add to Schedule](#)

**Affiliation:** Psomagen, Inc., Rockville, Maryland.

---

Various types of library kits are available for conducting whole genome sequencing (WGS) experiments. Each library kit has its own advantages and disadvantages. In this study, we performed a comparison of 10 different types of library kits that are currently available in the market. By using Illumina NovaSeq platform, these libraries were sequenced and analyzed with Illumina's Issac pipeline. For a fair comparison, all samples were randomly downsampled to have the raw throughput size of 100 GB. We compared the percentage of mappable reads, the percentage of de-duplicate reads, mappable mean depth, and the ratio of mappable to throughput mean depth. Among the 10 libraries, one library outperformed the others in most statistics measured in this comparison, two library kits had a relatively lower percentage of duplicated reads, and three library kits showed the relatively better result in uniformity. These results would be a helpful guideline for selecting library kit type and preparation for the best outcome of the WGS experiment.

## PgmNr 1866: Detection and phasing of small variants in Genome in a Bottle samples with highly accurate long reads.

### Authors:

W.J. Rowell; S. Chakraborty; P. Baybayan; R.J. Hall

[View Session](#) [Add to Schedule](#)

**Affiliation:** Pacific Biosciences, Menlo Park, CA.

**Introduction:** Long-read PacBio SMRT Sequencing has been applied successfully to assemble genomes and detect structural variants. However, due to high raw read error rates of 10-15%, it has remained difficult to call small variants from long reads. Recent improvements in library preparation, sequencing chemistry, and instrument yield have increased length, accuracy, and throughput of PacBio Circular Consensus (CCS) reads, resulting in 10-20 kb “HiFi” reads with mean read quality above 99%.

**Materials and Methods:** We sequenced 11 kb size-selected libraries from the Genome in a Bottle (GIAB) human reference samples HG001, HG002, and HG005 to approximately 30-fold coverage on the Sequel II System with six SMRT Cells 8M each. The CCS algorithm was used to generate highly accurate (average 99.8%) reads of mean length 10-11 kb, which were then mapped to the hs37d5 reference with pbmm2. We detected small variants using Google DeepVariant and compared these variant calls to GIAB benchmarks. Small variants were then phased with WhatsHap.

**Results:** With these long, highly accurate CCS reads, DeepVariant achieves high SNP and Indel accuracy against the GIAB benchmark truth set for all three reference samples. Using WhatsHap, small variants were phased into haplotype blocks with N50 from 82 to 146 kb. The improved mappability of long reads allows detection of variants in many medically relevant genes such as *CYP2D6* and *PMS2* that have proven 'difficult-to-map' with short reads. We show that small variant precision and recall remain high down to 15-fold coverage.

Sample	Coverage Depth	SNP Recall	SNP Precision	INDEL Precision	INDEL Recall	WhatsHap Phase Block N50
HG001	29-fold	99.89%	99.87%	98.09%	98.08%	100 kb
HG002	32-fold	99.94%	99.97%	98.86%	99.10%	146 kb
HG005	31-fold	99.92%	99.92%	99.12%	99.04%	82 kb

**Conclusions:** These highly accurate long reads combine the mappability of noisy long reads with the accuracy and small variant detection utility of short reads, which will allow the detection and phasing of variants in regions that have proven recalcitrant to short read sequencing and variant detection.

## **PgmNr 1867: Extraction of High Molecular Weight (HMW) genomic DNA for long-read NGS applications.**

**Authors:**

A. Zegers; D. Horejsh; D. Smith

[View Session](#) [Add to Schedule](#)

**Affiliation:** Promega, Fitchburg, WI.

---

Third-generation sequencing platforms, such as those from Oxford Nanopore Technologies and Pacific Biosciences, have in recent years offered researchers dramatic improvements in sequencing read length. Long, high-quality reads have become a meaningful tool in resolving structural variants, de novo genome sequencing or genome finishing. These advances are leading to a better understanding of human diseases and conditions, as well as aiding in microbiome and agricultural research.

While the sequencing technologies have advanced, researchers are often limited by the difficulties in obtaining high-quality DNA of sufficient size to realize the full potential of these platforms. This study describes an optimized approach to isolating intact HMW gDNA that eliminates the need for laborious gel plug-based methods and enables isolating larger fragments than existing commercial rapid prep kits. PFGE analysis shows that DNA obtained by this method is larger than from existing kits, but more importantly, significant performance improvements are seen in nanopore sequencing results (mean read length and N50), suggesting the DNA is of superior quality and thus greater utility for genomics applications.

## PgmNr 1868: Application of lean manufacturing methodologies in high throughput genomic sequencing.

---

The utility and application of genomics to understand disease, and the continuing trend to utilize genomics in healthcare, results in an ever increasing demand for greater sequence data generation. Despite the significant reductions in per-base sequencing cost over the last decade, the infrastructure, capital, and reagent costs are still relatively expensive. Top of the line sequencers can cost over 1 million dollars per instrument, and sequencing run costs can still be tens of thousands of dollars. With such high fixed cost associated with genome data generation, it is important to maximize capacity utilization and reduce the non-value add and wasteful workflow process steps. We demonstrate the application of lean manufacturing methodologies and visual management techniques to the genomic sequencing workflow, which results in achieving a sequencer utilization rate of around 90%, while three fold scaling our library preparation process to over 300,000 samples destined for exome and whole human genome sequencing annually.

By combining the sample preparation methods for both exome and whole genome sequencing into a unified, modularized workflow, samples and reagent supply chains can be optimized resulting in more efficient, and cost effective processing. Additional benefits include reductions to work in process and overall cycle times. Here, we illustrate the methodologies that enable low cost per base sequence data generation applicable across large sequencing cores, and modest sized data generation groups.

## **PgmNr 1869: NGS DreamPrep™ : A fully automated NGS library preparation solution from sample to quantified, pooled, and sequence-ready libraries.**

### **Authors:**

Illumina NovaSeq S4 flow cells have the ability to generate 10 billion single reads in a single run. To maximize this level of throughput and achieve the optimal cost savings, hundreds of samples may be pooled for each run. Manual library preparation of hundreds of samples can result in long turnaround times, increased errors, poor reproducibility and may require multiple lab personnel. The NGS DreamPrep is a walkaway solution designed and optimized for completely automated NGS library preparation and quantification. It combines Tecan's library preparation reagents, automation and fluorescence plate readers to produce sequence-ready, normalized and pooled libraries. Innovative library preparation technology minimizes workflow time and user interaction during automation. Integration of NuQuant®, a novel library quantification technology, into the library preparation allows automated library quantification, normalization and pooling on the instrument with no sample loss to QC procedures. The NGS DreamPrep system includes a Fluent® liquid handling platform optimized for NGS library preparation with integrated Infinite® F Nano+ plate reader for fast library QC. The NGS DreamPrep enables flexible library preparation for up to 96 samples in less than 4 hours for DNA and approximately 9 hours for RNA. Preparing 96 DNA samples using identical inputs generated libraries with no adaptor dimers, no dropouts and no edge effects. The mean yield (as measured by NuQuant) of all 96 libraries was 249.3 nM with a standard deviation of 24.6 nM showing high sample-to-sample reproducibility across the entire plate. Library molar concentrations were quantified by the integrated plate reader and subsequently pooled. Sequencing results showed a %CV of <15% between the number of sequence reads, demonstrating the accuracy of NuQuant library quantification. The NGS DreamPrep is an innovative solution for high-throughput NGS library preparation and quantification with walk-away automation.

## PgmNr 1870: Ultra-high-throughput PCR-free Whole Genome Sequencing (WGS) workflow.

### Authors:

---

Next generation sequencing has revolutionized family and population-based research and clinical applications. Baylor College of Medicine's Human Genome Sequencing Center (HGSC) generates whole genome sequencing (WGS) data in both research and clinical settings. To date, HGSC has sequenced over 62,000 WGS samples prepared as PCR-Free libraries to >35x coverage across several NIH large scale projects on Illumina HiSeq X Ten and NovaSeq platforms. NovaSeq supports ~3x greater throughput for WGS samples compared to HiSeq X Ten platform and has been tested and integrated in both pipelines. Therefore, the current practice of preparing libraries in batches of 96 becomes a rate limiting step for the NovaSeq WGS workflow. To address this need for delivery of high quality NGS libraries, HGSC is developing a robust sample preparation (libraries) in a 384-well format. Processing of libraries in batches of 384 also provides significant cost savings due to reaction miniaturization and 4x labor savings. However, there is no readily available commercial product or workflow that supports PCR-Free, library prep, in a 384-well format. Five liquid handlers (Labcyte Echo, Formulatrix Mantis/Tempest, Biomek iSeries, Tecan Fluent, Hamilton Star) were evaluated for pipetting accuracy and consistency. These platforms were also assessed for their ability to mix reagents, solvents, and beads as required at various steps during library preparation. Based on this evaluation, the Hamilton platform, configured with a 384 multi-channel was selected. A specially designed magnet and thermocycler customizations were also necessary. Illumina test PCR-Free libraries prepared on 384-well plates were successfully sequenced to generate 110Gb (37x coverage) of unique data with 97% covered to 20X depth sufficient for clinical interpretation. These metrics are comparable to WGS libraries currently being prepared on Beckman FXP robot in a 96-well format. Comparison of high quality variants showed a high concordance rate of 98.9% with NIST reference calls. A single 384 liquid handler can generate 9,168 libraries per month (~110k/yr), enough to support ~11 NovaSeq 6000 instruments. By increasing the library throughput, ensuring delivery of high quality sequencing data can be ensured for both research and clinical applications.

## PgmNr 1871: Utilizing phenotypic similarity analyses to distinguish and identify multiple molecular diagnoses.

---

With the availability of next-generation sequencing technologies, the field of human genetics has seen an unprecedented rise in molecular diagnoses and discovery of novel genes linked to rare diseases. Genome-wide data has given us the opportunity to uncover dual or multiple molecular diagnoses - pathogenic variants at two or more loci resulting in blended phenotypes. Re-analyses of exome sequencing (ES) data from a clinical diagnostic laboratory revealed that approximately 5% (101/2076) of cases that received a molecular diagnosis by ES had more than one molecular diagnosis. Development of phenotypic similarity scores (PSS) to assess the degree of similarity between two disease traits and their corresponding sets of human phenotype ontology (HPO) terms can be used to classify blended phenotypes as either 'distinct' or 'overlapping'.

In order to test the potential utility of PSS to identify subjects for whom an additional molecular diagnosis could more parsimoniously explain the patients' clinical features, we systematically evaluated genotype-phenotype associations for 92 patients previously reported to have dual molecular diagnoses by clinical ES. We first recapitulated our previously published analyses of identifying distinct and overlapping disease pairs using an updated set of PSS with HPO terms mapped to the current OMIM MorbidMap. We then used PSS to compare the observed set of clinical features for each patient (Pt) to the set of expected features for each identified molecular diagnosis (Pt-DzA, Pt-DzB) as well as the set of expected features for the dual molecular diagnoses (Pt-DzA+B). Using a 'goodness of fit' model to compare this new set of PSS, we observed that multiple molecular diagnoses that were classified as either distinct or overlapping were able to better explain the patients' clinical features compared to a single diagnosis (distinct,  $p < 2e-16$ ; overlapping,  $p = 2.3e-15$ ). The findings remained consistent even when the more explanatory molecular diagnosis was detected first (distinct,  $p = 2.9e-11$ ; overlapping,  $p = 1.3e-14$ ). We observed similar results using PSS in an independent cohort of 16 patients with multiple molecular diagnoses. In conclusion, PSS remain a robust method for classification of distinct vs. overlapping blended phenotypes. We further demonstrate that PSS can potentially be used as a framework to assess the potential for more than one molecular diagnosis, paving the way to advance our goal towards precision health.

## **PgmNr 1872: High-throughput, automated, magnetic bead-based bisulfite conversion of human DNA for methylation analysis.**

### **Authors:**

---

The ability to detect and quantify DNA methylation efficiently and accurately has become essential for the study of cancer, gene expression, genetic diseases, and many other important aspects of biology. To date, a number of methods have been developed to detect/quantify DNA methylation including high-performance capillary electrophoresis and methylation-sensitive arbitrarily primed PCR. However, the most common techniques used today still rely on bisulfite conversion.

Treating DNA with bisulfite chemically modifies non-methylated cytosine into uracil, methylated cytosine remains unchanged. Once converted, the methylation profile of the DNA can be determined using the desired downstream application. For single locus analysis, the region of interest is generally amplified following bisulfite conversion (i.e., bisulfite PCR) and then sequenced. However, recent advances in methylation detection allow the investigation of genome-wide methylation patterns, technologies include array-based methods, Pyrosequencing®, reduced representation bisulfite sequencing (RRBS), and whole genome bisulfite sequencing.

To this point all bisulfite conversion products have been dependent on manual manipulation of spin plates and columns or been of limited throughput. Here, we present an adaption of the clean-up of bisulfite converted DNA to a magnetic bead-based procedure on an automated extraction platform. We find that magnetic bead processed samples better and more consistently than established spin-column based procedures. This is demonstrated by consistent recovery, amplification and profile of the converted DNA from human samples. This novel workflow opens the door to reliable, high-throughput bisulfite conversion of human DNA samples for methylation analysis.

# PgmNr 1873: Evaluation of single-molecule long-read whole-genome shotgun sequencing on two reference microbiomes.

## Authors:

Y. Hu <sup>1</sup>; L. Fang <sup>1</sup>; C. Nicholson <sup>1,2</sup>; K. Wang <sup>1,3</sup>

## Affiliations:

1) Raymond G. Perelman Center for Cellular and Molecular Therapeutics, The Children's Hospital of Philadelphia, Philadelphia, PA.; 2) Department of Biology, University of Pennsylvania, Philadelphia, PA; 3) Department of Pathology and Laboratory Medicine, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA

Currently, 16S ribosomal RNA (rRNA) gene amplicons and shotgun meta-genome sequencing on Illumina platforms are two dominant approaches for analyzing microbiomes. Using the Oxford Nanopore platform, here we evaluated the feasibility to characterize complete microbial genomes and populations using single-molecule long-read whole-genome shotgun sequencing without any DNA amplification.

We first generated ~500X coverage Nanopore sequencing data on HM-276D Mock Community sample from the Human Microbiome Project. HM-276D is an evenly mixed DNA sample of 20 bacterial strains (each with 5% abundance). We assembled the 20 bacterial genomes into 60 contigs using canu, with contig N50 length of 2.98 Mb. Other computational tools such as wtdbg2 and OPERA-MS generated similar results. All 3 tools consistently achieved high accuracy (~99%) and completeness (~98.5%). In comparison, genome assembly on 160X coverage Illumina sequencing data generated N50 of 0.17 Mb with 4,575 contigs, suggesting that long-read sequencing can generate much less fragmented genome assemblies on microbiomes than short-read sequencing. Next, we generated ~1,000X coverage data of the HM-277D Mock Community sample, which is an unevenly mixed DNA sample of the 20 bacteria strains. For bacteria with higher relative abundances (>4%), at least 99.93% reference genome sequences were covered by assembled contigs. The fractions of exonic coverage of 16S rRNA genes were ~100% for 18 bacterial strains. Estimation of strain abundance from sequence data has a correlation of 0.895 (log scale) with known abundance in the reference sample. Furthermore, taxonomic binning accuracy was evaluated based on both HM-276D and HM-277D mock community, showing that ~99.99% bases can be correctly assigned to known bacterial species with a false positive rate close to zero.

Overall, our results demonstrated the technical feasibility to characterize complete microbial genomes and populations from error-prone Nanopore sequencing data in the absence of DNA amplification. We propose that future metagenomics studies will benefit from this approach to assemble complete microbial genomes, while maintaining the theoretical ability to detect DNA methylations and base modifications, infer repetitive elements and structural variants, and achieve strain-level resolution within microbial communities.

## PgmNr 1874: Integration of molecular chemistries supporting a full-length, mRNA sequencing library preparation method on a microfluidic circuit.

---

RNA sequencing (RNA-seq) is the gold standard for hypothesis-free profiling of the transcriptome and an essential biological tool. Because of its functional utility and widespread use, there is a need to simplify the complex steps of RNA-seq library preparation for next-generation sequencing (NGS) applications and to substantially reduce the costs associated with it. We are developing a library preparation solution that combines reagents, a microfluidics device (approximately the same size and shape as a standard 96-well plate), and an instrument to generate full-length, RNA-seq libraries. This microfluidic device is a new integrated fluidic circuit (IFC) that will enable automation of solid-phase sample enrichment, as well as multistep chemistries, after a single pushbutton script to activate the pneumatics and thermal controls on the instrument. The workflow will simplify the tedium and hands-on steps of library preparation while reducing costs because of the nanoliter volumes required on the IFC.

Our RNA-seq library preparation method supports simultaneous processing of up to 48 total RNA samples from many organisms, and it is compatible with Illumina® sequencing instruments. The method generates full-length, stranded libraries from random-priming of the polyadenylated RNA (polyA RNA) present in the total RNA. RNA samples, polyA selection beads, and common reagents are loaded in the carrier inlets on the IFC. The IFC is placed in the instrument and processing scripts are initiated. These scripts control the nine different reaction steps that occur sequentially, without user intervention, from polyA bead column formation through index PCR. Following sample index PCR, the libraries are delivered to individual sample-specific carrier outlets on the IFC for harvesting.

To demonstrate performance, we processed 48 total RNA samples from a wide variety of tissues, cell lines, and RNA from different organisms. We generated high-quality libraries from as low as 10 ng of total RNA. Our mRNA-seq libraries had less than 10% rRNA reads, replicate correlations greater than 99%, and high gene-level and transcript-level detection rates.

In conclusion, mRNA-seq library preparation can be simplified using automated microfluidics technology enabling solid-phase enrichment and multistep chemistries. This solution will help reduce costs while maintaining high-quality RNA-seq libraries.

## PgmNr 1875: Clonal analysis, genetic screening, and expression profiling at a single-cell level.

Novel methods for profiling clonal composition and phenotypes of primary and metastatic lesions at the single-cell level are required for understanding tumorigenesis mechanisms and development of anti-cancer drugs with unique mechanisms of action. In order to facilitate these studies, we developed a panel of lentiviral barcoded libraries to label and monitor the cancer cells in time course experiments *in vitro* and in mouse xenograft models. The barcodes are transcribed from lentiviral constructs and could be detected by NGS in a single-cell RNA expression profiling assay to identify the subpopulation of descendant cells derived from a single barcoded progenitor cell. Furthermore, cell barcodes were incorporated in conjunction with genetic effector libraries, such as sgRNA libraries, to identify clonal phenotypic changes induced by specific genetic disruptions in progeny cells derived from the single progenitor cell. However, while cell barcodes provide an effective way to group cells based on clonal origin in heterogeneous cell populations, expression profiling at a single-cell level remains challenging. Data will be presented showing how genetic screening and targeted RNA expression profiling of human cells combined with cell barcoding could significantly improve phenotyping of distinct cell populations.

## PgmNr 1876: Cap-dependent linker ligation increases specificity for full-length products compared to template switch reaction.

---

Nanopore enables full-length sequencing of RNA or cDNA. A fast and easy way to obtain full-length cDNA is the commonly used template switch reaction. The reverse transcriptase (RT) adds non-templated nucleotides (preferentially C's) at the end of a transcript which hybridize to abundant template switch oligos. However, non-templated nucleotides can also be added to fragmented RNAs or premature termination sites of the RT. Artificial Spike-in transcripts are an essential part to monitoring the quality of an RNA-Seq experiment, to control NGS sample preparation, base callers and algorithms by adding a ground truth to the NGS experiment. We used Lexogen SIRV™ set 3 containing 69 Spike-In RNA Variant controls, simulating alternative splicing of 7 SIRV genes plus antisense transcription, plus 92 ERCC Spike in controls (External RNA Controls Consortium Spike-In controls, Thermo Fisher Scientific Inc.). ERCCs are monoexonic but cover a concentration range of 6 orders of magnitude. TeloPrime is a full-length cDNA preparation kit offered by Lexogen. Exceptional 5'-Cap specificity is achieved with the proprietary CAP dependent linker ligation. We capped SIRV set 3 using the Vaccinia Capping Enzyme and protocol from NEB (M2080). Universal Human Reference RNA (UHRR) was spiked in with the capped SIRV set 3 before the sample was subject to a controlled degradation. Nanopore sequencing libraries were made either by using the template switching protocol or a modified TeloPrime protocol (v3) from intact and degraded RNA aliquots. The new TeloPrime v3 Nanopore libraries contain a 12 nt unique molecular Index (UMI) that is introduced with the RT primer, enabling to account for sequencer and PCR errors in high coverage NGS data. Degraded RNA resulted in shorter libraries for the less Cap-sensitive template switching protocol, but little delay in the PCR cycles, while for TeloPrime v3 degraded RNA libraries resulted in significantly less amplifiable library. The analyses of apparent transcript start site distributions by Nanopore sequencing showed a higher cap specificity for TeloPrime v3 than for the template switching protocol. Hence, TeloPrime v3 enables an increased accuracy for transcript 5' end detection.

## PgmNr 1877: Evaluation of RNA sequencing methods for low input samples.

RNA-seq is a sensitive and accurate tool for measuring gene expression across the transcriptome, but can be difficult to carry out for rare cell populations, small tissue samples, and other limited amounts of starting material. Here we compare three library construction methods for their performance in transcriptome analysis, including read alignment quality, strand specificity, rRNA contamination, coverage bias, and workflow. We titrated the input RNA down to as low as 100pg and tested each method using both technical and biological replicates using cells from mouse brain and granulocyte-monocyte progenitor cells. Sequencing was carried out on the Illumina NextSeq500, 75bp paired end, to a depth of 20-30 million reads per sample. Of the libraries that were sequenced, we observed similar alignment rates amongst the three methods, while other analysis metrics were variable. A key evaluation parameter for RNA-seq is strand specificity and only one protocol maintains strand information. Overall, high consistency of transcriptome counting was observed among different biological and technical replicates, while all methods yielded robust transcriptome counting and survey of the complexity of the expressed genes as well as uniformity in coverage. In summary, we found all three protocols to be robust and reproducible with low input RNA, and each protocol has applications depending on the researcher's experimental needs.

## PgmNr 1878: NuQuant: A fluorescence-based method for accurate quantification of NGS libraries in minutes.

---

Accurate quantification of NGS libraries is critical for a successful sequencing run. Currently used methods of quantification are time-consuming, costly, and can be highly variable. We have developed NuQuant, a novel method to accurately quantify NGS libraries, that can be performed with a simple fluorescent measurement. NuQuant is compatible with the common red fluorescence excitation/emission filter set (650/670 nm), making it compatible with a wide range of bench top fluorometers and fluorescent plate readers. We have developed a custom library quantification application for the Qubit fluorometer that directly provides the molar concentration of a library. Utilizing this application, we have demonstrated that NuQuant has excellent reproducibility across users from multiple sites. We now demonstrate the compatibility of NuQuant with standard fluorescence plate readers, enabling quantification of libraries in a high-throughput fashion. We have tested NuQuant on a variety of commonly used plate readers such as the Tecan Infinite 200 Pro and the Promega GloMax. Libraries in a 96-well format can be measured in a matter of minutes, without the need for sample dilution. Molar concentration of libraries was easily determined by utilizing a standard curve. We tested libraries with various input from 10ng to 500ng and insert size from 200bp to 500bp, and found good agreement between NuQuant values and a qPCR based quantification method. Most importantly, we observe good correlation between NuQuant library concentration and total number of sequenced reads. In conclusion, scientists with access to commonly used fluorescent plate readers can now use NuQuant to achieve rapid and cost-effective quantification of NGS libraries, generating highly uniform sequence reads in multiplex runs.

## PgmNr 1879: Global analysis of transcriptional start sites using Lexogen's Corall total RNA-seq library prep kit.

---

The actual transcriptional start sites (TSS) of processed as well as non-processed transcripts are of particular interest to many researchers. Cap-analysis gene expression sequencing (CAGE-Seq) is one favored method to globally assess TSS in given RNA sample. This method, however, only works for mature mRNA with an intact 5' cap and provides only limited information about the full-length transcript.

CORALL is Lexogen's new stranded total RNA library prep kit with excellent whole transcriptome coverage and unprecedented representation of 5' ends. Lexogen's proprietary methodology enables a particularly efficient coverage of 5' ends without a complete drop of sequencing reads towards the 5' ends - unlike most other whole transcriptome library prep kits. CORALL's comprehensive coverage thereby delivers improved transcript start and end site representation.

Here, we show in a proof of principle that RNA-Seq libraries prepared with CORALL excellently represent the actual 5' ends of transcripts. Read coverage was analyzed using the ERCC spike-in controls, which feature precise, known transcription start and end sites (TSS and TES, respectively). CORALL reads map more accurately to the exact ERCC TSS than competitor libraries, which fail to cover the true start sites. Additionally, CORALL provides elevated coverage at TES.

CORALL enables streamlined generation of Illumina-compatible libraries within 4.5 hours, featuring seamless integration of Unique Molecular Identifiers (UMIs) and exceptional protocol-inherent strand specificity (above 99 %). The fragmentation-free protocol uses Lexogen's proprietary Strand Displacement Stop and Ligation technologies to deliver complete transcript representation, and CORALL libraries can be prepared from as little as 1 ng of total RNA input. Flexible input types are supported including, rRNA-depleted, poly(A)-enriched, or total RNA from a wide variety of species, as well as degraded and FFPE RNA samples.

## PgmNr 1880: Stranded RNA-Seq next-generation library preparation kit for low inputs.

RNA-Seq technology allows for transcriptome profiling and the accurate measurement of transcript expression levels. This is important for the detection of differentially expressed genes across different treatments or biological conditions. Additionally, RNA-Seq has applications for identifying novel transcripts, novel splice junction sites, and gene fusions among others. However, one major challenge is the production of RNA-Seq libraries from a limited amount of starting material. Most RNA-Seq kits require >100 ng of total RNA in order to reliably generate high-quality RNA-Seq libraries. To overcome this challenge, we present the Swift RNA-Seq stranded library preparation workflow. Based on Adaptase™ technology, Swift RNA-Seq produces quality libraries from as little as 10 ng of starting total RNA. The high-efficiency Adaptase reaction successfully adds a truncated Illumina-compatible adapter following first-strand cDNA synthesis, avoiding the requirement for synthesis of the second-strand. Following Adaptase, ligation adds the second truncated adapter and indexing PCR completes the library preparation by incorporation of full-length indexed adapters. Swift RNA-Seq stranded libraries result in high mapping rates and maintain >98% strandedness, even at inputs as low as 10 ng. Additionally, Swift RNA-Seq libraries have low duplication rates, even coverage across transcripts, and high expression profile efficiencies. Compared to two leading RNA-Seq kits, the Swift RNA-Seq stranded kit identifies more transcripts and genes at low total RNA inputs (< 100 ng), with comparable metrics at high inputs. Further, Swift RNA-Seq libraries show negligible adapter dimers with no adapter titration required, does not require a PhiX spike-in for sequencing, and is compatible with gene-specific primers. Overall, the Swift RNA-Seq stranded library preparation kit provides an optimal library preparation kit for next-generation sequencing and excels particularly when total RNA inputs are limited.

## PgmNr 1881: Library preparation miniaturization: Effects of miniaturization on next generation sequencing data.

Gene expression of a single cell differs from the population from which it originates. This makes the identifying complex gene expression patterns associated with cellular functions and disease a challenge. Thus, funding requests for studies aimed at sequencing hundreds to thousands of single cells have been growing steadily. However, the inherent complexity of the chemistry required to generate cDNA from nanogram scale inputs of RNA can make the approach cost prohibitive.

This study demonstrates a fully-automated, high-throughput workflow for single-cell RNA sequencing at a miniaturized scale. This workflow from cell lysis through cDNA synthesis and library construction enables an economic method to prepare high-quality NGS libraries. The study compares critical factors like the quality of sequencing data, enzyme consumption, and costs, to characterize the degree of miniaturization possible without compromising data quality. For research use only. Not for use in diagnostic procedures.

## PgmNr 1882: Cell type specific differential expression from bulk tissue with single cell reference.

Bulk tissue sequencing is often used to probe genes that have tissue-level expression changes between biological cohorts. However, tissue are usually a mixture of multiple distinct cell types and the tissue-level changes are due to shifts of cell type proportions as well as cell type specific expression changes. Single-cell RNA sequencing (scRNA-seq) allows the investigation of the roles of individual cell types during disease initiation and development. Deconvolution methods have been developed to estimate and compare the cell type proportions between tissues with scRNA-seq data as reference. We focused on the "reverse" estimation of cell-type-specific expression and cell-type-specific differential test. Here we present a method MuSiC-DE to detect cell-type-specific differential expression with estimated cell type proportions by MuSiC, which utilizes not only cell-type specific gene expression from scRNA-seq data but also cross-cohort variation to characterize cell type compositions from bulk RNA-seq data in complex tissues, where ignoring the cross-cohort variation leads to attributing all variation to cell type proportions changes. With MuSiC-estimated cell type proportions, we propose a reverse estimation procedure that can detect cell type specific differential expression, allowing for the elucidation of the roles of genes and cell types, as well as their interactions, on disease phenotypes.

## PgmNr 1883: Long-read sequencing and phasing of mutations in *TP53* using Xdrop targeted enrichment.

Targeted enrichment of long DNA-fragments is advantageous if your focus is limited to specific regions in the genome. To obtain long-read sequencing information might be crucial for resolving structural variations or phasing of variants and/or mutations. Common approaches, such as long-range PCR and hybridization-based methods, have difficulties in enriching for very long fragments (>10kb) and may introduce chimeric molecules and other PCR-related artefacts during amplification. Here, we have evaluated the Xdrop technology, a novel low-input method for targeted enrichment of long DNA-molecules, to analyze mutations in *TP53*. The Xdrop technology utilizes short-range sequence information and only nanograms of input DNA to obtain long-range sequence information by isolation of large DNA-molecules in double-emulsion droplets. Locus-specific droplet PCR of short fragments (<100bp) is used for fluorescent tagging of the droplets, which could then be sorted by FACS. After sorting, the enriched DNA is released and emulsified into single-emulsion droplets and amplified by MDA. By only having one DNA-molecule per droplet the production of chimeras can be avoided during MDA. By using the Xdrop technology and PacBio SMRT sequencing we were able to produce continuous sequence up to 40 kb with reads over 10 kb in length. This allowed us to analyze the entire *TP53* gene in Jurkat cells and in chronic lymphocytic leukemia (CLL) patient samples. With a newly developed analysis pipeline we were able to phase the cancer mutations in the samples. Moreover, we are optimizing the protocol to obtain even longer reads and are evaluating the Xdrop technology for nanopore sequencing.

## **PgmNr 1884: Electrical detection of single base incorporations enables high accuracy sequencing on a small, scalable platform.**

DNA sequencing technologies have undergone tremendous development over the past decade. Though optical-based sequencing is responsible for the majority of data generated, it requires a large capital investment and aggregation of samples to achieve optimal cost per sample. Accurate DNA sequencing on an accessible platform that is small, scalable, modestly priced, and inexpensive to operate, will allow for a more distributed model where the power of genomics is put back into the hands of individual researchers.

GenapSys has developed a novel electronic-based platform capable of accurately detecting single base incorporations. The detection method, which utilizes CMOS chips, enables the system to be compact, accessible, and affordable. The platform is capable of generating 1.5 Gb of high-quality nucleic acid sequence in a single run, and we routinely generate sequence data that exceeds 99% raw accuracy with read lengths of up to 175 bp.

Here, we demonstrate the functionality of the novel impedance-based GenapSys sequencing technology and highlight the utility of this platform for variant detection in human samples. Performance was evaluated on several well characterized cell lines from the Genome in a Bottle (GIAB) Consortium including NA12878 and the Ashkenazim and Han Chinese Trio samples. Exome libraries were generated using the IDT xGen probe-based capture method and sequenced on the GenapSys GS111 to greater than 50-fold average coverage. We evaluated BCFtools and Google DeepVariant for variant calling. DeepVariant is an analysis pipeline that uses a deep neural network to call genetic variants from next-generation DNA sequencing data. The SNVs detected using the GenapSys platform correlated extremely well with those detected from Illumina sequencing data generated from the same samples and with the high confidence calls from the GIAB consortium.

**BACKGROUND:** Peripheral leukocyte gene expression is a potential biomarker for human health and disease. However, different methods to isolate cells and storage conditions of blood could affect leukocyte transcriptome, and how to reflect human physiological state preferably is largely unknown.

**METHODS:** We used RNA-seq to explore the differences in expression profiles between whole blood (WB) and leukocyte from Buffy Coat (BC), Red Blood Cell Lysis (RBL) and Peripheral Blood Mononuclear Cell (PBMC) and the effects of leukocyte with samples storage under different conditions.

**RESULTS:** RBL and PBMC reduced much more globin ( $1.00\% \pm 1.23\%$ ,  $0.06\% \pm 0.03\%$ ) than BC ( $17.48\% \pm 6.95\%$ ) and WB ( $24.46\% \pm 6.43\%$ ), and with higher transcripts mapping ratio and detected gene number. There were 481 genes observed lower expression in RBL and PBMC than WB and BC, which enriched in erythrocytes related pathway. While 616 genes which enriched in leukocyte related function, expressed slightly higher in RBL than WB and BC, but barely detected in PBMC. Compared to samples treated immediately, the integrity of leukocyte RNA had been little influenced by stored for 24h, while expression of much more genes significantly changed with blood stored at RT (2545) than at 4° (226) in 24h.

**CONCLUSIONS:** RBL reduced much more globin mRNA than BC, and remained more leukocyte information than PBMC, which was more suitable for researches about whole leukocyte function. Samples stored at 4° within 24h had little influence on gene expression, but these differences should also take into account in studies.

---

The retina is a heterogeneous tissue composed of multiple cell types with each playing a unique role for visual processing. For heterogeneous tissues, bulk RNA-Seq can only provide the average gene expression profile for all cells from the tissue, making the interpretation of the sequencing result challenging. Here we report a single-nuclei RNA-seq transcriptomic study on healthy human neural retinal tissue to identify transcriptome profile for individual cell types. In the pilot experiment, six retina samples from three healthy donors were profiled and RNA-seq data with high quality was obtained for 5873 single nuclei. All major cell types were observed from the dataset and signature genes for each cell type were identified by differential gene expression analysis, largely expanding the known cell type marker list. The gene expression pattern of the macular and peripheral retina was investigated at the cell type level, showing significant improvement from previous bulk RNA-seq studies. Furthermore, our dataset showed improved power in prioritizing genes associated with human retinal diseases compared to both mouse single-cell RNA-seq and human bulk RNA-seq results. In conclusion, we demonstrated that feasibility of obtaining single cell transcriptome from human frozen tissues to provide additional insights that is missed by either the human bulk RNA-seq or the animal models. Building on the success of the pilot project, we are expanding our study to generate 150,000 single-nuclei RNA-Seq from three health donor eye. Progress made in the expanded study will be reported.

## PgmNr 1887: Circulating microRNA profiling in systemic lupus erythematosus.

### Authors:

C. Francis <sup>1</sup>; H.J. Park <sup>1</sup>; S. Manzi <sup>2</sup>; F.Y. Demirci <sup>1</sup>

Systemic Lupus Erythematosus (SLE) is a chronic multisystem autoimmune disorder, which is mediated by multiple abnormalities in both innate and adaptive immune responses. MicroRNAs (miRNAs) are a class of small noncoding RNA molecules that contribute to epigenetic regulation by modulating gene expression at the post-transcriptional level. MiRNAs are known to play an important role in regulating both innate and adaptive immune responses. Circulating miRNAs have recently emerged as potential biomarker candidates for various human conditions, including autoimmune diseases. The primary objective of this study was to utilize a comprehensive plasma miRNA profiling data obtained from an SLE case-control discovery sample (n=60) to identify a candidate set of highly SLE-relevant circulating miRNAs to be further evaluated in large follow-up studies. MiRNA profiling data were obtained by running the miScript Human miRBase Profiler HC series of PCR arrays (containing 2402 miRNA qPCR assays) on pooled RNA samples (6 pools; 10 RNAs per pool) purified from blood plasmas obtained from 60 Caucasian subjects (30 SLE patients and 30 controls) to compare the circulating miRNA levels between the two groups. Of those plasma miRNAs expressed in >80% of all sample pools profiled, a total of 280 showed >2-fold expression difference between SLE cases and controls, of which 66 showed >25 fold down-regulation in SLE as compared to the control group. The plasma miRNAs that showed significant differential expression in SLE have included some previously reported SLE-associated circulating miRNAs as well as a number of newly implicated ones. *In silico* assessment of the biological functions/pathways regulated by highly SLE-relevant circulating miRNAs using DIANA-mirPath v3.0 has revealed a large number of targeted pathways/categories, including both already known (immune regulation/response, apoptotic processes, and epigenetic regulation) and some potentially new ones. In summary, our discovery study identified several highly SLE-relevant (previously reported + novel) plasma miRNAs that appear to contribute to SLE-associated circulating miRNA signature and warrant further confirmation/validation as potential biomarkers in large follow-up samples/studies. Development of clinically useful biomarkers is essential for better management of this heterogeneous and challenging systemic autoimmune condition that affects relatively young adults.

## PgmNr 1888: Gene expression signature of macrophages infected by *Mycobacterium leprae*.

Leprosy is an infectious disease caused by *Mycobacterium leprae*, a non-cultivable bacillus, making difficult the disease studies. This pathogen is intracellular and resides mainly in macrophages and Schwann cells. The global burden of leprosy was 210,671 new cases in 2017. Leprosy outcomes are importantly determined by human genetic factors. However, the leprosy genetic architecture is not clear. In order to help elucidate the important genes to disease, we decided to determine the gene expression signature for macrophages infected by *M. leprae*. First, we made the transcriptome for macrophages derived from monocytes (MDMs) from 30 healthy individuals (15 males and 15 females), using HumanHT-12 v4 BeadChip (Illumina). Principal component analysis (PCA) was applied and detected 91 differentially expressed genes in infected MDMs. In order to confirm the results, we tested the expression of these genes in 96 healthy individuals (48 males and 48 females), under the same experimental conditions, by using quantitative PCR (Delta Gene Assay, Fluidigm). Among the 91 genes, 17 had differential expression confirmed in MDMs infected: *ADAMDEC1*, *C15orf48*, *C3*, *CCL4*, *CCL4L2*, *G02S*, *PTGES*, *SLC7A11*, *SLC2A6*, *TMEM163*, *GNG2*, *HPSE*, *PRR5L*, *RNASE1*, *SELENOP*, *SERPINF1* and *MS4A6*. These genes are mainly related to cellular migration and metal homeostasis, being important to macrophages functions, but also for microorganism survival. These genes must compose the gene signature of MDMs infected by *M. leprae*, and are important to future strategies to determine new loci associated to leprosy risk.

---

**Background:**

The HLA region, located on chromosome 6, is one of the most diverse regions in the human genome with thousands of alleles present in the human population. Classical class I (HLA-A, -B, and -C) and class II (HLA-DR, -DP, and -DQ) HLA gene products function by presenting foreign antigens to T cells to trigger immune responses. The HLA complex is responsible for the regulation of the human immune system and thus may play an important role in Atopic Dermatitis (AD). AD is a common chronic episodic disorder manifested by itchy red patches. It is likely caused by interactions between an altered skin barrier and immune dysregulation.

**Methods:**

HLA typing was performed on patients of two clinical studies, VP-VLY-686-2102 and VP-VLY-686-3101. Both studies were a randomized, double-blind, placebo-controlled, multi-center study in patients with chronic pruritus associated with AD treated with tradipitant a novel neurokinin 1 (NK1) antagonist or placebo. The dataset consisted of 387 whole genome sequencing (WGS) samples. Human leukocyte antigen (HLA) gene region and its alleles were called from whole genome sequencing using data (average coverage 30X, Illumina NovaSeq).

**Results:**

DRB1\*01:02, amino acid variations at position 9 (pocket 9) was the top variant marginally associated with the prevalence of AD. The odds ratio was 3.42 (CI 95=1.11-10.47; p=0.0284). We have shown that 36 patients carry significantly more of these variants when compared to 11 in a control population. Furthermore, we detect a marginal association with IgE levels, limited by small *n* to be further discerned with the accrual of more samples. Within the 36 patients carrying one of the top three MHC II alleles (Table1), 6/36 patients (16.6%) carried a FLG Loss of Function mutation as compared to 24/181 (13.2%, p=0.5991).

## PgmNr 1890: Identifying candidate genes for hEDS: Initial results of the hEDS gene study.

### Authors:

---

Ehlers-Danlos syndrome (EDS) describes a collection of heritable disorders that have in common joint hypermobility. The presence of additional objective signs and pathogenic variants in more than a dozen genes categorizes a subset of affected individuals into 1 of 13 EDS subtypes. However, the largest group is characterized by hypermobility but without a pathogenic variant in the candidate genes and usually do not have the defining clinical features of the other types. In this group individuals can be formally diagnosed with the hypermobile subtype of EDS (hEDS) or further classified as having generalized hypermobility on the EDS spectrum (G-HSD). The hEDS GENE study is a multi-center, non-interventional study with the goal to identify genes associated with hEDS using a strategy of enrolling families with multiple members who meet the 2017 hEDS criteria. More than 94 people from 27 families have been enrolled and their exomes or genomes sequenced. These include three families with third-degree relatives (first cousins), five with second-degree relatives (aunt/niece or grandparent/grandchild), and 19 families with multiple first-degree relatives (parents/children or siblings). More than forty individuals are also enrolled resulting in a total of more than 134 participants. Initial analysis focused on using a statistical framework called Rare Variant Sharing (RVS) to identify potentially causal variants in our multiplex exome and genome families. With a sharing probability below 0.01, numerous variants have been identified including in collagen and FBN genes, which are associated with EDS. Interesting shared variants have also been identified in other members of the BMP and SERPIN gene families as well as multiple genes encoding proteins with ANKR domains. The potential functional significance of each of these is being evaluated using literature review and pathway analysis. Data from additional families and affected individuals are being interrogated to determine whether variation in these genes can be replicated.

## PgmNr 1891: Variants in the *INADL* gene are associated with worst itch (VAS) in atopic dermatitis samples.

---

The genetic background of atopic dermatitis (AD) is complex, and may vary not only with disease course and intensity, but also between different ethnicities. To investigate this variance, we examined individual outcome parameters of patients in clinical study VP-VLY-686-2102. This was a randomized, double-blind, placebo-controlled, multi-center study of 168 patients with chronic pruritus associated with AD. Study participants were treated with Tradipitant (VLY-686), a novel neurokinin-1 receptor (NK1R) antagonist or placebo. Subjects also consented to participate in pharmacogenetic analysis. Using linear regression, we directly tested the association between 14,322,979 SNPs and Worst Itch Visual Analog Scale (WI-VAS). Among the top loci identified to modify WI-VAS were variants in the *INADL* gene. *INADL* encodes InaD-like protein, which plays a role in tight junction formation. Tight junctions reside immediately below the stratum corneum and regulate the selective permeability of the paracellular pathway. Tight junction defects have been implicated in AD, as they may lead to impaired skin barrier function and immune dysregulation. The region, which contains the variant that is most significantly associated with change in WI-VAS, rs11207834 (p-value = 6.1E-5), has high regulatory potential. We observed a hindering effect of the minor allele on subjects' response in change of WI-VAS. The two cases in this study, which were heterozygous for the minor allele, were non-responders to treatment with Tradipitant. Thus, the minor allele is a potentially predictive biomarker for poor response to treatment with Tradipitant, or it may indicate that these patients require a higher dose for Tradipitant to be efficacious in reducing WI-VAS. Conversely, AD patients whose genotype contains the major allele of this SNP are expected to have a larger positive response to treatment. Pruritus has a large impact on AD patients' quality of life; thus the results of this analysis are relevant as they stratify treatment response in reduction of worst itch and may help personalize therapeutic approaches.

## PgmNr 1892: Whole genome sequencing reveals novel rare loss-of-function variants in the epidermal differentiation complex as predisposing factors to atopic dermatitis.

### Authors:

---

**Background:** The epidermal differentiation complex (EDC) includes over fifty genes encoding proteins involved in keratinocyte development. The proteins encoded are closely related in terms of function, and belong to three gene families: the cornified envelope precursor family, the S100 protein family and the S100 fused type protein (SFTP). Of these fifty genes, filaggrin (FLG) located on chromosome 1 q21, a member of the SFTP family, is the most studied in the context of skin barrier dysfunction.

**Methods:** We investigated the frequency and effect of rare loss-of-function (LOF) variants within the EDC in patients of a clinical study, VP-VLY-686-2102. Study VP-VLY-686-2102 was a randomized, double-blind, placebo-controlled, multi-center study in 168 patients with chronic pruritus associated with AD treated with tradipitant a novel neurokinin 1 (NK1) antagonist or placebo. The dataset consisted of 117 whole genome sequencing (WGS) samples. We were able to replicate the effect in the next batch containing 328 WGS samples part of clinical study VP-VLY-686-3101.

**Results:** We have shown that 45/117 AD patients carry significantly more, rare LOF mutations in the SFTP family of genes as compared to 55/316 in a control population ( $p=0.000004$ ). This group of EDC LOF rare variants (EDC-LR) consists of 20 variants observed in the 45 AD patients resulting in a calculated Odds Ratio of 2.96 and a Relative Risk of 2.38. Among the detected LOF variants, there are 26 cases of FLG LOF mutations as defined by R501X (rs61816761), 2282del4 (rs558269137), other LOFs in FLG as well as LOFs in FLG2, HRNR, LCE4A, LCE5A, TCHH, TCHHL1 and other members of the EDC. We were able to replicate the effect in another batch of 162 samples, OR 2.43,  $p=0.0001$  as compared with controls.

We examine the regional accumulation of rare LOF variants (with SKAT-O analysis), an effect that would be missed in a single marker genome-wide setting. To formalize, we performed two tests: on 1) the FLG region alone and 2) the entire EDC region (LOF set), comparing AD with controls (WGS). For the entire EDC, we obtained a p-value of  $4.7e-20$ , much lower than for FLG alone p-value of  $4.5e-6$ .

**Conclusions:** The two cohorts of whole genome sequencing of AD samples showed enrichment for rare variants in the EDC region in cases compared with controls. These significantly affect risk for AD. The identified LOF variants within the region can serve as biomarkers as well as help delineate the genetic profile in AD patients.

## PgmNr 1893: Evaluation of genetic variants in angiogenic growth factors with susceptibility to psoriasis.

**Affiliation:** Department of Human Genetics, Department of Human geneticsPUNJABI UNIVERSITY, PATIALA, INDIA, India

---

**Background:**Psoriasis is a chronic, immune-mediated inflammatory skin disease. The study was undertaken to analyse the polymorphic status of VEGF, FGF1 and FGF2 in psoriatic patients from North Indian population.

**Methodology:**Genotypes were analysed by PCR, RFLP, ARMS-PCR and tetra primer ARMS-PCR in 200 cases and controls. VEGF serum levels were measured by ELISA. Statistical analysis of the data was done by using SNPstats software, Graph-Pad prism v.5 and vassarstats.

**Results:**The dominant and recessive models showed thathomozygous genotypesof VEGF (rs1570360) play a protective role in psoriasis. However,over dominant model on the basis of gender showed no significant association.AA genotype was significantly associated with reduced risk of type1 psoriasis.On analyzing VEGF (rs2010963), homozygous CC genotype and minor C allele showed significant association with decreased risk of psoriasis. The dominant and overdominant models did not show any association whereas, recessive model showed that genotypes play a protective role. Moreover, the current study showed that no psoriasis risk is associated with VEGF (rs8333061) polymorphism. HT5 ATC haplotype was found to be associated with decreased risk of psoriasis. A significant correlation was found between VEGF serum concentrations measured before and after treatment. Serum VEGF level increased in patients, as compared to controls with significant correlation between serum VEGF levels (before and after treatment) and psoriasis severity. FGF1 Polymorphism of (rs34011) did not show any significant association with the risk of psoriasis whereas FGF1 (rs34010) homozygous AA and heterozygous CA genotypes withdominant and recessive models showed significant association with increased risk for psoriasis.The risk was enhanced in males patients with type1 and type 2 psoriasis.Overdominant model did not showed any association.Polymorphism of FGF2 (rs2922979) was found to be associated with increased risk of psoriasis.The dominant and recessive models also showed association of genotypes as risk factor for psoriasis

**Conclusion:**VEGF (rs1570360 and rs2010963) polymorphisms were found to be associated with decreased risk of psoriasis, whereas FGF1 (rs34010) and FGF2 (rs2922979) polymorphisms have association with increased risk of psoriasis. VEGF (rs8333061) and FGF1 (rs34011) showed no association with psoriasis. A strong association between clinical response to treatment and reduction of VEGF serum levels was also found.

## PgmNr 1894: Gene expression signatures in classical monocytes from African ancestry patients with systemic sclerosis.

---

Systemic sclerosis (SSc) is a rare fibrotic autoimmune disorder. It disproportionately affects African ancestry (AA) individuals who, despite the higher disease severity, are dramatically underrepresented in research. Monocytes show heightened activation in SSc, and in AA relative to European ancestry (EA) individuals. Monocytes are thus a good target tissue for elucidating disease mechanisms. In this study, we sought to characterize differential gene expression of classical monocytes in SSc patients and unaffected controls of African ancestry. Classical monocytes (CD14++CD16-) were FACS-isolated from 17 female AA SSc cases and 18 female AA controls. Total RNA was used to prepare RNA-Seq libraries using Illumina's TruSeq RNA Exome kit. Upon sequencing on an Illumina HiSeq2500 instrument, data was analyzed by Rosalind, with a HyperScale architecture developed by OnRamp BioInformatics. Briefly, individual sample reads were aligned to the hg19 reference genome using STAR and quantified using HTseq. Differential expression analysis was implemented using DESeq2 and functional enrichment analysis was performed using Advaita iPathway Guide. A total of 743 genes showed differential expression (FDR P-value <0.4). The top differentially expressed genes include the collagen *COL9A2*, the protein phosphatase *PPP1R14B*, the tubulin *TUBB4B*, the kinase-binding *AKAP1*, the ubiquitin ligase *RNF146*, the heparanase *HPSE*, the nuclear factor NF-Kappa-B activator *TRAF3IP2*, and the chromatin regulator *SMARCA4*. The SSc monocyte transcriptome showed an enrichment of genes in the AMPK signaling pathway, genes involved in chromatin organization, transcription factor binding, and glycogen storage diseases. The top upstream regulator is the MAPK11 kinase. Unlike what has been reported in different peripheral blood subsets in EA patients, our results show a weaker upregulation of genes involved in immune and inflammatory processes in monocytes from AA patients. Instead, our study reveals an upregulation of genes involved in cellular processes associated with transcription and energy regulation, consistent with an increased metabolic rate of these myeloid cells in SSc. These results support the increasing awareness that metabolic reprogramming has important roles in mediating immune and vascular responses. Collectively, these results support the need to understand the regulatory architecture of SSc in different cell types and in individuals of different ancestries.

## PgmNr 1895: A burden of rare functional genetic variants associated with Chiari Type I malformation and the co-occurrence with connective tissue disorders.

---

Chiari Type I Malformation (CMI) is characterized by herniation of the cerebellar tonsils below the foramen magnum and affects approximately 1% of the American population. Patients with CMI may experience a range of symptoms from headaches, to more significant neurologic morbidity such as blurred vision, muscle numbness and weakness, as well as spasticity. Some forms of CMI co-occur with connective tissue disorders (CTD), such as Ehlers Danlos Syndrome (EDS) (Milhorat et al 2007), and may have a unique patho-mechanism due to cranio-cervical instability. Thus, CMI patients with CTD (CTD+) may have different genetic risk factors than those without a history of CTD (CTD-).

To identify putative genetic risk variants, we performed next generation sequencing (NGS) on samples from 165 adult, Caucasian females with CMI who had been ascertained through the Chiari1000 project at University of Akron or a CMI family study at Duke University Medical Center. Using an Illumina TruSeq Custom Amplicon Library Prep kit, we targeted the coding regions of 21 CMI and EDS candidate genes. Sequencing was performed on an Illumina MiSeq v2 using 150bp paired end reads. Reads were aligned and variants were called using GATK best practices. Using gene-level burden analysis, we compared the frequency of rare, functional variants detected in CMI cases versus publically available ethnically matched controls from gnomAD. A secondary analysis compared the presence of rare variants between CTD+ and CTD- CMI cases.

Six genes (*COL5A2*, *COL6A5*, *COL1A2*, *NRP1*, *VEGFB*, *FLT1*) had significantly more rare variants in CMI cases compared to public controls. Interestingly, 25% of CMI cases possessed rare variants in *COL6A5*. We also identified four genes (*COL7A1*, *CDX1*, *VEGFA*, *DSE*) that were significantly different between CTD+ and CTD- CMI cases. A higher percentage of CTD- patients had variants in *COL7A1*, *VEGFA*, and *DSE* compared to CTD+ patients, while more CTD+ patients had variants in *CDX1* than did CTD- patients.

In summary, we have identified a burden of rare functional variants in CMI cases as compared to controls in several candidate genes. Variants in *COL6A5*, in particular, seem to be associated with CMI. We also have preliminary evidence that rare variants are differentially associated with CTD+ and CTD- forms of CMI. Our findings underscore the contribution of rare genetic variants to CMI, and differences in genetic etiologies of CMI with and without CTD symptoms.

---

Psoriasis is a chronic inflammatory disease of the skin believed to be triggered by environmental factors in genetically susceptible individuals. Gene expression data has increased our understanding of molecular contributors of psoriasis. However, few aberrantly expressed miRNAs in psoriasis have confirmed mRNA targets with biological functions in skin and a limited number of combined miRNA and mRNA sequencing studies have been performed. To increase our understanding of the psoriasis transcriptome and the miRNA-mRNA network, we sequenced small RNAs and ribosomal RNA-depleted total RNA of skin biopsies from patients with psoriasis vulgaris (n=75) and non-psoriatic controls (n=46). Comparing lesional psoriatic and control skin, we identified 270 differentially expressed ( $|\log_2FC| > 0.5$ , FDR < 0.05) miRNAs, of which 130 were upregulated and 140 were downregulated. The number of up- and downregulated ( $|\log_2FC| > 0.5$ , FDR < 0.05) mRNAs were 4,216 and 4,121, respectively. The differentially expressed mRNAs were analyzed by functional enrichment analysis using DAVID v6.8. For the upregulated genes, enriched functional annotation clusters included 'Immunity', 'Cell division' and 'Keratinization', and for the downregulated genes 'Glycoprotein/Cell membrane', 'Disulphide bond' and 'Cell adhesion'. Our results support a model for psoriasis as a result of perturbed interaction between keratinocytes and activated immune cells, leading to an increased proliferation rate of keratinocytes and epidermal thickening. We aim for further systematic analysis using pathway and network tools on miRNA and mRNA pairs with anti-correlated expression patterns. Increased knowledge of the transcriptome of psoriasis has the potential to provide new insight into the pathogenesis of psoriasis in addition to identification of biomarkers and therapeutic targets.

## PgmNr 1897: Comprehensive genomic analysis of data-driven dietary patterns in UK Biobank identifies novel loci and reveals causal associations.

---

Unhealthy diet is a leading risk factor for global morbidity and mortality. The modest, but real genetic contribution to dietary intake can now be explored in large-scale biobanks, such as UK biobank (UKB). We derived 170 data-driven diet traits from UKB questionnaires, including previously unstudied food intake quantitative traits (FI-QTs) and principal component-derived dietary patterns (PC-DPs). Linear mixed model genome-wide association studies (GWAS) on 143 significantly heritable diet traits in 450K Europeans identified 814 independent genetic loci ( $P < 5 \times 10^{-8}$ ), with 309 also surpassing a study-wide threshold ( $P < 3 \times 10^{-10}$ ). Of these, 205 are novel, and 447 were uniquely associated with either PC-DPs (136) or FI-QTs (311). GWAS of PC1, the most heritable PC-DP ( $h^2_g = 13\%$ ), identified the most loci ( $M = 140$ ) of any diet trait, explaining 6.5% of PC1 phenotypic variance. PC1, similar to previously described prudent vs. Western diet factors, captures positive wholemeal bread consumption and higher amounts of fruit, vegetables, fish, and water and negative white bread, butter/oil spreads, and higher amounts of processed meat and high-fat milk. Though Western and prudent dietary factors have been observationally associated with education and cardiometabolic disease, bidirectional Mendelian randomization (MR) revealed that while higher education shifts eating from Western towards healthier prudent eating (weighted median  $\beta = 0.82$ ,  $P = 6.6 \times 10^{-113}$ ), genetically-predicted prudent eating does not demonstrate causal evidence for reducing type 2 diabetes or coronary artery disease risk. We also identified several olfactory receptor loci associated with specific FI-QTs. SNP rs1453548, explaining >96% of sensitivity to beta-ionone aroma, is associated with increased tea intake. Comprehensive MR of this SNP demonstrates no widespread health impact of tea drinking; apparent causal evidence for decreasing smoking status is likely due to pleiotropy (beta-ionone is also in tobacco). In sum, comprehensive genomic analysis on diet has identified hundreds of associations and highlights the importance of complementary data-driven phenotyping. These results enable tests of causality for previous observational diet-outcome associations, advance our understanding of genetic architecture of diet, and inform public health.

## PgmNr 1898: The magnitude and impact of population differences on genetic risk scores for cardiometabolic traits.

---

Proposals for using genetic risk scores (GRS) for risk prediction in routine clinical settings have raised concerns about potential health inequalities that could result from limited predictive power of GRS in non-European populations. To provide a context for the implications of routine use of GRS in diverse populations, we assessed the predictive utility of NHGRI-EBI Catalog-derived GRS for cardiometabolic traits in 5,200 sub-Saharan Africans (AF), 9,594 European ancestry (EA) and 9,139 African American (AA) individuals. The predictive utility of the GRS was assessed using the additional phenotypic variance explained and increase in discriminatory ability over traditional risk factors. GRS-trait correlations were found to be strongest in EA. Predictive disparities of GRS between AF and AA were less pronounced but were better in AA, perhaps reflecting European admixture in AA. Among obesity related (OB), blood pressure (BP), lipids and glycemic traits that were evaluated, lipids had the clearest and most consistent GRS-trait gradient and predictive utility across all three ancestry groups. Total cholesterol (TC) showed the strongest GRS-trait association in all groups with GRS effect sizes of 0.226, 0.216 and 0.281 mmol/l per unit increase in GRS (all  $P < 0.0001$ ) among AF, AA and EA, respectively. The percent increase in explained variation attributable to GRS for triglycerides (TG), TC, low-density lipoprotein (LDL), high-density lipoprotein (HDL) and type 2 diabetes was, respectively: 2.4%, 25.1%, 31.0%, 37.5% and 12.4% among AF; 32.0%, 31.3%, 26.6%, 65.8% and 8.1% among AA; and, 47.2%, 95.4%, 127.1%, 10.6% and 25.5% among EA; showing up to a 20-fold and 5-fold greater predictive utility of GRS in EA relative to AF and AA, respectively. The above disparities were recapitulated in discriminatory power, whereby the predictive utility of GRS was 44-, 5- and 4-fold greater in EA relative to AF for raised TG, raised TC and raised LDL respectively; and 4-fold greater for raised TG, LDL and T2D in EA relative to AA. GRS of OB and BP traits showed a similar pattern. While the predictive performance of GRS tends to be lower in non-European populations, we show that it performed more poorly in African ancestry individuals with sub-Saharan Africans faring the worst. Further coordinated and sustained efforts are needed to increase the inclusion of underrepresented populations in genomic discovery to promote equitable benefit from translation of such discovery.

## PgmNr 1899: Discovery of 159 signals for random plasma glucose and dissection of its relationship with type 2 diabetes pathophysiology using GWAS within UK biobank.

---

Fasting plasma glucose (FG) and 2-hour post-prandial plasma glucose (2hGlu) are used as the gold standard tests for diagnosing type 2 diabetes (T2D). High non-fasting i.e. random plasma glucose (RG) levels may also indicate abnormal glucose homeostasis. We sought to characterise the genetic architecture of RG and its genetic relationships with other glycaemic traits and T2D. We performed a genome-wide association study of SNPs with MAF>1% for RG in non-diabetic individuals from the UK Biobank, adjusting for 1) age, sex and population structure (model1, N=401,810) and 2) additionally for time since last meal (model2, N=401,799). The LD score regression was used to evaluate the genetic correlation between RG, FG, 2hGlu, fasting insulin, glycated hemoglobin (HbA1c), homeostasis model assessment of beta cell function/ insulin resistance (HOMA-B/-IR), and T2D. We identified 159 loci associated with RG at genome-wide significance ( $P<5\times10^{-8}$ ), including two common coding variants within *GCKR* and *TET2* and four low-frequency nonsynonymous variants within *EDEM3*, *HERC1*, *NEUROD1* and *GLP1R*. Six loci reached statistical significance only when adjusting for time since last meal (*ADCY9/SRL*, *KCNQ1*, *ERN1*, *HECTD1/HEATR5A*, *SLC38A4*, *PDHX*), and nine without the adjustment (*MTNR1B*, *LOC440040*, *VEGFA/LINC01512*, *TRIM48*, *MIR588/RSPO3*, *RGS17*, *RREB1*, *RFX6/VGLL2*, *RREB1*). Of all the loci, 47 are established for T2D, three for FG, two for fasting insulin, two for fasting proinsulin and one for 2hGlu. Of the 367 established T2D signals with MAF>1%, 45% are nominally significantly associated with RG. We observed strong ( $r>0.6$ ) genetic relationships between RG and FG ( $r[SE]=0.86[0.05]$ ,  $P=1.04\times10^{-65}$ ), modest ( $0.3\leq r\leq 0.6$ ) with T2D ( $r[SE]=0.48[0.06]$ ,  $P=2.19\times10^{-15}$ ), HbA1c ( $r[SE]=0.43[0.06]$ ,  $P=1.04\times10^{-12}$ ) and HOMA-B ( $r[SE]=-0.39[0.07]$ ,  $P=2.35\times10^{-8}$ ), and weaker genetic correlation with HOMA-IR ( $r[SE]=0.28[0.07]$ ,  $P=4.31\times10^{-5}$ ). Our large-scale analysis of RG has detected FG- and T2D-associated variants, and the genetic correlation analysis also shows large genetic overlap between RG, FG, T2D and other glycaemic traits. Replication analysis in over 80,000 non-diabetic Europeans is on-going.

## **PgmNr 1900: LDL-C and type-2 diabetes: An inverse phenotypic association and genetic drivers in the UK Biobank.**

Although a low level of low-density lipoprotein cholesterol (LDL-C) is associated with protection against cardiovascular disease, some lines of evidence, including statin trials, suggest that lower LDL-C increases the risk of type-2 diabetes (T2D), and in some cases, obesity. Consistent with this phenotypic evidence, previous studies have also identified complex genetic relationships of lipids with T2D. Using data from the UK Biobank, we examined the prevalence of T2D and related traits across the range of LDL-C levels. We then used a genome-wide approach with several datasets to identify variants with opposing directions of effect on LDL-C and T2D. We find a higher prevalence of T2D, but not higher HbA1c or BMI, among individuals with low LDL-C. We identified known and novel genetic loci simultaneously associated with lower LDL-C and increased T2D (and vice-versa). These loci point to the liver as a principal tissue mediating these effects, and to pathways of triacylglyceride synthesis and glycerolipid metabolism. We thus confirm previous findings regarding the higher T2D risk among those with low LDL-C, and provide: 1) important insights into the mechanisms underlying this association, 2) more detailed phenotypic characterization of previously identified genetic variants, and 3) insight into the mechanisms potentially underlying the diabetogenic effect of LDL-C-lowering medications.

## **PgmNr 1901: Association between the high T2D prevalence and the genetic variants of HDAC4 and GCK interacting with heavy alcohol consumption in Korea.**

**Authors:**

---

Heavy alcohol consumption is known as an independent risk factor for type 2 diabetes (T2D), which is related with impaired glucose homeostasis and insulin resistance. The identification of genetic variants and the association with diseases may help to explain the genetic etiology of T2D. In this study, we aimed to search for the single nucleotide polymorphisms (SNPs) associated with T2D risk, which interact with heavy alcohol consumption. We conducted genome-wide interaction study using the Korea Association Resource (KARE) data. We found the two SNPs, HDAC4 (rs3791370) and GCK (rs758989) interact with heavy alcohol consumption in prevalence of T2D (odds ratio [OR] = 1.74, and OR=1.86, respectively). We further investigated the association between these SNPs and response to heavy alcohol consumption in risk of T2D prevalence after adjustment with age, BMI, smoking, physical activity, and history of diabetes. In heavy alcohol consumption group, hetero risky allele [TT+C/ C+TT] (OR=1.7) and minor homo risky allele [C+C] (OR=4.4) significantly increased the risk of T2D prevalence compared with non-alcohol consumption group. Moreover, we analyzed the insulinogenic index (IGI60), and Matsuda insulin sensitivity index (ISI) by combined genetic variants in HDAC4 and GCK and heavy alcohol consumption. The presence of risky alleles in heavy alcohol consumption group significantly decreased IGI60 levels. We found out two new genetic variants of HDAC4 and GCK, which interact with heavy alcohol consumption as an environmental factor in association with the prevalence of T2D and may be helpful to better understand the genetic basis of T2D.

## PgmNr 1902: Sex-specific changes in fat accumulation and metabolic parameters in a murine knockout model of *Lyplal1*.

### Authors:

GWAS studies have associated sex specific SNPs near *LYPLAL1* with central obesity as well as insulin levels and NALFD. The *LYPLAL1* protein is an acyl protein thioesterase that function to alter the location by deacylating proteins and changing their subcellular localization. We used CRISPR/Cas9 to generate a whole body *LYPLAL1* knockout (KO) mouse. We placed wild type (WT) and *Lyplal1* KO mice on a 'Western' diet containing levels of high fat and sucrose (HF/HS diet). During the 23 weeks that the mice were on the HF/HS diet, female KO mice gained less weight than their WT littermates. We carried out body composition measurements by TD-NMR at 14 weeks on the HF/HS diet and there was no change in lean body mass but less fat in female *Lyplal1* KO mice. Similar differences were not observed with male mice. To measure the detailed metabolic phenotype of the mice, after 20 weeks on the HF/HS diet, CLAMS phenotyping showed that was no differences in food intake or activity. Male KO mice showed an increase in fat metabolism but female mice did not. In GTT and ITT tests female *Lyplal1* KO mice were more responsive to glucose and insulin but male mice did not respond differently. After 23 weeks on HF/HS diet, mice were sacrificed, dissected and organs and fat depots weighed. Female KO mice had reduced visceral fat (gonadal white adipose tissue [gWAT], perirenal WAT [prWAT], and subcutaneous fat (inguinal WAT [iWAT]) but not brown adipose tissue [BAT] with gWAT the most significant. Similar changes were not observed in male mice. Blood chemistry values showed an increase in serum triglycerides and a decrease serum cholesterol in KO female mice and levels of Alanine transferase (ALT) and aspartate aminotransferase (AST) were lower in KO female mice compared to WT littermates. There was no difference in serum triglycerides or liver enzymes between the genotypes of male mice, but KO male mice had lower serum cholesterol than male WT mice.

These data collectively indicate a role for *LYPLAL1* in the metabolic response of female mice to a HF/HS 'Western' diet, with KO of *LYPAL1* protein decreasing visceral and subcutaneous adiposity, as well as improving glucose response and decreasing liver damage. Further examination of the mechanism of these novel diet-induced, sex-specific metabolic effects of *Lyplal1* KO will be critical to increasing our understanding of gender effects on human obesity, liver disease and metabolic syndrome.

## PgmNr 1903: Fine mapping of T2D linked 12q24 region in Finnish families.

---

**Aim:** Previously, a linkage for type 2 diabetes (T2D) was reported at the 12q24 (104-133Mb, b37) region in Finnish families with impaired insulin secretion (Mahtani M *et al.*, Nat Genet., 1996). We here aimed to fine-map the linkage peak in order to identify the putative causal variant/haplotype in the region.

**Material and Methods:** The linkage study included 34 individuals from six families. All family members underwent a dense GWAS and 12 individuals whole genome sequencing (WGS). We first performed family-based association (linear mix model), haplotype sharing analysis and checked the effect on insulin secretion at 30 min (INS30) levels in an independent sample (N>3500). Additionally, we also checked effect of identified variants on expression of nearby genes in human islets (N=191) and performed further validation in a human beta cell line.

**Results:** Family based association revealed most significant association with T2D ( $P=1.4 \times 10^{-4}$ ) for a common haplotype consisting of three missense mutations (rs14259-rs17852561-rs1169081). Association of variants shared by > 5 families with INS30 levels in independent samples revealed most prominent association ( $P<5.9 \times 10^{-5}$ ) for cluster of variants (like rs28629903 and rs1316787) located near the linkage peak and this cluster also influenced the expression of the *MLXIP* gene in colon. A haplotype sharing analysis using >0.5 cM long haplotypes, shared and transmitted among affected members of at least >2 families, revealed two haplotypes shared at regions 124.8 to 125.0 mb (*NCOR2*), and 127.85 to 128.5 mb (near to *TMEM132C*). The shared regions contain low frequency (0.01 to 4%) variants (rs11057587, rs11059329, rs148549814) which were associated with decreased INS30 levels and increased expression only of *TMEM132C* ( $P=0.004$ ) in human islets. *TMEM132C* expression was negatively correlated with insulin secretion in human islets in our previous work (Ottosson-Laakso E *et al.*, Diabetes, 2017) and siRNA mediated knock down in human beta cells leads to increase in insulin secretion ( $P=0.002$ ).

**Conclusion:** The 12q24 linkage families share clusters of common and low frequency variants that affect insulin secretion with the *MLXIP*, *TMEM132C* and *NOCR2* genes as plausible candidates. Of them, *TMEM132C* may be most interesting as functional data support a role in regulation of insulin secretion, *MLXIP* (*MondoA*) would also need further work to explore its potential involvement in impaired insulin secretion influencing the incretin pathway.

## PgmNr 1904: Pathway-based genetic risk scores in T2D risk predict associated phenome and related biomarkers.

**Affiliation:** Vanderbilt Genetics Institute, Vanderbilt, Nashville, Tennessee.

Type 2 Diabetes (T2D) is an important, complex and multi-faceted disease. In the United States, the prevalence of T2D has more than tripled in the years between 1998 and 2018. T2D is the number 7 cause of death in the United States and is also associated with increased risk of stroke, heart disease, chronic kidney disease, among other illnesses and with approximately \$327 billion annually for lost work and wages and medical costs. Diabetes is further complicated by comorbidities, which can cost more and further decrease average health-related quality of life (HRQoL) from an optimal 1 to 0.85 in patients with T2D without complications, to 0.64 in patients with T2D and two or more complications. It will be valuable to improve accuracy in predicting who will develop further complications and what types of complications these may be.

In this set of research, we sought to use genetics to elucidate biological mechanisms in phenotypically similar outcomes. We used genetic risk scores (GRSs) built from T2D GWAS variants, and subset them to three biological pathways (Insulin Secretion, Insulin Action, BMI-Dyslipidemia). We utilized a portion of the genotyped Vanderbilt medical center biobank (BioVU) from which we scored each participant in our dataset based on their GRS in each pathway and ran analyses examining associations of each of these scores with median lab values and presence of billing codes. We analyzed the association of each pathway GRS with up to 1814 billing codes and 260 median lab values. Liver disease and renal failure related billing codes were significantly associated only with the BMI-Dyslipidemia risk pathway (OR=1.14, P=8e-8 ) & (OR 1.11 P=1e-7), respectively, not with Insulin Secretion (OR=0.99, P=0.566) & (OR=1.00, P=0.874) nor Insulin Action pathways (OR=1.07, P=0.002) and (OR=1.05, P=0.015), respectively. Use of BMI as a covariate removed signals of statistical significance (Bonferroni p-value= in associations between the BMI-Dyslipidemia GRS and blood glucose (OR=1.043, P = 6.7e-6) and blood urea nitrogen (OR=1.040, P= 1.6e-5), but adjustment for BMI had no impact on signals between the other two pathway GRSs and their related labs. This indicates that BMI may be a more useful measurement to predict downstream risk in participants with T2D risk sourced from the BMI-dyslipidemia pathway.

Moving forward, we aim to leverage BioVU and other EHRs to find other significant biomarkers and comorbidities relating to biological pathways of risk.

---

Chronic kidney disease (CKD) is a common complex disease with an especially high prevalence in individuals with diabetes. CKD is hallmarked by progressive decline of glomerular filtration rate (GFR), a measure of kidney function, that often culminates in a state of complete renal failure known as end-stage renal disease (ESRD). A recent genome-wide association study (GWAS) meta-analysis of over 1 million individuals identified more than 300 loci associated with kidney function. Variants at these loci explain approximately 20% of the genetic heritability of estimated GFR (eGFR). We hypothesize that rare or lower frequency variants (minor allele frequency <5%) contribute significantly to the residual genetic variance of kidney function and that linkage analysis in large multigenerational pedigrees combined with next generation sequencing methods can not only help validate the findings of large GWASs, but can also identify novel loci of interest in CKD populations. Here, we apply this approach in the context of large multigenerational diabetes pedigrees identified using the Utah Population Database (UPDB), a unique population-based genealogy resource of Utah pioneers and their descendants that is linked to electronic health record data from the University of Utah Health Sciences Center. Using the UPDB, we identified 20 large multigenerational pedigrees, consisting of 1,581 individuals, with a high prevalence of CKD. 230 members of these pedigrees were genotyped using Illumina's Infinium CoreExome microarray. Variance component linkage analysis using SOLAR was conducted to identify eGFR-associated loci. As a complimentary approach, analysis of kidney-related traits and whole-genome sequencing data on a subset of these families was performed using pVAASST. Together, this combined approach highlights several rare missense variants in genes previously associated with CKD and has identified several novel genes that are likely associated with renal function in patients with diabetes.

## PgmNr 1906: A genome-wide CRISPR screen in human beta-cells for regulators of insulin content.

---

Genome-wide association studies have identified >400 signals in the genome associated with type 2 diabetes (T2D) risk, a large proportion of which are involved in pancreatic beta-cell dysfunction. We have previously shown how a targeted knockdown screen for insulin secretion can aid prioritisation of effector transcripts at these loci. To build on this work, we now extend this genome-wide using a pooled CRISPR/Cas9 knockout (KO) screen for insulin content in human beta-cells.

We implemented the pooled CRISPR/Cas9 screen in the human pancreatic beta-cell line EndoC-βH1, which is capable of physiologically relevant glucose-responsive insulin secretion. Insulin content was selected as the screening phenotype, as it is compatible with a FACS-based pooled screen. To validate our pipeline, we performed a small-scale screen using previously validated single guide RNAs (sgRNAs) for five genes and assessed their enrichment in cells sorted for low vs high insulin content. sgRNAs for *INS* and *PAM*, two genes with known negative effects on insulin content were enriched in the low insulin population, whereas control sgRNAs showed no enrichment (fold change *INS*: 3.58, *PAM*: 1.32, Ctrl: 1.07).

We performed two independent screens and transduced 650 million cells each with the genome-wide CRISPR library Toronto KnockOut v3 (TKOv3), which targets 18 053 protein-coding genes with 4 sgRNAs/gene. To account for different temporal effects of individual gene KOs and the slow growth rate of EndoC-βH1, cells were collected for FACS at two time points, immediately after puromycin selection and 14 days later. Cells were stained for intracellular insulin and we observed a wider distribution of insulin signal in TKOv3 transduced cells compared to control cells, indicating a wide range of KO-induced effects on insulin content. Low and high insulin content populations were sorted and sgRNA enrichment or depletion was analysed using next-generation sequencing to identify genes that have an effect on insulin content or are essential in beta-cells.

In summary, we have performed a genome-wide pooled CRISPR/Cas9 screen for insulin content in an authentic human beta-cell model. Our hits can now be integrated with genetic and epigenomic data at T2D-risk loci to prioritise effector transcripts for further mechanistic studies. Our unbiased CRISPR screening strategy has also identified unknown regulators of beta-cell function and survival which may aid cell replacement strategies for diabetes.

## PgmNr 1907: Understanding the genetic basis of type 2 diabetes risk: Whole genome sequence analysis of glycemic traits from the NHLBI's TOPMed Program.

---

Genetic studies have shown that for type 2 diabetes (T2D) risk and diabetes-related glycemic traits, common variant heritability is enriched within active regulatory regions of tissues important to diabetes and insulin resistance. Whole genome sequence (WGS) association analysis allows us to (1) fine-map known and novel loci with active regulatory regions, (2) determine the contribution of rare variants in active regulatory regions to the heritability of T2D risk and glycemic traits, and (3) perform rare variant tests which aggregate protein-coding variants and/or variants in active regulatory regions to increase statistical power. Here, we present a complete WGS analysis of fasting insulin (FI) and fasting glucose (FG) levels in phase 2 Trans-Omics for Precision Medicine (TOPMed) data (fasting glucose [FG] N=26,920 and fasting insulin [FI] N=23,361) with deep (>30x) sequence coverage in fourteen cohorts across five ancestry groups. For our single variant analysis, we restricted analysis to variants with minor allele count > 20 in ancestry-specific and cross-ancestry pooled analysis. We used linear mixed effects models (R/Bioconductor GENESIS in cloud-computing platforms) and adjusted for sex, age and BMI, with empirical kinship for relatedness and population structure. For rare variant analysis, we derived aggregation units from coding variant annotations, regulatory annotations from pancreatic islets, liver, muscle and adipose tissues, and annotation Principal Components (aPCs), a multi-dimensional summary of functional annotation scores. We used sequence kernel association test (SKAT) and the novel variant-Set Test for Association using Annotation infoRmation (STAAR), a general framework that incorporates annotation scores using an omnibus multi-dimensional weighting scheme. In single variant analysis, we observe 8 regions associated ( $P < 5 \times 10^{-8}$ ) with FG and 6 regions associated with log-FI, with most signals from common variants in known regions. In rare variant analysis, one test showed a (Bonferroni) significant association with FG using missense variants in *G6PC2*. At the *G6PC2* locus, multiple distinct associations were observed in the single variant tests, consistent with previous reports, and nominal significant associations were observed when aggregating predicted loss-of-function rare variants. Analysis with larger samples are planned. Our work refines the genetic architecture of glycemic traits using the full spectrum of genetic variation.

## PgmNr 1908: Genomics as a personalized medicine approach in type 2 diabetes risk prediction - P5 FinHealth.

In P5 FinHealth study we utilize polygenic risk scores (PRS) to provide personalized information on the individual disease risk related to three common diseases (coronary heart disease, type 2 diabetes and venous thromboembolism) for 3.400 volunteering participants. Participants will receive this disease risk information including genetic risk via a secure web portal. We study the value of returning genetic risk information and hypothesize that it would improve prevention, diagnostics and treatment.

We used polygenic risk scores containing up to 7 million genomic regions and validated them in whole genome genotyped population based FINRISK cohorts (N=20.000) using Cox regression models. Follow-up data from national health care registers allowed us to model the impact of genetic and traditional risk factors such as smoking, cholesterol, blood pressure and body mass index (BMI) on a person's risk of disease within the next 10 years.

Altogether 967 T2DM new cases were observed during the 10-year follow-up period. We observed that type 2 diabetes (T2DM) PRS significantly associates with the T2DM disease risk (HR:1.5 per 1 sd PRS, p-value:<2\*10<sup>-16</sup>). Also the top 8% of the FINRISK population who had inherited the highest PRS had fourfold increased risk for T2DM. Moreover, almost 30% of the people with >35 BMI and the highest PRS were diagnosed with T2DM during ten-year follow-up. T2DM incidents in >30 BMI group occurred at a younger age concurrently with higher PRS, and there was a seven-year difference of getting T2DM between the highest and lowest PRS group.

By combining the systemic genetic analyses with more traditional disease risk factors in the FINRISK cohort, we produced estimates on the impact of PRS and selected covariates on risk of T2DM. We use these estimates to assess the future risk of T2DM in P5 FinHealth participants. We start returning personalized health reports to the P5 participants during 2019. We will also provide a guidance tailored for each risk category to assist the health care via the study participant. The reception of the risk information will be monitored by questionnaires and new incidents followed using national health registers for five years. Our approach enables to identify the individuals within highest genetic risk and those with pre-disease symptoms.

## PgmNr 1909: Inactivating mutations in *SLC39A5*: Role in metabolic disease.

Recent human and mouse studies have underscored the role of zinc in insulin secretion and systemic glucose homeostasis. Randomized placebo-controlled zinc supplementation trials in humans demonstrated improved glycemic traits in patients with type 2 diabetes (T2D). Moreover, carriers of rare loss-of-function variants in *SLC30A8* (encoding an islet zinc transporter) have been reported to have 65% reduced T2D risk in a large multi-ethnic study. To further investigate the connection between zinc and metabolic traits, we employed a pathway-based target identification approach involving genome-wide association of loss-of-function variation in zinc transporters with glycemic traits and T2D risk. Using exome sequence data from participants of European ancestry in the Regeneron Genetics Center-Geisinger Health System DiscovEHR study, we identified rare loss-of-function variants (MAF<1%) in *SLC39A5* (gene encoding Solute Carrier Family 39, Member 5) that are associated with circulating zinc levels and T2D. Loss-of-function burden tests of *SLC39A5* were associated with increased circulating zinc levels (Beta = 1.1 SD, 95% CI 0.47-1.1,  $p = 5.4 \times 10^{-4}$ ) and decreased T2D risk (OR = 0.5, 95% CI 0.37-0.79,  $p = 1.6 \times 10^{-3}$ ). Furthermore, we report a mouse model of *Slc39a5* loss-of-function that results in significant elevation in circulating zinc levels and concomitant improvement in hepatic steatosis and hyperglycemia resulting from diet-induced obesity or leptin-receptor deficiency. Lastly, ongoing studies demonstrate that the improved liver function in these mice results from hepatic AMPK activation and increased hepatic lipid metabolism. Taken together, these results suggest *SLC39A5* as a potential therapeutic target for fatty liver disease and consequent metabolic derangements including T2D.

## PgmNr 1910: Association of ancient adaptive mitochondrial DNA haplogroups with type 1 diabetes.

---

The prevalence of type 1 diabetes (T1D) varies significantly across human populations, with the highest prevalence seen in Caucasian populations. Even among European populations, there are conspicuous differences with the highest prevalence in Finnish population (Patterson et al. 2012). To date, more than 70 T1D loci have been identified, however, the population difference of T1D susceptibility is still largely unknown. It has been well recognized that different ancient adaptive mitochondrial DNA (mtDNA) haplogroups have significantly different functional performance, thus have undergone extensive selection in the evolution of human populations (Tranah et al. 2011). In our study, we examined the association of mtDNA haplogroups with T1D in our T1D GWAS datasets. Population substructures of the sample were analyzed by principal component analysis (PCA) using PLINK1.9, and genetic outliers were removed. Altogether, 979 cases and 2009 controls of European ancestry were used for the association test. We determined the mtDNA haplogroups by the phylogenetic tree based software HaploGrep 2 (Weissensteiner et al. 2016), based on 163 mtDNA single nucleotide variants (SNV) genotyped by the Illumina HumanHap550 arrays. We tested 23 mtDNA haplogroups (A, B, C, D, F, G, H, I, J, K, L, M, N, P, Q, R, T, U, V, W, X, Z, and Undetermined) for genetic association by logistic regression adjusted for the first two principal components of the PCA for population stratification, with statistical significance Bonferroni correction level at  $\alpha = 0.05/23 = 2.17 \times 10^{-3}$ . One haplogroup was significant, i.e. Haplogroup V, OR (95%CI) = 3.200 (1.680, 6.097),  $P = 4.05 \times 10^{-4}$ . Another haplogroup demonstrated nominal significance without Bonferroni correction, i.e. Haplogroup K OR (95%CI) = 0.698 (0.528, 0.923),  $P = 0.012$ . Haplogroup V is most commonly seen in northern Scandinavian, which explains its association with the risk of T1D, but not simply marking Scandinavians (before correction OR (95%CI) = 3.627 (1.912, 6.879),  $P = 2.55 \times 10^{-5}$ ). In addition, we identified possible gender effect of Haplogroup K on the age-of-onset of T1D with nominal significance ( $P = 0.048$ ), i.e. later age-of-onset in males [mean of males vs females difference (95%CI) = 3.45 (0.033, 6.86)], which as well as the decreased risk of T1D might be explained by its function as an “uncoupling genome” and less oxidative damage, but the sexual dimorphism (Ventura-Clapier et al. 2017) warrants further investigations.

# PgmNr 1911: Family-based association analysis of type 1 diabetes replicates case-control associations and reveals sequence homology as a source of spurious association in exome chip analysis.

**Affiliation:** Center for Public Health Genomics, Univ Virginia, Charlottesville, Virginia.

---

**Background:** Type 1 diabetes (T1D) is a complex immune-mediated disease. Twin studies indicate about 50% of T1D risk is due to genetic susceptibility. Genome-wide association studies (GWAS) in unrelated subjects identified >40 regions affecting T1D risk, with fine mapping increasing resolution of putative causal variants. Despite substantial familial clustering, unbiased family-based GWAS have not been performed with large sample sizes. Here, we analyze a large cohort of affected families from the Type 1 Diabetes Genetic Consortium (T1DGC).

**Methods:** We genotyped 13,461 participants from 4,520 affected families using the Illumina HumanCoreExome BeadChip. We confirmed the accuracy of reported relationships with genotype-based relationship inference and tested T1D association using the transmission disequilibrium test. We evaluated novel associations in an independent collection of 2,150 T1D cases and controls with whole genome sequencing.

**Results:** Five known regions reached genome-wide significant ( $p < 5 \times 10^{-8}$ ) association with T1D - 1p13.2 (*PTPN22*), 6p22 (MHC), 11p15.5 (*INS*), 12q24.12 (*SH2B3*), and 12q13.2 (*IKZF4*). We initially identified a significant association with a missense variant in *PRKRA* (rs61999302). This variant has been reported in population genome sequencing projects and previously described as protective against autoimmune disease. Our analyses exhibited strong effects in opposing directions in African ( $OR = 3.4$ ,  $p = 1 \times 10^{-17}$ ) and European ( $OR = 0.4$ ,  $p = 3 \times 10^{-21}$ ) ancestry individuals. The minor allele of rs61999302 results in a local sequence with perfect homology to *HLA-DRB1\*07:01* within MHC haplotype A29-B44-DR7. We and others have shown *HLA-DRB1\*07:01-DQA1\*03:01-DQB1\*02:01* is an African-specific T1D risk haplotype ( $OR = 4.4$ ,  $p = 7 \times 10^{-18}$ ). Thus, association between rs61999302 and autoimmune disease may reflect the known association with HLA class II genes rather than *PRKRA*. Full sequencing of the *PRKRA* region will be required to definitively determine the source of associations with rs61999302.

**Discussion:** In this robust, family-based GWAS of T1D, we replicate known T1D loci and highlight sequence homology as a source of spurious association. This source can be difficult to detect because genotype cluster plots appear normal and alleles segregate appropriately (for rs61999302, all 228 informative trios were consistent with Mendelian inheritance). Caution should be taken when interpreting association results in regions with high sequence homology.

---

Type 2 diabetes mellitus (T2DM) is a major public health problem that accounts for nearly 90% of all those diagnosed with DM and is often associated with obesity, insulin resistance condition and dyslipidemia, which is described by a metabolic dysfunction resulting from an increased level of lipoproteins in the blood. Chronic periodontitis (CP) is an infectious-inflammatory disease defined by the loss of connective tissue surrounding the teeth and alveolar bone loss. Although bacterial infection is a primary cause, the disease progression depends on the production of host mediators in response to bacterial and metabolic products. In consequence of this microbial challenge, the CP induces local and systemic elevations of pro-inflammatory cytokines. CP can be recognized as the sixth major complication associated with DM, and was detected to a greater extent and severity in individuals with DM compared to normal individual. T2DM, dyslipidemia and CP are intrinsically interrelated pathologies, but to date no study has identified the transcriptomic profile related to these combined diseases. The aim of this study was to characterize the gene expression profile of subjects with poorly or well-controlled T2DM also affected by dyslipidemia and CP. Patients (n=150) were divided into groups: (G1) poorly controlled T2DM with dyslipidemia and CP; (G2) well-controlled T2DM with dyslipidemia and CP; (G3) normoglycemics with dyslipidemia and CP; (G4) systemically healthies with CP; and (G5) systemically healthies without CP. Microarray normalized by the RMA was submitted to the RankProd method to identify candidates for differentially expressed genes (DEGs) considering and thresholds. Functional enrichment analysis was performed using Ingenuity Pathway Analysis - IPA. DEGs were submitted to pairwise comparisons, and selected DEGs were validated by quantitative polymerase chain reactions. Validated DEGs verified from G1 versus G5 were: *TGFB11I*, *VNN1*, *HLADRB4* and *CXCL8*; G2 versus G5: *FN1*, *BPTF* and *PDE3B*; G3 versus G5: *DAB2*, *CD47* and *HLADRB4*; and G4 versus G5: *IGHG3*, *ITGB2* and *HLADRB4*. The molecular profile of individuals simultaneously affected by T2DM, dyslipidemia and CP, demonstrated by the validated DEGs main implications with inflammatory response, immune cell trafficking, and infectious diseases.

## PgmNr 1913: Meta-analysis in 433,540 East Asians identifies 49 new loci associated with type 2 diabetes.

### Authors:

Large-scale meta-analyses of genome-wide association studies (GWAS) have identified >240 loci associated with type 2 diabetes (T2D), primarily in analyses of individuals of European ancestry. With differences in linkage disequilibrium structure and allele frequencies across ancestry groups, large genetic studies in non-European samples may reveal additional loci shared across ancestry groups or ancestry-specific. We conducted the largest East Asian GWA meta-analyses to date in up to 433,540 individuals from across East Asia using genotypes imputed to 1000G Phase 3. Models were adjusted for age, sex, and other study-specific covariates, assuming an additive genetic model. Study-specific association summary statistics were combined using a fixed-effects inverse variance weighted meta-analysis. We identified 178 loci associated with T2D ( $P < 5 \times 10^{-8}$ ), including 129 known and 49 novel loci. While common variants at loci associated with T2D in both East Asians and Europeans exhibited strongly correlated effect sizes ( $r = 0.88$ ), we further identified associations specific to East Asians. Sex-stratified analyses identified one additional male-specific and two additional female-specific loci. *ALDH2* exhibited the strongest difference between males and females ( $P_{\text{het}} = 2.6 \times 10^{-19}$ ) with compelling evidence of association in males ( $P = 5.5 \times 10^{-27}$ ) and no evidence for association in females ( $P = 0.19$ ). At 88 East Asian-identified loci where no European signal has been reported within 500 kb of the East Asian lead variant, candidate genes were identified at 64 loci using colocalized eQTLs, coding variant annotation, PheWAS, and a literature search. Candidate genes include genes that encode key transcription factors in islets (e.g. *SIX3-SIX2*, *NKX6-1*, and *FOXA2*) and other tissue types (e.g. *ZBTB20*, *RANBP3L*, *ZNF703*, and *PPARA*), two miRNA clusters known to play a role in beta-cell function (*MIR17HG* and *DLK/MEG3*/miRNA cluster), and genes responsible for adipocyte and/or skeletal muscle differentiation and metabolism (e.g. *ADRB3*, *CALCR*, *DMRT2*, *JMJD1C*, *NFATC4*, and *GDAP1*). Overall, annotation of loci identified in East Asians suggests a strong role for insulin resistance in T2D pathogenesis through skeletal muscle, adipose, and liver development and function. Taken together, we identified novel T2D loci that provide a foundation for future biological research in T2D pathogenesis and offer potential targets for mechanisms for interventions in disease risk.

## PgmNr 1914: The utility of combining *CREBRF* genotype with BMI to screen Samoans for type 2 diabetes.

---

Type 2 diabetes is a major global health concern. This particularly affects Samoans, who have high rates of obesity (66% of women and 45% of men) and, as a result, face high rates of obesity-related morbidities including diabetes. In Samoa in 2013, 23% of women and 21% of men were diabetic. A minor allele of common genetic variant in Samoans, rs373863828 (*CREBRF*:p.R457Q) has been associated with a 1.6-fold lower risk of diabetes. The ADA recommends testing for diabetes in adults when BMI is  $>25 \text{ kg/m}^2$ . Such a threshold might be inappropriate for Samoans, and additionally, more precise thresholds could be determined with the addition of genetic information. Here we determine how the addition of *CREBRF* genotype affects the usefulness of BMI in predicting diabetes status in Samoans. In 2010, as part of the Soifua Manuia Study, we collected BMI, fasting glucose, diabetes diagnosis, age, and *CREBRF* genotype on 2,978 Samoan adults, 25–65 years old. We used receiver operating characteristic (ROC) curves analysis to assess the utility of BMI, via the area under the curve (AUC), in predicting diabetes status. These analyses were subsequently compared to models that included genotype. All models were conducted separately in men and women and included age as a covariate. We also calculated threshold values and specificity at 80% sensitivity, in men and women, both overall and by genotype group. The AUC for diabetes classification was 0.74 in women and 0.75 in men. Including genotype improved the AUCs to 0.75 in women and to 0.77 in men. However, these differences were not found to be statistically significant ( $p=0.61$  and  $p=0.52$ , respectively). In women, the 80% sensitivity thresholds for BMI were  $30.3 \text{ kg/m}^2$  overall (with 27% specificity),  $30.3 \text{ kg/m}^2$  for GG (30%),  $31.4 \text{ kg/m}^2$  for GA (30%), and  $29.7 \text{ kg/m}^2$  for AA (17%). In men, they were  $28.7 \text{ kg/m}^2$  overall (with 40% specificity),  $27.8 \text{ kg/m}^2$  for GG (39%),  $30.6 \text{ kg/m}^2$  for GA (48%), and  $32.2 \text{ kg/m}^2$  for AA (57%). These analyses show that higher Samoan-specific screen thresholds are merited, and that the addition of the *CREBRF* genotype does not usefully alter the ability of BMI to predict type 2 diabetes status as assessed by examining the change in the AUC. However, 80% sensitivity threshold values by genotype suggest that including *CREBRF* genotype may be beneficial over BMI alone, by improving specificity without loss of sensitivity. This benefit needs to be weighed nonetheless against the costs of genotyping for this variant.

## PgmNr 1915: Polygenic risk of obesity in Chilean children: The Santiago Longitudinal Study (SLS).

---

GWAS of body mass index (BMI) have identified hundreds of variants, although most findings have been revealed in European adults (EUR), with few GWAS in pediatric populations. The relevance of BMI-associated variants identified in adults has been assessed for childhood BMI using polygenic risk score (PRS), usually limited to tag SNPs reaching genome-wide significance. We aim to ascertain the relevance of PRS derived from >2M variants using EUR adult (PRS\_adult) GWAS of BMI and assess the association with BMI<sub>z</sub> scores (age/sex standardized BMI Z-scores using CDC panel) measured in Chilean children of the Santiago Longitudinal Study (SLS). BMI<sub>z</sub> was calculated for BMI at 5y, 10y, 16y (N=577, 770, 543, respectively). SNPs for inclusion in the PRS\_adult were selected from publicly available BMI GWAS data in more than 322K EUR adults and trained on a sample of 100K UKBiobank participants using PRSice. the best fit PRS\_adult included 583,374 variants and was subsequently used to calculate PRS\_adult in SLS, adjusted for principal components. The PRS\_adult was significantly associated with BMI<sub>z</sub> at 5y (P=2e-7), 10y (P=1e-11), and 16y (P=7e-13), and with a notable increase in variance explained variance (%V) across ages (R<sup>2</sup>=4.6%, 5.8%, 9.1% in 5y, 10y, 16y). Mean BMI<sub>z</sub> was statistically different (P<0.01) between the lowest (Q1) and upper quintiles (Q5) of the PRS across age groups. The greatest difference could be seen BMI<sub>z</sub> measured at 16y for which the mean BMI<sub>z</sub> of those in Q5 of the PRS\_adult was significantly different from all other quintiles. Further, the proportion of obese participants (BMI<sub>z</sub>≥95th%) in Q5 was significant at 16y (P=4.01E-6, 31%-Q5, 5.5%-Q1). This new derived PRS based on adults provides a notable increase in %V for BMI<sub>z</sub> in SLS over a PRS derived from 43 tag variants from a recent GWAS of BMI<sub>z</sub> in 35K EUR children (PRS\_child) (R<sup>2</sup>=1%, 1.9%, 1.3% at 5y, 10y, 16y). Notably, the performance of the PRS\_child peaked at age 10, while PRS\_adult increased from 5-16y. Our study adds to the recent body of literature that demonstrates the importance of PRS derived from GWAS for explaining variation in obesity-related traits and the generalizability across age groups. However, the moderate gain in %V and the difference in performance across ages between PRS\_adult and PRS-child highlight the importance of

selecting age-appropriate SNPs for inclusion in PRS. As such, we will address this and the potential benefit of deriving a PRS from multiethnic GWAS of BMI.

## PgmNr 1916: Tissue-specific transcriptome informed rare variant association analysis in type 2 diabetes.

---

In the analysis of rare variants in sequencing studies, current gene-based association methods are highly sensitive to the variants selected for aggregation. Enrichment for true functional variants is crucial for success. Due to ubiquitous alternative splicing of genes, most coding variants typically have multiple annotated consequences across alternate gene transcripts. Common practice, which assigns the most severe consequence across any transcript, is sub-optimal when the transcript concerned is rare, tissue-specific, or not expressed in disease relevant tissues. We introduce an integrated approach that assimilates tissue-specific transcriptome profiles to prioritize rare variants for gene burden analysis in type 2 diabetes (T2D).

Recently, we reported analysis of exome sequence data from 20,791 T2D cases and 24,440 controls across five ancestries. This analysis used a novel analytical approach, which assigns prior weights to variants based on their estimated probability of haploinsufficiency. Here, we expand this framework by incorporating tissue-level transcriptomes from two T2D relevant tissues. Using PacBio long-read sequencing, we profiled expression and abundance of 31,220 isoforms in 16,520 genes in islets and 34,718 isoforms in 16,199 genes in adipose. We explored whether transcriptome informed variant selection and weighting would improve power to detect rare variants underlying T2D.

We found no additional signals exceeding exome-wide significance (beyond the three reported previously). However, of the 1,232 genes with nominal significance ( $p \leq 0.05$ ) in the initial weighted analysis, 421 and 398 genes in islets and adipose showed stronger association in the isoform aware analysis.

Amongst the top 50 genes from the initial analyses, at *RXRG*, we found a stronger rare variant association with T2D using adipose-specific annotations ( $p=5.5 \times 10^{-4}$  to  $2.7 \times 10^{-5}$ ). *RXRG* had two isoforms in both tissues, but the dominant islet isoform (95%) was rare in adipose (6%) and differed in two terminal exons. The *TMEM216* gene had improved significance in adipose ( $p=1.0 \times 10^{-4}$  to  $9.4 \times 10^{-5}$ ) after excluding variants benign in the adipose isoform.

These findings demonstrate that, alongside continuing efforts to increase available sequence data for complex traits, there is a need to improve tissue-specific variant annotation and prioritization. This is key to improving the power of rare variant association methods and deriving tissue specific insights into disease pathology.

## PgmNr 1917: Insights into the correlation between gluten intolerance and metabolic disorders: A case study.

### Authors:

P. Kaur; R. Kaur

[View Session](#) [Add to Schedule](#)

**Affiliation:** Department Of Human Genetics, Punjabi University, Patiala, Punjab, India

---

Gluten intolerance is increasing at an alarming rate all over the world and becoming major area of concern. Mostly, it is observed in the females who have family history of various metabolic disorders such as diabetes, cancer, hypertension, abnormal cholesterol, obesity, etc. We have a case study elaborating the correlation between gluten intolerance and metabolic disorders. In F-I generation of this family, 1 (paternal grandfather) and 2 (paternal grandmother) are dead, reason not known by the proband; 3 (maternal grandfather) died by stroke; 4 (maternal grandmother) was diabetic, hypertensive, had abnormal cholesterol, suffered from celiac disease in later life and died. In F-II generation, 1 (paternal aunt) and 4 (paternal aunt) were normal; 2 (proband's father) died from prostate cancer and was hypertensive as well; 3 (paternal uncle) is suffering from diabetes and cardiovascular disease; 5 (paternal aunt) from asthma; 6 (maternal uncle) died when he was six months old due to thalassemia major; 7 (proband's mother) is suffering from diabetes, breast cancer and hypertension; 8 (maternal uncle) is hypertensive and dealing with stroke. F-III generation comprises three females, 1 (proband's sister) is suffering from polycystic ovary syndrome after giving birth to two kids; 2 (proband's sister) is unmarried, suffering from gluten intolerance and polycystic ovary syndrome and 3 (proband) is unmarried and suffering from gluten intolerance but have regular menstrual cycles. This pedigree shows a crosslink, between gluten intolerance and various metabolic disorders, which remains to be identified. Efforts are being made to identify the link using bioinformatics approach.

## PgmNr 1918: The genetics of circulating resistin in African ancestry populations.

### Authors:

---

Most genome-wide association studies (GWAS) for circulating proteins do not find genome-wide significant associations for variants within the coding gene. Resistin is one of few proteins for which GWAS consistently report variants within and near the coding gene (*RETN*). The present work sought to provide a nuanced perspective of the genetic regulation of circulating levels of resistin. We performed GWAS and fine-mapping analyses for resistin in 5621 African ancestry individuals, including 3754 continental Africans (AF) from the Africa America Diabetes Mellitus (AADM) Study and 1867 African Americans (AA) from the Howard University Family Study (HUFS). All genetic variants associated with resistin at genome-wide significance ( $p < 5 \times 10^{-8}$ ) in both the AF and AA samples, were within a 130kb region of the *RETN* gene suggesting *cis*-acting effects. The top variant (rs3219175, 75bp upstream of *RETN*) was the same in both samples and had a p-value of  $5.0 \times 10^{-111}$  in AF and  $9.5 \times 10^{-38}$  in AA, explaining 12.1% and 8.5% of variance in circulating resistin, respectively. Previous resistin GWAS reported the same single locus or only a weak secondary locus. In contrast, GWAS for insulin resulted in 13 genome-wide significant loci in AF and 1 in AA, none of which are near the gene coding for insulin (*INS*), consistent with findings of previous insulin GWAS. Pathway analyses mapped *RETN* exclusively to immune pathways and co-expression of *RETN* was primarily observed in immune cells. Bayesian fine-mapping using a stepwise conditional search around the lead SNP, revealed a cluster of 12 causal variants; 9 upstream of *RETN* and 3 downstream. Four of the causal variants are eQTLs for *RETN* expression in GTEx. Regulatory effects were found for 9 of the causal variants with predominant effects in immune cells, including promoter and enhancer effects in T-cells, enhancer effects and histone modifications in B-cells, and active enhancer and transcription start site flanks in neutrophils. Whole Exome Sequencing (WES) on a subset of 680 AA individuals detected only 1 genome-wide significant variant (rs4134852,  $p = 1.02 \times 10^{-12}$ ) upstream of *RETN*, suggesting that coding variants are unlikely to account for the GWAS observation. Our GWAS, fine-mapping, transcriptomic and functional annotation findings indicate that circulating resistin levels are determined primarily by noncoding variants upstream of *RETN*.

## PgmNr 1919: Validation and discovery of BMI-related variants in a Northern Nevadan cohort of the Healthy Nevada Project.

### Authors:

### Affiliations:

1) Institute for Health Innovation, Desert Research Institute, Reno, NV, USA; 2) Institute for Health Innovation, Renown Health, Reno, NV, USA; 3) Helix, San Carlos, CA, USA

---

The aggregation of Electronic Health Records (EHRs) and personalized genetics has led to novel discoveries relevant to population health. Here we use the Illumina Human OmniExpress-24 BeadChip and Helix Exome+ sequencing in combination with EHRs from Renown Health in Reno, NV to identify variants associated with BMI and severe class II obesity. Three genome-wide association studies (GWASs) of 500,000 variants on the Illumina platform of 6,645 Healthy Nevada Project participants identified published and novel variants that associated with BMI and obesity. After standard quality control measures, with age and gender as covariates, the first GWAS identified 20 variants associated with BMI ( $p < 1 \times 10^{-5}$ ). When adding Type II Diabetes (DM2) as a comorbidity in the second GWAS, 27 significant variants were identified, with several in common with the BMI-only GWAS. We found 12 variants within the *FTO* gene to be significantly associated with the quantitative BMI trait, an association which has been illustrated in many prior studies. This association was further validated by the Helix Exome+ sequencing of 20,000 additional Healthy Nevada Project (HNP) participants using the same statistical model, in which seven top associations (mean p-value  $7 \times 10^{-13}$ ) are variants in *FTO*. In the original GWAS cohort, *TDH* showed strong associations with BMI (five variants), likely through its secondary association to DM2. *TDH* is a pseudogene, which may be transcribed to an siRNA that regulates gene expression, and is not yet known to have a link to BMI. A third complementary case-control GWAS was performed to examine links with extreme obesity: this identified variants already linked to BMI, with more variants identified in *NEGR1* than in the quantitative BMI GWAS. *NEGR1* likely plays a role in body weight regulation, as identified by knockout mice in prior studies. A novel variant in *PFKFB3*, a gene not yet directly linked to BMI, was strongly associated with obesity in this case-control study and may be protective of developing obesity. Two phenome-wide association studies (PheWASs) examined phenotypic links to BMI and clinical associations to our obesity-associated variants. The first PheWAS identified strong associations between BMI and obesity to DM2, hyperlipidemia, hypertension, sleep apnea, GERD, and asthma. The second showed associations between SNPs in *TDH*, *NEGR1*, and *FAM167A-AS1* to DM2, and SNPs in *CABP5* to IBS. These studies highlight prior and novel links of BMI and obesity.

## PgmNr 1920: Large scale meta-analysis of genome-wide association studies for physical activity highlights shared genetic factors with education and obesity.

Low levels of physical activity (PA) and a sedentary lifestyle (SL) are well-established, modifiable risk factors for human health. Despite being moderately heritable ( $h^2 \sim 40\%$ ), our understanding of genetic factors influencing PA and SL are limited. Therefore, we performed the largest meta-analysis of genome-wide association studies (GWAS) to date, including up to 641,692 individuals of European (94%), African (2%), East Asian (1%), South Asian (1%), and Hispanic (2%) ancestries. We studied self-reported moderate-to-vigorously intensity leisure time PA (MVPA); leisure screen time (LST); sedentary behavior at work and commuting. Sex- and ancestry-specific associations were adjusted for age and study-specific covariates. Summary statistics were meta-analyzed using a fixed-effect, inverse-variance weighted approach.

We identified 123 PA and SL associated loci ( $p < 5 \times 10^{-9}$ ); 95 in European ancestry individuals and 28 additional loci in all ancestries combined. In total, 98 loci had not been identified for PA/SL traits before, 87 of which were previously associated with educational attainment (EA,  $n=81$ ) and/or obesity traits ( $n=77$ ). Genetic correlations between MVPA and LST were modest-to-high ( $r=-0.49$ ), as were their correlations with EA ( $r$  [0.43, 0.65]) and obesity traits ( $r$  [-0.41, -0.23]). We also observed genetic correlations with mental health, cancer and aging ( $r$  [-0.48, 0.45]). Using uni- and multivariable Mendelian Randomization (MR), we found that a 1SD genetically higher LST caused a 0.27SD higher BMI ( $p=3.09 \times 10^{-9}$ ). Conversely, a 1SD genetically higher BMI only caused a 0.09SD higher LST ( $p=7.26 \times 10^{-10}$ ). Multivariable MR showed that the bidirectional causal effects between LST and BMI were independent of EA. However, higher LST caused lower EA through an effect on BMI (univariable  $b=-0.48$ ,  $p=3.76 \times 10^{-30}$ ; multivariable  $b=-0.07$ ,  $p=0.24$ ), while higher EA caused lower LST independently of BMI (univariable  $b=-0.29$ ,  $p=5.55 \times 10^{-17}$ ; multivariable  $b=-0.31$ ,  $p=4.52 \times 10^{-17}$ ). Tissue and pathway analyses showed enrichment of gene expression in the central nervous system, especially in reward-related areas, such as basal ganglia, cerebellum, hippocampus and the limbic system. In addition, variants of known relevance for muscle performance in *ACTN3* showed suggestive associations with MVPA and LST ( $p=4.25 \times 10^{-8}$ ).

Genes in loci identified in our study point to the brain as a key player in PA regulation. Furthermore, we confirm that lower LST has a causal effect on higher BMI.

## PgmNr 1921: Genome-wide association study of circulating liver enzymes in the UK Biobank reveals an expanded role for manganese transporter SLC30A10 in liver health.

**Authors:**

L.D. Ward; H. Tu; M.M. Parker; G. Hinkle; P. Nioi

[View Session](#) [Add to Schedule](#)

**Affiliation:** Alnylam Pharmaceuticals, Cambridge, MA.

---

Liver diseases, including non-alcoholic fatty liver disease, cirrhosis, and hepatocellular carcinoma, represent a substantial area of unmet medical need. Susceptibility to liver disease is heritable, and genetic association studies of circulating liver enzymes have provided several potential therapeutic targets for liver disease, such as PNPLA3 and HSD17B13. Motivated by these examples, we studied genetic associations with alanine aminotransferase (ALT) and aspartate aminotransferase (AST) in 337,151 array-typed individuals and 128,382 exome-sequenced individuals from the UK Biobank. We discover 221 loci associated with ALT, 172 of which were previously unreported, and 263 loci associated with AST, 228 of which were previously unreported. The strongest previously-unreported association affecting both ALT and AST is a missense variant in *SLC30A10*, rs188273166 (Thr95Ile) which associates with higher ALT and AST levels (0.3 SD increase in ALT,  $p = 1.1e-21$ ; 0.4 SD increase in AST,  $p = 1.3e-28$ ). Carriers of this variant also have a higher risk of being diagnosed with ICD10 codes beginning with K75 (other inflammatory liver diseases; OR = 1.1;  $p = 0.03$ ), and have higher liver inflammation measured by hepatic MRI (1.6 SD increase in LIF,  $p = 0.03$ ). This SNP is found in approximately 1 in 500 White British individuals. SLC30A10 is a manganese efflux transporter, and homozygous loss-of-function causes a Mendelian syndrome of hypermanganesemia with dystonia, polycythemia, and hepatic dysfunction. Our results demonstrate for the first time that heterozygous missense mutation of *SLC30A10* is sufficient to cause increased susceptibility to liver damage.

## PgmNr 1922: Oceanian reference panels are crucial for understanding the impact of a Polynesian-specific variant on adiposity in Native Hawaiians.

---

Statistical imputation applied to genome-wide array data is the most cost-effective approach to improve the catalog of genetic variation in a cohort. However, because of ascertainment bias and a lack of representation in reference individuals, studies in minority populations incur greater inaccuracies in imputed genotypes, further contributing to the obstacles to study these populations. Here we examined the severity of such impacts by genotyping a functionally important Polynesian-specific variant, rs373863828 in *CREBRF* gene, in large number of Native Hawaiians (N=3,188) from the Multiethnic Cohort. Consistent with the initial findings in Samoans and other Oceanian populations, we found the variant is strongly and significantly associated with BMI ( $p = 7.5 \times 10^{-5}$ ). We showed that because of the current absence of Polynesian representation in publicly accessible population sequences, this variant or its proxy could not be studied through imputation. Moreover, the association signal at this Polynesian-specific variant could not be captured by alternative approaches such as admixture mapping. In contrast, highly accurate imputation can be achieved even when only a small number (<200) of internally constructed reference individuals were available, which boosts power for association testing (improved  $p = 1.5 \times 10^{-7}$  for BMI), and revealed strong associations with other adiposity and metabolic traits (e.g.  $p = 3 \times 10^{-6}$ , and  $1.4 \times 10^{-4}$  for hip circumference and T2D, respectively, using imputed data on up to 3,936 individuals). Taken together, our results suggest the alarming reality that the lack of representation would inhibit the discovery of functionally important population-specific loci such as *CREBRF*. Yet, they could be easily detected and prioritized with improved representation of diverse populations in sequencing studies.

## PgmNr 1923: The impact of variants in three genes: *MC4R*, *FTO* and *PPARG* in overweight and obesity in a Brazilian population.

Obesity and overweight are worldwide public health problems with relevant impacts on morbidity and mortality. The genetic predisposition is evident but still poorly understood. The majority of variants implicated so far have shown to have very modest contribution to these traits and great variability has been described across populations. In this work, we analyzed the association of three genes: *PPARG* (rs1801282) *FTO* (rs9939609) and *MC4R* (rs17782313) with the presence of overweight and obesity in a large Brazilian population. The case-control study involved 3641 individuals, comprising of 1622 patients with overweight or different degrees of obesity; and 2019 individuals with normal body mass index (BMI). Genotyping was performed by quantitative PCR and allele and genotype frequencies were determined for association analysis. All genes were associated with increased BMI, obesity or both. *MC4R* rs17782313-C was associated with obesity and overweight in both men and women (OR = 1.27,  $p = 0.038$ ). Interestingly for *FTO* the rs9939609-A allele was associated in both sexes however for women it was a risk factor (OR = 1.60,  $p = 0.013$ ) and for men, on the other hand, a protective factor (OR = 0.66,  $p = 0.015$ ) for both obesity and overweight. *PPARG* was the most associated gene in our sample, associated with overweight and all grades of obesity, and interestingly this association was restricted to women (rs1801282-G OR = 1.34,  $p = 0.004$ ). The combined effect of the three risk alleles on overweight and obesity showed an OR of 1.65 ( $p = 0.008$ ) considering both sexes and the association was even more pronounced in women (OR = 1.97,  $p = 0.002$ ). Our findings indicate that the three genes are robustly associated with overweight and different degrees of obesity in the Brazilian population, reaching together a relatively high impact on these traits. For *FTO* and *PPARG* this association was more pronounced or exclusive to women, suggesting a sex-specific genetic effect of these variants.

Insulin resistance (IR) is a common and increasing public health concern that precedes development of type 2 diabetes and cardiovascular disease. While GWAS studies have identified loci associated with IR related traits, environmental risk factors, causal genes, and their mechanisms remain largely unknown. We therefore developed a combined experimental and computational framework to provide mechanistic insights into GWAS loci.

We first model environmental effects on gene expression in liver, fat, and skeletal muscle, three key IR tissues. Specifically, we performed RNA-seq in HepG2 (human hepatocytes), SGBS (human adipocytes), and HMCL-7304 (human skeletal myocytes) cells treated with 21 different environmental perturbations related to IR (234 total samples). We identified thousands of treatment-specific, treatment-by-cell-type-specific, and shared differentially expressed (DE) genes underlying IR response pathways. The largest number of DE genes were observed for glucose (2,853), IGF-1 (1,676), TGFβ1 (1,644), and insulin (1,589) in HepG2 and for dexamethasone (3,706), IL-6 (3,129), TNF-α (2,232), and rosiglitazone (2,096) in SGBS cells.

We then combine these results with GWAS of IR-related traits. We show that genes differentially expressed in multiple treatments and cells were depleted from GWAS results ( $p = 1.41e-02$ ). To distinguish treatments whose association with disease are modifying risk, we compute transcriptional risk scores for each treatment in each cell-type by integrating our DE-by-treatment effects with TWAS effects generated from IR-related GWAS and GTEx eQTLs in IR-relevant tissues. We find several treatments that modify risk of IR-related traits. We further performed co-localization of IR-related trait GWAS and eQTLs from IR-related tissues to identify signals pointing to causal genes in each locus. We identified a single candidate gene for 30% of loci while in 30% of loci multiple genes showed signal. We validate the candidate genes through CRISPR-Cas9 technology in human adipocytes and skeletal muscle cells.

Overall, our results provide a broad resource of dynamics of the transcriptional landscape in IR-related tissues and demonstrate the advantages of large-scale characterization of effects of genetic variation in diversely-stimulated and pathologically-relevant cells.

Investigating the potentially causal effects of childhood obesity on diseases/traits in adulthood could help guide early intervention strategies. Here we aim to assess the causal effects of childhood BMI on adult traits/diseases using 2-sample Mendelian randomization (MR) with current available GWAS summary data. GWAS summary data of childhood BMI were downloaded from the Early Growth Genetics consortium (the sample numbers of the discovery and replication phase were 35,668 and 11,873, respectively). 783 summary datasets for outcomes were collected from public database. For outcomes genetically correlated with childhood BMI, MR estimates using inverse variance weighted analysis and alternate methods (MR-Egger, weighted median, and weighted mode) were performed. Heterogeneity test, MR-Egger, and MR-PRESSO were used to assess horizontal pleiotropy. 139 outcomes (GWAS data derived from at least 46,186 subjects) were genetically correlated with childhood BMI. As it might be expected, MR analyses showed that higher childhood BMI is a risk factor for general health outcomes and socioeconomic status. In addition to the known causal effects of childhood BMI on coronary artery disease, T2D, and osteoarthritis, we also found that higher childhood BMI was associated with increased risk of cholelithiasis (OR = 1.010, CI: 1.006 to 1.014,  $P = 1.62 \times 10^{-7}$ ), increased number of self-reported non-cancer illnesses ( $\beta = 0.1224$ , CI: 0.0830 to 0.1619,  $P = 1.15 \times 10^{-9}$ ), number of treatments taken ( $\beta = 0.1559$ , CI: 0.0990 to 0.2128,  $P = 7.76 \times 10^{-8}$ ) and increased Townsend deprivation index ( $\beta = 0.1201$ , CI: 0.0539 to 0.1863,  $P = 3.79 \times 10^{-4}$ ). For lifestyles, we observed a positive causal association between childhood BMI and adult smoking status ( $\beta = 0.0534$ , CI: 0.0365 to 0.0704,  $P = 6.65 \times 10^{-10}$ ), but childhood BMI was negatively correlated with adulthood alcohol drinking frequency ( $\beta = -0.1591$ , CI: -0.1970 to -0.1212,  $P = 1.90 \times 10^{-16}$ ). In summary, we generated a view of the causal effects of childhood BMI on adulthood traits. Our results suggested that early intervention of childhood BMI may offer help for the improvement of adulthood health status.

**Background:** In observational studies, higher body mass index (BMI) has been associated with increased incidence and mortality of bloodstream infection (BSI) or sepsis in the general population, but with reduced mortality among patients with BSI or sepsis. However, traditional observational studies are subject to bias and confounding. We wanted to evaluate the causal association of BMI with risk and mortality of BSI.

**Methods:** We used a population-based cohort in Norway followed from 1995 to 2017 (The HUNT Study). We carried out linear and non-linear Mendelian randomization analyses, including a wide range of sensitivity analyses to evaluate the robustness of the findings.

**Findings:** Among 55,908 participants, the mean age at enrollment was 48.3 years, 26,324 (47.1%) were men, and mean BMI was 26.3 kg/m<sup>2</sup>. During median 21 years follow-up, 2,547 (4.6%) subjects experienced a BSI and 451 (0.8%) died from BSI. Compared with a genetically-predicted BMI of 25 kg/m<sup>2</sup>, a genetically-predicted BMI of 30 kg/m<sup>2</sup> was associated with a hazard ratio (95% confidence interval) for BSI incidence of 1.78 (1.40 – 2.27) and for BSI mortality of 2.56 (1.31 – 4.99) in the general population, and for mortality of 2.34 (1.11 – 4.94) in an inverse-probability weighted analysis of patients with BSI.

**Interpretation:** Supportive of a causal relationship, genetically-predicted BMI was positively

associated with BSI incidence and mortality. Our findings contradict the “obesity paradox” where previous traditional epidemiological studies have found increasing BMI to be protective in terms of mortality for patients with BSI or sepsis.

## **PgmNr 1927: The causal role of central obesity and hyperuricemia on the risk of metabolic syndrome: Mendelian randomization analysis using 10,000 subjects.**

Hyperuricemia, the predecessor of gout, has been found to cluster with multiple components of metabolic syndrome (MetS). It is unclear whether hyperuricemia is a downstream result of MetS or may play an upstream role in MetS development.

Since central obesity is generally considered as the core of MetS; we investigated the causal relationship between uric acid and components of metabolic syndrome, using central obesity as a positive control. Taking advantage of the data from 10K participants of Taiwan Biobank, we carried out Mendelian randomization analyses with uric acid weighted genetic risk score (WGRS) and waist circumference WGRS as instrumental variables and metabolic syndrome components as the outcomes.

Using a generalized linear model, we found that uric acid WGRS was significantly associated with SBP, DBP, mean arterial pressure, triglyceride (positively for the above), and HDL-C (negatively). But it was not associated with fasting serum glucose, HbA1C, waist circumference, waist/hip ratio or BMI. On the other hand, waist circumference WGRS was associated with all the components of MetS including uric acid.

Our MR investigation confirms that central obesity is a causal agent of all MetS components including hyperuricemia and suggests that hyperuricemia does augment the risk of MetS, but not through accumulating fat or hyperglycemia.

Metabolic syndrome is one of the main causes of morbidity and mortality, and has become a major public health issue over the past decades. However, although the increase in the prevalence of metabolic syndrome is a worldwide trend and differences in prevalence between populations are known, the bulk of research efforts are concentrated on populations of European descent. In this study, we estimated the genetic parameters of triglyceride concentration in over 13,000 Japanese individuals from the Miyagi and Iwate prefectures, Japan, by applying a polygenic model approach. We calculated the heritability due to common genetic variants at the regional genetic level, by scanning the genome using clusters of 50 SNPs. We identified a number of significant loci, such as *LPL*, *APOA5*, and *SIK3*, and quantified their contribution to phenotypic variation. We also analyzed the chromosome heritability and found that it was proportional to the number of significant loci and the strength of the corresponding signals; in other words, the significant regions identified were located on the chromosomes that displayed a high heritability (e.g. chromosomes 8 and 11). This result was somewhat unexpected, given that we had not found this relationship to hold in a previous study that we conducted on other traits closely related to metabolic syndrome.

## PgmNr 1929: An exome-wide association study identifies novel non-synonymous variants associated with type 2 diabetes-related metabolites in the Korean population.

### Authors:

Previously, numerous genetic variants associated with T2D-related metabolites have been reported. Despite the efforts, however, most of the discovered variants were located within non-coding regions and further efforts for identifying coding variants are warranted. In this context, an exome array platform, designed for pursuing potentially functional variants, is an efficient approach to comprehensively catalog coding variants associated with various phenotypes. In this study, we performed an association study using 27,140 non-synonymous variants included in the Illumina HumanExome BeadChip and nine T2D-related metabolites identified by a targeted metabolomics approach for 2,338 Korean individuals from the Korea Association REsource (KARE). A linear regression analysis was performed to identify novel non-synonymous variants associated with T2D-related metabolites by adjusting age, sex, and BMI. Six loci were identified ( $P < 1.8 \times 10^{-6}$ , after the Bonferroni correction for multiple testing) including *CPS1* for glycine, *COL4A3*, *DYNC2H1*, *PTPRH*, *CCDC8* for creatinine, and *CYP4F2* for PC ae C36:0. Among them, *CYP4F2* was previously reported while the remaining five loci were newly associated in this study. Taken together, these findings may highlight the role of coding genetic variants for metabolite processing and enhance the understanding of the underlying biology of T2D-related metabolites.

---

Type 2 diabetes (T2D) affects ~10% of the global population and is a major cause of morbidity and mortality. Genetic variation contributes to T2D risk. While genome-wide association studies (GWAS) have identified >240 genetic loci for T2D, the disease mechanisms underlying these findings are mostly poorly understood. Plasma metabolites may contribute to T2D risk or reflect metabolic changes during T2D development. The investigation of the genetic basis for plasma metabolites has the potential to help us understand T2D disease mechanisms.

We profiled 1,562 plasma metabolites in 6,492 Finns in the METabolic Syndrome In Men (METSIM) study using ultra performance liquid chromatography - tandem mass spectrometry. We genotyped (n=10,066) and exome sequenced (n=9,957, ~80x) nearly all METSIM participants. More recently, we performed deep whole genome sequencing (~24x) in 3,074 METSIM participants and generated an integrated Finnish-specific genotype imputation panel. We imputed the remaining METSIM samples using this population-specific reference panel. We investigated phenotype missingness patterns and experimented with phenotype imputation using several methods including minimum-value, k-nearest neighbor, and random forest methods. In an initial GWAS of 20 amino acids, we confirmed multiple previously identified amino acids genomic regions including loci near *CPS1*, *GLDC*, *PKD1L2*, *ALDH1L1*, *GCSH*, *PRODH*, *ASPG*, *SNAI2*, *GLS2*, *SLC7A6*, and *ADAMTS3*, and implicated apparently novel loci at genome-wide significance ( $P < 5 \times 10^{-8}$ ) proximal to *KDM4C* and *WASHC3* that are relevant to amino acid biosynthesis and transport. We also identified amino acid associations with multiple T2D-associated variants, including variants near *GCKR*. We are continuing to carry out GWAS with each of the remaining plasma metabolites using the combined observed and imputed metabolic values. We plan to further explore shared genetic loci and infer pairwise causal relationships between plasma metabolites, T2D risk, and T2D-related quantitative traits. This research has the potential to discover metabolic biomarkers for T2D early intervention and personalized therapy. The findings will help guide functional experiments for T2D genetic associations and reveal T2D biological pathways.

## PgmNr 1931: Low polygenic risk attenuates the obesity-increasing effects of pathogenic mutations in *MC4R*.

### Authors:

N. Chami<sup>1</sup>; M. Preuss<sup>1</sup>; R.W. Walker<sup>1,2</sup>; A. Moscati<sup>1</sup>; R.J.F. Loos<sup>1,2,3</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) The Charles Bronfman Institute for Personalized Medicine, Icahn School of Medicine at Mount Sinai, New York, NY, USA.; 2) Department of Environmental Medicine and Public Health, Icahn School of Medicine at Mount Sinai, New York, NY, USA; 3) The Mindich Child Health and Development Institute, Icahn School of Medicine at Mount Sinai, New York, NY, USA

**Background:** Melanocortin 4 receptor (MC4R) deficiency, due to protein-altering mutations, is the most common cause of severe and early onset obesity. We examine why some carriers of pathogenic mutations that result in MC4R deficiency remain of normal weight, to gain insight into the mechanisms that control body weight.

**Methods:** We identified 69 obesity-increasing mutations (MAF<0.1%) in *MC4R* reported in the human gene mutation database (HGMD) and Clinvar that were available in ~450,000 individuals of the UK Biobank and calculated their penetrance and effect on obesity (BMI  $\geq 30$  kg/m<sup>2</sup>). We then focused on the most penetrant mutations with the largest effect on obesity and examined differences between normal weight and obese carriers. We calculated a genome-wide polygenic risk score for BMI (PRS<sub>BMI</sub>) to assess the polygenic contribution to body weight in normal weight and obese carriers.

**Results:** Of the 69 mutations, only 11 mutations had moderate to high penetrance ( $\geq 30\%$ ) and increased the odds of obesity by more than twofold. Twenty-nine of the 183 carriers of these 11 mutations were of normal weight. Body composition of normal weight carriers was similar to non-carriers, whereas obese carriers had a somewhat higher BMI (P=0.034) than obese non-carriers, due to greater lean mass (P=0.002). Normal weight carriers more often reported that, already at age 10y, they were thinner/average (72%) compared to obese carriers (48%) (P=0.02). The PRS<sub>BMI</sub> of normal weight carriers (PRS<sub>BMI</sub>= $-0.66 \pm 0.18$ ) was significantly lower than of obese carriers ( $0.40 \pm 0.12$ ; P= $8 \times 10^{-6}$ ), and also lower than that of normal weight non-carriers ( $-0.28 \pm 0.003$ ; P=0.04). Further, among *MC4R* mutation carriers, those with a low PRS<sub>BMI</sub> (bottom quartile) have ~5 kg/m<sup>2</sup> lower BMI (~14 kg of body weight for a 1.7m-tall person) than those with a high PRS<sub>BMI</sub> (top quartile).

**Conclusion:** Only 11 (16%) out of 69 previously reported *MC4R* mutations had high penetrance and increased risk of obesity, highlighting the importance of large-scale data to validate the impact of mutations observed in small-scale and case-focused studies. Furthermore, our results show that despite the key role of *MC4R* in obesity, the obesity-increasing effects of pathogenic *MC4R* mutations can be countered, at least in part, by a low polygenic risk, potentially representing other innate mechanisms implicated in body weight regulation.

## PgmNr 1932: Whole exome sequencing to identify genetic risk variants underlying obesity in pediatric patients.

---

### Introduction:

Childhood obesity is a major health problem in many countries. Its repercussions on health in both childhood and later adult life are well-known. Both genetic and environmental factors play a role in the development of obesity. Unraveling the relevant genes remains important since there is abundant evidence indicating that an individual's genetic background is crucial in determining obesity risk. In this study, we performed whole exome sequencing (WES) in 18 children with obesity to identify genetic variants that may contribute to childhood obesity.

### Methodology:

WES analysis was carried out in 11 males and 7 females [age (mean  $\pm$  SD): 12.8  $\pm$  3.3 years, race/ethnicity: Caucasian (67%), African American descent (28%), Hispanic (5%), body mass index (BMI): 39.7  $\pm$  11.0 kg/m<sup>2</sup>, 157  $\pm$  31 % of 95<sup>th</sup> percentile]. Variant annotation was performed using wANNOVAR. Genes related to obesity were identified from GWAS catalog, OMIM, GeneCards, Genetics Home Reference, NCBI Gene, CDC and PubMed. These obesity genes were then cross-referenced with the annotated WES data. Only the functional variants were selected for further analysis. MutationTaster, M-CAP and CADD were used to predict deleteriousness of amino acid changes. Variants predicted to be deleterious using the three algorithms, designated as pathogenic in ClinVar or generate a premature terminator codon were then analyzed individually for association with obesity.

### Results:

After analysis of WES variant data, we identified 14 DNA variants in the genes *KSR2*, *GIPR*, *POMC*, *PCSK1*, *PPARGC1B*, *SDC3*, *VPS13B*, *UCP2*, *UCP3*, *SDCCAG8* and *CEP290* predicted to be deleterious by several in silico prediction tools. We also found two variants within *BBS2* and *UCP3* that were designated as pathogenic in ClinVar. Of interest is a nonsense mutation that lead to a premature stop codon identified in *VPS13B* gene. This gene is implicated in the development of adipocytes, storage and distribution of fats in the body. Further investigation of this variant exploring its role in obesity may be warranted.

## Conclusion:

Whole exome sequencing and application of *in silico* tools significantly enhanced the discovery of genetic variants. Identification of these obesity-related genes can increase our knowledge about the mechanism of obesity development. It can also help in formulating strategies for the early prediction, prevention and management of obesity.

## PgmNr 1933: Investigating gene x environment interaction in BMI: Sex specific and age specific effects.

### Authors:

A. Dawes

[View Session](#) [Add to Schedule](#)

**Affiliation:** Molecular genetics team, LEVEL 3 RILD RD&E , University of Exeter, Exeter, Devon, England

Obesity is a global epidemic, with 26% UK adults obese in 2016. Body mass index (BMI) is used to classify overweight (BMI >25) and obese (BMI>30) patients. Genome wide association studies (GWAS) have discovered over 250 common variants associated with BMI, thought to increase BMI through a polygenic effect. Whilst BMI is highly heritable, heritability being approximately 70%, there is a considerable amount of variation in this heritability, of which environmental and lifestyle factors are thought to contribute towards. Few studies focus on the interaction of genetic and non-genetic factors, likely due to the lack of power in studies to previously detect small effect sizes.

This project aims to identify environmental and lifestyle factors that may influence the genetic associations with BMI. This project uses genotype and phenotype data from population-based studies, including the UK Biobank and GIANT consortium. We studied the following genetic and lifestyle interactions on BMI: age, sex, socio-economic status, smoking and sunscreen use as a negative control. Seventy-six single nucleotide polymorphisms (SNPs) previously associated with BMI were selected, and a 76-SNP genetic risk score (GRS) was generated. Linear regression interaction analysis using the GRS was used to identify the interaction effects.

The GRS sex Interaction effect compares women against men (0.0028, 95%CI: 0.0016, ?0.0039), while the GRS age interaction effect compares older to younger age groups (0.0034, 95%CI: 0.0023, ?0.0046). There is also evidence of interaction of socio-economic status (0.0021, 95%CI: 0.0009, 0.0031), and smokers (0.0048, 95%CI: 0.0028, 0.0052), but not for the negative control sunscreen use (-0.0023, 95%CI: -0.0038, -0.0007). Results for individual seventy-six SNPs follow similar trends as for the GRS results. The strongest sex interaction effects when compared to our negative control are seen in SEC16B (0.0272795, 95%CI: 0.0163921, 0.0381669) and NT5C2 (0.0213557, 95%CI: 0.0048956, 0.0378158).

In summary, there are sex specific and age specific genetic effects on BMI. Additional work to identify the mechanism of the sex specific and age specific interaction effects on BMI by these two variants is being undertaken. This includes a sex specific and age specific phenome wide association analysis investigation of these two genes against phenotypic traits associated with BMI.

## PgmNr 1934: Clinical utility of polygenic risk prediction for obesity across age, sex, and ancestrally diverse population subgroups.

Obesity results from gradual accumulation of fat over the life course. Because of its early onset, prevention is most effective early in life. Genome-wide association (GWA)-derived polygenic scores (PGS) provide a new tool to identify high-risk individuals that may benefit from additional preventive measures.

Here, we examine the ability of a PGS to predict adult obesity using the latest GWAS meta-analyses data from GIANT and test its performance across diverse sub-populations. Using PRSice, we built a PGS based on summary statistics (2.1M SNPs) of a BMI-GWAS meta-analysis in >322K individuals of European ancestry. The PGS that explained the most BMI variance (7.1%, LD>0.80, P<0.5) in a subset of 10K unrelated European-ancestry individuals of the UK Biobank (UKBB) was used for analyses in unrelated individuals of European (UKBB<sub>EUR</sub> N~405,646), African (UKBB<sub>AFR</sub> N~8,429), Hispanic (HCHS/SOL N~10,122) and East Asian (Biobank Japan (BBJ) N~154,871) ancestry. We tested association of the PGS with BMI and obesity classes I (BMI≥30kg/m<sup>2</sup>; [≥25kg/m<sup>2</sup> BBJ]), II (BMI≥35kg/m<sup>2</sup>; [≥30kg/m<sup>2</sup> BBJ]) and III (BMI≥40kg/m<sup>2</sup>; [≥35kg/m<sup>2</sup> BBJ]) and calculated its ability to predict obesity (Nagelkerke's R<sup>2</sup>; AUC<sub>ROC</sub>; PPV; sensitivity). The PGS explains the most BMI variance (r<sup>2</sup>=6.9%) in the UKBB<sub>EUR</sub>, ~4 times more than in other ancestries (1.7-2%), and slightly more in younger adults and women (except UKBB<sub>EUR</sub>: men>women). The explained variance decreased with

increasing obesity class (UKBB<sub>EUR</sub>  $R^2$ : 6.4-5.7%; other ancestries: 2-1%). Still, the predictive ability increased with increasing obesity class in UKBB<sub>EUR</sub> ( $AUC_{ROC}$  0.64-0.70), and improved when adding age and sex (0.65-0.73). The  $AUC_{ROC}$  in UKBB<sub>AFR</sub> and HCHS/SOL was low ( $<0.60$ ), but higher in BBJ (0.58-0.62). A predictive test that assumes the top PGS decile to predict obesity has a sensitivity of 17% and PPV of 42% in UKBB<sub>EUR</sub>, which increase to 28% and decrease to 4% in class III, resp. While sensitivity was lower in other ancestries, PPV was of similar magnitude.

Thus, the explained variance and predictive ability of the PGS is greater than any score reported before, but does not yet achieve the clinical utility minimum ( $AUC_{ROC} > 0.80$ ). Portability of PGS<sub>EUR</sub> to other ancestries is poor. We expect improvement as we build PGSs on ~40M variants from GIANT's upcoming meta-analyses ( $N > 3M$ ), develop ancestry-specific PGSs, and test their portability. We will also examine the predictive ability of PGSs while considering environmental factors.

## PgmNr 1935: Integrative analysis of GWAS and tissue-specific gene expression identifies candidate causal genes underlying obesity risk.

Obesity, as assessed by body mass index (BMI), is a heritable risk factor for several diseases, affecting >2 billion people worldwide. Genome-wide association studies (GWAS) have identified hundreds of genetic variants influencing obesity risk, mostly in non-coding regions, enriched in the central nervous system. One way to prioritize genes in each locus is to assess whether any of the identified variants are associated with gene expression levels (eQTL). However, the subsequent link from gene expression to disease is rarely made. Summary statistics Mendelian Randomization (MR), or SMR, is an MR approach that integrates GWAS loci with eQTL, and has been used to assess the causal relationship between expression of genes and diseases, such as obesity, using eQTL on whole blood. Tissue-specific information increases power for eQTLs with tissue-specific effects.

Here, we used SMR to prioritize genes within 536 obesity-associated loci by assessing whether observed eQTLs are causally associated with BMI. We integrated brain eQTL from CommonMind Consortium (n=467), ROSMAP (n=494) and GTEx (n=72), and blood eQTL from eQTLGen (n=14,115). We sought further confirmation using other gene-prioritization approaches (DEPICT) and examining the presence of predicted damaging coding variants via Mutation Significance Cutoff (MSC) in each locus.

We identified 119 candidate genes whose expression in blood appear to be causally associated with BMI, and find similar evidence for 163 genes in brain eQTL data (significantly more than in blood, FET  $p < 0.0001$ ), with 20 genes shared in both sets. In addition, 249 genes were prioritized by DEPICT (FDR < 0.05). Finally, 371 genes contain coding variants with predicted damaging effect, 20 of which are rare (MAF < 1%). In total, we identified 756 candidate genes in 351 of the 536 BMI-associated loci, 35 of which were prioritized by more than one line of evidence, e.g. *SLC35E2*, *LUZP1*, *NUCKS1*, *MACF1*, *IPP*, *FAF1*, *NEGR1*, *GPR88* and *ADCY3*. Some of these genes have already been established as obesity genes (*NEGR1*, *ADCY3*, *FAF1*), and others are supported by evidence from animal models (*MACF1*, *GRP88*, *NRXN1*, *NUCKS1*). With additional prioritization tools, we will provide further candidate genes and additional evidence.

The prioritization of likely causal genes is a critical step in the translation of GWAS results into functional follow-up studies to increase our understanding of the underlying biology and, in time, develop better therapeutics for obesity.

A substantial proportion of the heritability of obesity remains unexplained. To explore the contribution of rare variants to obesity, we analyzed whole-exome sequence (WES) data of severe childhood obesity cases (BMI standard deviation score > 3 and age of onset < 10 years) and healthy controls.

In stage 1, we used the WES data (927 cases and 4,057 INTERVAL controls) to perform gene-based and gene-set case-control analysis using all cases and cases stratified by developmental disorder (DD) status ( $N_{DD}=226$ ,  $N_{notDD}=701$ ). We used three nested variant filtering strategies: burden of very rare (minor allele frequency,  $MAF<0.025\%$ ) predicted loss-of-function variants (LOF); burden of very rare ( $MAF<0.025\%$ ) predicted deleterious variants by five *in silico* prediction tools (STRICT); SKAT-O analysis of variants with  $MAF<1\%$  and predicted deleterious by at least one tool (BROAD). Gene-based analyses were performed using SKAT in R. Gene-set analyses were performed using PLINK/SEQ gene-region tests, the SMP utility, and 20K permutations for gene-sets related to monogenic obesity, syndromic obesity, DD, loss-of-function intolerant ( $pLI>0.9$ ), or obesity/ BMI-associated loci (GWAS genes). In stage 2, 9 genes from stage 1 ( $p<10^{-4}$  and odds ratio,  $OR>1$ ) were sequenced in 1,810 cases and 2,647 Fenland controls, and meta-analyzed with stage 1.

We identify three genes (*PHIP*,  $P_{meta}=1.23\times10^{-5}$ ; *DGKI*,  $P_{meta}=7.93\times10^{-4}$ ; *ZMYM4*,  $P_{meta}=3.19\times10^{-7}$ ) with an excess burden of very rare variants predicted to affect function in obese cases compared to controls ( $OR>4.8$ ); *DGKI* and *ZMYM4* are novel. Deletions and frameshifts in *PHIP* have been reported in patients with DD and syndromic obesity. We observe for the first-time association with obesity without DD ( $P_{stage1}=7.00\times10^{-4}$ ,  $P_{stage2}=1.72\times10^{-2}$ ). Gene-set enrichment revealed an excess burden of very rare variants predicted to be deleterious in GWAS genes ( $OR=1.39$ ;  $CI_{95}=1.07,1.80$ ) and  $pLI>0.9$  genes ( $OR=1.17$ ;  $CI_{95}=1.07,1.27$ ). Enrichment was increased for GWAS genes that were also  $pLI>0.9$  ( $OR=3.54$ ;  $CI_{95}=1.80,6.95$ ). Results stratified by DD status suggest that  $pLI>0.9$  genes may have mutations underlying obesity with developmental delay while GWAS genes also  $pLI>0.9$  may point to

genes underlying common obesity.

In conclusion, WES of severe childhood obesity and healthy controls identifies novel genes and gene-sets influencing obesity in a non-fully penetrant manner, provides mechanistic insights and has diagnostic and therapeutic implications.

# PgmNr 1937: The association between the gut virome and adiposity traits in women.

## Aim

The relationship of gut virome with obesity is still not clear. This study systematically investigated the associations between gut virome and multiple adiposity traits in women.

## Methods

This study included 499 Chinese women aged 41-65 years. Total body and regional measures of total mass and fat mass were acquired using the dual-energy X-ray absorptiometry. Fecal samples were collected and analyzed using the Hiseq 4000 platform to obtain viral sequences, which were classified by taxonomic alignment against the NCBI reference genome database using Centrifuge software. The alpha diversity of gut virome was estimated using the Simpson index. The multivariate analysis was used to examine the associations of the alpha diversity and the abundance of individual viruses with multiple adiposity traits [body mass index (BMI), waist circumference (WC), hip circumference (HC), waist/hip ratio (WHR), whole body fat ratio (WBFR), android fat ratio (AFR), gynoid fat ratio (GFR), and android/gynoid fat ratio (AGFR)], with adjustment for age. The false discovery rate method was used for adjusting for multiple testing.

## Results

A total of 393 viruses were identified, 67 of them presented in over 10% of the sample and were subjected to further analysis. The alpha diversity of the gut virome was significantly associated with adiposity traits ( $P = 0.03$ ). Specifically, the Simpson index was significantly associated with BMI ( $\beta = 0.26$ ,  $P = 0.049$ ), WC ( $\beta = 1.12$ ,  $P = 0.002$ ), WHR ( $\beta = 0.008$ ,  $P = 0.009$ ), WBFR ( $\beta = 0.006$ ,  $P = 0.01$ ), AFR ( $\beta = 0.01$ ,  $P = 0.001$ ), and AGFR ( $\beta = 0.01$ ,  $P = 0.03$ ). In the individual virus analysis, three viruses, *Shigella phage SflI*, *Escherichia virus Wphi*, and *Escherichia phage Min27*, were significantly associated with multiple adiposity traits ( $q$  values for the overall tests =  $2.1 \times 10^{-4}$ , 0.008, and 0.036, respectively). Specifically, *Shigella phage SflI* was associated with BMI ( $\beta = 24.07$ ,  $P = 0.03$ ), WC ( $\beta = 89.18$ ,  $P = 0.04$ ), and WHR ( $\beta = 1.24$ ,  $P = 6.1 \times 10^{-6}$ ). *Escherichia virus Wphi* was associated with WC ( $\beta = 29.33$ ,  $P = 0.04$ ), WHR ( $\beta = 0.44$ ,  $P = 5.4 \times 10^{-4}$ ), and AGFR ( $\beta = 0.71$ ,  $P = 0.007$ ). *Escherichia phage Min27* was associated with AFR ( $\beta = -7.81$ ,  $P = 3.9 \times 10^{-4}$ ) and AGFR ( $\beta = -15.33$ ,  $P = 0.002$ ).

## Conclusion

Our study findings, for the first time, suggest the potential contribution of the gut virome in human adiposity traits. These findings may provide further insights into the biological mechanisms linking gut microbiota with the development of obesity in human.

## PgmNr 1938: Association study of *LEP* -2548 G/A polymorphism with obesity in North Indian Punjabi population.

### Authors:

---

Obesity is one of the biggest health epidemic worldwide. It is a well known nutritional disorder among developed countries, and is characterized as a major risk factor for cardiovascular diseases. It is a complex, multifactorial medical condition, affected by a strong interplay among genetic and environmental factors. Obesity is reported to be associated with several genes in addition to known factors, such as diet and lifestyle behavior. Leptin is an adipocyte derived hormone that plays a significant role in homeostatic system, by suppressing food intake and increased energy expenditure by binding to its specific receptor in the hypothalamus. Several mutations in the leptin gene have been shown to cause morbid obesity. Thus, the present study aimed to investigate the association of *LEP* -2548G/A polymorphism with obesity and its related traits in North-Indian Punjabi population. A total of 250 obese subjects and 300 non-obese controls were recruited for the present study from different regions of Punjab. Various anthropometric and physiometric measurements were taken for all the subjects using standardized protocols with written informed consent. Biochemical analysis was performed on the collected blood serum samples to estimate the lipid profile of all the subjects. The *LEP* polymorphism (rs7799039, -2548G/A) was screened using polymerase chain reaction based restriction fragment length polymorphism method and 10% of the samples were confirmed using sanger sequencing method. The frequency of homozygous recessive AA genotype was found to be significantly higher among obese subjects (14%) as compared to non-obese controls (8.3%). The obese subjects possessing the -2548 AA risk genotype had significantly higher BMI, WC, WHR, and TG levels in comparison to GA and GG genotypes. A significant association of -2548 G/A polymorphism was observed in the obese cohort under a recessive model, with the AA genotype providing two fold risk towards the susceptibility of obesity after adjusting for age, gender, diet and lifestyle behavior [OR (95% CI) : 2.06(1.14-3.74), p=0.016]. The -2548 A allele and the selected obesity related covariates accounted for 53%, 26% and 30.2% variation in body mass index (BMI), waist-to-hip ratio (WHR) and triglycerides (TG) respectively. This study provides a evidence of association of *LEP* -2548G/A polymorphism with various anthropometric traits and obesity risk in North Indian Punjabi population.

## PgmNr 1939: Genetic determinants of appetite hormones in adolescence: The Santiago Longitudinal Study (SLS).

**Introduction:** Adolescence is a critical period for the development of obesity and Hispanic/Latinos (H/L) are at especially high risk. Chronic imbalance of energy intake and expenditure, and further poor regulation of appetite leads to the development of obesity. Despite their importance, there is a paucity of studies on the genetic underpinnings of appetite-related hormone levels, in particular during adolescence. Thus, the current study aims to identify genetic factors associated with appetite hormone levels: leptin, adiponectin, ghrelin, and orexin among H/L adolescents.

**Methods:** Fasting serum appetite hormone levels were measured on a total of 543 H/L adolescents from the Santiago Longitudinal Cohort study aged 16-17 years. Genotypes were generated on the Illumina Multiethnic Genotyping Array with imputation to the 1000 Genomes Phase III AMR reference panel. Quality control included individual call rate >90%, SNP call rate >95%, imputation quality >0.5, Effective Allele Frequency (EAF) >0.05, gender mismatch, and ancestry outliers. We assessed the relationship between genetic variants and appetite biomarkers assuming an additive genetic model and adjusting for sex and population structure using principal components.

**Results:** We identified 39 suggestive loci ( $P < 5 \times 10^{-6}$ ,  $\pm 500$ kb, EAF range: 0.05–0.80) across four appetite biomarkers (9 for leptin, 8 for adiponectin, 9 for orexin, and 13 for ghrelin). Our top finding for orexin was for rs8036016 (EAF:0.17, beta:0.11,  $p: 6.8 \times 10^{-8}$ ). This finding is noteworthy as this intronic SNP is in the *GABRB3*, which has been previously associated with BMI and Prader Willi syndrome. Additionally, we generalized several SNP-trait associations previously observed in Non-Hispanic ancestry adults, including 10 SNPs in four different loci (*ADIPOQ*, *ST13P4*, *LYPLAL1*, *RFC4*) for adiponectin. A novel independent secondary signal was observed for adiponectin on chromosome 12, in *NCOR2*.

**Conclusion:** Our study findings demonstrate the importance of considering ancestry-specific variants, along with generalization of genetic variants previously identified in European adults, for a greater understanding of the role of genetic variation on appetite biomarkers. From a public health standpoint, this genetic interrogation of obesity and appetite biomarkers in adolescence will advance science in developmental pathophysiology, particularly relationships between obesity and appetite. Findings from the study need to be replicated in future research.

## PgmNr 1940: Genetic risk score for adult body mass index is associated with child and adolescent weight gain in an African population.

---

Ninety-seven independent single nucleotide polymorphisms (SNPs) are robustly associated with adult body mass index (BMI kg/m<sup>2</sup>) in Caucasian populations. The relevance of such variants in African populations at different stages of the life course (such as childhood) is unclear. We tested whether a genetic risk score composed of the aforementioned SNPs was associated with BMI from infancy to early adulthood. We further tested whether this genetic effect was mediated by conditional weight gain at different growth periods. Finally, we compared these results to a genetic risk score composed of SNPs found to be associated with BMI in this cohort to contrast correlation. We used data from the Birth to Twenty Plus Cohort (Bt20+), for 971 urban South African black children from birth to 18 years. DNA was collected at 13 years old and was genotyped using the Illumina MetaboChip array. The weighted genetic risk score (wGRS) for BMI was constructed based on 71 of the 97 previously reported SNPs. The cross-sectional association between the wGRS and BMI strengthened with age from 5 to 18 years. The significant associations were observed from 11 to 18 years, and peak effect sizes were observed at 13 and 14 years of age. Results from the linear mixed effects models showed significant interactions between the wGRS and age on longitudinal BMI but no such interactions were observed in sex and the wGRS. A higher wGRS was associated with an increased relative risk of belonging to the early onset obese longitudinal BMI trajectory (relative risk = 1.88; 95%CI 1.28 to 2.76) compared to belonging to a normal longitudinal BMI trajectory. Adolescent conditional relative weight gain had a suggestive mediation effect of 56% on the association between wGRS and obesity risk at 18 years. The results suggest that genetic susceptibility to higher adult BMI can be tracked from childhood in this African population. This supports the notion that prevention of adult obesity should begin early in life. The genetic risk score combined with other non-genetic risk factors, such as BMI trajectory membership in our case, has the potential to be used to screen for early identification of individuals at increased risk of obesity and other related NCD risk factors in order to reduce the adverse health risk outcomes later.

## PgmNr 1941: Adiposity genetic risk score predicts the development of obesity from childhood to adulthood.

**Background** The global burden of obesity is rising rapidly. Given its well-known adverse cardiometabolic consequences, we investigated whether genetic risk score (GRS) for adiposity may help to predict the development of obesity across the lifespan.

**Methods** The current study was carried out among 1,111 Bogalusa Heart Study (BHS) participants (782 whites and 329 African-Americans) with genome-wide association study (GWAS) data and at least one childhood and one adulthood measure of BMI. An effect-size weighted adiposity GRS was constructed using 97 independent variants that reached genome-wide significance in previous GWAS meta-analyses of BMI, with participants categorized according to quartile of GRS. Associations of both GRS quartile and the continuous GRS with obesity incidence were assessed in race-stratified analyses using two Cox proportional hazards models. Model 1 adjusted for baseline age, sex and ancestry principal components, while model 2 adjusted for covariables in model 1 along with baseline BMI.

**Results** On average, participants attended 7.6 study visits and were followed-up for approximately 29 years. At baseline, the mean age was 9.9 years and BMI was 17.2 kg/m<sup>2</sup>. Results of model 1 showed a positive, graded association between GRS quartile and incidence of obesity among participants of European ancestry (p-value for linear trend=  $2.50 \times 10^{-5}$ ), with a hazard ratio (HR) [95% confidence interval (CI)] of 1.94 (1.43, 2.64) when comparing the highest GRS quartile to the lowest GRS quartile. Although the association was attenuated when baseline BMI was added to the model (Model 2), with a HR (95% CI) of 1.54 (1.09, 2.19), the association remained statistically significant (p-value for linear trend=  $5.00 \times 10^{-3}$ ). Each standard deviation increase in the continuous GRS conferred a 26% and 15% significantly increased risk of obesity in models 1 and 2, respectively ( $P=2.10 \times 10^{-5}$  and  $1.47 \times 10^{-3}$ , respectively). There was no association between GRS and obesity incidence among African-American participants.

**Conclusion** Our results indicated that adiposity GRS may help to predict the development of obesity in individuals of European ancestry, even after accounting for childhood BMI. Given the rapidly decreasing genotype costs, genetic information should be further evaluated as a tool for targeted early prevention of this condition.

## PgmNr 1942: Integration of body fat and lean mass loci reveals genetic clusters with distinct cardiometabolic effects.

---

Body fat and lean mass play distinct roles in cardiometabolic risk but their genetic drivers have not been studied at scale. To identify genetic loci for body fat percentage (BF%) and fat-free mass index (fat-free mass/height<sup>2</sup>, FFMI), we performed GWAS on 463,352 UK Biobank participants and exome chip meta-analyses on 112,443 individuals. We identified 1,197 loci for BF% or FFMI, of which 209 reached genome-wide significance for both traits ( $p < 5 \times 10^{-9}$ ). Despite pronounced sex differences in BF% and FFMI, only 3% of loci had sex-dimorphic effects. To prioritise genes affecting body composition, we performed conditional analyses at 65 coding variants (MAF < 5%) that reached genome-wide significance. We identified 20 independently associated coding variants, including variants in *ZNF800*, *RAPGEF3*, *PDE3B* and *ZBTB7B*. The latter (MAF = 2.3%) has been reported for higher BMI and we show that it exerts its effect through increased FFMI with no effect on BF%.

To assess the implications of body composition on health, we created genetic scores following K-means clustering on betas for BF%, FFMI, BMI, height, and WHRadjBMI for common variants reaching genome-wide significance. For each cluster, we conducted tissue enrichment analyses using DEPICT, Mendelian randomization analyses for cardiometabolic traits and association testing of cluster-specific genetic scores to traits in 3 cohorts. We identified 6 clusters, of which 3 represent overall large body size (higher BF%, FFMI and BMI) that show enrichment in the central nervous system and associations with higher cardiometabolic risk. Two additional clusters reflect normal weight adiposity (higher BF%, lower BMI and FFMI) that are enriched in digestive, bone, muscle and adipose tissues. Genetic scores for these 2 clusters are positively associated with leptin, inflammatory and glycemic markers and T2D risk. The last cluster, representing gluteofemoral adiposity (higher BF% and BMI, lower WHRadjBMI) is enriched in adipose tissue and associated with lower glycemic markers, a favorable lipid profile and lower T2D and CHD risk.

Systematic integration of associations of BF% and FFMI loci with multiple anthropometric traits can identify genetic clusters with distinct cardiometabolic effects not adequately captured by BMI. Our findings support the notion that genetic susceptibility to high BF% increases cardiometabolic risk even in the context of a lower BMI, and that higher BF% driven by gluteofemoral fat is metabolically favorable.

## PgmNr 1943: Performance of genetic risk scores in a multi-ethnic study.

Genomic studies have provided critical new insight into the biology of complex traits, drug development, and clinical guidelines. However, these studies have overwhelmingly been performed in populations of European descent, biasing our understanding of complex trait genetics.

In light of differential genetic architecture known to exist between populations, biased representation in research can exacerbate existing disease and health care disparities. Critical variants may be missed if they are at a low frequency or completely absent in European populations. Even more concerning, in previous work we showed strong effect-size heterogeneity across ancestries for published GWAS associations. As such, risk prediction scores derived in one population will be unlikely to accurately rank an individual's risk in other populations.

Herein, we describe the recent work of the Population Architecture using Genomics and Epidemiology (PAGE) study to investigate how current derivations of genetic risk prediction tools would perform for cardiometabolic phenotypes in participants of diverse ancestry. Using the PAGE data comprising over 51,000 individuals with globally representative genetic ancestry, we created polygenic risk scores (PRSs) for harmonized cardiometabolic traits based on published effect sizes from established GWAS consortia of predominantly European-descent participants. Race/ethnicity-specific estimates of correlation,  $R^2$ , between the PRS and the measured trait were computed. For all traits, the  $R^2$  for African Americans is ~40-50% smaller than the  $R^2$  for European ancestry; the  $R^2$  for Hispanics and Asians falls in the middle except for lipid traits, where the  $R^2$  for Hispanics is similar to that for European ancestry. Similar trends were also observed when extending this framework to more recent genome-wide risk prediction scores employing millions of variants weighted for European linkage disequilibrium with LDpred. As expected overall, using European-derived SNP weights to generate multi-ethnic PRS results in substantial reduction of prediction accuracy. We describe implications both for understanding genome architecture and for personalized medicine in diverse, modern datasets such as PAGE.

## PgmNr 1944: Association between genetic admixture estimates for 5 ancestral populations and serum lipid levels in Pacific Islanders.

Extensive epidemiological literature has shown differential risks for cardiovascular disorders (CVD) among different ethnic groups across the globe, but whether such differences may be due to genetic or non-genetic factors is hard to dissect due to cultural and environmental confounders. We conducted a community-based study aiming at identifying genetic risk factors for several complex diseases in a high-risk population of Pacific Islanders residing in Guam and Saipan. We analyzed the genetic structure of our study population and individual-level admixture estimates based on unsupervised clustering algorithm implemented in ADMIXTURE software using genome-wide SNP data and a reference panel of diverse global populations. We found that our study population had a high degree of admixture derived from 5 ancestral populations, representing Marianas Islanders (MI) (mean percentage of heritage: 43%), East Asians (EA) (mean: 22%), Micronesians (MC) (mean: 19%), Europeans (EU) (mean: 13%), and Melanesians (mean: 3%). Here, we examined the association of these genetic ancestry estimates with 3 fasting serum lipid measures - total cholesterol (total-C), HDL-C and triglycerides (TG) - in 1,853 subjects. Covariates included age, sex and diabetes. All 3 traits were significantly associated with genetic ancestry ( $p < e-4$  to 0.035). Individuals with MI ancestry tended to have modestly higher total-C than other ancestries. Total-C levels were higher in MI compared to MC ( $\beta = 0.066$  s.d. unit difference between 2 groups,  $p = 0.0076$ ), while the levels were comparable among the other ancestral backgrounds. On the other hand, EA ancestry was associated with the highest HDL-C levels ( $\beta = 0.93$  s.d. unit,  $p < e-4$ , compared to all other ancestries combined), while the levels were comparable among the 4 other ancestral backgrounds. MI ancestry was also associated higher TG levels compared to the other ancestral groups. MI ancestry had significantly higher TG compared to EA ( $\beta = 0.50$  s.d. unit,  $p = 0.0020$ ), EU ( $\beta = 0.70$  s.d. unit,  $p = 0.0079$ ) and MC ( $\beta = 0.86$  s.d. unit,  $p < e-4$ ). In summary, there were significant and large differences in lipid levels among people with different genetic ancestral backgrounds, particularly for HDL-C and TG. Although genetic ancestry estimates may still be confounded by shared environmental factors, the present findings suggest that admixture mapping may be potentially a powerful approach for identifying unique CVD loci in Pacific Islanders.

## PgmNr 1945: Accurate prediction of human height and Body Mass Index (BMI) in Asian population.

High-throughput genotyping technologies such as high-density SNP-array and Next-Generation Sequencing gives us opportunity to understand human complex traits and diseases better. One can perform targeted-sequencing that mostly focuses on disease associated (clinically-associated) rare variants. And we can simply compare all derived variants with known databases, HGMD and ClinVar. However, it is well-known that rare variants could only solve less than 15% of all cases for complex traits. We still do not fully understand every part of our genome, how those non-annotated part could do their role. Polygenic risk scoring (PRS) uses previously reported tens and hundreds of alleles with high odd-ratios. But, we cannot guarantee that those variants are common in general population without any symptoms. Moreover, it would not be possible to estimate complex traits and diseases with such a small number of alleles. Another limitation is that one cannot predict if there is very little previous study. There are several argument that polygenic risk scoring does not doing well in Asian and African populations. We have developed a novel algorithms, RRMS, which can give least number of candidate markers for accurate prediction of traits with low heritability by deep learning method. We have successfully demonstrate our methods to predict human BMI and Height. We were able to select 1,725 SNPs to predict human BMI from 8,840 individuals with correlation  $R=0.7$  (estimated vs. observed). 2,216 SNPs to height with  $R=0.8$ . Previous estimation stated that it requires order of 4 (tens of thousands of markers) to predict heritability range between 0.2 ~ 0.3. It requires thousands of SNPs to predict height and BMI due to low heritability. We have compared with UKBB and KNIH data for validation and ethnic differences. We will show what would be the differences between Caucasian vs. Asian in terms of haplotype and marker effects.

The liver is the largest solid organ and a primary metabolic hub. Recent advances in next generation sequencing allow the study of gene expression profiles of single cells, potentially leading to discovery of new and rare cell sub-populations. In recent years, intact cell nuclei were used to perform single-nuclei RNA-seq (snRNA-seq) for cell types difficult to dissociate and for flash-frozen archived tissue samples. Several studies have reported a high correlation between nuclei and cells relative gene expression. The difference in transcriptomics profiles between defined liver cell populations stems from a precise genetic control of gene expression mostly driven by cell type specific enhancers. HiCap is a targeted chromosome conformation capture technique that allows studying long-range distal interactions between such enhancers and their target promoters. Mass spectrometry-based proteomics analysis are today the first choice to verify the tissue protein levels. In this study, we performed snRNA-seq of a human liver sample to identify sub-populations of cells based on the nuclear transcriptomics. In 4282 single nuclei the average number of active genes were 1377 per nucleus. The major cell types were hepatocytes, sinusoidal endothelial cells, cholangiocytes, Kupffer cells, Nk/T/B cells and interestingly both activated and several groups of inactive hepatic stellate cells. We then integrated long-range HiCap data from the same liver for 23 497 promoters and found 119 233 interactions ( $p < 0.05$ ) to distal elements. We observed reasonable correlation between proteomics and *in silico* snRNA-seq bulk data ( $r = 0.47$ ) using tissue-independent gene-specific protein abundance estimation factors. We specifically looked at genes of medical importance. The *DPYD* gene is involved in the pharmacogenetics of fluoropyrimidines toxicity and some of its variants are analyzed for clinical purposes. We identified a new putative polymorphic regulatory element, which could contribute to variation in toxicity. Hepatocellular carcinoma (HCC) is the most common type of primary liver cancer and we investigated all known risk genes. We found a complex regulatory network for the *SLC2A2* gene with 16 candidate enhancers. Three of them harbor somatic motif breaking and other mutations in HCC in the Pan Cancer Analysis of Whole Genomes dataset and are candidates to contribute to malignancy. Our results highlight the potential of a multi-omics approach in the study of human diseases.

## PgmNr 1947: Genetic architecture of molecular phenotypes and their relationship with the genetics of T2D: A DIRECT study.

While GWAS studies have produced many associations between genetic variants and complex diseases, we still lack an understanding of the cellular changes that mediate their activity. For this, the DIRECT consortium built a cohort of 3,029 prediabetic and newly diagnosed T2D subjects, genotyped and with gene expression, metabolites and targeted proteins measurements in whole blood. Here, we present work on understanding how genetic variants perturb molecular networks, and their relationship with genetics of diseases.

First, we identified 59,972 independent cis-eQTLs for 15,305 genes, 1,593 independent cis-pQTLs for 397 proteins; as well as 2,320 trans-QTLs for 1,670 genes and 6,033 for 224 proteins (FDR 1%). We observed a substantial allelic heterogeneity, with 83.7% of genes and 84.1% of proteins associated with two or more variants, with many signals shared: 413 pQTLs shared lead SNP or were in high LD ( $R^2 > 0.9$ ) with an eQTL for the same gene (*CXCL1*, *IL18*), or nearby genes. However, we saw discordance in effect size across omics with 67% of the strongest pQTLs associated with weaker eQTLs. Across tissues, we identified in blood the majority of the eQTL signals from the 44 GTEx tissues and the InsPIRE pancreatic islets ( $\pi_1$  from 81% (testis) to 98% (brain)). For pQTLs we observed between 4.1% (heart) and 43.1% (adipose) of eQTLs in other tissues as pQTLs in whole blood. However 20 proteins, such as GDF2 and MBL2, had no expression of the corresponding gene in blood, pointing out to genetic regulation of gene expression in other tissues such as liver were detected as pQTLs in blood.

Next, we looked for evidence of shared genetic effects across QTLs and GWAS variants, identifying 99 co-localizing eQTLs and GWAS variants for T2D, including a co-localizing signal for the *TCF7L2* locus in a secondary signal (rs7918400). Although no eQTL was found in blood to share a signal for the strongest known GWAS association (rs7903146). Finally, to investigate how the molecular network responds to T2D development, we looked for evidence of T2D specific genetic regulation identifying 66 significant genotype-by-T2D interactions affecting gene expression and 113 affecting protein levels (FDR 5%).

Our results show how large multi-omics studies in blood can recapitulate the genetic effects from other tissues, suggesting candidate genes for GWAS variants as a consequence of our ability to replicate most genetic effects found in smaller, disease relevant studies.

## PgmNr 1948: Whole genome sequencing identifies novel early onset asthma susceptibility locus.

---

Asthma is one of the most common chronic conditions in children. However, despite the importance of asthma in pediatrics most genetic studies carried out to date have been performed in adults of European ancestry. As such, the basis of early onset asthma remains poorly understood, particularly in individuals of non-European ancestry. Here, we sought to identify genetic determinants of early onset asthma in a discovery cohort of 2113 African American (AA) asthmatics with recurrent exacerbations vs. 2081 AA controls from the Center for Applied Genomics (CAG) biobank at CHOP. Whole genome sequencing (WGS) data was generated on all 4194 samples through the TOPMed program. The replication cohort consisted of 3922 AA samples from the SAPPHIRE cohort, 2088 cases with asthma onset  $\leq 12$  vs and 1834 controls. Replication WGS data was also generated through TOPMed.

Association testing was performed using generalized linear mixed models (GLMM) in GMMAT. GMMAT fits a GLMM with covariate adjustment and random effects to account for population structure and relatedness. Score tests were generated for each variant followed by Wald tests to estimate effect sizes. For rare variants, burden and SKAT tests were carried out using SMMAT.

Association analysis identified multiple genome wide significant SNPs at a novel locus on chr7p15.3 that has not been previously associated with asthma. The association was replicated in an independent cohort of early onset AA asthmatics from the SAPPHIRE study. The associated variants mapped to an intergenic region upstream of *DNAH11* (rs2529168, disc P  $4.7 \times 10^{-8}$ , OR 1.47; rep P 0.018). *DNAH11* encodes a ciliary dynein protein that is involved in the movement of respiratory cilia. Recessive LOF mutations in *DNAH11* result in primary ciliary dyskinesia which is characterized by bronchiectasis and upper respiratory tract infections. Rare variant analysis in *DNAH11* identified 17 potentially pathogenic alleles in the cohort distributed between 12 rare variants. Burden and SKAT tests were not significant, indicating the mutations were unlikely to be driving the association. We report association of variants at 7p15.3 in WGS data from AA children with early onset asthma and recurrent exacerbations, a locus which has not been previously reported in larger GWAS of asthma in European ancestry adults. This study highlights the benefit and necessity of phenotypically targeted studies and the inclusion of ancestrally diverse individuals in genetic studies.

## PgmNr 1949: Genetics of very early onset inflammatory bowel disease: *IFIH1* and *PLCG2* as causative gene loci and evidence for a gene burden model.

---

Very early onset inflammatory bowel disease (VEOIBD) manifests before 6 years of age; early-onset and primary location of inflammation (colon instead of small bowel) makes VEOIBD clinically distinct from adult onset IBD. The frequent occurrence of familial cases implies genetic susceptibility for IBD. As part of the Baylor-Hopkins Center for Mendelian Genomics, we performed WES in a cohort of 25 unrelated probands clinically diagnosed with VEOIBD. We found 6 rare variants (<0.01) in the known IBD gene, *NOD2*, in 6 unrelated probands, including one proband with the known risk allele, *NOD2*-p.R311W. We identified rare, likely loss-of-function (LoF), heterozygous (4 probands) or compound heterozygous (1 proband) variants in *IFIH1* in 5 of 25 probands; in 4 of the 5 families the variant was inherited from an unaffected parent(s): including 3 paternally inherited pedigrees and the proband with compound heterozygous alleles. We also identified 4, rare, heterozygous, functional (3 missense and 1 nonframeshifting) variants in *PLCG2* (4 unrelated probands). Segregation analysis of the *PLCG2* variants in 2 of the 4 families showed the variant to be inherited from the father (one affected and one unaffected). Two probands were double heterozygous for *NOD2* and *PLCG2* rare variants; one of these probands also had a heterozygous, rare (not found in the IBD Exomes Browser), predicted to be deleterious (SIFT, MutationTaster and PolyPhen) *IFIH1* variant (p.Val929Ile). Heterozygous, missense, gain-of-function (GoF) variants in *IFIH1* cause Aicardi-Goutieres syndrome and Singleton-Merten syndrome. Heterozygous LoF variants in *PLCG2* cause familial cold autoinflammatory syndrome and autoinflammation, antibody deficiency, and immune dysregulation syndrome. None of the probands in our cohort had features of syndromes previously associated with *IFIH1* GoF or *PLCG2* LoF variants. An *IFIH1* variant (p.Ile923Val) has previously been shown to account for an IBD GWAS signal, and one patient with autoinflammation, antibody deficiency, and immune dysregulation syndrome has been reported to have ulcerative colitis. Together, these findings implicate heterozygous *IFIH1* (LoF) and *PLCG2* rare variants with incomplete penetrance (possibly caused by maternal imprinting) in the VEOIBD trait and suggest that a gene burden model may contribute to some cases of VEOIBD.

## PgmNr 1950: Understanding the contribution of known cardiovascular-related genes to sudden cardiac death in patients undergoing hemodialysis.

Cardiovascular diseases (CVDs) are the leading causes of death in patients with chronic kidney disease (CKD). In patients requiring dialysis, CVD accounts up to 60% of all deaths. In the general population, atherosclerotic disease (e.g. myocardial infarction) is the primary cause of cardiovascular death, and fewer than 5% of patients have sudden cardiac death (SCD). In contrast, among patients on dialysis, SCD accounts for 25-30% of all CV deaths. The increased frequency of SCD as the cause of cardiovascular fatality in CKD begins prior to the onset of dialysis, indicating that the dialysis procedure is not the only risk. We sought to identify associations between SCD and 174 genes associated with inherited cardiac conditions (ICCs) among patients receiving hemodialysis. Samples are selected from the Evaluation Of Cincacalcet HCl Therapy to Lower Cardiovascular Events (EVOLVE) trial. A clinical events committee adjudicated all participants to determine outcomes. Total of 126 SCD cases (37 African American [AA] and 89 European Ancestry [Eur]) and 107 controls (34 AA and 73 Eur) matched for age, sex, race, dialysis vintage, and diabetes were identified. NextGen sequencing was done using the TruSight Cardio kit (Illumina, San Diego CA). Variants were annotated using ANNOVAR and filtered based on function and gnomAD minor allele frequency (MAF) < 0.05. We conducted burden tests using RVTESTS and RAREMETAL to identify enrichment of variants among cases or controls for SCD. Three distinct models of variant collapsing were tested; 1) individual genes, 2) 17 groups of genes each associated with an ICC (Disease), and 3) 11 groups of genes based on gene function defined by GeneCards (gene function). We identified 4,014 single nucleotide variants (SNVs) in 143 genes. After filtering for predicted function and MAF, 2,109 variants (1,624 in Eur and 1,526 in AA) were retained for analysis. After multiple testing correction, statistical significance threshold was  $p=0.0003$  ( $0.05/143$ ). No statistically significant association between SCD and individual genes was identified. Disease-based burden test did not yield significant associations. Lastly, gene function-based burden test also did not yield any significant associations. In conclusion, we found no statistically significant associations between rare variants among genes associated with inherited cardiac conditions and sudden cardiac death in patients undergoing hemodialysis in this modest sized study.

## PgmNr 1951: Spontaneous *DENND1A* mutations among naturally hyperandrogenic female rhesus macaques associate with multiple phenotypic components of human polycystic ovary syndrome (PCOS).

Polycystic ovary syndrome (PCOS) is a common endocrine disorder affecting about 15% of reproductive aged women. Patients display hyperandrogenism (elevated testosterone (T) levels), disruption of normal ovulation, ovarian release of follicle regulating antimüllerian hormone (AMH), disruption of ovary-stimulating gonadotropin and increased risk for insulin resistance, type 2 diabetes and obesity. Female fetuses exposed to high T levels *in utero* are at increased risk for PCOS. The heritability of PCOS is estimated to be 70% but the particular genes involved are not well understood. GWAS analyses in women have identified several genes of interest, including *ERBB4*, *FSHB* and *DENND1A*. We investigated PCOS-related traits in rhesus macaques (*Macaca mulatta*) in two ways. Experimental exposure of fetal female rhesus macaques to T produces PCOS-like characteristics including adult hyperandrogenism and ovarian dysfunction with hypergonadotropic function, as well as increased visceral fat, insulin resistance and risk for type 2 diabetes. In addition, we identified a separate cohort of naïve female macaques with elevated circulating T (high T). Naturally occurring high T females exhibit infertility, elevated gonadotropin and AMH, insulin resistance and a trend towards higher BMI.

We performed whole genome sequencing on 20 naïve female macaques with high T levels and 21 controls (normal T). We found a missense mutation that alters the highly conserved clathrin binding domain in *DENND1A* that is associated in high T macaques with elevated AMH levels ( $p=2.6 \times 10^{-3}$ ), a risk factor for PCOS in women. This aspartic acid-to-asparagine mutation in *DENND1A* has CADD score of 21, suggesting probable effect on protein function. In addition, the macaque with the highest AMH level is heterozygous for this mutation and a second missense (threonine-to-methionine) change in *DENND1A* protein. The second mutation is also likely to be functional (CADD score 13.7) and is associated with both AMH ( $p < 1.75 \times 10^{-3}$ ) and insulin levels ( $p = 3.08 \times 10^{-6}$ ) in high T female macaques. Meta-analyses of women with PCOS and controls report significant association between a variant adjacent to *DENND1A* and PCOS, with odds ratio 1.22 (Day et al., 2018). These results suggest that naturally occurring genetic variation among rhesus macaques provides a valuable new model of PCOS. Additional studies increasing sample size and extending genetic analyses are in progress.

# PgmNr 1952: Genome-wide meta-analysis revealed multiple novel loci associated with serum uric acid levels in Japanese individuals.

---

**Aims:** Gout is a common arthritis caused by elevated serum uric acid (SUA) levels. Here we investigated loci influencing SUA in a genome-wide meta-analysis with 121,745 Japanese subjects and have compared our results with those of previous GWASs and combined them.

**Methods:** We performed a genome-wide meta-analysis based on three Japanese cohorts including those of the Japan Multi-institutional Collaborative Cohort (J-MICC) Study, the Kita-Nagoya Genomic Epidemiology (KING) Study, and the BioBank Japan (BBJ). We also performed the trans-ethnic meta-analysis across the present study and the Global Urate Genetics Consortium (GUGC)-based study to carry out fine-mapping analysis and identify further novel loci associated with SUA. We compared the SNP-based heritability ( $h^2$ ) of SUA in our Japanese meta-analysis and the GUGC-based study. The heritability estimates were calculated from summary statistics of SNPs, which were assessed in both studies and have MAF  $\geq 1\%$  in both studies.

**Results:** We identified 8,948 variants at 36 genomic loci ( $P < 5 \times 10^{-8}$ ) including eight novel loci. Of these, missense variants of *SESN2* and *PNPLA3* were predicted to be damaging to the function of these proteins; another five loci—*TMEM18*, *TM4SF4*, *MXD3-LMAN2*, *PSORS1C1-PSORS1C2*, and *HNF4A*—are related to cell metabolism, proliferation, or oxidative stress; and the remaining locus, *LINC01578*, is unknown. We also identified 132 correlated genes whose expression levels are associated with SUA-increasing alleles. These genes are enriched for the UniProt transport term, suggesting the importance of transport-related genes in SUA regulation. Furthermore, trans-ethnic meta-analysis across our own meta-analysis and the GUGC has revealed 15 more novel loci associated with SUA. The  $h^2$  (standard error) estimates were 14.0 % (4.3%) for our Japanese study and 14.4% (3.9%) for the European study

**Conclusions:** Our findings provide insight into the pathogenesis, treatment, and prevention of hyperuricemia/gout, and they provide a potential basis for the development of new treatments for these diseases.

## PgmNr 1953: ATP-binding cassette (ABC) transporter recessive mutations in biliary atresia cases.

---

Biliary atresia (BA) is an aggressive neonatal disorder characterized by progressive fibrosclerosing obliteration of the extrahepatic biliary tract in a few weeks after birth. Early surgical intervention by Kasai portoenterostomy to establish bile flow is critical to survival, yet disease progression to liver cirrhosis occurs in many patients, leaving liver transplantation the only option. BA has the highest prevalence of 1/5000 live births in the Southeast Asian population, 3 to 4 times higher than the US and European populations. Pathogenesis of BA remains uncertain. Consistent and robust evidence supporting theories of viral infection, immune dysregulation, environmental and multifactorial causes are yet to be established. Multiple genetic studies in different ethnic groups have identified *ADD3* as a susceptibility gene of BA, yet disease-causal genetic risk factor is still in search. We conducted a whole exome sequencing study on 83 trios from the Southeast Asian population, and identified 148 rare non-synonymous *de novo* and inherited recessive mutations in 135 genes that were predicted to be damaging, and expressed in liver or bile duct tissues according to public databases and in-house BA liver organoid gene expression dataset. KEGG pathway analysis showed that ATP-binding cassette (ABC) transporter was significantly enriched (false discovery rate: 0.042), involving 4 genes (*ABCA7*, *ABCA8*, *ABCC6*, *CFTR*) with recessive variants in 4 subjects. In particular, recessive *ABCA7* variants were carried by 2 BA subjects, one of which had 2 *ABCA7* and a *ABCC6* recessive mutations. In mice, *Abcc6* deficiency causes altered gene expression of other bile salt and lipid transporters. *ABCA7* is involved in lipid transport and plays an important role in lipid homeostasis. *ABCA8* regulates lipid efflux, whereas *CFTR* regulates bile secretion at the apical membrane of biliary epithelial cells, and is associated with cystic fibrosis. Since altered bile acid metabolism can induce cholestatic liver injury, our initial findings warrant further functional studies on the specific functions of these ABC transporters in liver and biliary tissues, and their potential link with BA.

## PgmNr 1954: A fifty-year follow-up of familial Hirschsprung disease.

### Authors:

---

We describe familial Hirschsprung disease (OMIM 142623) with histologically proven congenital intestinal aganglionosis in the probanda, her two affected brothers, her two affected daughters and in the extended family three first cousins (two males and one female). Originally this family was described in 1967 as part of systematic study of the genetics of Hirschsprung disease (Family 21 in E. Passarge, New Eng J Med 1967; 276:138-143). It presumably involves the highest number of affected members documented. In all patients the non-syndromic long segment disease (HSCR type 2) is present. At the age of 8 months in 1965 the probanda was admitted to Cincinnati Children's Hospital for ileostomy. In part she was then under the care of one of the authors (EP), at that time a resident in pediatrics. During the following 15 years she required 41 surgical procedures of the GI tract or the rectum. In spite of the complicated course she is well adjusted to her disorder. This family was recently re-investigated, including two daughters of the probanda also affected with long segment Hirschsprung disease. In one daughter a 40-cm aganglionic segment of the colon has been removed, in the other a 26-cm long segment. Both daughters also have required multiple additional surgical procedures. A variant S32L has been detected in the *RET* gene (OMIM 164761) in the mother and the two affected daughters. However, in the light of the complex genetics of Hirschsprung disease this is unlikely to be the only cause. Further molecular studies are under way.

Hirschsprung disease, a genetically heterogeneous and clinically variable disorder, results from the absence or malfunction of intestinal ganglion cells. Functionally variants (mutations) in the *RET* gene and three non-coding *RET* variants (rs2435357, rs2506030, rs7069590) and in at least 13 other genes and five predisposing regions contribute in different ways to the etiology.

At least three signal effector pathways are required for normal migration and development of intramural intestinal ganglion cells, (i) the RET tyrosine-kinase receptor and its ligand GDNF (glial-cell-derived neurotrophic factor, OMIM 600837), (ii) endothelin type B receptor (EDNRB, OMIM 600837) and its ligand EDN3 (endothelin 3, OMIM 131244), (iii) SOX10 transcription factor (OMIM 602229). Owing to reduced penetrance a functionally relevant variant in each of the genes involved is neither necessary nor sufficient to cause intestinal aganglionosis.

## PgmNr 1955: Genome-environment interactions for inflammatory bowel disease in the UK Biobank.

### Authors:

A. Yang; L. Jostins-Dean

[View Session](#) [Add to Schedule](#)

**Affiliation:** Kennedy Institute of Rheumatology, University of Oxford, Oxford, United Kingdom

**Introduction:** Inflammatory bowel disease (IBD) is a relapsing, debilitating condition with rising global prevalence that comprises Crohn's disease (CD) and ulcerative colitis (UC). It results from an inappropriate immune response to gut bacteria, but the causes of this dysbiosis are not well understood. Previous studies have identified 260 genetic variants and ~25 environmental predictors for IBD. While a combination of genetic susceptibility and environmental exposure is thought to lead to IBD, few large gene-environment interaction studies have been performed, so this combined genetic-environmental burden remains poorly characterized. We therefore embarked on a large-scale study of genome-environment (specifically, polygenic risk score (PRS)-environment) interactions that predict IBD.

**Methods:** For this study we used the UK Biobank, a prospective cohort study collecting genome-wide genotyping and phenotype data for ~500,000 participants. Using self-report and electronic health records, we identified 1948 CD and 3720 UC patients after quality control. We used 232 known genetic variants to construct PRSs for CD, UC, and overall IBD, which all associated with their respective diseases ( $p < 1e-16$ ). Based on prior literature and biological plausibility, we tested 27 candidate environmental variables and their interactions with the PRSs for association with CD, UC, or IBD in a logistic regression model.

**Results:** We found 15 environmental variables that associate with IBD, some of which confirm previous studies, others which differ from previous reports or are novel. For example, we replicated associations for red meat consumption (OR for CD=1.05,  $p=7e-4$ ), appendectomy (OR for IBD=0.37,  $p=1e-6$ ), years on hormone replacement therapy (HRT) (OR for CD=1.09 per SD years,  $p=3e-5$ ), dietary fiber (OR for IBD per SD fiber=0.94,  $p=4e-3$ ), and years of cigarette smoking (OR for CD=1.10 per SD years,  $p=7e-3$ ; OR for UC=0.86,  $p=4e-7$ ). Meanwhile, we found a novel association for maternal smoking around birth (OR for IBD=1.10,  $p=9e-4$ ). In addition, we uncovered a new PRS-dietary fiber interaction (OR interaction for IBD=0.94 per SD fiber per SD PRS,  $p=9e-3$ ) and new PRS-HRT interactions (OR interaction for UC=0.94 per SD HRT per SD PRS,  $p=7e-4$ ).

We will also present estimates of gene-environment interactions for individual IBD risk variants, and an estimate of the total additional heritability of IBD risk explainable by gene-environment interactions.

---

Mayer Rokitansky Küster Hauser (MRKH) syndrome represents a disorder of Mullerian development with an incidence of 1/5000 that can include renal aplasia and cervical somite anomalies. While functional models have elucidated numerous candidate genes, only *WNT4* (OMIM 158330) variants have been firmly associated with a phenotype of MRKH with hyperandrogenism. Familial clustering of cases further suggests MRKH has a genetic etiology, and human genetics studies have identified candidate genes and genomic regions that contribute to a proportion of cases. DNA extracted from 71 probands with phenotypic features consistent with MRKH was submitted for exome sequencing (ES). ES data were analyzed for rare, likely deleterious SNVs and CNVs.

Cohort wide analysis for a burden of rare variants within a single gene identified likely damaging variants in *GREB1L* (OMIM 617805), a known disease gene for renal hypoplasia and uterine agenesis, in 5 probands. An additional case including deletion of *GREB1L* was found by CNV analysis. In screening for rare, predicted deleterious variants in 19 candidate genes, potential molecular diagnoses in 6 cases were found involving *PAX8*, *LHX1*, *GATA3*, *HOXA13*, and *TBX6*. CNV analysis revealed an approximately 500kb deletion in 16p11.2, involving *TBX6*, in 3 additional cases. In two cases, likely damaging variants in known disease genes for syndromes with overlapping phenotypic features were found (*TBX3*, *MNX1*).

MRKH has been suggested to be a genetically heterogeneous condition with studies describing candidate gene variants in one or two probands. Copy-number variation of genomic regions, such as 16p11.2, have been described in multiple cases suggesting that these contribute to a substantial portion of heritability in MRKH. In our study, SNV and CNV involving *TBX6* and *GREB1L* are proposed molecular diagnoses for 11/71 (15%) of cases, supporting them as candidate disease genes in MRKH. Furthermore, the finding of 3 known disease genes associated with syndromic features that overlap with MRKH (*GREB1L*, *MNX1*, and *TBX3*) in 7 probands suggests that candidate gene approaches should include genes associated with component phenotypic features of interest (e.g. abnormalities of uterine development) rather than limiting candidate genes to those associated with the exact

manifestation of the studied disease (e.g. MRKH). This approach will enable further elucidation of the full spectrum of clinical presentation associated with variants in known disease genes.

## Introduction

Despite its high prevalence, the genetic basis of irritable bowel syndrome (IBS) is poorly understood, with only a single known locus passing the genome-wide significance threshold in previous genome-wide association studies (GWAS). The wealth of phenotypical and genomic data contained in the UK Biobank (UKBB) typically allows for more powerful analyses. However, the IBS diagnoses needed for this purpose are recorded using various definitions for different subsets of the population. We combined data covering multiple definitions of IBS in a GWAS meta-analysis to identify novel genetic risk loci.

## Methods

We developed a digestive health questionnaire for the UKBB, asking about a previous diagnosis of IBS and symptoms relevant for a diagnosis via Rome III Criteria. We combined the 174,778 responses with existing UKBB data in the form of self-reported illnesses (at UKBB enrolment) and hospital in-patient data supplied by clinicians (ICD-10 codes). We compared these diagnostic sources by conducting a GWAS for each definition using linear mixed models as implemented in BOLT-LMM, before pooling UKBB cases and controls with independent cohorts to maximize power. Genome-wide significant signals were then included in a replication study by 23andMe.

## Results

IBS diagnoses arrived at by different means showed poor overlap (3.8 - 26.8% pairwise, among fully-examined patients), but nonetheless produced highly consistent, yet not identical, associations (min. pairwise  $r_g=0.70$ ,  $SE=0.06$ ) in individual GWAS. By combining IBS diagnoses across these diagnostic sources in the UKBB (40,548 cases, 360,845 controls) and several other cohorts from the Bellygenes initiative (12,852 cases, 139,981 controls), for a total of 53,400 cases and 433,201 controls, we identified 6 novel associations. These were provisionally mapped to genes involved in colon cell cycle control (*FAM120A*, *PHF2*) and bipolar disorder (*DOCK9*). All signals were subsequently replicated in an independent 23andMe cohort (205,252 self-reported cases and 1,384,055 controls). Genome-wide results (observed  $h^2=0.0247$ , 95% CI [0.022, 0.028], LDSC intercept=0.9951,  $SE=0.007$ ) show considerable overlap with those previously reported for insomnia ( $r_g=0.42$ ,  $SE=0.05$ ), depression ( $r_g=0.53$ ,  $SE=0.05$ ) and neuroticism ( $r_g=0.63$ ,  $SE=0.09$ ).

## Conclusion

We have uncovered novel genetic risk loci for IBS susceptibility that emphasize the potential role of the brain-gut axis in IBS development.

## PgmNr 1958: The genetic architecture of liver cirrhosis: A multi-trait genome-wide association analysis.

Liver cirrhosis is a leading cause of death worldwide and plasma levels of alanine transaminase levels are a marker of liver injury. The genetic architecture of liver cirrhosis is largely unknown. We undertook a multi-trait genome-wide association analysis including alanine transaminase levels (n=382895, UK Biobank), 5770 cases of cirrhosis and 572850 controls from seven cohorts to identify novel genetic determinants of cirrhosis. We identified 12 novel loci at genome-wide significance ( $p < 5 \times 10^{-8}$ ). A variant downstream of *EFNA1*, encoding the ephrin A1 receptor expressed on hepatocytes, associated with reduced cirrhosis risk (OR 0.90,  $1.7 \times 10^{-37}$ ). A missense variant in *APOE* (rs429358, C1310R) associated with protection from cirrhosis (OR 0.84,  $p = 9.2 \times 10^{-38}$ ) but higher risk of coronary artery disease (OR 1.10,  $p = 2 \times 10^{-9}$ ). A common missense variant in *MARC1* (rs2642438, A165T), an enzyme expressed in hepatocytes, associated with protection from cirrhosis (OR 0.91,  $p = 1.2 \times 10^{-44}$ ) and lower total cholesterol levels ( $-0.03$  SD,  $p = 1.9 \times 10^{-36}$ ). An independent rare predicted damaging missense variant in *MARC1* (M187K, 0.9% frequency) also associated with lower total cholesterol levels ( $-0.05$  SD,  $p = 2 \times 10^{-8}$ ) and protection from cirrhosis (OR 0.75,  $p = 0.01$ ). We developed a polygenic score for cirrhosis using 16 independent genome-wide significant variants. Individuals in the top 1% of the polygenic score were at similar risk of cirrhosis (OR 2.80,  $p = 6 \times 10^{-14}$ ) as homozygous carriers of known variants causing hereditary hemochromatosis (OR 3.24,  $p < 2 \times 10^{-18}$ ) or alpha-1-antitrypsin disease (OR 3.36,  $p = 0.06$ ) and had a five-fold increased risk of death from liver disease (OR 5.02,  $p = 4.5 \times 10^{-9}$ ). These findings identify novel therapeutic targets for the prevention and treatment of cirrhosis and suggest that a polygenic score could be used to identify individuals predisposed to liver cirrhosis.

## PgmNr 1959: Large-scale genome-wide association study identifies candidate genes for childhood steroid-sensitive nephrotic syndrome.

---

Idiopathic nephrotic syndrome (INS) is the most common cause of kidney disease in children, about 80% of pediatric patients respond to steroid treatment and are classified as steroid-sensitive NS (SSNS). Previous genome-wide association studies (GWASs) have identified *HLA-DR/DQ* as the predominant genetic risk factors of childhood SSNS in multiple populations. Our group reported the first GWAS for childhood SSNS in Japanese, genome-wide significant associations were identified in *HLA-DR/DQ* region (*J Am Soc Nephrol*, 2018).

To identify more loci contributing to susceptibility to childhood SSNS, we performed an extended GWAS with the largest sample size to date. In the discovery stage, 1,018 patients with childhood-onset SSNS and 3,331 adult healthy controls with Japanese ancestry were genotyped using Affymetrix 'Japonica Array'. Whole-genome imputation was conducted using a phased reference panel of 2,036 healthy Japanese individuals (2KJPN panel). Quality control (QC) was performed to exclude the samples with low calling rate (<97%) and the variants with low genotyping rate (<97%), minor allele frequency (MAF) <0.5% and Hardy-Weinberg equilibrium (HWE) test P-value <1×10<sup>-5</sup>. Association analysis was conducted using logistic regression with the adjustment of gender and principal components. In discovery stage, the most significant association was detected in *HLA-DR/DQ* region (P=2.80×10<sup>-33</sup>, odds ratio (OR)=2.49). HLA fine-mapping was done by imputing classical HLA genes (*HLA-A*, *-C*, *-B*, *-DRB1*, *-DQB1*, *-DPA1* and *-DPB1*), 870 cases and 2,903 controls passed the post-imputation QC (call threshold>0.4). *HLA-DRB1\*08:02-DQB1\*03:02* was identified as the most significantly susceptible haplotype (P-value after multiple corrections [Pc]=1.16×10<sup>-22</sup>, OR=3.38), while *HLA-DRB1\*13:02-DQB1\*06:04* was the most significant protective haplotype (Pc=1.63×10<sup>-16</sup>, OR=0.18). Heterozygous patients with *HLA-DRB1\*08:02-DQB1\*03:02* and *HLA-DRB1\*13:02-DQB1\*06:04* present at lower frequency (1/870=0.11%) than in healthy individuals (15/2903=0.52%), although the difference is not significant (P=0.14), suggesting a dominant effect of the protective haplotype over the susceptible haplotype. Furthermore, two regions on chromosome 19 and 9 achieved genome-wide significance (P=4.94×10<sup>-20</sup>, OR=1.90; P=2.54×10<sup>-8</sup>, OR=0.72). Replication studies were successfully performed in other Asian sample sets.

## Background

Serum alanine aminotransferase (ALT) level is an inflammatory marker for patients with hepatitis C virus (HCV) infection. Patients with elevated ALT levels had increased risk for hepatocellular carcinoma. We performed a genome-wide association study to explore single nucleotide polymorphisms (SNPs) associated with serum ALT levels and validated the findings in an external set.

## Methods

In genome-wide discovery phase we included 892 anti-HCV seropositives seronegative for hepatitis B surface antigen. The serum ALT levels were measured at baseline and during the follow-up period from 1991 to 2005. All of the study participants were free of hepatocellular carcinoma. They were examined by the Axiom™ Genome-Wide CHB SNP array. SNPs with call-rate < 97%, minor allele frequency < 5%, and deviating from Hardy-Weinberg equilibrium ( $p < 10^{-6}$ ) were excluded. Baseline serum ALT level was treated as a quantitative trait in the analyses. Additive models were used to estimate the effect of the SNPs. Internal validation was performed on repeated serum ALT measurements of the same study participants to evaluate whether these SNPs were associated with the long-term changing patterns of ALT levels. In addition, external validation was performed on 496 study participants with the same criteria in Taiwan Biobank. Logistic regressions were used to estimate odds ratios (ORs) and 95% confidence intervals (CIs) of the SNPs associated with serum ALT levels ( $> 45$  vs.  $\leq 45$  U/L).

## Results

Among 806 study participants passing quality control, 357 (44.3%) were with serum ALT levels  $\leq 15$  U/L, 319 (39.6%) (15, 45] U/L, and 130 (16.1%)  $> 45$  U/L. Among 564,464 SNPs included in the analyses, ten candidate SNPs had  $p$  value  $< 10^{-5}$ . Based on serial measurements of serum ALT levels, there were 158 (19.6%) had ALT persistently  $\leq 15$  U/L, 327 (40.6%) ever  $> 15$  U/L but never  $> 45$ , and 321 (39.8%) ever  $> 45$  U/L. There were six SNPs located in chromosome 9, 11, 13, 14 and 15 were significantly associated with serum ALT levels ever  $> 45$  U/L, showing consistent associations with elevated serum ALT levels. Finally, we found rs12376677 [OR: 1.75 (1.22-2.51)] and rs568800 [OR: 1.32 (1.06-1.64)] were associated with elevated serum ALT levels among individuals with HCV infection in the external validation set.

## Conclusions

Genetic variants were found to be associated with elevated serum ALT levels. The potential mechanisms for these SNPs need further investigations.

## PgmNr 1961: Identification of susceptibility loci for reproductive traits in Samoan women.

---

Obesity is a global public health problem with severe effects on not only cardiovascular health but also reproductive health in women. Menstrual irregularities and a wide spectrum of reproductive endocrine disorders are associated with higher body mass index (BMI). The high prevalence of female obesity (66.3%) in Samoa and the population's genetic isolation make it an ideal population for discovery of susceptibility genes involved in female reproductive phenotypes.

To detect genes and variants associated with reproductive traits in Samoan women in the Soifua Manuia Study, we performed GWAS with genotyped and imputed variants (via a Samoan-specific reference panel) for levels of biomarkers related to ovarian health and a type of infertility called polycystic ovary syndrome (PCOS) (1) anti-Müllerian hormone (AMH,  $n=831$ ), (2) total testosterone (TT,  $n=790$ ) and (3) sex hormone binding globulin (SHBG,  $n=995$ ). Serum TT and SHBG levels were assayed with a chemiluminescent automated immunoassay, and AMH with an ultrasensitive ELISA assay. Association of SNPs with  $MAF \geq 0.01$  was assessed using linear mixed model adjusted for age, age<sup>2</sup>, principal components of ancestry, and empirical kinship.

For testosterone, we observe genome-wide significant ( $p < 5 \times 10^{-8}$ ) SNPs on 9q34.2 in the intergenic region between *LCN1P1* and *ABO* with the highest peak at rs9411365 ( $p = 3.75 \times 10^{-9}$ ). *LCN1P1*, lipocalin 1 pseudogene 1, is expressed in ovaries and may bind testosterone as does lipocalin 1. For SHBG, the top 2 SNPs are in 6q23.3 (rs4270801,  $p = 1.95 \times 10^{-7}$ ) and in 12q23.3 downstream of *CASC18* (rs17037733,  $p = 5.18 \times 10^{-7}$ ). rs4270801 is located downstream of *MYB* 5kb distal of *MIR548A2* and has potential regulatory function (RegulomeDB score=4). For AMH, the 2 top SNPs are in 14q24.3 (rs7156476,  $p = 1.75 \times 10^{-6}$ ) and in 9q31.1 (rs1008300304,  $p = 1.93 \times 10^{-6}$ ). rs7156476 (Samoan MAF=0.13, non-Samoan MAF=0.48) is located proximally to *FOS* which acts as a gonadotropin-releasing hormone repressor. rs1008300304 (Samoan MAF=0.017, non-Samoan MAF=0.00016) is in intron 3 of *SLC44A1* and is 1Mbp proximal to variants associated with age at menarche in an earlier candidate gene study. In total, 10 loci for TT, 18 loci for SHBG and 9 loci for

AMH were suggestively significant ( $p < 10^{-5}$ ).

Additional models that adjust for covariates such as BMI, smoking and menstrual status are necessary to refine these findings. Subsequent replication in Samoans and other Polynesians is needed to validate these findings.

## PgmNr 1962: Whole exome sequencing of congenital isolated hypogonadotropic hypogonadism reveals known and novel candidate genes.

---

Congenital isolated hypogonadotropic hypogonadism (IHH) is a highly heterogeneous disorder, both clinically and genetically, which leads to delayed puberty and infertility due to developmental abnormalities of the reproductive system. Dozens of genes were found responsible for the pathogenesis of IHH to date. However, due to its incomplete penetrance and complexity, the molecular basis of IHH and its contribution remain elusive, and genome-wide systematic analysis of patients with IHH is still lacking. Here, using whole exome sequencing (WES), 18 unrelated males with IHH and their normal parents were enrolled for screening known genes related to IHH and analyzing novel candidate genes with 2500 in-house healthy control individuals. Ten coding variants of 7 known IHH genes (*FGFR1*, *PROKR2*, *CHD7*, *ANOS1*, *PNPLA6*, *POLR3A*) and eighteen variants of 18 novel candidate genes are identified in 17/18 (94.4%) patients. All of variants we identified are heterozygous. The novel candidate genes we found in this study mainly participate in development of olfactory bulb, migration of GnRH neuron and regulation of key signal pathway in forebrain. In addition, half of cases (9/17, 52.9%) harbor at least two mutations in distinct genes. Interestingly, the heterozygous mutation, *PROKR2* W178S, previously reported several times, is recurrent in three patients in our cohort along with other mutations of different genes. In all, the results of our study provided a mutational landscape for patients with IHH and strongly suggested that IHH is in favor of polygenic model.

### Background

Haptoglobin (*HP*) is the primary endogenous scavenger for cell free hemoglobin (CFH) released during hemolysis. CFH is present in 80% of septic ICU patients. Higher CFH levels correlate with worse organ dysfunction and mortality. A common *HP* genetic variant *HP2* cannot scavenge CFH as effectively as wild type *HP1*. Using a murine sepsis model and a cohort of septic ICU patients, we tested the hypothesis that individuals with *HP2* would have increased lung inflammation and injury, and increased risk for the acute respiratory distress syndrome (ARDS).

### Methods

In transgenic littermate mice homozygous for murine homologues of human *HP1* and *HP2*, we modeled polymicrobial sepsis with elevated CFH by injection of intraperitoneal cecal slurry and intravenous CFH. We measured survival at 72 hours, and lung inflammatory markers myeloperoxidase (MPO) activity and CXCL1 levels from bronchoalveolar lavage (BAL) fluid. We quantified lung microvascular permeability in excised whole lungs by Angiosense<sup>680</sup> NIR imaging and lung endothelial apoptosis by TUNEL assay. In a cohort of septic critically ill adults, we genotyped *HP* in 344 patients by real-time PCR and imputed *HP* genotype from Illumina microarray data in an additional 152 patients. We defined ARDS cases by the Berlin Criteria for at least one day during the first four ICU days. We used logistic regression to measure *HP* genotype's association with ARDS, controlling for clinical risk factors.

### Results

In the murine sepsis model, *HP2* homozygotes (*HP2-2*) had decreased survival at 72 hours ( $P = 0.03$ ) and increased lung inflammatory markers: both MPO activity ( $P=0.014$ ) and BAL CXCL1 ( $P=0.011$ ). *HP2-2* mouse lungs had worse vascular permeability ( $P=0.037$ ) and increased endothelial apoptosis

( $P=0.004$ ). In 496 septic ICU patients, 76 (15.3%) were *HP1-1*, 196 (39.5%) were *HP2-2*, and 224 (45.2%) were heterozygotes. 185 (35.8%) developed ARDS. Each *HP2* allele increased ARDS risk by  $OR=1.41$  (95% CI: 1.06-1.88,  $P=0.018$ ) when controlling for common clinical risk factors. Notably, *HP2* affected ARDS risk only in patients with elevated CFH levels ( $P=0.026$ ,  $N=411$  for elevated CFH vs  $P=0.46$ ,  $N=81$  for no CFH).

### *Conclusions*

Septic *HP2-2* mice develop more severe acute lung injury compared to wild type *HP1-1*, and humans with *HP2* have increased ARDS risk during sepsis when CFH levels are elevated. Genotyping the *HP2* variant may have use in guiding risk-stratification and development of novel therapies targeting CFH as an injury mediator in ARDS.

---

Chronic obstructive pulmonary disease (COPD), diagnosed by reduced lung function, is a leading cause of morbidity and mortality. We performed whole genome sequence (WGS) analysis of lung function and COPD in a multi-ethnic sample of 10,678 participants from population- and family-based studies, and 8,499 individuals from COPD-ascertained studies in the NHLBI Trans-Omics for Precision Medicine (TOPMed) Program. We recapitulated 11 known GWAS loci and identified 21 distinct novel associations, including four common variants from stratified analysis of African Americans. Two novel

common variants showed evidence of replication in the UK Biobank consisting of 321,047 White British samples (rs74469188: nearest gene = *CMIP*,  $P_{\text{discovery}}=2.3\times10^{-8}$ ,  $P_{\text{replicate}}=1.4\times10^{-5}$ ; rs7188378: nearest gene = *FTO*,  $P_{\text{discovery}}=3.4\times10^{-8}$ ,  $P_{\text{replicate}}=2.0\times10^{-4}$ ). For rs5953026 identified for FVC in TOPMed White samples, it had a significant association with increased peak expiratory flow in UK Biobank (nearest gene = *ZNF157*,  $P_{\text{discovery}}=3.3\times10^{-8}$ ,  $P_{\text{replicate}}=0.0018$ ). In the gene-based burden test using rare putative loss of function (pLoF) variant, *MMP25* and *ARHGEF17* were significantly associated with FVC and FEV1/FVC, respectively (*MMP25*: 15 rare pLoF variants,  $P_{\text{burden}}=9.2\times10^{-7}$ ; *ARHGEF17*: 5 rare pLoF variants,  $P_{\text{burden}}=7.7\times10^{-5}$ ). Phenome-wide analysis in the UK Biobank demonstrated associations with respiratory failure and pulmonary hypertension for two low frequency variants (rs371740347: nearest gene = *CFHR5*; rs114353081: nearest gene = *ERCC8*), while FVC associated variants in Xp11.3 were colocalized with cis-eQTL from GTEx. Our study demonstrates the advantages of deep sequencing in heterogeneous, multi-ethnic samples for identification of genetic associations with common, infrequent and X chromosome variants.

---

**Introduction.** Men and women with chronic obstructive pulmonary disease (COPD) present differently with regards to symptom severity, disease outcome, and comorbidities. Women typically develop the disease with lower smoking exposure and experience more airway obstruction and less alveolar destruction than men. The mechanism underlying these differences is unknown, but may be related to differences in genetic susceptibility or nicotine metabolism. Predicted gene expression approaches provide an approach for linking genetic variants to biologic mechanism.

**Objectives.** Our goal was to systematically investigate the effect of genetic variation on predicted gene expression in males and females with COPD.

**Methods.** We used S-PrediXcan, a novel tool for imputing gene expression based on information gathered by the Genotype-Tissue Expression (GTEx) project. We ran S-PrediXcan in 44 tissues using previously published COPD GWAS results for men (N=167,020) and women (N=194,174) with COPD diagnostic codes in the UK Biobank. We then used WebGestaltR to identify functional categories with gene enrichment in both Kyoto Encyclopedia of Genes and Genomes (KEGG) and Gene Ontology (GO).

**Results.** We identified 138 genes significantly associated with COPD in men and 130 in women ( $p \leq 0.001$ ). Of these genes, only 12 overlapped between sexes. No genes were significantly associated after multiple testing correction. To understand the biological process affected by these genes, we ran enrichment analysis using the top 1,000 genes by p-value in men and women. Enrichment analyses identified three GO categories and 24 KEGG pathways in men and four GO categories and zero KEGG pathways in women that were significantly enriched. The most significantly enriched GO categories in men were all associated with immune response signaling, while in women, all were associated with glycoprotein metabolism and glycosylation.

**Conclusion.** These findings suggest that the biological mechanisms underlying COPD may differ between men and women, which could have important implications for COPD prevention, risk stratification, and treatment and advance personalized medicine for individuals with COPD.

## PgmNr 1966: RNA sequencing analysis of lymphoblastoid cell lines in an African-American Crohn's disease cohort.

---

### Introduction

Crohn's disease, a subtype of inflammatory bowel disease (IBD), is an immune-mediated disorder that involves any part of the gastrointestinal tract. In recent years, there has been a steady increase in reported cases of Crohn's disease in African-Americans. In this study, we have carried out RNA-Seq analysis to compare the gene expression profiles of lymphoblastoid cell lines (LCL) from patients with Crohn's disease and healthy controls from African American ancestry.

### Methods

RNA sequencing was carried out on LCLs from 60 Crohn's disease patients and 60 healthy controls with a median read length of 100bp. RNA-Seq library preparation was performed with the Illumina® TruSeq Stranded mRNA Library Prep kit. Paired-end sequencing was performed on the Illumina® HiSeq 2500 instrument with a 2x100 bp setup in Rapid mode. Quality control checks on raw sequence data were done using FastQC. Low-quality reads and adapters were trimmed using Trimmomatic. Reads were mapped to the human genome (GRCh37) using STAR aligner. Differential expression analysis was done using Cuffdiff and edgeR.

### Results

The top genes that were upregulated included immunoglobulin genes, *IGHV3-66*, *IGKV3D-7*, *IGKV1D-13*, *IGKV1-33*. The downregulated genes that were identified are *TRBV- T Cell Receptor Beta Variable 27* - which has a role in antigen recognition, *IGHV3-73* which is an Immunoglobulin gene and *MT3*, part of the Metallothioneins that have been shown to have altered expression in inflammatory bowel disease in certain populations. Expression quantitative trait loci (eQTL) studies, comprehensive pathway and alternative splicing analysis are ongoing and will be presented.

### Conclusion

In this study, we harnessed the power of transcriptomic profiling to detect genes of interest in Crohn's

disease. Identifying the dysregulated genes will contribute to the understanding of the molecular pathways involved in this chronic condition. This could potentially lead to novel therapeutic targets, biomarkers of disease severity and prognosis in this disease.

## PgmNr 1967: Association of protein tyrosine phosphatase non-receptor type 22 gene functional variant (C1858T) with genetic susceptibility of psoriatic arthritis in Kuwaiti Arabs.

---

Psoriatic arthritis (PsA) is a chronic, systemic inflammatory arthritic disease characterized by joint inflammation that is associated with cutaneous psoriasis, and can lead to pain, swelling or stiffness in one or more joints. Epidemiological evidence has shown a higher heritability for psoriatic arthritis compared with psoriasis vulgaris. It has been considered to result from a complex interplay between genetic, immunologic and environmental factors. A single nucleotide polymorphism [C1858T] in the protein tyrosine phosphatase (*PTPN22*) gene which encoded Arg620Trp in the lymphoid protein tyrosine phosphatase (LYP) has shown to be a negative regulator of T-cell activation. Recent evidence suggests that it shows an association with different autoimmune disorders. This study investigated an association between *PTPN22* gene [C1858T] functional variant genotypes and susceptibility of psoriatic arthritis in Kuwaiti patients. We have investigated the association of *PTPN22* gene functional variant [C1858T] in 105 Kuwaiti patients with psoriatic arthritis and compared it to that in 214 healthy controls. Genotypes for *PTPN22* gene [C1858T] variant were determined by using a PCR-RFLP method. The frequency of homozygous variant genotype (TT) was found to be significantly higher in PsA patients compared to that in the controls (OR 19.7,  $p < 0.0001$ ). Collectively, the variant genotype was detected in homozygous and heterozygous combinations in 30% patients ( $p < 0.0001$ ) compared to 16% in the controls. The variant genotype was associated more strongly with PsA patients of age (25-34y). No correlation was detected between the variant genotype and gender of the PsA patients. Our data shows an association of *PTPN22* gene functional variant [C1858T] with psoriatic arthritis in Kuwaiti patients and highlights its role in determining the genetic susceptibility along with other factors.

## PgmNr 1968: A machine learning classifier trained on zebrafish periderm enhancers prioritizes orofacial-cleft-associated variants near *KRT18* for functional tests.

---

Genome wide association studies have identified 40 loci associated with risk for orofacial cleft. A current challenge in the field is to distinguish functional single nucleotide polymorphisms (SNPs) from those merely in linkage disequilibrium with them. In many of the loci mentioned above the candidate risk gene is expressed in palate epithelium. Identifying the functional subset of SNPs at these loci may be facilitated by an improved understanding of the sequence constraints of enhancers active in oral epithelium, including in the superficial or periderm layer of it. As models for this cell type, we deployed zebrafish periderm, mouse embryonic palate epithelium, and a human oral keratinocyte cell line. We carried out ATAC-seq on each of these epithelial cell types and on a complementary mesenchymal tissue; ATAC-seq peaks present in the former and not the latter, and positive for the H3K27Ac histone mark in relevant published datasets, were candidates for epithelium-specific enhancers. We trained machine-learning classifiers on such candidates, and used the classifiers to rank orofacial cleft-associated SNPs near the *KRT18* gene, which is expressed in oral periderm. All three classifiers identified rs2070875 to be the SNP with the strongest effect on the score of the element harboring it; the significance of this finding was strongest with the classifier trained on zebrafish periderm enhancers. Allele-specific reporter assays in an oral epithelium cell line confirm that rs2070875 alters an epithelial enhancer. This study provides tools for prioritizing orofacial cleft associated SNPs near genes expressed in oral epithelium for functional tests.

---

The societal and patient-centered impacts of end-stage osteoarthritis (OA) among United States Veterans are profound. OA has a strong genetic component with heritability estimates >30%. Previous genome-wide association studies (GWAS) have been performed primarily in populations of European descent. We sought to leverage the rich resource of the Million Veteran Program (MVP) to test the hypothesis that genetic variants explain a meaningful proportion of OA prevalence in a large, ethnically diverse cohort. Genotype variants were typed using the Affymetrix Axiom Biobank Array (MVP Release 3) and imputed results were generated using the 1000 Genomes reference panel. In an effort to replicate known findings and identify new genetic variants and regions associated with OA, we analyzed a total of 338,368 MVP participants between 40-80 years of age, of whom 185,169 carry an OA diagnosis (ICD9 715.x or ICD0 M15-M16). Analyses were stratified by major ancestry group: European (n=251,665), African American (n=57,645), Hispanic (n=19,956) and Asian (n=2,354). After quality control steps, each SNP was tested for association with OA under an additive model adjusted for age, sex and population substructure using PLINK2. Results from the stratified analyses were combined in a meta-analysis using METAL. Similar to previously published OA GWAS among our top significant findings are known BMI variants. Future directions include evaluating whether significant findings replicate in the UK Biobank as well as investigating association of genetic variants with end-stage joint replacement.

Funding was provided from the Department of Veterans Affairs Office of Research and Development, Million Veteran Program Grant I01 RX002745-01.

## PgmNr 1970: Gut virome and bone mineral density in postmenopausal women.

---

Osteoporosis is a metabolic bone disease characterized by reduced bone mineral density (BMD), increased risk of fractures which can cause long term disability and mortality. Animal studies have highlighted the important role of the gut virome in human health. However, no studies have investigated the potential effect of gut virome on bone health. In this study, we included 499 Chinese postmenopausal women aged 41-65 years. The dual-energy X-ray absorptiometry was used to measure BMD in different body sites. Stool samples were collected and analyzed using the HiSeq 4000 platform. Viral sequences were classified by taxonomic alignment against NCBI reference genome database using Centrifuge software. Partitioning around medoids algorithm based on Jensen-Shannon distance was used to cluster the viral enterotypes. We estimated the alpha-diversity by using Shannon index. Partial spearman correlation was performed to investigate the association between viral composition and BMD phenotypes. Constrained linear regression was applied to detect BMD-related viruses. Linear discriminate analysis was then used to identify viral biomarkers for differential osteoporosis status. The samples were clustered into three viral enterotypes, where the most enriched bacteriophages were *Staphylococcus phage SPbeta-like*, *Shigella phage SflV* and *uncultured crAssphage*. Alpha-diversity of virus was negatively correlated with lumbar 1 to lumbar 4 BMD ( $\beta=-0.100$ ,  $P=0.027$ ) and four species including *Shigella phage SflI* ( $\beta=3.23E-05$ ,  $P=0.030$ ), *Staphylococcus phage SPbeta-like* ( $\beta=1.06E-04$ ,  $P=0.005$ ), *Salmonella virus HK620* ( $\beta=-3.23E-05$ ,  $P=0.039$ ) and *Enterobacteria phage mEp460* ( $\beta=-3.83E-05$ ,  $P=0.006$ ) were found to be related to ulna-radius-ultra distance BMD. In total, 21 viruses were identified as biomarkers for distinguishing between normal, osteopenia and osteoporosis groups. Our study, for the first time, provided evidence that human gut virome may influence the regulation of bone metabolism. These findings may contribute to a better understanding of the biological mechanisms underlying osteoporosis.

## PgmNr 1971: Genetic studies of height-associated protein expression levels.

---

Genome-wide association studies (GWAS) have identified thousands of common genetic variants associated with human height, implicating hundreds of genes and loci. However, the mechanisms by which many of these genes affect human height are still poorly understood. Integrating knowledge of phenotypic interaction with protein expression levels can help disambiguate the functional underpinnings of these associations.

Objective: To interrogate biological function at height-associated loci in the GH/IGF signaling pathway.

Design/Methods: We used data from the Cincinnati Genomic Control Cohort (CGCC), a community-based cohort comprised of 1,020 children surrounding Cincinnati. Protein expression levels for proteins (free, total *IGF-1*, intact, total *IGFBP-3*, *PAPP-A2*, *IGF-2*, *IGFBP-5*) were measured by ELISA and corrected for age- and sex-effects. In this abstract, we associated protein-level phenotypes using plink qassoc, corrected for 20 principal components, and stratified by sex and population, in ~870 European- and African-descent individuals. Meta-analyses were performed using the METAL fixed-effects model. GWAS of anthropometric traits were performed in the UK Biobank of ~400,000 individuals using Bolt-LMM, or curated from publically available summary statistics.

Results; We identified 17 independent genome-wide significant protein-level-associated loci ( $p < 5 \times 10^{-8}$ ). The two most robust associations were, or were in tight LD with, previously identified expression quantitative trait loci (eQTLs). The *IGFBP-3* locus is associated with serum total *IGFBP-3* and *IGF-2* levels. Despite falling within a height locus, conditional analyses show the effect on protein levels is independent of the height signal ( $p = 2.8 \times 10^{-31}$  post conditioning). However, conditional analyses show the protein level signal colocalizes with sitting height ratio (SHR, sitting height divided by standing height). The *IGFBP-5* locus is associated with *IGFBP-5* levels and is also independent of height signal identified in the region ( $p = 3.3 \times 10^{-32}$  post conditioning). Preliminary analyses show this signal to be colocalized with birth weight.

Conclusion: We have identified novel pQTLs for *IGF-2*, *IGFBP-3*, and *IGFBP-5* that act independently from human height but may interact with related anthropometric traits including SHR. Additionally, this suggests that SNPs affecting adult height in these loci do not work via increasing serum levels of these proteins but rather through a different and undetermined mechanism.

## PgmNr 1972: Multi-locus variation of Notch and Hedgehog signaling pathways potentially contributing to cases of limb anomalies.

**Background:** Spatial and temporal regulation of Notch and Hedgehog (Hh) signaling during limb bud development is critical for normal growth and patterning of vertebrate limbs. Rare variant mutant alleles in genes encoding members of these pathways are associated with a spectrum of limb developmental phenotypes. The majority of disease associations involve a single gene with monoallelic variation cosegregating in an autosomal dominant fashion with reduced penetrance or as a sporadic birth defect in association with a *de novo* mutational event. The molecular etiology of reduced penetrance, frequently observed amongst families with limb malformations, remains mostly unresolved. Recent studies have shown that penetrance of congenital scoliosis due to variation at the *TBX6* locus can result from a null allele and a common variant non-coding allele that reduces expression to a level below haploinsufficiency. Moreover, a two-loci mutational burden model in the *SMAD6*-*BMP2* and *TBX4*-*FGF10* pathways can explain penetrance of craniosynostosis and lethal lung developmental disorders, respectively.

**Methods:** We hypothesized that multi-locus pathogenic variation in a signaling pathway important to limb development might underlie the penetrance of some limb birth defects. We applied exome sequencing (ES) and array comparative genomic hybridization (aCGH) to affected individuals from seven unrelated families with morphologically heterogeneous limb malformations.

**Results:** In each of the seven studied families, likely damaging multi-locus pathogenic variation was found in genes encoding proteins of the Notch and Hh signaling pathways. Affected individuals harbored rare variants ( $MAF \leq 0.001$ ) in at least two genes of the implicated pathways. This included

single-nucleotide and copy-number variants in previously disease-associated genes such as *GLI2*, *HOXD13*, *DYNC2H1*, *PTCH1*, *SUFU*, *BHLHA9*, and *FGFR1* as well as genes not previously known to be associated with limb deformities in humans such as *NLK*, *HAND2*, *DNER* and *EIF3A*. Additionally, two probands were found to harbor common single nucleotide variants in *HES3*, a transcription factor that plays a role in Notch signaling.

**Conclusions:** Our data suggest a possible epistatic interaction of rare variants in factors of the Notch and Hh signaling pathways in individuals with limb malformations. Further study of additional family members can elucidate the relationship between intrafamilial genotypic variability and disease trait expression.

---

Although common-variant based genome-wide association studies (GWAS) have identified loci associated with osteoporosis and fractures, such approaches have inherent limitations and it is unlikely to impute less common, rare and structural variations that have larger effect sizes and might reveal unique pathways influencing bone metabolism. Bone mineral density (BMD) at lumbar spine (LS) and femur neck (FN) has been used to diagnose osteoporosis. Previously, we reported the largest common-variant GWAS analysis (N=~400k) on estimated BMD from heel bones. However, the identified loci only explained ~20% variance of BMD, comparing to the 85% BMD heritability estimated from twins. Thus, current common-variant based GWAS approach only detects a small fraction of genetic heritability. To explain the missing heritability, whole-genome sequencing (WGS) is rapidly being incorporated into mainstream biomedical researches to provide comprehensive enumeration of sequence variation. To identify novel less common and rare variants that are associated with BMD, we utilized the deep-coverage WGS (average 30X coverage) in ~10K Caucasian participants obtained from Amish, CHS, FHS, SAFOS and WHI studies (the NHLBI TOPMED Program) as well as ALSPAC and TWINSUK studies. We first performed gene-based collapsing association tests (allele-count and SKAT tests) to identify rare functional coding variants (MAF  $\leq$  0.5%) of BMD. Only loss-of-function, missense with deleterious effects and protein-altering short insertion/deletion coding variants were included. Covariates adjusted in the models included age, age<sup>2</sup>, sex, weight, height, ancestral genetic background, cohort studies and menopause status (women only). To consider potential familiar relatedness among subjects, a linear mixed-effect model with kinship/genetic relationship matrix was applied. Genome-wide significance was  $p < 4.27 \times 10^{-6}$  after Bonferroni correction. The most significant association was found in *IGHE* gene ( $p=7.18 \times 10^{-8}$ ) with lower LS BMD. The other novel findings included *SLC26A11*, *ERGIC3* and *STMN1* genes associated with LSBMD. No

genome-wide association was found for FN BMD, but strong association ( $p < 10^{-5}$ ) was found with *TFAP2E*, *CYP2B6*, *GDF10* and *IL6* genes. Additional analyses on BMD and fracture are underway to include functional non-coding variants (e.g. variants affecting gene regulation in bone cells), which will provide a comprehensive ascertainment on sequence variants and their impact to bone health.

## PgmNr 1974: Genome-wide association study identifies three loci associated with chronic widespread musculoskeletal pain.

---

Chronic widespread musculoskeletal pain (CWP) is a complex trait with poorly understood pathogenesis. Heritability estimates of CWP range between 48-54% indicating a substantial genetic contribution. Candidate gene approaches to study genetic factors contributing to CWP have yielded inconsistent findings. Genome-wide association studies (GWAS) of CWP are limited. We performed the largest so far GWAS for CWP using 249,843 participants of Northern European descent from questionnaire responses within UK Biobank, aged 40-72 years. CWP cases (n=6914) were identified by combining self-reported diagnosis of pain all over the body, simultaneous pain in knee, shoulder, hip and back lasting for 3+ months, and those with a doctor's diagnosis of fibromyalgia. We identified 3 genomic loci (2 in chromosome 3, 1 in chromosome 22) having genome wide significance ( $p < 5E-08$ ). The loci include genes *RNF123*, *ATP2C1* and *COMT*. Four additional loci were identified at suggestive at  $p < 5E-07$ . Gene-based analysis identified additional 20 associated genes (MAGMA  $p < 2.631E-6$ ), of which only *ARVCF*, adjacent gene to *COMT*, had been implicated to pain. This is the first study to identify *COMT* as associated with CWP using an agnostic study approach, but it has been widely investigated as a candidate gene (e.g. CWP/Fibromyalgia, sciatic pain, neuropathic pain, shoulder pain, headache, cancer pain). A significant positive genetic correlation was observed with body mass index ( $rg=0.3071$ ,  $p=8.81E-18$ ), depressive symptoms ( $rg=0.65$ ,  $p=2.06E-36$ ) and neuroticism ( $rg=0.3931$ ,  $p=1.68E-19$ ). Our study suggests new genes underlying the pathophysiology of CWP/fibromyalgia. Gene expression and tissue enrichment analysis as well as replication effort are underway

---

Human height is a highly heritable and classic polygenic trait. The GIANT consortium has previously identified hundreds of variants associated with adult height; a HapMap-imputed meta-analysis with UK Biobank of ~700,000 individuals yielded 3290 near-independent SNPs with  $p < 10^{-8}$ . These provided a prediction accuracy of ~19.5% in an independent European-ancestry sample. We are performing a much larger GWAS for height, thus far including >1.4 million people from 278 studies covering six major ancestries, imputed to the 1KG Phase 3 and (for European-ancestry samples) HRC reference panels. Linear mixed models and four principal components were used to account for relatedness and population stratification. After QC filters, we identified 2295 autosomal loci >1Mb apart that have signals at genome-wide significance. The strongest-associated (lead) variants, in each locus included 168 with frequency <5%, and 6 insertion/deletion variants. Because of the large sample size apparently distinct loci could reflect weak LD with very strong associations >1Mb away. We used GCTA-COJO to perform conditional joint analysis from summary statistics to address this issue and to identify independent signals within loci. This analysis identified 3,925 likely independent association signals with  $p < 10^{-8}$ . Of these, 233 signals had lead variants with frequency <5%, and the 3,925 variants clustered in many fewer (725) genomic loci >1 Mb apart. These variants had a prediction accuracy of ~23.3% in 8,552 independent unrelated European-ancestry samples. Using S-BayesR we find that prediction based on common HapMap 3 SNPs yields an accuracy of ~32.3%. We are further increasing sample size to ~3 million and performing trans-ethnic meta analyses, fine mapping using results from multiple ancestries, pathway gene set analyses, prediction in multiple ancestries, and X chromosome analyses. The large number of signals and loci will more completely define the genetic

and biologic basis of human height and provide general insights into contribution of common and low frequency variants to polygenic traits.

## **PgmNr 1976: Genomic prediction of osteoporotic fracture risk using machine learning techniques on 1,103 SNPs of 5,133 individuals in the cohort study of osteoporotic fractures in men.**

---

Predicting an individual's disease risk from genomic variants remains a major challenge due to complex gene interactions and regulations. Osteoporosis is a common, silent, and costly disease without symptoms. Correctly identifying individuals who will sustain osteoporotic fracture is critical for preventing this devastating outcome in aging population worldwide. Numerous Single Nucleotide Polymorphisms (SNPs) associated with osteoporotic fracture were discovered by GWAS and GWAS meta-analysis. However, how to best utilize these genetic variants to effectively predict an individual's fracture risk remains unclear. Traditional statistical approaches lack the flexibility or the adequacy to model complex gene interactions and regulations. Thus, we developed several machine learning models of genomic data and ran experiments to identify the best machine learning model for fracture prediction. We used genomic data of Osteoporotic Fractures in Men cohort Study (N=5,133) as the data source. Genotype imputation was conducted at the Sanger Imputation Server. 1,103 fracture-associated SNPs were identified and corresponding genetic risk scores were calculated for each participant. Traditional fracture risk factors and genomic variants were included for analysis. Data were normalized and split into a training set (80%) and a validation set (20%). Synthetic Minority Over-sampling technique was used to account for low fracture samples rate in the data. Fracture prediction models were built using random forest, gradient boosting, and multi-layer perceptron (MLP) with backpropagation algorithms separately and logistic regression was used as a reference model. The fracture prediction performance of each model was assessed by area under the ROC curve (AUC), recall, and precision in the validation set. We found that the performance of MLP in predicting fracture was the best among the four models, with AUC of 0.98, recall of 0.70, and precision of 0.84. The performance of random forest and gradient boosting were also better than that of logistic regression. Random forest and gradient boosting had the AUC of 0.94 and 0.93, recall of 0.64 and 0.62, and precision of 0.59 and 0.77, respectively. Logistic regression had the worst performance with AUC of 0.90, recall of 0.55 and precision of 0.30. Thus, we concluded that all three machine learning techniques had better fracture prediction performance than logistic regression, and MLP performed best for fracture prediction in men.

## PgmNr 1977: Exome sequencing of a multiplex family with idiopathic scoliosis implicates *KIF7* in IS pathogenesis.

---

**Background:** Idiopathic scoliosis (IS) is an axial developmental disorder of the spine with a strong familial genetic component. Given the significant variability in presentation and progression of this condition in otherwise normal individuals, the genetic architecture of IS is believed to be complex in nature. One strategy for gene identification is the study of a single multiplex family with IS that potentially harbors a rare causal personal variant that can be related to disease expression.

**Methods:** Peripheral blood samples were collected from a large multiplex family affected with IS. We extracted DNA and performed exome sequencing for three affected individuals. Bioinformatic filtering identified unique, low frequency variants (MAF <5%) that were shared by all members of the family and were predicted to be damaging to the protein. This gene list then underwent gene ontology enrichment analyses (GO, PANTHER, BiNGO) to identify enriched gene categories. Genes within top GO terms were prioritized for further study in zebrafish through CRISPR-Cas9 knockouts. Zebrafish phenotypes were studied through direct visualization, histological staining, and micro-CT.

**Results:** Within this family, 19 variants were found in 19 genes that passed bioinformatic filtering. Of the 19 variants, 16 are nonsynonymous SNPs, 1 is an in-frame insertion, 1 is in a splice site, and 1 is a stop-gain variant. Gene prioritization resulted in study of *KIF7*, which encodes a motor protein in the ciliary axoneme. Sanger sequencing of this variant in additional members of the family confirmed that this variant segregated with the phenotype of affected vs unaffected individuals. Generation of *Kif7* mutant zebrafish resulted in homozygous mutants that exhibit spinal curvatures in early larval stages through adulthood.

**Conclusion:** Study of a single multiplex family with IS demonstrated that a variant in *KIF7*, a cilia-related gene, is potentially related to the scoliotic phenotype. Functional studies within a knockout zebrafish model support this observation. Ciliopathy related genes have been reported to be related to IS potentially through a dysregulation of signaling pathways driving segmentation and somite production of the axial skeleton. Further study of this gene family in additional IS families and IS cohorts are needed.

## PgmNr 1978: Targeted sequencing in genetic screening and gene discovery in sporadic polydactylies.

### Authors:

---

### Background

Polydactylies are a highly heterogeneous group of skeletal deformities in clinical and genetical. The purpose of this study was to gain insight into the frequencies of genetic variants in genes implicated in polydactyly by targeted sequencing.

### Methods

A total of 181 patients diagnosed with polydactylies were recruited over a period of 3 years. Targeted sequencing was performed for 721 genes associated with the pathogenesis of skeletal dysplasia, and candidate variants were selected using bioinformatics analysis.

### Results

After bioinformatics analysis and filtering process, a total of 890 rare variations identified as “loss of function” or “deleterious” variants in 98.9% (179 of 181) of cases with polydactyly by targeted sequencing. For each sample, an average of 4.9 variants were identified. Among the six non-syndromic polydactyly associated genes, five mutations were identified in *GLI3* and one novel mutation was identified in Zone of polarizing activity (ZPA) regulatory sequence (ZRS). Among the known syndromic polydactyly associated genes inherited in dominant manner, fifteen mutations were identified in seven genes in fifteen polydactyly cases.

### Conclusions

This study demonstrates the feasibility of targeted sequencing for the molecular diagnosis of polydactyly. However, this panel still display genes with low or no diagnostic yield.

---

Craniosynostosis (CS) arises from premature closure of one or more cranial vault sutures in infants. Following up the independent associations we identified for *BMP2* (rs1884302) and *BBS9* (rs10262453) in our genome-wide association study (GWAS) for sagittal nonsyndromic CS (sNCS), we conducted a GWAS for another midline defect, metopic NCS (mNCS). Our analysis of 228 non-Hispanic white (NHW) case-parent trios from an international sample identified three variants that exceeded

genome-wide significance ( $P \leq 5 \times 10^{-8}$ ): rs781716 ( $P = 4.79 \times 10^{-9}$ ; odds ratio [OR]=2.41) intronic to *SPRY3*; rs6127972 ( $P = 5.61 \times 10^{-9}$ ; OR=2.26) intronic to *BMP7*; and rs62590971 ( $P = 4.05 \times 10^{-8}$ ; OR=0.38) located ~155 kb upstream from *TGIF2LX*. Only the association for rs6127972 ( $P = 0.004$ , OR=1.45) was replicated in an independent NHW sample (194 unrelated mNCS cases, 333 controls) with a meta-analysis  $P = 3.11 \times 10^{-9}$  (OR=1.45). Both rs1884302 and rs10262453, identified in our sNCS GWAS, were genotyped in our mNCS discovery and replication samples. The variant rs10262453 was borderline significant in our discovery sample ( $P = 9.22 \times 10^{-5}$ , OR=1.72), replicated ( $P = 0.0004$ , OR=1.61), and had a meta-analysis ( $P = 1.33 \times 10^{-7}$ , OR=1.62). Notably, the C allele for this variant was over-transmitted in mNCS probands, whereas the A allele was over-transmitted in sNCS probands. We sequenced all seven exons of *BMP7* in 183 mNCS cases, of which 118 were included in the 228 mNCS discovery sample case-parent trios, and did not identify any variants with obvious deleterious effects. *BMP7* expression and BMP7 protein secretion were measured in mesenchymal stem cells derived from matched fused metopic and open sutures from the same probands, and no significant difference was observed, regardless of the rs6127972 genotype. Functional assessment of rs6127972 using western blot and ELISA produced no difference in BMP7 expression or protein levels in synostotic metopic versus open sutures. Data from luciferase studies suggested that the locus may act as a repressor element with the risk allele exerting stronger repression. Zebrafish transgenic analysis produced inconclusive results. In summary, our GWAS identified *BMP7* (rs6127972) to be strongly associated with mNCS, providing support for the role of *BMP7* in skeletal development. Our meta-analysis of sNCS and mNCS GWAS data identified *BBS9* (rs10262453) as a risk variant for both subtypes. These findings provide additional important insights into genetic antecedents for midline CS.

## PgmNr 1980: *LRP5* gain of function mutation and osteopetrosis: An illustrative case and review of the literature.

---

**INTRO:** Autosomal dominant osteopetrosis type 1 (ADO1) is a rare disease caused by heterozygous, gain-of-function mutation in the low-density lipoprotein receptor-related protein 5 (*LRP5*) gene. *LRP5* codes for a coreceptor in the canonical Wnt signaling pathway, which is known to be involved in the development of some bone disorders and plays a crucial role in bone mass regulation. Here we describe the case of a 51-year-old female who presented with severely elevated bone density, atypical skeletal findings, and an acquired Chiari malformation.

**METHODS:** The study participant was seen as part of an IRB-approved protocol associated with the NIH Undiagnosed Diseases Program (UDP). The UDP evaluates individuals with severe medical conditions that remain refractory to diagnosis despite extensive clinical workup. *LRP5* variants were identified by clinical exome analysis. Targeted clinical studies were used for phenotyping. Intracranial volume was measured by CAT scan-based 3D reconstruction.

**RESULTS:** The subject showed many typical features of *LRP5* associated osteopetrosis including increased bone mineralization, a palatal torus and a history of an inability to float in water. Less common characteristics included a Chiari malformation. Molecular analysis detected a known osteopetrosis-associated *LRP5* mutation and also mutations in two potentially modifying genes *DIO2* and *CYP12A1*. Intracranial volume stabilization was seen to occur after institution of sex hormone suppression therapy. Features of our case showed overlap with previously reported cases, notably on the severe end of the phenotypic spectrum.

**DISCUSSION:** We present a case of severe *LRP5*-associated osteopetrosis along with detailed phenotyping data. Chiari malformations are a known but unusual complication of osteopetrosis likely resulting from osseous changes of the skull. Management of osteopetrosis can be challenging. In this case, treatment to suppress sex hormones caused an apparent stabilization supporting the consideration of that therapy as a treatment in this condition. Finally, we consider a hypothesis that changes in the *DIO2* and *CYP12A1* genes may modify the *LRP5* phenotype.

## PgmNr 1981: Deciphering disorders involving scoliosis and comorbidities.

### Objective

The Deciphering disorders Involving Scoliosis and COMorbidities (DISCO) international study group is committed to interpret the genomic data produced from subjects with scoliotic phenotype, to increase the diagnostic yield and to decipher the novel genetic etiology and the disease mechanisms. Our ultimate goal is to provide precise clinical practice guidelines for molecular diagnosis and disease management, genetic counseling, and even targeted therapy to the patients.

### Method

Through the past eight years, we have been collecting DNA sample and clinical information from patients with deformities involving scoliosis and their available family members. Exome sequencing (ES) or whole genome sequencing (WGS) were performed on these patients and families to explore the genetic etiology underlying scoliosis and comorbidities. Candidate genetic/genomic variants were studied using *in vivo* and *in vitro* models.

### Results

In total, we have sequenced 3723 patients and family members using either ES (N=2923) or WGS (N=800). Their clinical diagnoses included congenital scoliosis (N=1300), adolescent idiopathic scoliosis (N =300), Mayer-Rokitansky-Kuster-Hauser (MRKH) syndrome (N=710), short stature (N =730) and SAPHO syndrome (N =120). These genetic data have enabled publication of 50 scientific papers and 53 abstracts in international. Novel genes such as *MYH3* were identified to be associated isolated scoliosis, while *HOXA10* and *BMP4* have been linked to scoliosis involving multi-system malformations.

### Conclusion

Our investigations into the pathogenesis of scoliosis advanced our understanding of somitogenesis during development and the course of scoliosis conditions. We unraveled the risk factors and potential mechanisms of scoliosis and other disease, and develop more effective clinical diagnostic

strategy and intervention methods based on these discoveries. By translating our research findings into clinical application, DISCO study group increased the diagnostic yield and improved disease management for those patients suffering scoliosis.

AIS is a rotational deformity of the spine that affects ~3% of children worldwide. Genetic contributions to AIS are complex and largely undiscovered. Our group and other researchers previously identified AIS common risk loci by GWAS. More recently we reported a multi-ethnic meta-analysis that identified new common variant associations in inter-and intra-genic non-coding regions. Gene-functional enrichment analysis found significant perturbation of pathways involving cartilage development. To discover new AIS disease genes, we have performed a new GWAS of 11,469 non-Hispanic white subjects (1,358 cases/10,111 controls) in which restricted our search space to common (MAF>0.01) missense variants in the cartilage exome (GO:0051216). In the discovery stage, three variants surpassed a nominal significance threshold after multiple testing correction ( $P<5.3E-4$ ): P1335L in *COL11A1* [ $P=5.6E-05$ ]; K286E in *IMPAD1* [ $P=2.4E-4$ ] and T263I in *TGFB1* [ $P=3.5E-4$ ]. To validate our findings, we performed a meta-analysis (N=96,693) that combined the discovery summary statistics for the three variants with data from independent cohorts from Japan (n=79,211), Hong Kong (n=3,062), and Missouri (n=2,951). We obtained the strongest signal in P1335L in the *COL11A1* ( $P=4.3E-9$ , OR=1.11) gene that encodes the alpha1 chain of type XI collagen. Separately, whole exome sequencing in 73 families identified a novel P738L mutation (CADD=24) that arose *de novo* and a rare (gnomad\_AF=0.0001) mutation (G1420S, CADD=28) that displayed dominant inheritance in another family. Log2 Counts Per Million (log2CPM) from two independent RNA-Seq studies confirmed high *COL11A1* expression in mouse chondrocytic cell line (log2CPM=6.3, mean=2.0, sd=4.5) and mouse intervertebral disc (IVD) (log2CPM=11.1, mean=3.3, sd=2.8). Type XI collagen, a fibrillar collagen composed of alpha 1,2, and 3 peptide chains, is important for fibril-forming and structural organization of cartilages including the IVD. In humans, heterozygous disruptive *COL11A1*

mutations cause Marshal and Stickler syndromes, and a common haplotype at this locus has been associated with degenerative disc disease. Moreover, enrichment of rare *COL11A2* mutations has been described in cohorts with severe AIS. From these results we hypothesize that missense changes in the collagen XI triple helix, particularly at conserved proline or glycine residues, may alter the integrity of the IVD and predispose to AIS during rapid growth.

## PgmNr 1983: Transcriptome-wide association study identifies novel candidate genes associated with osteoporosis.

### Authors:

M. Zhu; P. Yin

**Affiliation:** Center for Biomedical Information Technology, Shenzhen Institutes of Advanced Technology, Chinese Academy of Sciences, Shenzhen, Guangdong, China

---

Osteoporosis (OP) is a polygenetic disease which is usually characterized by low bone mineral density (BMD). GWAS studies have identified hundreds of genetic loci associated with BMD. However, the causality of these loci remains elusive. To identify causal genes of the associated loci, we detected trait-gene expression associations by Transcriptome-Wide Association Study (TWAS) method, which directly imputes gene expression effects from GWAS summary data, using a statistical prediction model trained on GTEx reference transcriptome data, restricting at OP, blood and muscles-skeletal tissues data. Then we performed a colocalization analysis using the COLOC software, which evaluated the posterior probability with different patterns: association characterized by a single shared causal variant or two distinct causal variants, termed *PP4* and *PP3* in the COLOC notation respectively. The ultimate analysis identified 276 TWAS-significant genes at a Bonferroni-corrected threshold of  $P < 3.7E-8$ , including 142 genes showing strong evidence of a single shared causal variant with *PP4*  $> 0.8$  and 134 exhibiting evidence of joint causal variants with *PP3*  $> 0.9$ . Among them, 210 potential causal genes were validated by VarElect tool, which indicates them of directly or indirectly involved in OP with literature evidences. Further several candidate genes were enriched for differential expression genes in osteoblasts cells expression profiles (GSE35956 and GSE35959) from GEO database, including *IBSP*, affecting calcium and hydroxyapatite binding, and *CD44*, regulating alternative splicing of gene transcription, and *SPTBN1*, interacting with calmodulin in a calcium-dependent manner and candidate. Protein-protein interaction and pathway enrichment analysis detected several OP-associated pathways, including the MAPK signaling pathway and Osteoclast differentiation, B cell receptor signaling pathway. Transcriptome fine-mapping identifies more disease-related genes and provide additional insight into the development of novel targeted therapeutics to treat OP and reduce the risk of fracture.

## PgmNr 1984: Genetic fine mapping identifies novel *de novo* mutations in chromosome 22 potentially associated with the risk of non-syndromic cleft palate only (nsCPO).

---

Nonsyndromic cleft palate only (nsCPO), a type of orofacial cleft, is a common congenital craniofacial developmental malformation in humans. Recent studies have revealed a number of genetic variants in several candidate genes and chromosomal regions associated with the risk of nsCPO. Our overarching aim is to perform chromosome wise genetic fine mapping studies to identify additional novel mutations associated with nsCPO risk.

We have earlier shown presence of novel functional variants within chromosome 1 as risk factors for nsCPO. In the presented study, we used exome sequencing data from 4 subjects (proband, affected brother, mom and dad) to discover *de novo* variants within chromosome 22 that may be involved in the complex genetic etiology of nsCPO.

Peripheral blood was obtained following informed consent, genomic DNA was isolated and pair-end exome sequencing was performed at 100X depth of coverage on Illumina's HiSeq2500 next-generation high-throughput sequencing system. Exome sequencing data was processed using Galaxy and variants were called using SAMtools and GATK Unified Genotyper. Common overlapping variants were filtered out using Western European (CEU) genomes in the 1000 Genomes Project. Variants were annotated using human reference database (GRCh37.75), snpEFF (likely effect) and ClinVar (clinical annotations).

Consequently, 72,580 variants were found in Chromosome 22 with a QUAL score >30. Since our focus was to look for *de novo* mutations, variants with at least one mutant allele in the proband and the affected sibling (homozygous mutant or heterozygous) and none in either parent (homozygous wild type) were considered. Eighty (80) *de novo* variants were discovered. These included genes implicated in inborn genetic diseases including CDC45 (chr22:19483898:T/C), PI4KA (chr22:21067806:C/G), MCM5 (chr22:35815296:C/T), TMPRSS6 (chr22:37475013:aa/aAGa), and TRIOBP (chr22:38104705:A/T). Interestingly, ClinVar clinical annotations revealed CDC45 and MCM5 are associated with Meier-Gorlin syndrome (OMIM# 224690), a genetic disease characterized by cleft palate as one of the symptoms.

Thus, our study identified novel *de novo* genetic mutations within chromosome 22 as potential risk factors for nsCPO.

## PgmNr 1985: The role of *FZD6* and related genes in craniofacial morphogenesis.

---

Craniofacial birth defects are the most common structural abnormalities at birth. They include nonsyndromic cleft lip and palate (NSCLP), which has a prevalence of 1 in 700 and affects approximately 4000 newborns in the United States annually. Although many genes have been implicated in NSCLP etiology, only a portion of the heritability has been explained. We have previously identified *FZD6*, a receptor in the Wnt pathway, as a NSCLP gene in a large multigenerational family and further shown that knockdown or overexpression of *fzd6* causes cartilage and bone abnormalities in zebrafish. Additionally, we and others have shown that loss of co-receptor *lrp6* causes bilateral cleft lip, while knockdown and mutant forms of *lrp5* cause abnormal craniofacial cartilage phenotypes in zebrafish. Furthermore, the facial region completely fails to form in mice deficient for *dkk1*, a *Wnt* antagonist. These genes collectively act at the receptor level of the  $\beta$ -catenin mediated Wnt signaling, which is known to play an important role in craniofacial morphology.

The goal of this study was to evaluate the effects of gene dosage perturbations for *fzd6* and related genes in zebrafish using craniofacial morphometry. First, we evaluated  $\beta$ -catenin activation during craniofacial development utilizing a stable zebrafish reporter line. Reporter expression was analyzed from 1-7 days post fertilization (dpf) and was highly active in the oral cavity and other facial regions between 3-5 dpf. As development progressed,  $\beta$ -catenin expression became restricted to cells around the peri-oral region. Upon *fzd6* knockdown, morphometric analysis revealed that head width ( $p=0.0002$ ), olfactory distance ( $p=0.0002$ ), mouth perimeter ( $<0.0001$ ) and mouth width ( $p=0.0005$ ) were significantly reduced while mouth height was increased ( $0.006$ ) in morphant embryos compared to controls. *Lrp5*, *Lrp6* and *dkk1b* knockdown embryos are being evaluated in a similar manner and will also be presented.

The results of this study provide important information about the effects of *FZD6* and related  $\beta$ -catenin/Wnt pathway genes in craniofacial development and morphogenesis.

## PgmNr 1986: Kabuki syndrome: Long time follow-up of two patients and the importance of a multidisciplinary team.

---

Kabuki syndrome (KS [MIM 147920]) is a rare and variable genetic disorder that affects 1 in 30,000 – 86,000 individuals. This disorder is characterized by typical dysmorphic features, failure to thrive in infancy and later obesity, skeletal anomalies and dermatoglyphic changes and intellectual disability. Some cases associate cardiac and renal defects. Mutations in genes *KMT2D* (12q13.12) [MIM 602113] and *KDM6A* (Xp11.3) [MIM 300128] are known to cause KS.

We describe 2 patients diagnosed in Iași Regional Medical Genetics Centre to illustrate the importance of the clinical findings for the diagnosis, the evolution of the clinical picture in time, as well as particular findings associated. In both cases the diagnosis of Kabuki syndrome was confirmed using DNA sequencing.

Both cases are each represented by the only child of young, healthy, unrelated couples and family history is negative. In one case the pregnancy has been uneventful and the child was born at full term, natural birth, without particular events in the neonatal period, while in other the baby was born at an early term and the mother had a varicella-zoster infection in the seventh month of pregnancy and developed chickenpox. In both of them intellectual development has been delayed.

Case 1 (male, 9 years old): growth deficiency and microcephaly, typical dysmorphic face, persistence of fetal fingertip pads and clinodactyly of the 5th digits, joint laxity, hypotonia and moderate intellectual disability. Investigations revealed congenital heart defects and hydronephrosis.

Case 2 (male, 15 years old): normal growth, typical dysmorphic face, brachydactyly in hands and feet and persistence of fetal fingertip pads, genital anomalies (unilateral cryptorchidism and phimosis) and inguinal hernia (all surgically corrected) and mild intellectual disability. In time he developed gynecomastia. Investigations revealed congenital heart defects and unilateral renal ectopia and dysplasia.

The follow-up showed tendency to particular obesity, progression of renal dysfunction and behavioural changes in both cases. The evolution over time of the dysmorphic facial features of both patients will be illustrated in the study.

In conclusion, we present two cases of KS to exemplify the changing of the clinical picture in time, to present particularities and to discuss the importance of a multidisciplinary team for a correct management of the patient and family.

## PgmNr 1987: Contribution of rare variants in the noncanonical Wnt/planar cell polarity pathway genes to nonsyndromic cleft lip and/or palate.

Nonsyndromic cleft lip with or without cleft palate (NSCL/P) is a complex trait, which etiology is largely influenced by common variants. Increasing evidence has also been observed for the role of high-effect rare variants, such as those in cadherin-catenins adhesion complex genes. These pathogenic variants have been mostly detected segregating in familial cases, which comprise 30% of all NSCL/P. While genes of the canonical Wnt/b-catenin pathway have been associated with NSCL/P, Wnt/Planar Cell Polarity (PCP) pathway has been underexplored in this context. Wnt/PCP plays an important role in vertebrate craniofacial development, e.g. during neural crest cells (NCC) migration. Our aim is to determine the relevance of rare variants in Wnt/PCP genes to NSCL/P, by sequencing 9 PCP genes in 251 probands of familial NSCL/P cases. Genes included in this study presents enriched expression during craniofacial development and intolerance to loss-of-function variants (according to Sysface and gnomAD databases). Using Ampliseq sequencing platform and Miseq (Illumina), we have found, in *CELSR3*, *DVL3*, *FZD7*, *PRICKLE1*, *VANGL2*, *WNT5A* and *WNT11*, a total of 27 rare (<0.5% in gnomAD) missense variants with CADD score >20, and one private heterozygous frameshift deletion in *PRICKLE1*. Aggregation of rare variants was not observed for any PCP gene, comparing patients with Brazilian controls from ABraOM database, although borderline significance was found for *PRICKLE1* (P=0.05), and *WNT11* (P=0.06). As *PRICKLE1* is highly intolerant to LoF variants, we investigated segregation of the frameshift variant, and found segregation in proband's affected mother and brother. Exome sequencing was performed in these three individuals, and no candidate variant was found in genes previously implicated with orofacial clefting. In addition, presence of copy number variants was refuted by array CGH in the proband. We suggest that rare variants in core Wnt/PCP genes are not a prevalent cause of NSCL/P; nevertheless, a *PRICKLE1* frameshift variant is the most probable cause of NSCL/P in a Brazilian family. The role of *PRICKLE1* in NSCL/P etiology has been supported by mouse mutants, which may present cleft of the upper lip and palate. In addition, *PRICKLE1* has also been shown to regulate levels of the cleft-associated epithelial cadherin prior to NCC delamination in zebrafish. Our results may thus represent the first case of a *PRICKLE1* pathogenic variant segregating in familial NSCL/P.

Nonsyndromic orofacial clefts (OFCs) are among the most prevalent birth defects, affecting on average 1 in 700 births. Maternal smoking is the most well-established environmental factor that may contribute to OFC risk; however, gene-environment interaction studies continue to show conflicting results, possibly due to heterogeneity in risk by maternal and fetal smoking detoxification gene variants. We examined the interaction effects between first trimester maternal smoking (active and passive) and variants in 7 smoking detoxification genes (maternal and fetal *CYP2E1*, *ELAVL2*, *GRID2*, *GSTP1*, *NAT2*, *TBK1*, *ZNF236*) on risk of nonsyndromic OFCs. We combined individual-level data from 5 population-based studies — Iowa Case Control Study, National Birth Defects Prevention Study, Norway Facial Clefts Study, Norwegian Mother and Child Cohort, and Utah Child and Family Health Study—to create the largest population-based case-control sample to date for this assessment, consisting of 1,330 (1,743) case children (mothers) and 2,549 (3,417) control children (mothers). We evaluated interactions using multivariable logistic regression, including fixed effects for study site, maternal age and education at delivery, pre-pregnancy body mass index, and first-trimester alcohol consumption and folic acid/multivitamin use. We show that *CYP2E1* and *TBK1* increase OFC risk through maternal genotypes in the presence of maternal active and passive smoking. *NAT2* however, seems to affect OFC risk through the fetal genotype in the presence of any maternal passive smoking. *ZNF236*, on the other hand, acts via both maternal and fetal genotypes in combination with all types of smoking behavior measured in this study. These findings suggest meaningful heterogeneity in the risk of OFC associated with maternal smoking by genetic variants in several smoking metabolism genes. This study also confirms passive smoking as a teratogenic factor for OFC and further shows its interactive effects with smoking metabolism genes to increase OFC risk.

## PgmNr 1989: A locus on 4q28 is a laterality modifier with opposite effects for left- and right-sided cleft lip.

Despite the symmetry of the human face, unilateral orofacial clefts (OFCs) are twice as likely to occur on the left side than the right; a ratio that cannot be explained by random chance so we looked to identify factors that might contribute to this sidedness difference. Past OFC studies sought to identify general OFC risk factors and were not designed to be able to identify variants specific to laterality subtypes because they combined them and assumed identical risks. We therefore performed genome-wide association studies to identify modifiers of cleft lip laterality in a multiethnic sample of 2,142 total cases with cleft lip only (CLO) or cleft lip with cleft palate (CLP). We performed separate analyses for CL and CLP given evidence from human genetics, epidemiology, and model systems that these can have distinct etiologies. In the CL analysis (N=216 LCL, 130 RCL) we identified a novel signal on 4q28.1 ( $p=8.4 \times 10^{-8}$ ) in which the minor alleles increased risk for LCL 3.5-fold over RCL. We then compared each group of cases to 1700 independent controls, which revealed that that SNPs at this locus influenced risk in opposite directions: the allele that increased risk for LCL ( $p=2.0 \times 10^{-6}$ ; OR=1.84) was protective for RCL ( $p=0.01$ ; OR=0.84). These effects were consistent between the European and Latinos cases that comprised the largest two population groups in our sample, indicating that this result was not driven solely by a single population group. Furthermore, the 4q28.1 locus showed no effect on overall risk of CL nor for any type of CLP ( $p=0.2$ ; N=638 LCLP, 416 RCLP). The associated SNPs were located in an intergenic region ~400kb downstream of *FAT4*, a protocadherin involved in planar cell polarity. In vitro studies suggest that *FAT4* is partially responsive to SHH signaling as addition of SHH to cranial neural crest cells suppresses *FAT4* expression. We performed mouse in situ hybridization experiments and showed that *Fat4* expression localized to the mesenchyme of the “elbow” of the medial nasal processes, whereas *Shh* is expressed in the distal end. Interestingly, *SHH* mutations primarily are associated with midline cleft lips suggesting that these genes may cooperate in upper lip development. This study identifies, for the first time, genetic risk underlying cleft lip laterality subtypes by identifying the 4q28.1 locus as a modifier of CLO sidedness. This may provide insights into the development of other human organ asymmetries or their pathology.

---

Orofacial clefts (OFCs) are the most common craniofacial malformation in humans, affecting 1 in 1000 live births around the world. Approximately 70% of cleft lip with/without cleft palate cases and 50% of cleft palate only cases are classified as nonsyndromic OFCs, a complex trait with a strong genetic component. Linkage studies, GWAS, and candidate gene studies have identified a number of genetic risk variants, with GWAS being the most successful. However, GWAS approaches focus on common variants and overlook rare inherited and *de novo* variants. All types of variants (common, rare, *de novo*, etc.) appear to confer risk to OFCs but have not been thoroughly assessed for their contribution towards nonsyndromic OFCs. Therefore, we performed whole-genome sequencing (WGS) on 760 case-parent trios with nonsyndromic OFCs. In order to identify *de novo* variants that may contribute to nonsyndromic OFCs, we developed a stringent filtering pipeline to process and analyze the WGS data; following bioinformatics processing, variants were prioritized, further filtered based on allele balance, and visually inspected using Integrative Genomic Viewer to manually curate a list of high confidence *de novo* variants. We prioritized predicted loss-of-function variants found in 56 European trios with cleft palate only and 256 Latino trios with nonsyndromic cleft lip and palate for curation. We identified loss-of-function *de novo* variants in *CHD7*, *COL2A1*, *CTNND1*, *TFAP2A*, and *RPL5*. Loss-of-function mutations in the genes cause syndromes involving OFCs, but our trios notably lacked the additional phenotypic features required for clinical diagnosis of a syndrome. This suggests that variants in known syndromic OFC genes may also be contributing to nonsyndromic OFCs. Therefore, we closely examined *de novo* variants in *IRF6* and *GRHL3*, which cause the most common OFC syndrome, Van der Woude syndrome. We identified three *de novo* missense variants, two in *IRF6* and one in *GRHL3*. Additionally, we found high confidence *de novo* missense variants in OFC candidate genes previously nominated by GWAS or animal models: *FAF1*, *THADA*, and *SHROOM3*. Overall, the identification of *de novo* variants in a large cohort of case-parent trios with nonsyndromic OFCs provides the strongest evidence to date for a role for *de novo* variants in OFC etiology.

---

Recent Alzheimer disease (AD) genome-wide studies have found associations with multiple loci involved in immune and inflammatory pathways including the MHC II region. To pinpoint the causative variant(s) in this region, we tested the association of HLA alleles with AD in European ancestry (EA), African American (AA), and Caribbean Hispanic (CH) unrelated participants (7,024 AD cases, 6,574 controls) in the Alzheimer Disease Sequencing Project (ADSP) and with an AD proxy outcome (report of AD-type dementia in at least one parent) among individuals of British ancestry in the UK Biobank (34,127 AD cases, 239,254 controls).

The UK Biobank imputed the HLA genotypes (n=226 alleles) using HLA\*IMP:02. For the ADSP, we called the HLA genotypes (n=445 alleles) from the ADSP WES and WGS samples using the HLA-Genotyper software tool we developed. A single-variant level analysis was first performed within ancestry and sequencing platform (UKBB British (imputed), ADSP EA (WES) +ADSP EA (WGS), ADSP CH (WGS), and ADSP AA (WGS) with AD status as outcome, and age (as appropriate for the study design), sex and principle components as covariates. Meta-analysis of results across all populations and datasets was performed using SeqMeta.

Meta-analysis revealed two genome-wide significant alleles (HLA-DQA1\*03:01, OR=0.90, P=2.66x10<sup>-8</sup> and HLA-DQB1\*03:02, OR=0.88, P=2.87x10<sup>-8</sup>) that were protective in all groups (study specific ORs between 0.34 and 0.90). Previous reported findings for AD association with HLA-DRB1\*15:01 (OR=1.00, P=0.55) and HLA-DQA1\*01:02 (OR=1.00, P=0.89) did not replicate in the UKBB Cohort.

To examine the protective influence of these alleles in other diseases, we performed a PheWAS with ICD10 diagnoses in the UK Biobank cohort. DQA1\*03:01 was significantly protective for two autoimmune diseases: multiple sclerosis (OR= 0.65, P=2.33x10<sup>-12</sup>) and celiac disease (OR=0.36, P=9.14x10<sup>-55</sup>). HLA-DQB1\*03:02 was also significantly associated with celiac disease (OR=0.61, P=1.22x10<sup>-11</sup>) and multiple sclerosis (OR=0.66, P=5.10x10<sup>-7</sup>). Notably, cognitive decline has been

observed in persons affected with multiple sclerosis and to a lesser extent celiac disease. These results suggest that these diseases share a common immune or inflammatory pathway. Future studies of the protective mechanism of these HLA alleles may provide insight into the neurobiology of cognitive decline and dementia and suggest novel therapeutic approaches for these disorders' shared cognitive decline.

---

Polygenic risk scores (PRSs) have shown promise in predicting complex disease risk attributable to genetics. These risk scores have become more accurate as genome-wide association studies (GWASs) grow yet can be biased by the individuals selected in the training dataset.

Despite comprising only ~16% of the global population, Europeans account for ~79% of the current GWAS catalog. This presents a challenge for modeling PRSs in non-European cohorts because PRS analyses 1) require large discovery GWAS sample sizes to approach genetic-variant-based heritability and 2) become unreliable and unpredictably biased when using European GWASs for non-European cohorts. To address this problem, Coram et al. devised XP-BLUP which combines trans-ethnic and ethnic-specific data in a two-component linear mixed effects model. The present study applies XP-BLUP to asthma, a complex disease for which morbidity and mortality is greater among African Americans (AA) compared to European Americans.

Using European Transnational Asthma Genetics Consortium (TAGC) GWAS summary statistics, we implemented XP-BLUP to compute PRSs in an AA population available through the *Consortium on Asthma among African-ancestry Populations in the Americas* (CAAPA). After quality control, we included 3,740 unrelated individuals (1,223 cases, 2,517 controls) with GWAS array data imputed against the TOPMed reference panel. Model training was based on 80% of the cohort, and model testing (risk scoring) was based on the remaining 20%. We included 389 asthma-associated TAGC variants in the AA samples for the disease-specific variance component. While the standardized PRSs were not highly predictive of asthma, they discriminated between cases and controls better than random chance (OR [95% CI]=1.36 [1.12-1.66], p=0.002, and AUC=0.57). The PRSs ranged from -3.3 to 4.8 SD units and a 3-unit increase in PRS corresponded to a 2.5-fold increase in asthma risk. Subsetting to childhood-onset asthma yielded similar results. In contrast, standard PRS models (single component linear model trained on CAAPA and LDpred trained on TAGC) could not discriminate between cases and controls all with p>0.3.

In summary, the resultant risk scores were concordant with phenotypic outcomes and may provide a

good representation of the contribution of genetic variants to asthma. Increasing GWAS training sample sizes, especially those of African ancestry, would contribute to improved risk profiling of genetic predisposition to disease.

## PgmNr 1993: Utilizing whole genome sequence data to elucidate the genetics of total serum IgE concentrations.

**RATIONALE:** Total serum IgE (tIgE) is an important mediator of allergic disease. tIgE is highly elevated in atopic diseases such as asthma, rhinitis, conjunctivitis, atopic dermatitis and food allergy, and elevated tIgE is associated with coronary artery disease. tIgE is an important intermediary phenotype of asthma, and has a higher heritability than asthma; with heritability estimates ranging between 40-80%. In order to better understand risk factors for atopy in the context of asthma, we performed a multi-ethnic whole genome meta-analysis of tIgE using TOPMed sequence data.

**METHODS:** Data from Barbados Asthma Genetics Study, The Genetic Epidemiology of Asthma in Costa Rica and the Childhood Asthma Management Program, Severe Asthma Research Program and Framingham Heart Study (FHS) were included in our meta-analysis. Analysis strata were defined based on study, race/ethnicity and asthma status (n=6,104 total, n=1,352 African ancestry, n=4,571 European ancestry, n=2,117 asthmatics). Linear mixed effect models (which allows for adjustment of relatedness) was run through the ENCORE web server using TOPMed freeze6a data (SAIGE software) separately for each stratum. Results were combined using inverse-variance meta-analysis.

**RESULTS:** We confirmed four of the five genome-wide associations previously reported ( $P \leq 10^{-5}$ , *FCER1A*, *IL13*, *MHC class II* and *STAT6* gene loci). SNPs in the vicinity of *STAT6* achieved genome-wide significance ( $P \leq 5 \times 10^{-8}$ ). This region also achieved genome-wide significance in the previous FHS GWAS of tIgE. *STAT6* is a transcription factor that affects Th2 lymphocyte responses mediated by IL-4 and IL-13, and has been identified by genome-wide association studies (GWAS) of asthma performed by the Trans-National Asthma Genetic Consortium (TAGC) and the Consortium on Asthma among African-ancestry Populations in the Americas (CAAPA). Two novel loci with suggestive associations ( $P \leq 10^{-6}$ ) not previously reported by GWAS of tIgE were located in the vicinity of the genes *LRRC32+GUCY2EP* and *RIMBP2+STX2*, respectively. *LRRC32* has previously been reported by a GWAS of atopic dermatitis.

**FUTURE WORK:** Our next steps are to include additional TOPMed studies with available tIgE data

(Genetic Epidemiology of COPD and Genetics of Cardiometabolic Health in the Amish) in the meta-analysis and genotype array data from other sources (CAAPA, Genetics of Asthma Susceptibility to Pollution, Atopic Dermatitis Research Network) imputed using the TOPMed reference panel.

---

The use of mouse models in asthma research has led to valuable insights on airway pathology and functional analyses of putative disease-related genes such as those identified through genome-wide association studies. Numerous mouse model protocols, primarily driven by exposure to allergen(s), have been developed for the goal of investigating hallmark human disease features. Despite their demonstrated utility in research, however, questions remain regarding how accurately mouse models represent human asthma. Furthermore significant protocol variation exists among published mouse model studies, yet protocol differences have never been assessed systematically with regards to how variation impacts model similarity to human disease. Therefore, we sought to evaluate how effectively mouse models of asthma mimic the gene expression differences seen between human cases and controls to aid in model selection and interpretation. To achieve this goal, we used data from eight previously published studies of differential expression in cases versus controls to create a disease-state classifier. After mining the literature for existing mouse model gene expression datasets and performing RNA sequencing on models from our laboratory, we applied our disease-state classifier to estimate a similarity score based on the concordance in expression of key human disease genes in each mouse model. Mouse models varied in similarity scores estimates by both magnitude and within-treatment group variance. Using data generated by our lab, we tested the impact of sampling gene expression from either whole lung or isolated airway tissue as well as variation in mouse genetic background across 31 inbred strains. These data demonstrated that sampling gene expression from isolated airway samples could provide stronger signals in downstream analyses and that genetic background of mouse used considerably impacts similarity to the human disease state. Finally, using hierarchical clustering and pathway analyses we identified genes that are consistently upregulated in mouse models concordantly with human disease and pathways that are discordant. These findings serve as a resource for the asthma research community to aid in the selection of mouse model parameters, evaluate the impact of mouse genetic background, and determine pathway concordance or discordance between human disease and mouse models to gain important context for maximizing the utility and accuracy of findings from mouse models.

---

To further elucidate the genetic architecture of asthma, we conducted a genome-wide association study (GWAS) in UK Biobank, followed by a meta-analysis with GWAS results from the Trans-National Asthma Genetic Consortium (TAGC) that in total included 8,365,715 SNPs common to both datasets in 88,486 cases and 447,859 controls. 66 novel genomic regions were associated with asthma and replicated nearly all (142/145) previously known genomic regions, bringing the total number of susceptibility loci identified to date to 211. Altogether, the 66 novel loci explained an additional 1.5% of the heritability for asthma, reflecting the modest nature of the susceptibility alleles' effect sizes. Furthermore, the asthma risk alleles at 17 of the novel loci exhibited directionally consistent associations with decreased forced expiratory volume in one second (FEV<sub>1</sub>), of which 10 were also associated with decreased forced vital capacity (FVC). Bioinformatics analyses revealed enrichment of asthma-associated variants colocalizing to DNase I hypersensitive sites in several biologically relevant tissues, with particularly significant enrichment in B and T cells. In addition, 52 novel loci yielded at least one *cis* expression quantitative trait locus (eQTL) in one or more tissues, the most significant of which were in blood and immune cells. These observations are consistent with the enrichment analyses pointing to lymphocytes as playing important roles in asthma. Interestingly, *CD52*, which encodes a membrane glycoprotein present at high levels on the surface of lymphocytes, monocytes, and dendritic cells, was one of only two candidate causal genes that also yielded an eQTL in the lung. More notably, alemtuzumab is an anti-CD52 (αCD52) antibody that results in preferential and prolonged depletion of circulating T and B cells and is FDA approved for treating multiple sclerosis and chronic lymphocytic leukemia. Functional validation of *CD52* was demonstrated through treatment of mice with an αCD52 antibody that not only mimicked the immune cell-depleting activity of alemtuzumab but also significantly reduced pulmonary inflammation, airway epithelium thickness, and allergen-induced airway hyperreactivity. Our collective results provide additional insight into the genetic determinants of asthma, provide further evidence that the immune system plays a prominent role in its pathogenesis, and suggest that *CD52* represents a potentially novel therapeutic target for treating asthma.

## PgmNr 1996: Whole genome sequencing to study rare gene-by-air pollution interactions that influence lung function in minority children.

**Introduction** Baseline lung function, quantified as forced expiratory volume in the first second of exhalation (FEV<sub>1</sub>), is a standard diagnostic criterion used by clinicians to identify and classify lung diseases. FEV<sub>1</sub> is strongly influenced by genetics, with an estimated heritability as high as 55%. Numerous genetic loci have been associated with FEV<sub>1</sub>, and there is clear evidence that genetic ancestry contributes to FEV<sub>1</sub> variation. Several epidemiological studies have identified early-life exposure to air pollution as a significant predictor of baseline lung function. FEV<sub>1</sub> is a complex phenotype that has been shown to be heavily influenced by both environmental and genetic factors. Although numerous studies have tried to identify the genetic and environmental factors responsible for variation in FEV<sub>1</sub>, the majority of the heritability remains undefined. We hypothesize that a portion of the “missing heritability” for FEV<sub>1</sub> may be explained by gene-by-environment (GxE) interactions.

**Methods** We performed whole genome sequencing on 3,000 ethnically diverse children with asthma, including Puerto Ricans, Mexican Americans and African Americans. We performed gene-by-air pollution analyses using early-life and lifetime exposure to air pollution (O<sub>3</sub>, NO<sub>2</sub> and PM<sub>2.5</sub>). We applied a variance component test, iSKAT, to identify interactions between sets of rare variants with each air pollution measurement. All models were adjusted for age, sex, global ancestry, and the main effects of the set of rare variants and air pollution.

**Results and Conclusions** We identified rare variants in *IDH1* interact with lifetime PM<sub>2.5</sub> to influence FEV<sub>1</sub> in Puerto Rican. Our preliminary results indicate that GxE interactions play a significant role in FEV<sub>1</sub> variation.

**Acknowledgements** We thank all NHLBI/TOPMed, NHGRI/GSP and NIMHD investigators and participating centers who have contributed to the generation, quality control, coordination and management of the data used in this study. We gratefully acknowledge Fred Lurmann for providing the air pollution data and the study participants who provided clinical and biological data for this study.

---

Asthma is a complex disorder with both genetic and environmental contributions. In particular, rhinovirus (RV) infections are an important risk factor for childhood onset asthma and for asthma exacerbations throughout life. Three RV species (RV-A, RV-B and RV-C) cause a variety of respiratory tract infections, ranging from mild colds to severe illness requiring hospitalization. All RV-B strains and most RV-A strains use the intracellular adhesion molecule 1 (ICAM-1) receptor for entry into cells. A variant in *ICAM1*, rs5498 (A/G; Lys694Glu), results in decreased ICAM-1 expression on the cell surface. We investigated the effect of this variant on RV-associated illnesses in children 4 to 12 years of age (n=146 with asthma; n=131 without asthma) enrolled in the prospective RhinoGen study in Madison, Wisconsin. Children were observed for 5 weeks during each of 2 successive RV seasons in the fall and spring. Illnesses were recorded and RV species were identified by partial sequencing during each illness. Children were grouped as having 0 vs.  $\geq 1$  RV-A and 0 vs.  $\geq 1$  RV-B illnesses; analyses included sex as a covariate. As expected, children with asthma had overall more RV-A illnesses compared to those without asthma (49.3% vs 42.0%;  $p=0.031$ ), but unexpectedly the G allele was associated with more RV-A illnesses in both groups (additive model;  $p=0.043$ ). In contrast, RV-B illnesses were less common in children with asthma (10.6% vs 15.4%;  $p=0.020$ ). Moreover, there was no genotype effect on RV-B illnesses in children with asthma ( $p=0.805$ ), but a negative association between RV-B illnesses and the number of G alleles in children without asthma ( $p=0.016$ ). This pattern was further reflected in a strong gene-by-asthma interaction on RV-B illnesses ( $p=0.0057$  for genotype,  $p=0.0013$  for asthma status,  $p=0.029$  for the interaction). Our results show that the *ICAM1* G allele, which results in reduced ICAM-1 receptor levels, is associated with less RV-B infection in non-asthmatic children only and with more RV-A illnesses in both asthmatic and non-asthmatic children. We have therefore identified a genetic variant in a viral receptor that has opposite effects on risk for RV-A and RV-B illnesses, and different genotype effects on the occurrence of RV-B illnesses in children with and without asthma. These results highlight the genetic complexity of response to RV infection, an important risk factor for asthma onset and exacerbation.

## PgmNr 1998: Whole-genome sequencing and cell-type specific RNA sequencing of a multiplex pedigree identifies genes for juvenile idiopathic arthritis.

---

Pediatric autoimmune diseases are genetically complex, and to date, GWAS appears to confirm that common variants underlie susceptibility to autoimmune conditions. It remains a challenge, however, to identify high-impact pathogenic variants with a clear mechanism in autoimmune disease progression. Juvenile idiopathic arthritis (JIA) is the most common pediatric rheumatic disease, affecting approximately 1 in 1000 children. Current GWAS candidate genes account for approximately 18% of JIA susceptibility, and other susceptibility genes remain to be uncovered. Pedigrees with multiple affected first-degree relatives provide a unique opportunity to discover heritable genetic susceptibility that might be otherwise difficult to detect. Pathogenic variants, even if private to a single family, have the potential to uncover novel disease mechanisms. In this study, whole-genome sequencing (WGS) was performed on a two-generation multiplex pedigree, and RNA was isolated and sequenced from circulating CD4+ T cells, a highly implicated cell type in JIA, of the three affected children. Rare ( $AF < .01$ ) single nucleotide variants in cases were investigated with Pedigree Variant Annotation, Analysis, and Search Tool (pVAASST), a computational tool for prioritizing rare variants with predicted pathogenic effects while considering co-segregation of alleles with the phenotype within a pedigree. Top candidate genes were screened against a larger cohort ( $n = 40$ ) of WGS JIA patients to investigate their potential contribution to disease. Differential expression analysis comparing CD4+ T cells of affected siblings ( $n = 3$ ) and CD4+ T cells of unrelated controls ( $n = 3$ ) replicates previous observations of differential expression of *JUN* and *NFKBIA*, while also revealing novel differences in transcriptional profiles within this pedigree, even during clinical remission. These differentially expressed genes also suggest areas of investigation in non-coding regions of the genome, particularly within this pedigree. Our results invite further investigation into novel disease mechanisms in JIA that could involve crosstalk between lymphocytes and osteocytes. In particular, our candidate genes highlight components of inflammatory pathways not previously implicated in JIA pathology.

Among the >240 genetic loci described to date which confer susceptibility to inflammatory bowel disease, a small subset have been fine-mapped down to an individual, noncoding single nucleotide polymorphism (SNP). To illustrate a model mechanism by which a presumed-causal trait-associated noncoding SNP can function, we analyzed rs1887428, located in the promoter region of the Janus kinase 2 (*JAK2*) gene. Using affinity purification-mass spectrometry (AP-MS), we determined that the risk/G allele is bound preferentially by the transcription factor (TF) RBPJ, while the protective/C allele is bound preferentially by the homeobox TF CUX1, impacting reporter gene expression. This SNP did not have significant expression quantitative trait locus (eQTL) associations. To identify target genes of the variant, we constructed subclones of the Jurkat cell line by CRISPR/Cas9 genome editing that were homozygous for the risk or the protective allele of the SNP of interest. Our results at the transcriptome level show that while rs188748 only has a very modest influence on *JAK2* expression, this effect was amplified downstream through the expression of pathway member *STAT5B* (>4-fold). In a CpG methylation study of human donor samples, the risk allele of rs1887428 was associated with increased DNA methylation of the *JAK2* promoter. These results reveal that even in the absence of a consensus TF binding motif or eQTL evidence, a putatively causal SNP can be characterized to yield insight into inflammatory bowel disease mechanisms.

## PgmNr 2000: Single cell transcriptome analysis of circulating plasmacytoid dendritic cells and switched memory B-cells in SLE patients reveals transcriptional subsets within the classical cell lineages.

**Background/Purpose:** Both plasmacytoid dendritic cells (pDCs) and switched memory B cells (SMBCs) are considered to be key effector cells in systemic lupus erythematosus. It seems likely that within these classical cell lineages, additional diversity of function will exist that will contribute to disease pathogenesis. To explore this question, we performed single-cell RNA sequencing in pDCs and SMBCs from SLE patients and controls to assess gene expression patterns and cellular sub-groupings within these lineages.

**Methods:** pDCs and SMBCs from SLE patients (n=10) and Healthy controls (n=5) were purified by magnetic separation. For deep sequencing, we used the Fluidigm C1 HT system with 800 capture site chips to capture single cells. Single cell capture was verified by direct visualization using the Array Scan system, allowing us to remove empty wells and wells with multiple cells. After quality control and adaptor trimming, the data was analyzed using SeqGeq software. pDCs and SMBCs were clustered using UMAP and pseudo-time analysis was performed using the Monocle program. Type I IFN activity in SLE plasma was measured using reporter cell assay.

**Results:** A total of 2774 pDCs and 2578 SMBCs from SLE and healthy controls passed the quality control and were used for further analysis. In pDCs, we observed unique clusters for patients with high interferon, low interferon and controls, indicating that the IFN response is a major determinant of overall gene expression patterns in SLE patient pDCs. IFN signature in pDCs correlated with circulating type I IFN activity in the SLE patients measured at the same time. Other genes upregulated in pDCs included the type I interferon regulator *AXL* and *MACC1*. The SMBCs were heterogenous in patients and controls, and in contrast to the pDCs the overall clustering pattern was independent of the IFN score. SMBC clusters were predominantly defined by genes indicating cellular activation or proliferation such as *HLA-DRs* and *CREB1*, or genes associated with nucleic acid processing such as *DNASE1* and *SNORD3B-1*.

**Conclusions:** We find distinct clusters of cells defined transcriptionally within the pDC and SMBC lineages, and the transcripts which define these subgroups differ between cell lineages. Type I IFN induced transcripts are important to pDC diversity, while in SMBCs transcripts related to cellular activation and nucleic acid processing are critical markers of transcriptional heterogeneity.

Many illnesses differentially affect men and women, in many cases for unknown reasons. For example, lupus affects nine times more women than men, whereas schizophrenia affects more men and tends to affect men more severely. We found that alleles that increase expression of complement component 4 (C4) genes offer strong protection from lupus while increasing risk for schizophrenia, and that both effects are stronger in men than in women. Common inherited combinations of C4A and C4B gene copy number associated with 7-fold variation in risk for lupus ( $p < 10^{-117}$ ), with C4A genes offering strong protection and C4B more modest protection, and both contributing independently of other variation in the MHC locus. The effects of C4 alleles were stronger in men, among whom common C4 alleles generated 14-fold variation in risk (vs. 4-fold among women). Similarly, alleles of C4 affected schizophrenia risk twice as strongly in men as in women. In cerebrospinal fluid and plasma, C4 and its effector protein (C3) were more abundant in adult men than adult women ( $p < 10^{-5}$ ). Sex differences in ambient levels of C4 and C3 may help explain the larger effects of C4 alleles in men, women's greater risk of SLE, and men's greater vulnerability to schizophrenia.

## PgmNr 2002: Association of FUT2 and ABO with Crohn's disease in Koreans.

Fucosyl transferase 2 gene (*FUT2*) at 19q13 is a well-known Crohn's disease (CD) susceptibility locus in Caucasians. *FUT2* encodes the alpha-1,2-fucosyltransferase responsible for the synthesis of the H antigen, the precursor of the ABO histo-blood group antigens in body fluids and the intestinal mucosa. Homozygotes for any nonfunctional *FUT2* allele fail to express ABO antigens on their mucosa, called non-secretors. Non-secretor phenotype has been associated with CD. The two most common alleles causing the non-secretor phenotype are rs601338 (W143X) in Europeans and rs1047781 (I129F) in East Asians. The *ABO* gene encodes for glycosyltransferase enzymes which transfer specific sugar residues to the H antigen. Given that Crohn's disease is thought to arise from dysregulated mucosal immune responses to the gut flora and both the ABO blood group and the *FUT2* secretor status affect the composition of the gut microbiota, the goal of this study was to evaluate the associations of variants of *FUT2* and *ABO* with CD in Koreans. Previous candidate gene association study in a Caucasian population found no effect of *ABO* variants in CD risk, but found that non-secretors and non-O blood carriers are at higher CD risk. We examined the association of rs1047781 in 1,735 patients with CD and 8,074 healthy controls and confirmed its association at genome-wide significance:  $OR_{combined} = 1.30$ , 95% confidence interval (CI) = 1.21-1.40,  $P_{combined} = 3.52 \times 10^{-12}$ . The *ABO* locus showed genome-wide significant association with CD in Asians ( $P_{meta} = 2.35 \times 10^{-8}$ ). Following stratification on the basis of *FUT2* genotype, carriers of the secretor O blood group were significantly protective against CD compared to the secretor non-O blood group ( $OR = 0.63$ , 95% CI = 0.54-0.73,  $P = 2.86 \times 10^{-9}$ ). In conclusion, we confirmed the previously reported association of *FUT2* with CD in Korean population at genome-wide significance, and report that the O blood group and *FUT2* secretor status are protective factors against Crohn's disease in Asians.

---

Systemic lupus erythematosus (SLE) is an autoimmune disease affecting millions worldwide and is now diagnosed 10 times more often than 50 years ago in Western countries. Genome-wide association studies (GWAS) have identified more than 500 associated single nucleotide polymorphisms. Most of these associations localize to incompletely understood regulatory regions. EBV was nominated as a potential environmental factor by immunochemistry and epidemiological studies, but the mechanism is not known.

For characterization of the intersections of transcription factor (TF) DNA binding sites at SLE risk loci we applied the RELI (Regulatory Element Locus Intersection) simulation (Nat Genet 50:699, 2018). The 347 risk alleles for SLE in European ancestry curated from published genome wide association studies (GWASs) and candidate gene studies, all at  $p < 5 \times 10^{-8}$ , were reduced to 83 loci after pruning as a consequence of linkage disequilibrium. We evaluated the available 53 virally encoded TF ChIP-seq (chromatin immunoprecipitation with DNA sequencing) datasets and complemented this analysis with the results from 11,483 human TF ChIP-seq datasets.

We found that, 52 (62.7%) of 83 the European SLE risk loci are occupied by the Epstein-Barr virus Nuclear Antigen 3C (EBNA3C) protein (OR=3.7,  $P=1.96 \times 10^{-18}$  after Bonferroni correction), EBNA2 (OR=4.2,  $P=4.17 \times 10^{-18}$ ), EBNA leader protein (EBNALP) (OR=3.3,  $P=5.53 \times 10^{-18}$ ), EBNA3B (OR=6.0,  $P=4.19 \times 10^{-18}$ ). The 3 viral (EBNALP, EBNA3C, EBNA2) and more than 300 human TFs (all with  $P < 1 \times 10^{-6}$ ) cluster together in an optimal subset of approximately 56% known loci in SLE with  $p < 1 \times 10^{-100}$ , revealing possible gene-environment interaction and identifying the genetic regulatory mechanisms that alter disease risk. More than 85% of the top 100 associated TF ChIP-seq datasets were collected from EBV transformed B cell lines in the Latency III program of viral expression, for which EBNALP, EBNA3C and B, EBNA2 are viral gene products. Therefore, these results further

nominate EBV for a role in the pathogenesis of SLE by a mechanism operating in transformed B cells through the EBV Latency III program of viral expression.

## PgmNr 2004: Shared associations across autoimmune diseases improves fine-mapping resolution in 129,124 samples.

### Authors:

Genome-wide association studies in the autoimmune and inflammatory diseases (AID) have identified hundreds of susceptibility loci, but fine-mapping these to underlying causal variants remains challenging. Fine-mapping resolution is a function of statistical power and, ultimately, of sample size; meaningful resolution increase requires large increases in sample size, which are unlikely where samples and resources are limited. As an alternative approach, we sought to leverage the extensive sharing of associations between AID by combining cases and controls across diagnoses to increase sample size.

To do so we obtained and analyzed genotype data for controls and cases diagnosed with one of six AID, all genotyped on the Immunochip, a fine-mapping array densely interrogating 188 AID-associated loci. After quality control, population outlier removal, and resolution of duplicates and relatives, we analyzed data from 52,542 healthy controls and 76,582 individuals with one of celiac disease, inflammatory bowel disease, multiple sclerosis, rheumatoid arthritis, systemic lupus erythematosus or type 1 diabetes.

We computed conditionally independent case/control association statistics in each disease by grouping samples into country-level strata, performing logistic regression in each stratum with principal component covariates, and conditioning on sequentially identified lead SNPs. We then used joint likelihood mapping (JLIM) to identify conditionally independent associations shared between pairs of the six diseases, which we could combine in a cross-disease meta-analysis. Of the 269 unique associations in 77 loci that met JLIM inclusion criteria (P value thresholds and overlapping  $r^2 \leq 0.5$  windows), 50 were shared between two diseases, and 11 between at least three of six diseases (JLIM  $P < 0.05$ ). Nine loci exhibited effects that differed in direction between diseases.

In each of the 77 loci, we meta-analyzed all strata drawn from diseases sharing an effect, and assessed fine-mapping resolution increase as the change in the number of SNPs included in the 95% credible interval (95CI). In each disease separately, we observed a mean of 45.6 (s.d. 89.0) SNPs in the 95CI; after cross-disease fine-mapping, this improved three-fold to a mean 15.1 (s.d. 21.9) SNPs per 95CI.

We therefore show that effects are shared widely across AID, and that cross-disease meta-analysis can meaningfully increase fine-mapping resolution.

## PgmNr 2005: Genotypic diversity observed within a large cohort of Armenian patients with late-onset familial Mediterranean fever.

---

**Introduction:** Familial Mediterranean fever (FMF) as an autoinflammatory disease, results from mutations in the *MEFV* gene mainly with an autosomal recessive mode of inheritance. The age of onset of FMF varies, with about 60% and 90% of patients experiencing their first attack before the age of 10 and 20 years, respectively. Hence, FMF with the first attack occurring at the age of  $\geq 40$  years (i.e. late-onset FMF) is rare and only a few small studies have addressed this disease subset.

**Objectives:** This work aimed at investigating the molecular genetic characteristics of Armenian patients diagnosed with late-onset FMF.

**Methods:** Genomic DNA isolated from 354 Armenian late-onset FMF patients were analysed for the 12 most common *MEFV* mutations plus SAA1 isoforms 1.1, 1.3 and 1.5 using multiplex PCR and reverse-hybridisation. Mutational spectra and resulting genotypes were then matched against the clinico-demographic profiles collected for these patients.

**Results:** Of all 354 patients, 194 (54.80%) were female and 160 (45.20%) were male. The following genotypes were significantly associated with the late-onset variant: M680I/E148Q ( $P=0.004$ ), M694V/E148Q ( $P<0.001$ ) and V726A/V726A ( $P=0.001$ ). Of note, 12/354 (3.39%) patients were found to be homozygous for the M694V mutation.

**Conclusions:** Our data suggest that late-onset FMF is more prevalent in women and is of greater genetic diversity than previously reported. Further studies including late-onset FMF patients homozygous for *MEFV* mutation M694V are ongoing and may lead to the identification of novel disease-modifying mechanisms.

Myasthenia Gravis (MG) is a heritable autoimmune disorder that affects the neuromuscular junction. One characteristic of the disease is its sex-specific onset at different ages. At early onset (<50 years old) it affects mainly females, whereas at late onset (>50 years old) it affects mostly males. The purpose of this study is to elucidate the genetic factors that contribute to the susceptibility of MG. Here, we are presenting the results of i) the largest GWAS meta-analysis for MG on the largest MG dataset to date (1183 cases and 2509 controls- including a novel dataset and two previously published datasets); ii) the first ever Copy-number Variation (CNV) analysis of rare variants on MG; and, again for the first time iii) a cross-disorder meta-analysis of MG with other autoimmune disorders (Systemic Lupus Erythematosus, Multiple Sclerosis, Autoimmune Thyroid Disease and Rheumatoid Arthritis). We observe the strongest association in the HLA-B gene (rs2905714, OR=2.235,  $p=3.02 \times 10^{-7}$ ). We also identify a novel locus (rs4142030, OR=1.946,  $p=4.9 \times 10^{-7}$ ) at the THEMIS gene. Our rare CNVs analysis detects an enrichment of CNV burden in cases for CNV count (OR 1.17 [1.13–1.22],  $p=2 \times 10^{-16}$ ) and CNV gene count (OR 1.2 [1.18–1.24],  $p=2 \times 10^{-16}$ ) metrics. In the cross-disorder meta-analysis, we detect variants significantly associated across multiple different autoimmune disorders, as well as significant novel SNPs arising in the meta-analysis but not in the individual studies. We also describe independent analyses focusing separately on early and late-onset cases, to investigate the genetic variants implicated in each onset. Our analysis confirms previous findings and reveals novel genetic variants that contribute to the development of MG. Our results shed light into the genetic architecture of MG and point to the potential of a shared genetic mechanism across different autoimmune disorders.

## **PgmNr 2007: Comprehensive analyses of genetic, epigenetic, and transcriptomic data to elucidate the mechanisms of systemic lupus erythematosus (SLE).**

Systemic lupus erythematosus (SLE) is a prototype autoimmune disease with extreme heterogeneity. There are significant differences between different major ethnicities in disease prevalence, average onset age, and severity. Understanding the disease mechanisms and the mechanisms underlying disease association is crucial for targeted treatment of the disease and precision medicine in SLE. In a recent effort to identify susceptibility genes for SLE, we have assembled the largest sample collection on Han Chinese from several cohorts from Hong Kong, Guangzhou, and Anhui, China. Through meta-analysis of genome-wide association studies of these data, we have identified 40 new susceptibility loci for SLE reaching genome-wide significance. Interestingly, a number of these loci showed clear specificity for Chinese populations compared to European data, despite that there is adequate power in Europeans cohorts. The shared loci between Chinese and European ethnicities for SLE showed close correlation in their signature of recent positive selection measured by iHS(the integrated haplotype Score), while the loci with ethnic specificity demonstrated little correlation in their selection signature. The differences in susceptibility loci suggest that there might be differences in the disease mechanisms between major ethnicities. We present results on a comprehensive analysis of the susceptibility genes by integrating data on eQTL, gene expression profiles, cell-type specific open chromatin and histone markers for enhancers, and differential DNA methylation in SLE patients compared to that of controls. Analyses of multi-omics data allow us to have a better understanding of disease mechanisms and the mechanisms of genetic associations.

## Introduction

Blood levels of C3 and C4 are used in clinical practice to screen for evidence complement activation. Here, we hypothesize that EHR-derived C3 and C4 levels can be used as quantitative endophenotypes to identify genetic regulators of the complement pathway.

## Methods

We performed a GWAS for C3 and C4 levels within the eMERGE Network, which consists of 12 medical centers contributing EHR and genotype data for 98,918 patients. C3 and C4 levels were available for a total of 3,903 and 3,952 individuals, respectively. Genetic association tests were performed using linear regression within 3 major ancestral groups. Complement levels were log-transformed and adjusted for sex, center, and genetic ancestry. Meta-analysis was performed using the inverse-variance-weighted method. We used linkage disequilibrium score regression to estimate the heritability of C3 and C4, and to test for genome-wide genetic correlations.

## Results

We detected two genome-wide significant loci for C3 levels: *CFH* locus on chr.1q31.3 (rs3753396-A, Beta=0.05, 95%CI 0.04-0.15, P=5.97x10<sup>-9</sup>) and C3 locus on chr.19p13.3 (rs11569470-A, Beta=-0.05, 95%CI -0.07 to -0.03, P=4.90x10<sup>-08</sup>). For plasma C4 levels, we confirmed large effects of the C4 copy number variant locus on chr.6p21.32 (rs3135353-C, Beta=0.17, 95%CI 0.14-0.20, P=1.24x10<sup>-36</sup>) and detected a new locus on chr.11p13 (rs58520479-G, Beta=0.08, 95%CI 0.04-0.11, P=4.35x10<sup>-08</sup>). The overall SNP-based heritability of C3 and C4 was estimated at 15% and 63%, respectively. C3 levels had negative genetic correlation with systemic lupus erythematosus (rg=-0.39) and positive correlation with CAD (rg=0.38), essential hypertension (rg=0.42), and albuminuria (rg=0.33). C4 levels had positive genetic correlation with LDL (rg=0.25), total cholesterol (rg=0.35), triglycerides (rg=0.20), CAD (rg=0.22) and essential hypertension (rg=0.20). Moreover, C4 levels had negative genetic correlation with SLE (rg=-0.77), primary sclerosing cholangitis (rg=-0.69), type 1 diabetes (rg=-0.43), celiac disease (rg=-0.51), Crohn's disease (rg=-0.26), plantar warts (rg=-0.25), scarlet fever (rg=-0.37), positive tuberculosis test (rg=-0.35), cold sores (rg=-0.34) and shingles (rg=-0.17). These results were further refined by locus-specific PheWAS analyses.

## Conclusions

Our study indicated that C3 and C4 levels have significant heritability and exhibit genetic correlations with a wide range of autoimmune, inflammatory, infectious, and cardio-metabolic traits.

## PgmNr 2009: Cross-population polygenic risk score predictions improved by prioritization of variants in predicted cell-type-specific regulatory elements.

Genome-wide association studies (GWAS) have implicated thousands of associations between complex traits and genetic variants, most of which reside in the noncoding genome and have poorly understood regulatory function. We and others have identified noncoding regulatory elements harboring large proportions of genetic variation. However, our growing knowledge of genetic susceptibility factors risks benefitting mostly European populations due to preferential bias in genetic studies. For example, polygenic risk scores (PRSs) strongly predict polygenic traits but translate poorly between ancestries, possibly due to improper modeling of ancestry-specific linkage disequilibrium (LD).

We hypothesized that PRSs would better translate between ancestries if we prioritized variants with predicted regulatory function. To this end, we identified regulatory elements associated with transcription factors (TFs), which regulate genome-wide programs such as cell-type-specific gene expression and chromatin dynamics.

We collected all 3,158 TF occupancy profiles (ChIP-seq) from NCBI. After merging experiments of the same TF and cell type, we applied our previously published strategy called IMPACT to predict cell-state-specific regulatory elements from 732 unique TF/cell-type binding profiles. To identify shared regulatory mechanisms between Europeans and East Asians, we partitioned the heritability of 12 polygenic traits with stratified-LD score regression using a European GWAS (N=38,242) and an East Asian GWAS (N=22,515). Notably, for rheumatoid arthritis (RA), we observed that 34 IMPACT annotations captured significant proportions ( $p < 0.05$ , Bonferroni corrected) of European RA heritability, 29 (74%) of which also captured East Asian RA heritability. Motivated by evidence of shared biology between populations, we selected these 29 IMPACT annotations to evaluate the predictive power of a cross-population PRS. Compared to a PRS based on all SNPs, prioritizing the top 5% of IMPACT variants resulted in a significant increase in predictive performance from European to East Asian ancestry (19%  $R^2$  increase, 96% decrease in  $R^2$  using deprioritized 95%) and vice versa (20% average  $R^2$  increase, 91% decrease in  $R^2$  using deprioritized 95%) averaged across these 29

annotations.

In conclusion, we find that our strategy may be used to improve the cross-population predictive performance of PRSs and narrow the gap between ancestry-specific disparities in genetics research and clinical practice.

## PgmNr 2010: Exploration of shared genetic susceptibility loci between type 1 diabetes and rheumatoid arthritis in the Pakistani population.

---

**Objective.** Type 1 diabetes (T1D) and rheumatoid arthritis (RA) are autoimmune diseases. It is known that certain genetic loci and factors that increase the overall autoimmunity risk can be shared among different autoimmune diseases. We sought to replicate seven T1D-related SNPs that have been previously reported to be associated with RA susceptibility in a small set of mixed family-based and case-control Pakistani sample in a relatively large and independent RA case-control sample from the same population.

**Methods.** Seven T1D-associated SNPs (*GLIS3*/rs7020673, *BACH2*/rs11755527, *SKAP2*/rs7804356, *GDSMB*/rs2290400, *C6orf173*/rs9388489, *LOC399716*/rs947474 and *DLK1-MEG2*/rs941576) were genotyped in a large Pakistani RA case-control sample (n=1,959) using TaqMan® SNP genotyping assays.

**Results.** None of the tested SNPs showed statistically significant association with RA susceptibility, however, one SNP (*GLIS3*/rs7020673) showed a trend for association (OR= 0.88, p=7.99E-02). *GLIS3* is expressed in the cartilage and regulated by suppressor of the fused homologous gene that encodes a negative regulator of hedgehog signaling.

**Conclusion.** Our study has failed to replicate the previously reported association of seven T1D-associated SNPs with RA risk in a large sample from the same population. Thus, our results do not support a major role of these T1D SNPs in affecting RA susceptibility in the Pakistani population.

## PgmNr 2011: Multi-ancestry fine mapping of interferon lambda and the outcome of acute hepatitis C virus infection.

### Authors:

C. Vergara <sup>1</sup>; P. Duggal <sup>1</sup>; A. Valencia <sup>2,3</sup>; G. Wojcik <sup>4</sup>; M. Taub <sup>1</sup>; HCV Genetics Consortium

---

Clearance of acute infection with hepatitis C virus (HCV) is associated with the presence of the TT allele of the rs368234815 (TT/ΔG) dinucleotide polymorphism in *IFNL4* on chromosome 19q13.13. We aimed to fine-map this region to detect possible causal variants that may contribute to clearance of HCV infection. First, we performed targeted sequencing of the genomic segment containing the *IFNL1-IFNL4* genes in 64 individuals sampled according to rs368234815 genotype: TT/clearance (N=16) and ΔG/persistent (N=15) (genotype-outcome concordant) or TT/persistent (N=19) and ΔG/clearance (N=14) (discordant). Sequencing primers were designed to precisely map paired reads to increase accuracy of genotyping calls in this complex region. We identified 25 SNPs with a difference in counts of alternative allele > 5 between clearance and persistence individuals. Then, we evaluated those markers in an association analysis of HCV clearance conditioning on rs368234815 in two independent groups of European (N=1717, 692 clearance/1025 persistence) and African ancestry (N=1835, 320 clearance/1515 persistence) individuals and meta-analyzed the results. Logistic regression adjusting for HIV status and three principal components of ancestry was performed in each ancestry group and meta-analyzed using a fixed effect model. 10/25 variants located in the *IFNL3-IFNL4* region were associated with HCV clearance ( $P < 0.05$ ) in the conditioned analysis with lead SNPs rs4803221 (Meta-analysis  $P=4.9 \times 10^{-4}$ ) and rs8099917 ( $P=5.5 \times 10^{-4}$ ). In the European ancestry group, the individuals carrying the haplotype rs368234815ΔG/rs4803221C were 1.7x more likely to spontaneously clear HCV than those with the rs368234815ΔG/rs4803221G haplotype (95% CI: 1.3-2.3,  $P=3.6 \times 10^{-5}$ ). For another nearby SNP, the haplotype of rs368234815ΔG/rs8099917T was significantly associated with HCV clearance compared to rs368234815ΔG/rs8099917G (OR: 1.6, 95% CI: 1.3-2.2,  $P$  value:  $1.8 \times 10^{-4}$ ). We identified four variants as possible causal variants in the region: rs368234815, rs12982533, rs10612351 and rs4803221 (posterior probability 0.27-0.61). Our results are consistent with a main signal of association being shared across populations driven by one or more functional variants represented by rs368234815, with additional contributions from rs4803221, and/or nearby SNPs in linkage disequilibrium including rs8099917 in the European ancestry population.

## PgmNr 2012: Fine mapping the 17q12-21 asthma locus using whole genome sequences from African Americans.

---

Asthma is a common complex disease characterized by lower airway inflammation, airflow obstruction and symptoms of wheezing, coughing, and breathlessness. Asthma GWASs have identified over 60 childhood-onset asthma loci, including a locus on chromosome 17q12-21 that is the most highly replicated and most significant locus identified in European ancestry (EA) populations. However, associations between SNPs at this locus and asthma in African Americans (AAs) have been equivocal, despite increased asthma severity and prevalence in AAs. One potential reason for this discrepancy may be due to the extensive linkage disequilibrium (LD) block at this locus in EA populations (~200kb) being significantly less in AAs. As a result, SNPs tagging causal risk alleles in EA populations may not tag causal risk alleles in AAs. Here, we sought to characterize the genetic variation and haplotype structure at this locus in whole genome sequences from EA and AA individuals. To this end, we curated publicly available data from the Consortium on Asthma in African-ancestry Populations in the Americas (CAAPA) and the EVE Consortium; 258 AA and 100 EA individuals with asthma were included in this study. We first phased variants across the locus using the Michigan Imputation Server and then used ChromoPainter to assign haplotypes. We used 5 SNPs that tagged the risk and protective haplotypes in EA populations to determine the number of additional recombinant haplotypes in AAs. As expected in the EA sample, only two common (>5% frequency) 5-SNP haplotypes were observed: one corresponding to asthma risk and one to asthma protection (59.0% and 34.5%, respectively); the remaining 6.5% included 5 additional rare (recombinant) haplotypes. In contrast, we observed 5 common and 8 rare haplotypes in AAs. The EA risk and protective haplotypes accounted for 41.7% and 10.7%, respectively of AA haplotypes, with 3 additional common haplotypes occurring at 17.6%, 15.7%, and 5.4%, and 8 rare haplotypes accounting for the remaining 8.9%. One common haplotype (15.7%) was absent in the EA sample. The decreased frequency of the protective haplotype in AAs compared to the EA sample (10.7% v. 34.5%) may contribute to the increased prevalence of asthma in AAs, and the high frequency of recombinant haplotypes could potentially contribute to increased severity. CW is supported by the Howard Hughes Medical Institute through the James H. Gilliam Fellowships for Advanced Study program.

## PgmNr 2013: Trans-ancestral dissection of urate and gout associated major loci *SLC2A9* and *ABCG2* reveals primate-specific regulatory effects.

**Background:** Gout is a complex inflammatory arthritis affecting ~20% of people with an elevated serum urate level (hyperuricemia). Gout and hyperuricemia are essentially specific to humans and other higher primates, with varied prevalence across ancestral groups. *SLC2A9* and *ABCG2* are major loci associated with both urate and gout in multiple ancestral groups, with abundant epistatic interactions observed in urate particularly in the *SLC2A9* adjacent region. However, fine-mapping has been challenging due to extensive linkage disequilibrium underlying the associated regions.

**Results:** Leveraging trans-ancestral meta-analyses, we generated single-variant resolution mapping for *SLC2A9* (rs3775948 for urate and rs4697701 for gout) and *ABCG2* (rs2622621 for gout). Both *SLC2A9* and *ABCG2* were heavily involved in chromatin interactions with multiple regulators including super-enhancers in a tissue-specific manner, and colocalized with ten and three primate-specific elements respectively. The *SLC2A9* variant rs4697701 was within an ancient enhancer whereas the *ABCG2* variant rs2622621 was within a primate-specific transposable element. Further, the *SLC2A9* super-enhancers and primate-specific elements were all within the *SLC2A9*-adjacent epistatic interaction region. The epistatic interactions were statistically replicated in the gout cohorts, and supported by recent functional evidence of enhancer-promoter interactions and promoters with distal enhancer effects in human cell lines.

**Conclusions:** The interplay of common functional variants and multiple level regulators drives the associations in *SLC2A9* and *ABCG2* and regulates their urate transport function in a primate-specific manner.

## PgmNr 2014: Identification of rare variants contributing to disseminated coccidioidomycosis susceptibility after infection.

**Introduction:** Disseminated coccidioidomycosis (DCM) is a rare and serious complication of infection with the soil-resident fungal pathogens *Coccidioides immitis* or *C. posadasii*. The majority of symptomatic infections (est. 50,000/yr) are limited to the lung (pulmonary coccidioidomycosis; PUL), presenting as community acquired pneumonia and self-resolving. However, in 600-1000 cases per year, the infection spreads to skin, liver, spleen, bone, and brain, among others. Genetic variation and ancestry are major risk factors for dissemination in immunocompetent patients, with DCM observed in 7-50% of African-American patients in contrast to ~1-2% of Caucasian or Hispanic patients. However, the mechanism(s) underlying dissemination remain unknown. We hypothesized that genetic susceptibility factors would be infrequent pathogenic variants with allele and gene-level heterogeneity that functionally converge on shared biological processes and pathways that are differentially burdened between DCM cases and PUL controls.

**Methods:** We recruited the largest ever cohort of patients for investigation of the genetics underlying coccidioidomycosis pathophysiology, comprised of 535 putatively immunocompetent patients from Arizona and California (n=147 DCM; n=388 PUL) with IRB-approved informed consent for genetic analysis, rigorous clinical screening, and laboratory-confirmed coccidioidomycosis. DNA was extracted from blood, and exomes were sequenced by the Broad Institute. Variants were jointly called across all samples using Genome Analysis Toolkit and resulting VCF files were filtered using VCF tools for variant call quality, read depth, and allele frequency. Processed files were annotated using SnpEff/SnpSift and additional analyses performed in R.

**Results:** 546,022 qualifying variants were observed in the complete dataset including rare mutations in candidate immune response genes in DCM cases, and genes previously implicated in susceptibility to fungal infections from immunocompromised patient case studies (IFNGR1, STAT1, IL12RB1), and in animal models (CLEC7A/DECTIN1, CARD9). Work is ongoing to control for demographic variation and confounding, and future work on this dataset will include gene set burden testing using sequence kernel analysis (SKAT-O).

**Conclusion:** This preliminary work describes a new genetically characterized cohort for disseminated

coccidioidomycosis and suggests that DCM is associated with discrete mutations in genes associated with immune function.

## PgmNr 2015: The NIAID Centralized Sequencing Initiative: An integrated framework for research sequencing with clinical validation and return of results for immune disorders.

**Aims:** Immunological disorders encompass a wide spectrum of phenotypes of both multifactorial and complex Mendelian etiology characterized by reduced penetrance and variable expressivity. Efforts to understand these disorders require multifaceted approaches to phenotypic refinement, variant interpretation, and functional studies in a large cohort of patients. In light of these needs, the Centralized Sequencing Initiative (CSI) was established at the National Institute of Allergy and Infectious Diseases (NIAID) to provide streamlined genomic and phenotypic data generation, bioinformatics, quality control, clinical variant interpretation, results reporting, and genetic counseling in order to facilitate gene discovery and patient care for patients with immunological conditions at the National Institutes of Health (NIH).

**Methods:** Process development of the protocol included hiring clinical and research staff, creating a clinic scheduling and referral process from 35 protocols at NIAID studying a diverse group of immune disorders, engaging in education and outreach, collaboration with multiple teams for data processing and analyses, and integrating exome sequencing orders and results into the NIH electronic health record (EHR).

**Results:** Since the start of the protocol two years ago, 2029 patients have been enrolled with 448 patients receiving reports uploaded into the EHR. Informed consent is obtained in person at the NIH or remotely. Research exome sequencing is followed by clinical Sanger validation in a CLIA CAP laboratory at the Department of Laboratory Medicine at the NIH, with a subset of patients undergoing clinical CMA optimized for exonic coverage of immune system genes. Phenotyping using HPO terms in PhenoTips, integrated with genomic data analysis using Seqr, is enabled by the NIAID Genomic Research Integration System (GRIS). All analyses are completed by a clinical molecular geneticist, followed by review and possible functional studies with principal investigators at NIAID. Results include primary and secondary findings. Patients receive genetic counseling and coordination of care upon clinical confirmation. Data is shared in order to facilitate discovery of monogenic and polygenic

contributions to immune system disorders.

Conclusion: By integrating multiple systems at the NIH, this protocol represents a systematic multidisciplinary approach for large-scale reliable and consistent research sequencing with clinical validation and return of results.

---

Recent genome-wide association studies (GWAS) have identified over 200 loci that are associated with inflammatory bowel diseases, but the mechanisms by which these variants influence the disease are largely unknown. Recently, methods have been developed to predict disease associated genes by integrating GWAS and expression quantitative trait locus (eQTL) data. As integration of SNPs in established loci and eQTL data for Asian Crohn's disease (CD) has never been conducted before, we first constructed eQTL database using RNA sequencing data of whole blood tissue from 101 Korean patients with CD. We identified 135,164 cis-eQTL and 3,816 eGenes with FDR less than 0.05. A significant proportion (96.5-98.7 %) of overlapped eGenes with those identified in previous eQTL studies showed the same direction of allelic effects. The significantly enriched pathways of these 3,816 eGenes include neutrophil degranulation, small molecule biosynthetic process, etc. We then used eQTL and GWAS CAusal Variants Identification in Associated Regions (eCAVIAR) to colocalize of lead SNPs in CD GWAS (899 cases and 3,805 controls) and cis-eQTL analysis of 101 CD patients. The integrated analysis identified likely target genes, *TNFSF15* and *GPR35*, at two reported loci with co-localization posterior probability (CLPP) greater than 0.01 and 0.95 for total credible set posterior probability. Their risk alleles were associated with lower expression level of *TNFSF15* and *GPR35*, respectively. This resource would be useful to understand of gene expression regulation and prioritize findings from genome-wide association studies in Asians. Our eQTL browser can be accessed at "http://asan.crohneqtl.com/".

---

Hepatitis C virus (HCV) is a major cause of chronic liver disease, hepatocellular carcinoma, and end-stage liver disease. Genome-wide association studies have identified three loci with independent effects on HCV spontaneous clearance, Major Histocompatibility Complex (MHC), interferon lambda locus *IFNL4-IFNL3* (19q13.2) and G-protein-coupled receptor 158 gene at 10p12.1, in both African ancestry and European ancestry populations. We fine-mapped the MHC region to determine the contribution of classical alleles and amino acid changes for Class I and II HLA. 1600 individuals of European ancestry (594 clearance/1006 persistence) and 1869 individuals of African ancestry (338 clearance/1526 persistence) were included. Samples were genotyped with Illumina Omni1-Quad BeadChip and imputation of classical HLA alleles and amino acids was performed using HIBAG. We tested for association with SNPs, classical alleles and amino acids using logistic regression models, adjusting for HIV status and ancestry principal components, and meta-analyzed the results using META. The top association signal was located upstream of the Class II genes *DQB1* and *DQA2* (rs2647011 C>A,  $P_{\text{meta}}=1.1 \times 10^{-18}$ ,  $OR_{\text{EA}}: 0.59$   $P=3.78 \times 10^{-11}$ ;  $OR_{\text{AA}}: 0.57$   $P=3.7 \times 10^{-9}$ ). Two classical HLA alleles were independently associated with clearance in that region in both populations: *DQB1*\*03:01 ( $P_{\text{meta}}=3.8 \times 10^{-12}$ ,  $OR_{\text{EA}}: 1.61$ ,  $P=7.6 \times 10^{-8}$ ,  $OR_{\text{AA}}: 1.62$ ,  $P=9.5 \times 10^{-6}$ ) and *DRB1*\*01:01 ( $P_{\text{meta}}=1.47 \times 10^{-7}$ ,  $OR_{\text{EA}}: 1.68$ ,  $P=2.0 \times 10^{-4}$ ,  $OR_{\text{AA}}: 2.36$ ,  $P=2.0 \times 10^{-4}$ ). In *DQB1* the residues 9, 13, 26, 45, 53, 55, 71 and 87 were significantly associated ( $P_{\text{meta}} < 4 \times 10^{-4}$ ) with either spontaneous clearance or persistence of HCV infection. In *DRB1*, there were 13 residues associated with infection outcome, of which 71 and 86 were most significantly associated, but neither 71 nor 86 explained the *DRB1*\*01:01 signal. Global association models based on long range Ancestral HLA haplotypes will be included in the analysis. Our findings suggest that two classical alleles completely account for the main association of HCV clearance with the HLA locus observed in populations of European and African ancestry. We are evaluating the associated amino acids individually and together to determine their contributions. This will be critical for vaccine design and assessment of vaccine efficacy at preventing chronic infection.

---

Stevens-Johnson syndrome (SJS) and its severe condition with extensive skin detachment and a poor prognosis, toxic epidermal necrolysis (TEN) are immunologically mediated acute inflammatory vesiculobullous reactions on the skin and mucous membranes. Previous studies utilizing SNP array-based genotyping identified the susceptibility loci of cold medicine-related SJS/TEN with severe ocular complications (CM-SJS/TEN with SOC). However, little is known about the contribution of rare variants and structural variants to development of CM-SJS/TEN with SOC. We performed the whole-genome sequencing of 133 patients with CM-SJS/TEN with SOC and 418 healthy control subjects to discover the broad spectrum of genetic variation. Whole-genome resequencing discovered 18.8 millions SNPs, 1.7 million insertion/deletions, 670 thousand microsatellites and 10 thousands large-scale structural variants after filtrations. Genome-wide association tests on these variants identified the association of microsatellite polymorphism near CDH12 gene and the aggregation of rare coding variants on TRPM8 gene. Majority of the common variants were found in non-coding regions suggesting the regulatory role of genetic variations in the pathogenesis of CM-SJS/TEN with SOC.

---

**Background:** Immunoglobulin A (IgA) is one of the major effectors of the adaptive immune system and plays a role in several common diseases, including mucosal infections, inflammatory bowel disease, celiac disease, and IgA nephropathy.

**Method:** We performed a multiethnic GWAS for serum IgA levels in 41,263 individuals of European, African, East Asian and Hispanic/Latino ancestry. The log-transformed IgA levels were tested using linear model controlling for age, sex, and genetic ancestry. A meta-analysis with dense imputation across 18 cohorts was performed using a fixed-effects model, followed by fine-mapping of significant loci, and co-localization with blood eQTLs. The genetic relationships between serum IgA levels and human disease traits were tested using genome-wide genetic correlation analyses. Additionally, we performed PheWAS for genome-wide polygenic score for IgA levels within the eMERGE Network, which consists of 12 medical centers contributing EHR and genotype data for a total of 98,918 patients.

**Results:** African ancestry was associated with higher serum IgA levels, while European ancestry was associated with lower levels compared to other ancestries. This was confirmed by genetic admixture analysis in the US-based cohorts. In the trans-ethnic GWAS analysis, we replicated 9 known loci and

discovered 10 novel loci associated with serum IgA levels. Cumulatively, these loci explained 1.2% of variance in serum IgA levels. Co-localization analysis with whole blood eQTL dataset revealed 9 loci with strong co-localization (posterior probability > 0.8), prioritizing several novel candidate genes. Genome-wide genetic-correlation analysis pointed to significant correlations between serum IgA levels and IgA nephropathy ( $r^2=0.32$ ), multiple sclerosis ( $r^2=0.23$ ), type 2 diabetes ( $r^2=0.17$ ), and body mass index ( $r^2=0.13$ ), and negative correlations with celiac disease ( $r^2=-0.27$ ), inflammatory bowel disease ( $r^2=-0.12$ ), as well as infections, including bacterial meningitis ( $r^2=-0.35$ ), rubella ( $r^2=-0.22$ ) and shingles ( $r^2=-0.23$ ).

**Conclusion:** We report a multiethnic GWAS for serum IgA levels with discovery of 10 novel loci. Our findings provide novel insights into the genetic regulation of the IgA system and its potential role in human disease. While individuals who inherit higher levels of IgA may be protected against pathogens and gut inflammation, they may be at a higher risk of IgA nephropathy, multiple sclerosis, diabetes and obesity.

Multivariate methods increase power of association detection. We aimed to discover disease associations by analyzing deep phenotype data using multivariate GWAS followed by finemapping and phenome-wide analysis of proposed causal variants.

Assessing 66 quantitative traits in the population-based FINRISK study, hierarchical clustering identified one highly correlated cluster of 12 inflammatory markers – mainly interleukins and growth factors (n=6,890) – for which we performed multivariate GWAS applying Canonical Correlation Analysis. We then performed a phenome-wide association study (PheWAS) in the FinnGen study (n=135,638) across 1,801 disease endpoints for variants suggested causal by a newly developed multivariate finemapping approach.

Within the multivariate results we identified 11 independent genome-wide significant loci, 3 of which (*F5*, *ABO*, *C1orf140*) were not detected by univariate analyses. 8 loci had previously been associated with at least one of the cluster traits while 3 were novel. Multivariate finemapping identified 18 variants as likely causal variants underlying the 11 loci. These variants were associated with 25 disease endpoints in FinnGen ( $p < 1e-4$ ), spread across 5 of the 18 variants. A majority of these disease associations (19/25) were for two variants located in the *F5* and *ABO* loci. These 19 associations would have gone undetected had we used univariate GWAS. Neither of these two variants had previously reported disease associations in GWAS catalog. In the *F5* locus rs3820060 was protective (OR=0.91,  $p=5.9e-5$ ) for venous thromboembolism (VTE) and increased the risk of demyelinating disease (OR=1.52,  $p=1.6e-5$ ). The effect was independent of the well-known *F5* Leiden mutation (rs6025) and the protective effect for VTE was replicated in UK Biobank (UKBB). In the *ABO* locus rs550057 increased the risk of 17 diseases in FinnGen, including 11 diseases related to VTE, pulmonary embolism or other disorders of veins as well as 6 other diseases, such as heart failure and endometriosis. Most of these associations (13/17) were replicated in UKBB ( $p < 1e-6$ ). These findings

suggest an even broader scope of functions phenome-wide for *ABO* and *F5* than previously described.

Our results demonstrate that compared to univariate analyses, multivariate analysis of biomarker data reveals a considerably increased amount of genetic associations with several diseases, and combined with large biobank-based PheWAS provides a new approach to disease association discovery.

## PgmNr 2021: Genome-wide association study for serum galactose-deficient IgA1 in IgA nephropathy.

### Authors:

**Objectives:** IgA nephropathy (IgAN) is the most common primary glomerulonephritis worldwide. Galactose-deficient IgA1 (Gd-IgA1) plays a key role in the pathogenesis of IgAN. Although the heritability of serum Gd-IgA1 levels is high (ranging from 54% to 80%), the genetic association between Gd-IgA1 and IgAN has not yet been clearly determined. To further identify novel susceptibility loci, we carried out a genome wide association study (GWAS) for serum Gd-IgA1 levels in IgAN patients.

**Methods:** We performed a quantitative trait GWAS for serum Gd-IgA1 levels, with discovery and follow-up in 1,127 IgAN patients in a Chinese population. Gd-IgA1 levels were measured using a *Helix aspersa* lectin-based ELISA method. The mRNA levels of susceptibility genes in peripheral blood mononuclear cells (PBMCs) were evaluated by mRNA microarrays (Affymetrix PrimeView Human Gene Expression Array and Illumina HT-12 v4 Expression BeadChip). To search for genotype-phenotype associations in IgAN, linear regression was used for quantitative traits and logistic regression for binary and ordinal variables.

**Results:** We identified two loci passing genome-wide significance, including *GALNT12* ( $P = 1.67 \times 10^{-8}$ , Beta = 0.68) and *C1GALT1* ( $P = 3.10 \times 10^{-8}$ , Beta = 0.24). Additionally, we confirmed reported association of *C1GALT1* with serum Gd-IgA1 levels, including rs1008897 ( $P = 9.75 \times 10^{-3}$ ) and rs13226913 ( $P = 3.89 \times 10^{-2}$ ), which are common variants in Europeans but rare in East Asians (MAF 34% vs. 5% and 58% vs. 7%). *C1GALT1* variant associated in our study is in partial linkage disequilibrium with rs1008897 ( $D' = 0.92$ ,  $r^2 = 0.07$ ) and rs13226913 ( $D' = 0.44$ ,  $r^2 = 0.02$ ). Compared with healthy controls ( $n = 61$ ), *GALNT12* and *C1GALT1* showed lower mRNA expression in PBMCs from IgAN patients ( $n = 94$ ) (0.86-fold change,  $P = 1.00 \times 10^{-6}$  and 0.90-fold change,  $P = 1.92 \times 10^{-4}$ , respectively). Sub-phenotype analysis showed that the risk allele of *GALNT12* variant was associated with decreased serum C3 levels ( $P = 0.02$ , Beta = - 0.05).

**Conclusion:** Our study identifies two loci, which encode two enzymes (*GALNT12* and *C1GALT1*) involved in O-linked glycosylation, are associated with serum levels of Gd-IgA1 in IgAN. Down-regulation of these two enzymes may contribute to the generation of aberrantly glycosylated IgA1 in IgAN.

## PgmNr 2022: Study of differences in susceptibility genes for high-altitude polycythemia in Highland people.

---

**Background:** High-altitude polycythemia (HAPC) is a chronic high-altitude disease characterized by excessive proliferation of red blood cells. HAPC primarily affects people who for prolonged periods live in hypoxic environments. Common over time. The most frequent symptoms of HAPC include headache, dizziness, breathlessness and sleep disorders. Although chronic hypoxia is the leading cause of HAPC, the fundamental pathophysiologic processes and molecular mechanisms responsible for its development are unclear. We, therefore, sought to explore the hereditary factors related to HAPC susceptibility in highland populations.

**Methods:** This case-control association study involved 141 people (70 patients and 70 healthy controls). In our study, we aimed to investigate the associations between susceptibility to HAPC and 529 candidate genes that are related to the oxygen metabolism in red blood cells.

**Results/conclusion:** Using the unconditional logistic regression analysis, false discovery rate (FDR) calculation, and Bonferroni correction we found that PDK1, RUNDC3B, EPO, RELN, MET, PTK2, TDRD1, TCL1A, STAT3, STAT5A, IL12RB1, and NF2 gene polymorphisms were associated with increased risk of HAPC. We determined gene-specific differences and found 12 gene enrichments on the pathway of 16, the main enrichment in the PI3K-AKT pathway, JAK-STAT pathway, and HIF-1 pathway.

**Keywords:** High-altitude polycythemia; highland people; SNPs

## PgmNr 2023: Association of ADAM17 SNPs with TNF $\alpha$ inhibitor response in rheumatoid arthritis patients.

### Authors:

H.J. Kim <sup>1</sup>; H.R. Yeon <sup>1</sup>; S.O. Kang <sup>1</sup>; K.H. Min <sup>1</sup>; H.A. Kim <sup>2</sup>; E. Kim <sup>3</sup>; K.E. Lee <sup>1</sup>

---

**Background:** Patients with rheumatoid arthritis receive treatment modulating TNF and interleukins. However, about 30% of these patients respond poorly and genetics have a potential role in this variability. A disintegrin and metalloproteinase 17(ADAM17), also known as tumor necrosis factor- $\alpha$  converting enzyme(TACE) is a membrane bound enzyme that cleaves immune cell surface cytokine and cytokine receptor, such as TNF $\alpha$  and IL-6, which led to the speculation that inhibition of this metalloprotease might have beneficial effects in autoimmune diseases. Thus, we evaluated the influence of ADAM17 genetic polymorphisms on the treatment response of TNF $\alpha$  inhibitors.

**Method:** Seven SNPs of ADAM17 were selected based on <http://grch37.ensembl.org/index.html> with minor allele frequency of greater than 10% in Japanese and Han Chinese. Genotyping analysis was performed using SNaPshot assay and Taqman genotyping assay after extracting gDNA from blood or buffy coat obtained from patients, who received TNF inhibitor in Ajou University Hospital and Chungbuk National University Hospital in Korea. Clinical data of Patients were collected from electronic medical records and statistic analysis were performed using IBM SPSS Statistics 25.

**Result:** There were six patients (1%) who had medication changes of more than once within the TNF $\alpha$  inhibitors. Among the seven SNPs of our interest, two SNPs revealed statistically significant differences in medication changes (rs117645314 and rs117179141 both  $p=0.018$ ). These two SNPs were found to be in linkage disequilibrium(LD) relation. Multivariate regression analysis was performed to examine the independent effect of variables. Body weight and rs117645314 were significantly associated with medication change after adjusting for age, weight, sex, and rs117645314. ( $r^2=0.367$ )

**Conclusion:** This study showed that ADAM17 can be a possible marker for the treatment response of TNF $\alpha$  inhibitor.

## PgmNr 2024: Association of response to TNF- $\alpha$ inhibitors with rheumatoid arthritis-related SNPs.

### Authors:

---

**Background:** Rheumatoid arthritis (RA) is an autoimmune disease characterized by chronic inflammation that mainly affects the joints. The pathogenesis of RA remains unknown, however, a number of studies suggest that genetic component may be responsible for up to 60% of susceptibility to RA. This suggests that genetics could play an integral part in disease susceptibility and treatment. **Method:** Eleven candidate SNPs were selected by using PubMed text-mining related to RA. We collected clinical data to measure the response to TNF- $\alpha$  antagonist treatment for remission using 28-joint count Disease Activity Score (DAS28) and subcomponents [tender joint count (TJC), swollen joint count (SJC), erythrocyte sedimentation rate (ESR) and patient's general health (GH)]. Our primary endpoint was the difference in DAS28 at baseline and 6 months follow-up ( $\Delta$ DAS28). Secondary outcome was the difference in TJC28, SJC28, ESR, and GH at baseline and 6 months follow-up ( $\Delta$ TJC28,  $\Delta$ SJC28,  $\Delta$ ESR, and  $\Delta$ GH).

**Results:** Eleven SNPs revealed no statistically significant differences in  $\Delta$ DAS28. However in secondary outcome, RETN rs3745367 showed statistically significant difference in both  $\Delta$ TJC28 and  $\Delta$ SJC28 (p value = 0.039 and 0.038, respectively). According to independent t-test results,  $\Delta$ SJC28 in patients with CC or CT were significantly higher when compared to TT-carriers in RETN rs7408174. Patients carrying GG in RETN rs3745367 and CC in CD226 rs763361 showed statistically higher DAS28 difference when compared to patients with other alleles ( $3.77 \pm 0.69$  in GG/CC and  $2.32 \pm 1.74$  in other alleles,  $p = 0.034$ ). GG/CC-carriers when compared with patients carrying other alleles in rs3745367/rs763361 also revealed statistically significant differences in  $\Delta$ TJC28 ( $18.00 \pm 4.24$  versus  $5.94 \pm 7.57$ ,  $p < 0.001$ ) and  $\Delta$ SJC28 ( $14.00 \pm 8.08$  versus  $4.34 \pm 5.44$ ,  $p = 0.019$ ).

**Conclusion:** This study showed that RA patients carrying GG/CC in rs3745367/rs763361 showed favorable response to TNF- $\alpha$  inhibitor treatment, using the endpoint of the difference of DAS28, TJC28 and SJC28 between at baseline and 6-month follow-up. Our results revealed that RETN and CD226 SNPs could be determinants of response in TNF- $\alpha$  inhibitor treatment.

## **PgmNr 2025: Identifying novel high-impact rare disease-causing mutations, genes, and pathways in exomes of Ashkenazi Jewish inflammatory bowel disease patients.**

### **Authors:**

Y. Wu; C. Sevim Raybak; Y. Itan

[View Session](#) [Add to Schedule](#)

**Affiliation:** Institute of Personalized Medicine, Icahn School of Medicine at Mount Sinai, New York, NY.

---

The Ashkenazi Jewish (AJ) population is predisposed to inflammatory bowel disease (IBD) arising via a founder effect approximately 30 generations ago. Most IBD genomic studies were done in Europeans, following the genome-wide association studies approach of common alleles/complex disease architecture. In this study we aim to detect IBD-related rare high-impact variants, genes and pathways within the AJ population. We genetically identified in whole exome sequencing (WES) data of the IBD Genetics Consortium 4,968 Ashkenazi Jewish samples, of them 1,905 IBD cases and 3,063 controls. We employed functional impact and population genetics filters to collect credible genetic variants in the IBD and controls WES data. Based on filtered high-impact variants, gene burden cases-controls analysis revealed several novel and highly significant IBD-related mutations and genes, as well as well-established Crohn's disease genes, including NOD2. We then performed Phenome-Wide Association Studies (PheWAS) analyses on Mount Sinai's BioMe Biobank and tested classification performance of polygenetic risk scores (PRS) derived from filtered variants. The PheWAS analyses replicated known IBD associations verifying the novel mutations and genes results, and discovered new phenotype associations as well. PRS exhibited promising power in identifying IBD in AJs (AUC=0.8209). Finally, we estimated biological pathways that were significantly enriched in AJ IBD cases' significant genes. Our results provide insights into high-impact rare variants, their harboring genes and associated pathways that contribute to IBD in the AJ population.

## PgmNr 2026: Unmapped exome sequencing reads reveal a potential role for virome variation in childhood HIV-1 disease progression.

**SIGNIFICANCE:** Human immunodeficiency virus (HIV) infection remains a major public health burden across sub-Saharan Africa. Children perinatally infected with HIV exhibit extremes in their temporal progression to AIDS - Rapid Progressors (RPs) develop AIDS 3-6 months of HIV infection, whereas Long-Term Non-Progressors (LTNPs) show no signs of AIDS  $\geq 10$  years after infection, even without therapy. The genetic factors underpinning this variability in African children remain unknown, but viral co-infection has been postulated as a potential contributor.

**METHODS:** We used VirusFinder v.2 pipeline to detect viral sequences from unmapped exome sequencing reads from blood samples of 812 HIV+ children from Botswana and Uganda, equally distributed between LTNPs and RPs.

**RESULTS:** Among the  $\sim 1\%$  of reads ( $N=2.9 \times 10^8$ ) that didn't map to the human genome, we found evidence for 19 viral species (median identity  $> 90\%$ ). Consistent with population ascertainment and sampling conditions, phiX174, human Herpes, and HIV were most commonly observed but didn't differ significantly by group. Ugandan samples showed a higher diversity index for viral communities than Botswana ( $p=4.6 \times 10^{-13}$ ), characterized by the relatively common occurrence of Togaviridae, Herpesviridae, and Anelloviridae. LTNPs were more likely to have detectable viral sequences than RPs (78% vs 65%;  $p=0.00004$ ; OR, 1.9; 95%CI (1.4 - 2.6)), specifically, a significant excess of the Anelloviridae family ( $p=0.0003$ ;  $q=0.004$ ; OR, 3.98; 95%CI (1.7-10.2)), and predominantly the Torque Teno virus (TTV) species ( $p=0.0003$ ; OR, 3.1 95%CI (1.7-5.9)), a viral class that has recently been implicated in immune suppression during HIV co-infection. This was independent of covariates including gender, contig counts, and other viral families present. This trend was still evident when stratified by country although it was no longer statistically significant in Uganda (Botswana;  $p=0.00004$ ; Uganda;  $p=0.06868$ ).

**CONCLUSION:** We demonstrate the potential of next-generation sequencing to inform complex disease studies in African populations. Our results imply that the blood-virome could act as a proxy biomarker for disease progression, and that temporal variation in exposure and infection with TTV could play an important role in determining HIV disease progression. Studies of host variants influencing HIV disease progression in African children will need to take account for concomitant viral

co-infection.

## PgmNr 2027: An Epstein-Barr virus (EBV) transcription co-factor, EBNA2, concentrates at variants in the risk loci of Kawasaki's disease.

---

Kawasaki disease (KD), also known as mucocutaneous lymph node syndrome, is an idiopathic, acute, multisystem, inflammatory, and self-limited vasculitis, usually affecting infants and children younger than 5 years of age. Occasionally, the coronary artery vasculitis of KD is lethal. Many viruses and bacteria have been suggested as potential causes of the disease. Epstein-Barr virus (EBV) has been discarded as an etiology by multiple authors because of lowered frequencies of serologic responses in KD at presentation.

From published genome wide association studies (GWASs) and candidate gene studies in KD patients we extracted 11 single nucleotide polymorphisms (SNPs) in Asian ancestry studies, all at  $p < 5 \times 10^{-8}$ , which reduce to 5 independent loci by pruning the set markers in linkage disequilibrium with each other. We evaluated 11,482 TF ChIP-seq (chromatin immunoprecipitation with DNA sequencing) datasets, which include 53 viral TFs. To determine whether the intersections of transcription factor and co-factor (TF) DNA binding sites concentrate at variants contained in the KD risk loci, we applied the RELI (Regulatory Element Locus Intersection) (Nat Genet 50:699, 2018).

Significant binding was found in 14 TF ChIP-seq datasets for 9 human TFs (BACH2, RELA, H3F3A, EP300, POLR2A, MED1, SPI1, POU2F2 and NFXL1) and one viral TF, all with  $P < 1 \times 10^{-6}$  after Bonferroni correction. Unexpectedly, the binding of EBV Epstein-Barr virus Nuclear Antigen 2 (EBNA2) to DNA in the 5 KD risk loci is >27-fold enriched compared to the whole genome with  $P = 9.6 \times 10^{-14}$ . Among 5 loci only 4 are occupied by human and viral TFs consistent with their having a regulatory role. Twelve (85.7%) of 14 ChIP-seq datasets were obtained from B cell lines, 9 (64.3%) of them are from EBV-transformed B cell lines in the Latency III program of viral expression in which EBNA2 is an expressed viral gene products. These results show that features characteristics of the EBV transformed B cell expressing EBNA2 correlate with the genetic mechanism(s) of pathogenesis in at least some children with Kawasaki disease. These results are consistent with, but do not establish, causation.

## PgmNr 2028: A GWAS of neonatal sepsis shows significant genetic differences between males and females.

---

Late Onset Neonatal Sepsis is a serious perinatal condition, involving widespread infection, immune disruption, organ dysfunction, and in 15-30% of cases, death. The initiation of this disorder requires contact with infectious agents in the perinatal period and this presents opportunities to prevent exposure, but these behaviors cannot be 100% effective. Thus, it is critical to identify host susceptibility factors, gain etiologic insights, and develop interventions that predict and help the neonates at greatest risk. Here we performed a case control genome wide association study using the Illumina MEGA Consortium V2 Beadchip to identify genetic factors that associate with neonatal sepsis. Participants were identified in hospitals from several European countries (NeoMero Consortium: Estonia, Greece, Italy, Lithuania, the Netherlands, Spain, the UK, and France), and after initial quality control processing there were 224 cases and 273 controls. Because neonatal sepsis is more common in males and some etiologic factors may differ between the sexes, we performed combined and sex-stratified association analyses. Additionally, because the X chromosome encodes a number of immune related genes, we included it in the GWAS and performed sex-stratified quality control and association analyses in the X chromosome data. We identified multiple SNPs, 71 in total, that associated with neonatal sepsis at  $p < 1 \times 10^{-4}$  in at least one of the five adjusted logistic regression analyses, but did not detect any genome wide significant associations ( $p < 5 \times 10^{-8}$ ). However, we observed large differences in the findings between males and females. None of the top SNPs in males were associated with sepsis in females (at  $p < 0.05$ ), and none of the top SNPs in females were associated among the males (at  $p < 0.05$ ). These statements hold for both the autosomal and X chromosome variants. When the top SNPs from these sex-stratified analyses were analyzed in the full study population, most of the sex\*SNP interaction terms were significant and they were highly significant for all female top SNPs. Finally, we note that the association between *IL-10* variation and neonatal sepsis previously reported, was also observed with 5 SNPs in our combined analysis (at  $p < 0.05$ ). These results indicate that genetic susceptibility factors for neonatal sepsis likely differ by sex and future etiologic research should routinely involve sex-stratified sensitivity analyses.

## PgmNr 2029: Causal role of L-glutamine and 3-ureidopropionate in sickle cell disease complications: A Mendelian randomization analysis.

### Affiliations:

1) Biochemistry, University of Montréal, Montreal, Quebec, Canada; 2) Duke Molecular Physiology Institute, Duke University Medical Center, Durham, North Carolina, United States of America; 3) Department of Medicine, Division of Hematology, Duke University Medical Center, Durham, North Carolina, United States of America; 4) Red Cell Genetic Disease Unit, Hôpital Henri-Mondor, Assistance Publique-Hôpitaux de Paris (AP-HP), Université Paris Est, IMRB - U955 - Equipe no 2, Créteil, France

In 2017, the FDA approved for the first time in 20 years a new drug to treat sickle cell disease (SCD). The drug, Endari, is an oral L-glutamine metabolite that acts by reducing oxidative stress in erythrocytes. The conclusions from the phase 3 randomized clinical trial suggested that treatment with L-glutamine reduces pain crises and hospitalization rate (Niihara *et al.*, NEJM, 2018). Our goals were to confirm the clinical trial findings using an alternative, genetics-based strategy, and to identify other metabolites causally implicated in the clinical heterogeneity observed in SCD patients.

Employing a targeted metabolomics platform, we profiled 129 metabolites from the plasma of two SCD cohorts from Paris, France (GEN-MOD (n=406)) and North Carolina, USA (OMG-SCD (n=300)). To prioritize metabolites, we performed correlation analyses between metabolite levels and 6 SCD complications (pain crises, cholecystectomy, retinopathy, leg ulcer, priapism, aseptic necrosis) or estimated glomerular filtration rate (eGFR). We assessed statistical significance via permutation test and used 2-sample Mendelian randomization (MR) methods to test for causality. We obtained MR instruments associated with metabolites of interest from two large metabolite GWAS performed in healthy Europeans (Shin *et al.*, Nature Genetics, 2014, n=7,824; Long *et al.*, Nature Genetics, 2017, n=1,960). We derived SNP associations with SCD clinical outcomes from the large African-American CSSCD cohort (n=1,278).

We identified a causal relationship between L-glutamine levels and pain crises requiring hospitalization (odds ratio (OR) [95% confidence interval]=0.68 [0.52 - 0.89], P=0.005). Our MR study estimates a 32% reduction in pain crises with one standard deviation increase of L-glutamine. This estimate is comparable to the 33% reduction in hospitalization due to emergency room visit observed in SCD patients treated with L-glutamine vs. placebo in the clinical trial. We identified 71 other significant associations (FDR<5%) between metabolite levels and SCD-related complications or eGFR. Two-sample MR analyses revealed a causal association between 3-ureidopropionate and eGFR: a standard deviation increase in 3-ureidopropionate leads to an eGFR increase of 0.07 mL/min per 1.172 m<sup>2</sup> (P=9.7x10<sup>-4</sup>).

MR analyses provide additional evidence to support the causal role of L-glutamine in modulating pain crises in SCD. Additionally, we found a tentative causal link between 3-ureidopropionate levels and

eGFR.

**Objective** The causality and pathogenic mechanism of microbiome composition remain elusive in many diseases, including autoimmune diseases such as rheumatoid arthritis (RA). This study aimed to elucidate gut microbiome's role in RA pathology by a comprehensive metagenome-wide association study (MWAS).

**Methods** We conducted MWAS of the RA gut microbiome in the Japanese population ( $n_{\text{case}} = 82$ ,  $n_{\text{control}} = 42$ ) by utilizing whole-genome shotgun sequencing of high depth (average 13 Gb per sample). Our MWAS consisted of three major bioinformatic analytic pipelines (phylogenetic analysis, functional gene analysis, and pathway analysis).

**Results** Phylogenetic case-control association tests showed high abundance of multiple species belonging to the genus *Prevotella* (but other than previously reported *Prevotella copri*) in the RA case metagenome. The non-linear machine learning method efficiently deconvoluted the case-control phylogenetic discrepancy. Gene functional assessments showed that the abundance of one redox reaction-related gene was significantly decreased in the RA metagenome compared to controls. A variety of biological pathways including those related to metabolism (e.g., fatty acid biosynthesis and glycosaminoglycan degradation) were enriched in the case-control comparison. A population-specific link between the metagenome and host genome was identified by comparing biological pathway

enrichment between the RA metagenome and the RA genome-wide association study (GWAS) results. No apparent discrepancy in alpha- or beta-diversities of metagenome was found between RA cases and controls.

**Conclusion** Our shotgun sequencing-based MWAS highlights a novel link among the gut microbiome, host genome, and pathology of RA, which contributes to our understanding of the microbiome's role in RA etiology.

# PgmNr 2031: The effects of common *TMPRSS6* and *TF* variants on iron status in healthy Gambian women of reproductive age.

## Authors:

M. Jallow <sup>1</sup>; S. Campino <sup>2</sup>; A. Prentice <sup>1</sup>; C. Cerami <sup>1</sup>

[View Session](#) [Add to Schedule](#)

## Affiliations:

1) The Nutrition Theme, Medical Research Council Unit The Gambia at London School of Hygiene & Tropical Medicine, Atlantic Road Fajara, P.O. Box 273 Banjul, The Gambia; 2) Department of Infection Biology, Faculty of Infectious and Tropical Diseases, London School of Hygiene & Tropical Medicine, Keppel Street, London WC1E 7HT, UK

## Background

Anaemia is a global health problem affecting women of reproductive age and children in low-and middle-income countries the most. Nutritional deficiencies, infection and genetic risk factors are the major drivers. However, the role of genetic factors particularly in settings where the prevalence of anaemia is high, has not been fully investigated. Genome-wide association studies have identified numerous single nucleotide polymorphisms in the *TMPRSS6* and *TF* genes which are linked to impaired iron status. However, the effects of these SNPs on anaemia in West African populations have not been investigated.

## Objectives

To investigate the effects of SNPs in *TMPRSS6* and *TF* genes on iron status in healthy Gambian women of reproductive age.

## Methods

We analyse data from women of reproductive age (15 to 49years), n=227, with genotype data on *TMPRSS6* (rs2235321, rs855791, rs4820268, rs2235324, rs2413450 and rs5756506) and *TF* (rs3811647 and rs1799852), and iron biomarker data (serum iron, unsaturated iron binding capacity (UIBC), transferrin, ferritin soluble transferrin receptor (sTfR), transferrin saturation (TSAT) and total iron binding capacity (TIBC) and hepcidin) collected prospectively as part of the MRC Keneba Biobank, in The Gambia. We investigated the effects of genotype on the iron status.

## Results

The minor allele (G) of *TMPRSS6* rs4820268 showed elevated serum iron [17.02 (5.25) vs 12.63 (4.82) *p*-value=0.039], TSAT [27.9 (10.3) vs 19.1 (6.7); *p*-value=0.022], and ferritin [33.6 (16.0) vs 32.7 (36.1); *p*-value=0.025], and decreased TIBC [62.2 (6.9) vs 67.8 (9.5); *p*-value=0.046], GG vs AA genotypes respectively. Inversely, the minor allele (A) of *TF* rs3811647 showed reduced TSAT [22.3 (11.2) vs 26.7 (12.9), *p*-value=0.024], elevated transferrin [3.1 (0.8), *p*-value=0.019], TIBC [68.2 (10.7) vs 62.2 (11.2), *p*-value=0.001] and UIBC [53.5 (13.5) vs 46.2 (13.9), *p*-value=0.001], GA vs GG genotypes respectively.

**Conclusion**

*TMPRSS6* rs4820268 minor allele (G) may be protective against low iron status whereas, the minor allele (A) of *TF* rs3811647 may predispose to low iron status. We aim to further analyse a larger dataset and with more SNPs both individually and in combination with other ones, and different in populations groups to further gain more insight into the effects of SNPs within the iron regulatory genes on the risk of anaemia. This may enable the development of a genetic risk score for anaemia.

---

3q29 deletion syndrome is a rare (1 in 30,000) genomic disorder associated with cognitive disability, autism, generalized anxiety disorder, and a 40-fold increased risk for schizophrenia (SZ). The Emory 3q29 Project (<http://genome.emory.edu/3q29/>) unites an interdisciplinary team toward the common goal of understanding the phenotypic spectrum, natural history, and molecular mechanism of the 3q29 deletion. To facilitate investigation of the 3q29 deletion phenotype, our team has developed a comprehensive, transdiagnostic phenotyping protocol for both diagnostic and dimensional assessments (Murphy MM et al, 2018). We have now directly evaluated 20 individuals with the 3q29 deletion (average age = 12 years, range 6-26) for cognitive ability, anxiety, attentional deficits/executive function, fine motor function/cerebellar dysregulation, social disability, and prodrome/psychosis. Using strict diagnostic criteria, our study subjects qualify for diagnoses as follows: 56% intellectual disability, 30% autism spectrum disorder (ASD), 30% generalized anxiety disorder, and 10% psychosis or SZ. This enrichment of psychosis is noteworthy given that the majority of our study subjects have not yet approached the age at risk for SZ. 63% of our study subjects qualify for a diagnosis of Attention Deficit/Hyperactivity Disorder (ADHD), which was not previously appreciated as part of the 3q29 deletion phenotype. When we consider quantitative measures, we find that cognitive ability is mildly impacted (average IQ = 73, range 99-46) but more than 60% of our study subjects have subtest scores that differ by more than 1 standard deviation. Verbal ability is typically a strength (average = 80), and spatial reasoning is a weakness (average = 66). 75% of study subjects with 3q29 deletion exhibit significant graphomotor weakness, and this is driven by motor coordination deficits. Males have spatial reasoning scores that are on average 12 points lower than females, and motor coordination deficits are also more pronounced in males, suggesting sex-dependent effects in this domain. Taken together, these data a) illuminate the phenotype of 3q29 deletion syndrome; b) provide specific direction for clinical and educational support; c) will be crucial for connecting phenotypic deficits to molecular mechanism; and d) inspire future directions to understand whether second hit mutations, polygenic background, or environmental exposures contribute to the heterogeneity of the disorder.

## PgmNr 2033: *In vivo* modeling of the 2q13 reciprocal CNV reveals multiple phenotypic contributors and genetic interactions.

---

Copy number variants (CNV), a subclass of structural variation, alter gene dosage through either haploinsufficient or triplosensitive pathomechanisms and are an established source of mutational burden in neurodevelopmental traits. Here, we investigate an experimentally tractable reciprocal CNV at 2q13. Over 50 deletion and 20 duplication carriers have been reported, and affected individuals display a constellation of variable phenotypes including head size defects, psychiatric phenotypes, seizures, facial dysmorphisms, and cardiac anomalies. The minimum overlapping region among reported cases comprises eight genes (*FBLN7*, *BUB1*, *TMEM87B*, *MERTK*, *Z3CH8*, *ACOXL*, *ANAPC1*, *BCL2L11*), and for a majority of loci, evidence is lacking from single nucleotide variants in healthy or diseased individuals to support a role in phenotype(s). Dosage gain models, generated by overexpression of each human transcript in zebrafish embryos, did not identify any mRNAs capable of inducing a detectable head size or craniofacial phenotype in isolation. Pair-wise overexpression of all possible gene combinations showed that three discrete pairs resulted in significant craniofacial defects. However, we observed thirteen pairs that resulted in microcephaly, with the majority of *ACOXL* pairs leading to head size reduction. Dosage loss zebrafish models for *tmem87a*, *anapc1* and *bcl2l11* individually displayed relevant phenotypes, such as microcephaly and craniofacial abnormalities. Further, pair-wise co-suppression of genes that demonstrated no detectable phenotype in sub-effective doses revealed epistatic events, similar to the overexpression studies and consistent with the mirror phenotypes of humans. Finally, placement of *ANAPC1* or *TMEM87A* on a protein affinity network comprised of phenotypically-related genes implicated in autism, intellectual disability, and head size phenotypes showed putative involvement in discrete functional modules governing cell cycle progression and endoplasmic reticulum targeting, respectively. Our data suggest that phenotype-specific epistatic interactions both within the 2q13 locus and also in *trans* with functionally relevant genes outside the 2q13 region likely drive neuroanatomical and/or craniofacial abnormalities associated with this CNV.

## PgmNr 2034: The emerging role of *RBFOX1* in visual impairment genetics.

**Authors:**

F. Bolduc; S. Weber

[View Session](#) [Add to Schedule](#)

**Affiliation:** Dept Pediatrics, Univ Alberta, Edmonton, Alberta, Canada

---

**BACKGROUND.** Several individuals with neurodevelopmental disability (NDD) also present with clinically relevant visual impairment (VI). While VI can sometimes be difficult to recognize early on, its impact on daily functioning is significant for the individual, the family and educators. VI is not systematically reported in individuals with NDD. Here, we identified 2 individuals from the same family with an *RBFOX1* intragenic heterozygous deletion with visual processing defects.

**METHODS:** We used comparative genomic hybridization to identify a copy number variation (CNV) in individuals with NDD seen in our neurogenetic clinic. We also reviewed the published literature to develop a comprehensive clinical description of *RBFOX1*. Next, we conducted a pathway analysis to identify possible mediators of visual impairment in individuals with an *RBFOX1* CNV.

**RESULTS:** The role of *RBFOX1* role in intellectual disability, anxiety, sleep difficulty and focal epilepsy as well as renal and cardiac malformations has been previously reported. We identified a novel potential role with cortical visual impairment in 2 individuals with an intragenic *RBFOX1* deletion with overlapping clinical characteristics. Our pathway analysis revealed several genetic links between *RBFOX1* and VI.

**DISCUSSION:** Our findings highlight the need to further document the presence of visual impairment in analysis of NDD phenotypes as it has a potentially relevant clinical phenotype. Our results also support the recent findings in a mice model of *RBOX1* where visual impairment was reported.

## PgmNr 2035: Polygenic score profiling of quantitative lipid traits: Lessons from a specialized dyslipidemic cohort.

### Affiliations:

1) Robarts Research Institute, Schulich School of Medicine and Dentistry, Western University, London, ON, Canada; 2) Department of Biochemistry, Schulich School of Medicine and Dentistry, Western University, London, ON, Canada; 3) Department of Biomedical Data Science, Stanford School of Medicine, Stanford University, Stanford, CA, United States of America; 4) Department of Medicine, Schulich School of Medicine and Dentistry, Western University, London, ON, Canada

**Introduction:** Polygenic scores (PSs) are often calculated in prospective cohorts representing generally healthy populations. Because of this, characterizing polygenic underpinnings of a quantitative trait's full phenotypic spectrum can be challenging given the rarity of phenotypic extremes, which are of interest in the context of human health and disease. In dyslipidemia patients from a tertiary referral clinic, we aimed to establish polygenic profiles for the three main blood lipid traits—low-density lipoprotein cholesterol (LDL-C), triglyceride (TG), and high-density lipoprotein cholesterol (HDL-C)—with a focus on the extremes of each trait.

**Materials and Methods:** We performed PS analyses on patients using a 10-SNP LDL-C score (N=1,226), 16-SNP TG score (N=1,406), and 9-SNP HDL-C score (N=1,298). For clinical utility, we utilized smaller PSs that incorporate SNPs with the largest phenotypic effects. "Extreme scores" reflect an excess of trait-raising SNPs and are defined as scores  $\geq 90^{\text{th}}$  percentile, as calculated in the 1000 Genomes cohort. For each PS analysis, patients were stratified by clinically relevant thresholds for the associated trait (i.e. for the LDL-C score, patients were stratified by LDL-C level). Odds ratios were calculated between stratification groups of a trait, and differences in mean PS for each stratification group were assessed with a Kruskal-Wallis test using Dunn's multiple test adjustment.

**Results:** As LDL-C levels increased, the prevalence of extreme LDL-C PSs increased, except for patients with the highest LDL-C levels, as their PSs were similar to those with normal levels. As TG levels increased, the prevalence of extreme TG PSs increased; patients with the highest TG levels were 5.30-fold [3.47-8.06;  $P < 0.0001$ ] more likely to have an extreme PS compared to those with normal levels. As HDL-C levels increased, the prevalence of extreme HDL-C PSs increased; patients with the highest HDL-C levels were 2.37-fold [1.32-4.33;  $P = 0.003$ ] more likely to have an extreme PS compared to those with normal levels.

**Conclusions:** Polygenic profiles of each lipid trait were unique. High LDL-C had a less pronounced polygenic basis, suggesting a more prominent monogenic component. Conversely, high TG and HDL-C had a stronger polygenic basis. Evaluation of patients at phenotypic extremes allows for more efficient use of resources to define clinically relevant genetic determinants for diagnosis and possibly tailored interventions.

## PgmNr 2036: Unexplained familial hypercholesterolemia in African Americans: No detectable mutation does not necessarily imply a polygenic basis.

---

Extreme values of quantitative traits or rare severe phenotypic presentations can be caused by individual mutations of very large effects segregating in Mendelian fashion. Alternatively, such phenotypes may reflect extremes of polygenic or oligogenic genetic inheritance. Beyond importance for basic genetics, this distinction is practically important for the design of genetic studies that can follow either Mendelian or complex trait paradigm. Currently, sequencing studies of rare phenotypes attribute only a fraction of cases to an obvious monogenic cause. Frequently, individuals with extreme phenotype have family members with milder presentation. Thus, it is expected that family history is informative about genetic architecture of severe phenotypes. We investigated this hypothesis in a series of population genetics computer simulations and the analysis of cases of severe familial hypercholesterolemia (FH) in African American individuals.

Recent work on FH in patients without known causative mutations in *LDLR*, *APOB* and *PCSK9* suggests that a large fraction of such cases may be attributed to polygenic inheritance whereby a large number of small-effect mutations collectively result in extreme LDL-C levels that are comparable to levels in patients with monogenic FH. It remains unclear to what extent the family history is informative to distinguish monogenic and polygenic FH patients with extreme LDL-C levels. We developed a population and statistical genetics framework to simulate families of individuals with extreme LDL-C levels and calculated the fraction of monogenic FH cases conditional on population genetics parameters, varying prevalence, and pedigree structure.

We applied our simulation framework to real pedigrees from 124 African American families with individuals that are clinically ascertained to have autosomal dominant FH with no causative mutations in known FH genes. Families with and without a causative mutation were indistinguishable under a wide range of models. Moreover, family history did not provide substantial information to distinguish likely monogenic or non-monogenic basis for unexplained FH in these families. These findings have significant implications for study design of rare and unexplained genetic conditions as well as genetic testing strategies for new gene discovery, prevention and treatment of FH in underrepresented African American individuals.

## PgmNr 2037: Genetics of hypertriglyceridemic acute pancreatitis: Analysis of a prospective acute pancreatitis cohort and a complex family.

**Background.** Acute pancreatitis (AP) is a sudden, life-threatening inflammatory disorder. Hypertriglyceridemia (HTG) associated AP (HTG-AP) is a common subtype that is associated with higher rates of morbidity and mortality. The risk of HTG-AP is proportional to plasma triglyceride levels driven by genetic and environmental factors. While familial HTG and chylomicronemia syndromes are well defined, the underlying genetics of well-defined AP cohorts are unknown.

**Methods.** The Pancreatitis-associated Risk Of Organ Failure (PROOF) trial includes consecutive subjects with AP admitted to UPMC Presbyterian Hospital between 2006 and 2016. Among the first 500 patients, 68 (13.6%) had TG>200 mg/dL identified within 72 hours of admission. These included TG≥200 and <500 mg/dL (n=26); TG>500 and <1000 mg/dL (n=12); TG≥1000 and <2000 mg/dL (n=6); and TG ≥2000 mg/dL (n=25). HTG-AP patients were matched ~2:1 with AP without HTG (AP). The final analysis cohort included 92 HTG-AP cases, 188 (AP) and a HTG-AP proband with 8 HTG relatives. Whole exome sequencing and whole-genome genotyping using the GSA microarray (Illumina, San Diego, CA, USA) were conducted in collaboration with the Regeneron Genetics Center.

**Results:** A GWAS in our cohort replicated association between HTG-AP and a high-risk *FADS1* locus haplotype ( $p<1e-5$ ). The homozygous risk haplotype was in 3.9% of AP and 13.5% of HTG-AP with TG>1000 mg/dL: allele dose correlated with TG category ( $P<0.05$ ). Pathogenic variants in *LPL* were seen in 7/92 HTG-AP cases and 0/188 AP controls ( $p<0.0005$ ). In HTG-AP cases: *APOA5* (n=8, one complex with an *LPL* variant) *LMF1* (n=7 VUS); *APOC2* (n=2); and *GPIHBP1* variants (n=2, one complex with an *LPL* variant). A HTG-AP proband with a family history of HTG had a complex genotype with two *SPINK1* pancreatitis variants, and HTG risk variants in *APOA*, *ADRB2*, *GCKR*, *FABP1*, and *FABP2* shared in various combinations in affected family members. Pathogenic variants in AP patients with TG>200 and <500 mg/dL, *APOA5* (n=3/26) & *GPIHBP1* (n=1/26); TG≥500 to <1000 mg/dL, *APOA5* (n=2); TG>1000 and <2000 mg/dL *LPL* (1/6); and TG >2000 mg/dL variants in *LPL* (n=6/25) & *APOA5* (n=1/25). No patients with BMI>40 had a pathogenic coding variant (n=9).

**Conclusions:** Patients with HTG-AP and BMI under 40 harbor multiple genetic risks, with pathogenic *LDL* having the strongest effect on TG levels >1000 mg/dL. The *FADS1* risk haplotype is associated with

HTG-AP. Effective therapies may require a precision medicine approach.

## PgmNr 2038: Genetic structure underlying lipids metabolites linked to human diseases.

---

Systematic genome-wide association studies of 'omics phenotypes highlighted shared genetic components between many molecular traits and human diseases. However, our understanding of the genetic structure underlying molecular traits and their role in common human diseases remains very limited. Here we used 10,000 participants from the Finnish Metabolic Syndrome In Men (METSIM) cohort, a unique resource including measurements for over 150 correlated lipid metabolites along genome-wide genetic data, to assess potential links between complex human phenotypes and genetic structure underlying these lipids metabolites. We first applied top-of-the-art univariate and multivariate approaches in METSIM to select a subset of approximately 500 independent SNPs associated with at least one metabolite. We next performed a clustering of these SNPs with the objective of identifying directional signatures across the 150 metabolite dimensions, while circumventing the issue of choosing a coded allele (i.e. to avoid symmetric clusters due to random allele coding) and accounting for correlation between association statistics due to phenotypic correlation. We achieved this goal by applying a *K-medoids* clustering based on absolute cosine dissimilarity, where each single SNP was weighted by its Euclidean norm to account for association signal strengths. After validating our approach through simulations, we assessed the biological relevance of the identified clusters of SNPs by estimating their enrichment for association with dozens of human diseases and phenotypes using independent GWAS summary statistics. We found several clusters to be highly enriched for association with very specific outcomes, including in particular coronary heart disease, schizophrenia, celiac disease, and years of education. These strong features suggest new hypothetical genetic mechanisms on those outcomes, and highlight the importance of integrative approaches to decipher complex structure underlying multidimensional phenotypes.

Current understanding of lipid genetics has come mainly from studies in European-ancestry populations; limited effort has focused on Polynesian populations, whose unique population history may provide insight into the biological foundations of variation in lipid levels. Here, we performed an association study of 4 lipid traits: total cholesterol, high-density lipoprotein (HDL), low-density lipoprotein, and triglycerides (TG) and genetic variants in 5q35, a region that has shown suggestive association with HDL in Micronesian and Polynesian peoples and no previous evidence of association in Europeans.

We performed association testing between variants on 5q35 and lipid levels in the discovery cohort comprising 2,851 Samoans using linear mixed modeling with imputed genotypes based on Samoans sequenced via TOPMed and adjusting for age, sex, principal components of ancestry, and relatedness. Fine-mapping analyses highlighted an association between a stop-gained variant (rs200884524; c.652C>T, p.R218\*) in *BTNL9* and HDL (discovery cohort:  $\beta = -1.99\text{mg/dL}$ ,  $p = 4.49 \times 10^{-8}$ ; replication cohort of 1,522 Samoans and American Samoans:  $\beta = -1.35\text{mg/dL}$ ,  $p = 0.0017$ ; replication cohort of 2,378 Māori and Pacific individuals living in Aotearoa/New Zealand:  $\beta = -0.90\text{mg/dL}$ ,  $p = 0.003$ ; meta-analysis of all cohorts:  $\beta = -1.35\text{mg/dL}$ ,  $p = 4.75 \times 10^{-11}$ ). rs200884524 is also associated with TG (discovery cohort:  $\beta = 14.38\text{mg/dL}$ ,  $p = 3.63 \times 10^{-6}$ , Samoan replication cohort:  $\beta = 8.29\text{mg/dL}$ ,  $p = 0.061$ , Aotearoa/New Zealand replication cohort:  $\beta = 6.67\text{mg/dL}$ ,  $p = 3.51 \times 10^{-5}$ ; meta-analysis:  $\beta = 8.3\text{mg/dL}$ ,  $p = 1.02 \times 10^{-9}$ ). This variant accounts for 1.02% and 0.7% of the variation in HDL and TG respectively in

the discovery cohort.

rs200884524 has a MAF of  $<0.0002$  in gnomAD; of the 50 alleles seen in gnomAD, 45 are from East Asians. However Samoans have a MAF of 0.218 in the discovery cohort (0.215 and 0.101 in the Samoan and Aotearoa/New Zealand replication cohorts respectively). Consistent with these disparate allele frequencies, this variant showed evidence of positive selection (PBS score of 0.477, 99.6 percentile in the Samoan genome;  $nS_L$  score of 1.78, 98.3 percentile in the Samoan genome).

BTNL9 is expressed in adipose, breast, and lung tissue (GTEx). Additional work is necessary to characterize the relationship between variation in *BTNL9* and lipid levels; however, these initial findings fine map the suggestive association in 5q35, providing evidence of a new contributor to the genetic architecture of lipids in Polynesian peoples.

## PgmNr 2040: A novel variant in *CETP* is associated with higher HDL-cholesterol in people of Polynesian ancestry.

Common variants in Cholesteryl ester transfer protein (*CETP*) are associated with differences in HDL-cholesterol (HDL) levels in most ancestral groups. However, no studies have examined whether genetic variation in *CETP* associates with HDL among people of Polynesian ancestry.

An HDL GWAS using the Illumina CoreExome platform was conducted in 2,594 people of Polynesian ancestry (Aotearoa/New Zealand [A/NZ] Māori, Cook Island Māori, Sāmoan, Tongan, Niuean and Pukapukan) living in A/NZ. Using 55 *CETP* gene sequences, genetic variants common in people of A/NZ Polynesian ancestry (>5%) but extremely rare (<0.001%) in gnomAD were selected for follow-up. A set of 2,851 Sāmoans (cohort I) using imputed genotypes based on Sāmoans sequenced via TOPMed and a set of 1,510 directly genotyped Sāmoans and American Sāmoans (cohort II) were used to replicate initial findings. The A/NZ analysis was adjusted for age, sex and principal components of ancestry, whereas the Sāmoan cohorts were adjusted for age, sex, principal components of ancestry and relatedness. Selection was calculated via the haplotype-based statistic (nSL) using the selscan program.

Three variants within *CETP* (rs183130, rs247617, rs9939224) were genome-wide significant in the A/NZ Polynesian. Closer inspection found a novel Polynesian-specific variant (NC\_000016.10:g56971035C>T, *CETP*:p.P177L) associated with higher HDL levels in the A/NZ ( $\beta$ =11.3 [9.1, 13.5] mg/dL,  $p=9.1\times10^{-24}$ ), Sāmoan cohort I ( $\beta$ =8.7 [7.4, 10.1] mg/dL,  $p=3.0\times10^{-37}$ ) and cohort II ( $\beta$ =8.3 [6.7, 9.9] mg/dL,  $p=4.5\times10^{-25}$ ). The MAF for the A/NZ Polynesian, Sāmoan cohorts I and II were 3.4%, 4.4% and 4.9% respectively but this variant is unobserved in gnomAD. The

variances in HDL explained by the variant in the A/NZ cohort and S?moan cohort I were 7.7% and 5.1% respectively. Analysis of this variant showed moderate evidence of positive selection (nSL score of 1.52 with an empirical percentile of 92%) in the S?moan cohort I. A CADD score of 25.6 places the variant in the top 1% of predicted deleteriousness. Secondary analysis conditional on this variant shows that all other variants associated with HDL within or close to *CETP* did not reach genome-wide significance.

Our results show that a unique variant in *CETP* contributes strongly to the phenotypic variation of HDL in people of Polynesian ancestry. This improved understanding of *CETP* variation in people of Polynesian ancestry allows insights into differences in control of HDL in this population.

## PgmNr 2041: Genetic drivers of serum lipid and liver disease co-heritability are enriched in the FXR/RXR pathway.

### Authors:

**Background:** Nonalcoholic fatty liver disease (NAFLD) is epidemiologically associated with high triglycerides (TG), high low-density lipoprotein cholesterol (LDL-C) levels, and low high-density lipoprotein cholesterol (HDL-C) levels. Part of the global obesity epidemic, NAFLD is projected to be the number one cause of liver disease worldwide by 2020. Whether NAFLD and blood lipid levels may share a common genetic etiology is unknown.

**Methods:** We used gene set enrichment analysis (GSEA) implemented in MAGENTA to identify pathways enriched for lipid GWAS associations from published summary statistics, then tested these pathways for enrichment with NAFLD associations from two populations with computed tomography measured NAFLD. Effects of variants in enriched pathways were independently tested on liver function tests and serum lipids in participants from the UKBiobank.

**Results:** European genetic associations from the Global Lipids Genetics Consortium (N >95,000) were tested for pathway enrichment using MAGENTA, identifying 58 pathways enriched for HDL-C, LDL-C, or TG GWAS associations. CT measured NAFLD GWAS associations from individuals of European-ancestry (N=7,126) were then tested for enrichment in these 58 lipid-associated pathways, and three pathways (FXR/RXR Activation, Hepatic Cholestasis, and Chylomicron Mediated Lipid Transport) were found to be enriched (P < 0.01). Of these three pathways, only FXR/RXR Activation replicated this enrichment for CT measured NAFLD genetic associations in individuals of African-ancestry (N=3,124) (P=0.0058). The FXR/RXR pathway was not enriched for associations with other comorbid traits including blood pressure (N=275,000), body mass index (N= 249,796), and waist to hip ratio (N=77,167) obtained from publically available data, suggesting that the enrichment was specific to NAFLD and serum lipids. Within the FXR/RXR pathway, genes showing high credibility (Bayes factor > 3 vs. other genes in the pathway) include PPARA, APOB and SLCO1B1. Variants in the FXR/RXR pathway replicate liver damage decreasing alleles increasing LDL cholesterol in the UKBiobank (N=389,565).

**Conclusions:** These results identify the FXR/RXR pathway as having an overlapping genetic etiology for dyslipidemia and fatty liver. Variants in the FXR/RXR pathway have opposite effects on NAFLD and serum lipids consistent with reported FXR agonist effects [PMID 28145001, PMID 27109453], suggesting that human genetics can help inform drug effects.

## PgmNr 2042: Phenome-wide copy number variation burden association study on 23 phenotypes in 10,000 participants from the eMERGE Network.

---

Recent studies on copy number variations (CNV) have suggested that an increasing burden of CNVs is associated with susceptibility or resistance to disease. However, no systematic CNV burden association analysis has been done on a wide range of phenotypes. We performed a phenome-wide CNV burden association analysis to explore global CNV burden effects associated with multiple phenotypes in subjects from the electronic Medical Records and Genomics (eMERGE) Network. The CNV calls were generated using PennCNV and QauntisNP and retained only the regions with at least 50% intersection. We tested for significant associations between CNV burden, measured as base pairs of duplication and deletion, in 10,525 samples and 23 phenotypes based on ICD9 diagnosis and lab values from five eMERGE sites. Logistic or linear regression models were fit to the data to evaluate the associations between CNV burden and phenotypes, adjusting for age, sex, the first three principal components of ancestry, and eMERGE sites. The datasets per phenotype were split into discovery and replication dataset based on the genotyping center. However, LDL and HDL, which were only available from a single genotyping center, were randomly and equally split into discovery and replication dataset. Then, we ran association tests for the discovery and replication dataset as well as the combined dataset. We found several statistically significant associations replicated between cholesterol phenotypes and duplication burden in Total Cholesterol Median (discovery FDR =  $2.7 \times 10^{-4}$ , replication FDR =  $9.6 \times 10^{-2}$ , combined FDR =  $1.3 \times 10^{-2}$ ) and LDL (discovery FDR =  $3.7 \times 10^{-2}$ , replication FDR =  $9.6 \times 10^{-2}$ , combined FDR =  $2.7 \times 10^{-3}$ ). Triglyceride Median was also significantly associated in discovery and combined dataset (discovery FDR =  $3.7 \times 10^{-2}$ , combined FDR =  $5.5 \times 10^{-2}$ ), but was not replicated. Further, we performed a pathway-based CNV burden analysis to better understand the

biological functions of the genes within duplication for 2 significant cholesterol phenotypes. We found 11 pathways associated with Total Cholesterol Median (FDR < 0.05), including fat digestion and absorption, systemic lupus erythematosus, and PPAR signaling, which are already known to be associated with cholesterol phenotypes. These findings indicate that cholesterol-related phenotypes might be more associated than other traits with global CNV burden. This study warrants further exploration in other complex diseases caused by high cholesterol.

# PgmNr 2043: A phenome-wide and genome-wide analysis of triglyceride levels in the Healthy Nevada Project cohort.

## Authors:

1) Institute for Health Innovation, DRI, Reno, NV; 2) Institute for Health Innovation, Renown Health, Reno, NV

---

Background: In 2017, Renown Health and DRI conceived the Healthy Nevada Project (HNP): merging an extensive Electronic Health Record (EHR) database and genotypic data of 10,000 individuals based on the Illumina Human OmniExpress-24 BeadChip in a single Northern Nevada cohort. Methods: Here, a genome-wide association study (GWAS) was performed on 4,960 HNP participants to assess genotypic association of triglyceride levels against 498,709 quality-controlled genotypes. Standard quality control measures were implemented (>95% SNP call rates, >95% individual call rates, Hardy-Weinberg Equilibrium  $p > 1 \times 10^{-6}$ , minor allele frequency >.5%). PLINK v. 1.9 performed associations using age, gender, BMI, and Type 2 Diabetes (DM2) as covariates, and the standard log-additive genetic model. Two independent PheWAS analyses were performed: one examined associations between significant SNPs identified in the GWAS and EHR phenotypes based on ICD codes; the second PheWAS identified associations between triglyceride levels and ICD-based diagnoses. Both used the R package **PheWAS**. ICD9 and ICD10 codes were aggregated via a mapping from the Center for Medicare and Medicaid services. A polygenic weighted risk score was computed via SNP effect sizes and minor allele counts; linear regression on transformed data measured its contribution on phenotypic variance. Results: This study identified 48 statistically significant SNPs associated ( $p < 5 \times 10^{-8}$ ) with triglyceride levels, many reported in prior studies. SNP rs17159164 in the *DOCK4* gene ( $p = 7 \times 10^{-14}$ ); SNPs rs1260326, rs780094, and rs780093 in *GCKR* ( $p < 2 \times 10^{-11}$ ); and rs2544164, rs426968 and rs2598272 in *LRGUK* ( $p < 2 \times 10^{-8}$ ) were previously linked with triglyceride response, hypertriglyceridemia, and DM2, respectively. Strong associations with SNPs and lipid levels, metabolic syndrome, and Crohn's disease were also identified. The risk score based on the 48 SNPs explained 11% of the cohort variation in triglyceride levels ( $p = 3 \times 10^{-14}$ ). PheWAS results indicated that triglyceride levels associate strongly with DM2 ( $p < 1 \times 10^{-35}$ ), an established association, obesity ( $p < 1 \times 10^{-28}$ ), hypertension ( $p < 1 \times 10^{-18}$ ), and other phenotypes not yet previously reported. SNPs identified in the GWAS associated with other phenotypes: abnormal glucose levels, anemia, DM2, gout, and vascular disease. Conclusion: This HNP study validates prior genomic and phenotypic associations with triglyceride levels and points to additional novel links using the Healthy Nevada Project.

## PgmNr 2044: Information management systems for biobanking in Taiwan Biobank.

**Authors:**

[View Session](#) [Add to Schedule](#)

**Affiliation:** Taiwan Biobank, Academia Sinica, Taipei, Taiwan

---

Taiwan biobank (TWB) is a large population-based cohort study and biobank that was established as a resource for research on complex interactions between environmental, phenotypic and genomic factors in the development of chronic diseases and healthy ageing. Our aim is to improve the health of future generations. TWB plans to recruit a large and comprehensive prospective study with 200,000 participants between the age of 30 and 70 from the general population with no history of cancer, and another 100,000 patients with chronic diseases of public health importance. This study has collected extensive phenotypic and genotypic details from individual participants, including the data from questionnaires, physical examination, biomedical test, image inspection, experimental information, biospecimens, omics information, and longitudinal follow-up for a wide range of health-related outcomes.

In order to manage the recruitment and information status of disease participants, TWB has developed a variety electronic systems, including Central Authentication Management System (CAMS), Subject Personal Information Management System (SPIMS), Subject Tracking Management System (STMS), Clinical Data Management System (iQuestion), and Laboratory Information Management System (LIMS). With the help of these systems, TWB employees can quickly and systematically synchronize data with each recruitment station and center. To address the importance of privacy protection issue, these systems depend on different authorizations for different employees with different roles in TWB.

TWB is available for open access to any bona fide researchers who wish to use it to conduct research. To achieve our goal, TWB will start to release the information more actively. Through international cooperation, TWB will to be a resource for the national and international scientific community to data request. The release of this large-scale population data will greatly benefit human biomedical research.

## PgmNr 2045: Age-related changes in gene expression of muscle and cartilage reflect overlapping aging biology.

### Authors:

E. Quillen

[View Session](#) [Add to Schedule](#)

**Affiliation:** Molecular Medicine, Wake Forest School of Medicine, Winston Salem, North Carolina

Aging is a key risk factor for nearly all common, complex diseases. However, age-related changes in gene expression across tissues are poorly understood, hindering our ability to distinguish between shared and tissue-specific alterations in transcription that may contribute to diseases of aging. This study examines this question in muscle and cartilage – two musculoskeletal tissues of distinct developmental origins – in 19 baboons (*P. anubis*).

At necropsy, tissue samples were collected from the distal vastus lateralis and unblemished lateral articular cartilage of the distal femur. No live animals were used or euthanized for the purposes of this study. RNA was extracted and mRNA libraries sequenced on the Illumina HiSeq2500. Reads with a Phred score greater than 30 were retained and aligned to the Panu 3.0 (Ensembl 92) reference genome using the STAR aligner in Partek Flow. Transcripts were collapsed to gene level and TPM normalized. Genes with non-zero counts in at least 7 animals were included in subsequent analyses resulting in 14,174 genes for the muscle analysis and 14,178 genes for cartilage.

Differential expression between young ( $N = 10$ ,  $12.9 \pm 1.44$  years, human equivalent 38.7 years) and old ( $N = 9$ ,  $19.7 \pm 1.33$  years, human equivalent 59.1) animals was evaluated using a Student's t-test for each tissue. Ranked by p-value, 43 of the 100 most differentially expressed (DE) genes in muscle and cartilage overlapped with all showing the same direction of change (69.8% decreasing with age). These values are nearly identical when the top 500 most DE genes are considered. The most DE gene between the young and old animals for both tissues was *GCAT*, a nuclear gene involved in glycine production in mitochondria that has been linked to biological aging. Based on DAVID annotation, the 43 overlapping genes are significantly enriched for the GO term neuromuscular junction, suggesting some specificity in musculoskeletal aging. Strong DE was also seen for *ERCC8*, a gene involved in DNA repair, and transcription factor *NFAT5*, both of which are ubiquitously expressed. Interestingly, while the top 100 DE genes in the muscle sample fell within the top 218 most DE cartilage samples, 25 of the 100 most DE cartilage genes are ranked in the bottom half of muscle genes.

Future work will examine the expression of DE transcripts in trabecular bone and incorporate proteomic data into a multi-omic analysis to further evaluate tissue-specific aging in the musculoskeletal system.

## PgmNr 2046: Executive function GWAS in a multi-ethnic cohort implicates region on chromosome 1.

Cognitive abilities have a significant impact on quality of life and cognitive impairment is a recognized public health burden. Cognition is comprised of several domains including executive function, which represents higher-order cognitive abilities. Measures of executive function are heritable. A large GWAS in European Ancestry individuals identified *CADM2* to be significantly associated with executive function. However, genetic studies in minority populations are lacking. Therefore, we performed a GWAS in the Northern Manhattan Study, a multi-ethnic cohort to identify common variants (CVs) influencing executive function. A neuropsychological exam was administered to participants and executive function was assessed using the difference in time to complete color trails test forms 1 and 2 as well as the odd-man-out subtests 2 and 4. A Z score for executive function was calculated by averaging the Z-transformed test scores on these tests. Participants were genotyped using the Affymetrix 6.0 array and these data were imputed to the 1000 genomes phase 1, v3 reference panel. Linear regression, implemented in PLINK, was performed to test the association of CVs (minor allele frequency > 5%) with the executive function Z score, adjusting for age, sex, education and principal components of ancestry. Analyses were performed separately within the three race/ethnic groups (Hispanic, non-Hispanic Black and non-Hispanic White) and then meta-analyzed. A p-value <  $5.0 \times 10^{-8}$  was considered significant. Our GWAS revealed an intergenic region on chromosome 1 to be significantly associated with increased executive function (top SNP rs2788328  $\beta=0.22$ ,  $p=8.1 \times 10^{-10}$ ). A replication cohort with a similar race/ethnic distribution was not available; however, we performed a look-up in the CHARGE European Ancestry sample and found no association between this region and executive function. To explore the findings in our study further, we additionally tested rs2788328 for association with each of the individual tests comprising the combined executive function Z-score. These analyses revealed a strong association with color trails test form 2 ( $\beta=0.26$ ,  $p=2.2 \times 10^{-8}$ ) and performance on the odd-man-out tests ( $\beta=0.17$ ,  $p=5.6 \times 10^{-5}$ ). No association was observed between rs2788328 and color trails test form 1 ( $\beta=0.02$ ,  $p=0.66$ ). Together, these findings present new insight into the genetic underpinnings of cognition, as it pertains to executive function, using an underrepresented population.

---

Aging is a complex process characterized by progressive degeneration in cellular and organismal functions, leading to increased disease susceptibility and death. While our understanding of biological drivers of aging has improved dramatically, most studies have focused on animal models with extremely short lifespans. Large-scale, high-throughput DNA sequencing studies of human aging are still at their infancy. Deciphering the genetic mechanisms of aging may help understand causes of many age-related pathologies and healthy aging. To define sex-specific age thresholds of long-lived individual (LLI) status, we utilized data from the United States National Vital Statistics Reports (1997-2015) and calculated the top 10% of extreme-long lived females and males lived  $\geq 95$  and  $\geq 92$  years, respectively. We performed genome-wide association analyses in the largest dataset of LLI to date, including two independent cohorts of LLI of Ashkenazi Jewish and German descent. Exome sequence data were merged with genome-wide SNP chip genotypes and imputation performed. A total of 12,975,494 and 14,612,329 variants with MAF  $>1\%$  were analyzed from German and Ashkenazi Jewish cohorts, respectively. We next performed a Case:Control analysis in each cohort with 663 Ashkenazi Jews and 1,294 German LLI compared to 410 and 2,149 controls (Females  $<95$ , Males  $<92$ ), respectively, followed by meta-analysis. We observed significant associations to variants at *APOE* and *FOXO3A* after Bonferroni correction, as well as nominally associated population-specific variants in genes involved in lipid transport and mitochondrial function. Additionally, we compared between LLI and controls a genome-wide sum of rare (MAF  $<1\%$ ) predicted loss-of-function variants (pLoFs) and predicted deleterious missense variants. Interestingly, the LLI showed a significant small increase in heterozygous pLoF and predicted deleterious missense variants, but a significant small decrease of homozygous variants. These findings suggest protective effects of haploinsufficiency for certain genes and deleterious effects of complete loss of function for other genes. Ongoing work is focused on determining the genes with variants in LLI and control individuals and follow-up of the identified genes and variants to gain mechanistic insights with the goal of informing therapeutics or other interventions to promote healthy human aging.

## PgmNr 2048: The genome-wide association study for the age distribution of facial metrics in Korean populations.

---

Growth and alteration in craniofacial morphology arouses interest in many fields of science, especially physical anthropology, genetics and in the scope of forensic sciences. We performed the analysis of craniofacial morphology alteration by the gender and the aging stage in Korean populations. We studied 15 facial metrics using two large Korean populations (1,926 samples of Korea medicine Data Center cohort and 5,643 of Ansan-Ansung cohort). Among them, total 12 metrics showed the gender differences and tendencies of aging alteration. Increasing tendencies according to aging were observed in Brow ridge height, Upper lip height, Nasal tip height, Profile nasal length and decreasing tendencies were observed in Outer canthal width, Right palpebral fissure height, Left palpebral fissure height, Right upper lip thickness, Left upper lip thickness, Nasal tip protrusion, Facial base width, Lower facial width, consistent in both independent populations. We conducted the genome-wide association studies for the facial metrics using Asian Precision Medicine Research Array. In conclusion, our findings suggest that aging (over 40 ages) might affect sizes of eyes, nose length, the upper lip thickness, and facial width, possibly due to loss of elasticity on the face. Therefore, the facial metric change could be applied to individual's age prediction and the esthetic facial care.

## PgmNr 2049: *BET1L* is associated with survival time in the Japanese population.

---

Human lifespan is considered to be a heritable trait. Whereas previous studies have reported dozens of lifespan-associated genetic loci through genome-wide association studies (GWAS), the majority of these studies tested an association between parental death information and genotype of their children. Furthermore, most of such studies have been conducted in the European population. Here, we report the result of GWAS for survival time in 137,693 Japanese individuals who participated in the Biobank Japan (BBJ) project. Of these individuals, 31,324 (22.7%) were died in the average follow-up period of 7.44 years after the registration of BBJ. Following the genotype imputation using the EAS samples of 1000 Genomes project as a reference, we performed sex-stratified GWASs using 6,108,833 single nucleotide polymorphisms. A meta-analysis of the single genomic-control (GC) corrected sex-stratified GWASs revealed one locus satisfied genome-wide significance (*BET1L*;  $P_{\text{meta}} = 2.39 \times 10^{-8}$ , Hazard ratio = 0.92). Intriguingly, a statistically significant dominance effect was observed ( $P$  for dominance = 0.02). The lead variant rs76612380 is common in the Japanese population (minor allele frequency [MAF] = 11%); however, low-frequency (MAF < 5%) in non-East Asian populations of the 1000 Genomes project. When we categorized the causes of death into five categories (malignant neoplasms, cardiovascular diseases, cerebrovascular diseases, pneumoniae, others), the identified locus was not associated with them ( $P = 0.29$ ). By integrating the eQTL data of GTEx project, we observed a significant overlap between the association signal of GWAS and eQTL of *BET1L* gene in muscle skeletal. Furthermore, we found that the variant suggested as a protein truncating variant for *BET1L* in muscle skeletal by the splice disruption model of GTEx project was in linkage disequilibrium with the lead variant of the identified locus ( $r^2 = 0.98$ ). A gene-set enrichment analysis using PASCAL with reconstituted gene sets implemented by DEPICT implicated that genes

relevant to *BCAR1* protein-protein interaction (PPI) subnetwork were associated with survival time ( $P = 1.54 \times 10^{-7}$ ; false discovery rate =  $2.22 \times 10^{-3}$ ). These results suggest that individual differences in expression of *BET1L* in muscle skeletal may influence survival time, and provide insights into the genetic architecture underlying human lifespan.

## PgmNr 2050: Novel genes associated with facial skin features in Chinese population.

### Authors:

Y. Li; Y. Shan; D. Wang; X. Liu

[View Session](#) [Add to Schedule](#)

**Affiliation:** BGI-Shenzhen, Shenzhen, Guang Dong, China

---

### Background

Skin is our body's largest organ. It's affected by every aspect of our life, from genetics to diet and environments. Facial skin can signal youth, fertility and health. Recent studies have revealed that up to 60% of the facial skin variation between individuals can be attributed to genetic factors. However, existing GWAS studies have been using many subjective features of skins as phenotypes which may introduce biases and noises. This study is aiming to objectively assess various features of facial skin and explore genes contributed to skin variations in Chinese population.

### Method

The skin features were measured using the VISIA® Complexion Analysis System in 800 individuals. The photographic images were captured with standard, cross-polarized, parallel polarized, and ultraviolet light. Images were taken in two different close-up views (front and left lateral 37°) for each subject to quantify the scores for spots, wrinkles, pores, texture, and erythema. 30X whole genome sequencing were performed. A GWAS across 7,236,472 common variants (MAF >0.01) were conducted adjusting for gender and top two PCs of population stratification.

### Result

Three genome-wide significant signals were identified from variant-based association. One significant gene was identified from gene-based association. The associations between *OCA2-HERC2* region and pigmentation was confirmed (rs75295597,  $P = 4.46E-8$ ). Gene *SH3RF3* was associated with pores (gene-based  $P = 6.12E-7$ ). Novel signal rs13069665 ( $P = 4.48E-8$ ) was associated with textures. The signal tags the region of gene *RBMS3*, which has been reported to be associated with Systemic lupus erythematosus.

### Discussion

This is the largest skin genetic study in Chinese population. The identified genes could provide insights of mechanism of skin problems and aging, which could be used for developing better skin care approaches.

## PgmNr 2051: Novel metabolomic pathways associate with longitudinal declines in physical performance among middle-aged adults: Evidence from the Bogalusa Heart Study.

### Authors:

**Background:** Declining physical performance predicts cognitive impairment, reductions in quality of life, disability, chronic disease exacerbation, and mortality. We conducted a metabolome-wide association study to identify novel metabolites associated with change in physical performance measures over 2.9 years of follow up in middle-aged adults.

**Methods:** Bogalusa Heart Study participants (35% African American, 58% female, ages 34-58 years) underwent non-invasive physical performance measurement at baseline and follow-up exams, using gait speed (N=1,227) and grip strength (N=1,164). Baseline serum metabolites were quantified using untargeted ultrahigh-performance liquid chromatography-tandem mass spectroscopy. Multivariate adjusted linear regression was used to assess the relationship between metabolites and baseline physical performance measures. Metabolites significant after Bonferroni correction were carried forward for assessment of association with declines in gait speed and grip strength, in a sub-sample with available data, over 2.9 years of follow up, with additional adjustment for baseline measures.

**Results:** Twenty-one metabolites associated with baseline gait speed and six with grip strength, including five metabolites that associated with both phenotypes ( $P < 4.2 \times 10^{-5}$ ). Two metabolites were associated with preservation or improvement in gait speed, including: behenoyl sphingomyelin (d18:1/22:0)\* ( $P < 0.05$ ) and sphingomyelin (d18:1/22:1, d18:2/22:0, d16:1/24:1)\* ( $P = 2.4 \times 10^{-3}$ ). Six metabolites were associated with decline in gait speed, including: gamma-glutamylphenylalanine, N2,N2-dimethylguanosine, 5,6-dihydrouridine, N-acetylalanine, N-acetylneuraminate, and N-formylmethionine (all  $P < 0.05$ ). Five of six metabolites tested for change in grip strength had consistent effect directions with the baseline analysis, however none met statistical significance thresholds. Sphingolipid Metabolism was the biological sub-pathway associated with a protective effect on gait speed. The metabolites most represented among those associated with detrimental effects on gait speed were modified nucleosides.

**Discussion:** These results add to the accumulating evidence suggesting an important role of the human metabolome in physical performance, and suggest that its underlying biological pathways may be implicated in frailty and accelerated aging phenotypes. Further research on genomic loci that predict the identified metabolites is warranted.

## PgmNr 2052: Genetic determinants of mosaic loss of the Y chromosome and their impact on age-related disease in the VA's Million Veteran Program.

Mosaic loss of Y chromosome (LOY) in peripheral blood cells is a phenomenon implicated in several aging and mortality-related disease processes in men (Forsberg *Hum. Genet.* 2017). The unique characteristics of the growing 460,000-person Million Veteran Program (MVP) cohort -- genetically diverse, majority male, and older (middle 50% age range of 54-70) -- are ideal for studying LOY. We measured LOY in men using the median log-R ratio of male-specific Y chromosome SNPs (mLRR-Y) on the Affymetrix Biobank Array. This array intensity-based metric was validated by sequencing a subset of the same samples (N=2000) and comparing intensity to the mapping frequency of Y reads.

We classified 421,326 male samples in MVP according to genetic ancestry. Overall, 25,255 of 288,388 (8.8%) of men with European ancestry (EUR), median age 66, showed evidence of LOY. A lower frequency of LOY was observed in African American (AA) men (1,909 of 73,795, or 2.6%; age 60) and Hispanic American men (1,016 of 30,321, or 3.3%; age 60). LOY frequency differences between populations were highly significant even considering the difference in age distribution ( $p=3E-142$  between EUR and AA).

We then conducted a GWAS separately amongst male EUR and AA populations on LOY, with age and smoking status as covariates. A GWAS on 236,404 EUR samples identified 70 loci with genome-wide significance, which included 18 of the 19 loci reported by an earlier UK Biobank-based study (the remaining one had  $p=6.5E-07$ ). Further, a GWAS on 65,150 AA samples identified 4 loci with genome-wide significance, of which one did not overlap with the EUR-based GWAS. In the non-overlapping locus, all 11 variants that were genome-wide significant had a MAF between 2-3% in AA samples, but less than 0.1% MAF in EUR samples. However, other variants in chr2.p13 showed significant associations in the EUR-only GWAS, suggesting different LD structure.

The GWAS results were followed up using a summary statistics-based colocalization analysis across

multiple traits associated with LOY. For regions that share a causal variant between LOY and a trait with a posterior probability greater than 0.9, statistical fine-mapping based on meta-analyzed summary statistics was applied. The list of causal variants was further narrowed by combining signals across the diverse ancestries in MVP. Thus, the large sample size and unique characteristics of MVP enabled the discovery of 52 novel loci and further elucidation of LOY in aging and disease.

## PgmNr 2053: Comparison of multiple omics aging clocks.

---

**Background:** Biological age, a measure of deterioration and aging that is distinct from chronological age has been found to predict disease and mortality (Fischer et al., 2014). Since the first published measure of biological age: Hannum's epigenetic clock, closely followed by Horvath's epigenetic clock, aging clocks have been built using telomere length (Zhang et al., 2014), facial morphology (Chen et al., 2015), metabolomics (Fischer et al., 2014), glycomics (Kristic et al., 2014) and proteomics (Enroth et al., 2015). However, comparison between clocks has so far been limited. The ORCADES study is a deeply annotated cross-sectional cohort with approximately 1,000 individuals, where multiple omics assays such as circulating plasma proteins, lipids, glycans and metabolomics are available, enabling consistent comparisons in a common dataset.

**Aims:** (i) To replicate and potentially improve published aging clocks, and partition aging across omics assays (ii) for the first time to compare their accuracy in predicting age in a single dataset (iii) for the first time to analyse the effect of giving up smoking on the evolution of biological clock age (iv) to test the association between age acceleration estimates and ageing and disease phenotypes.

**Methods:** Elastic net regression were used to create multiple omics clocks in a training set and their accuracy assessed in a testing set and an additional independent cohort, in univariate and bivariate analyses.

**Results:** We replicate existing clocks, (with some improvement of our proteomics clock over Enroth et al's,  $r = 0.83$ ) in predicting chronological age. We find our protein clock ( $r = 0.93$ ) outperforms our IgG glycan and metabolite clocks ( $r = 0.74$  and  $r = 0.77$  respectively). In pairwise bivariate analysis we find large but not complete overlap between clocks. We show that there is a significant difference of excess biological age (3-4 years) between current and non-smokers of the same chronological age and for the first time, the effect of having formerly been a smoker on biological age. Finally, we show that increased age acceleration estimated by clocks are consistently associated with increased BMI, cortisol and stroke across omics clocks.

**Conclusions:** Proteins more accurately predict chronological age than glycans and glycans can track the benefits of giving up smoking. Multi-omics clocks appear to track both overlapping and distinct aspects of aging and offer the prospect of identifying distinct aging pathways.

## PgmNr 2054: Tobacco smoking has no influence on buccal telomere length among Portuguese master students.

### Authors:

M. Brito <sup>1</sup>; P. Azevedo <sup>2</sup>; A. Coelho <sup>1</sup>; L. Veiga <sup>1</sup>; A. Costa-Veiga <sup>1,3</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Health and Technology Research Center, Escola Superior de Tecnologia da Saúde de Lisboa, Instituto Politécnico de Lisboa, Lisbon, Lisboa, Portugal; 2) Escola Superior de Tecnologia da Saúde de Lisboa, Instituto Politécnico de Lisboa, Portugal; 3) CISP, Centro de Investigação em Saúde Pública, Escola Nacional de Saúde Pública, Universidade Nova de Lisboa, Portugal

---

In Portugal, the average age of starting tobacco consumption is around 16 years, with an increase on consumption in recent years. The use of tobacco is a risk factor for age-related diseases, being one of the main causes of death and a risk factor for several chronic diseases, including diseases of the cardiovascular system, diabetes and cancer. Different studies shown a clear relationship between tobacco smoking and oxidative stress, which is one of the factors that accelerate the shortening of telomers. The aim of this study was to evaluate the effect of tobacco smoking on the relative length of telomers in master students as a biomarker of health status. A cross sectional study was performed by assessing relative Telomere Length (TL) in 131 master students. TL was evaluated from buccal swabs in 44 males and 89 females (aged between 18 and 52 years, mean 26.4) by multiplex quantitative Polymerase Chain Reaction (PCR). This technique consists in determining the relative ratio (T/S) between the telomere region copy number (T) and a single copy gene (S), albumin gene, using a relative standard curve. Mann-Whitney tests were used to detect TL differences between smokers and non-smokers and addiction levels (Light vs Moderate or Heavy). Statistical analysis were adjusted for age, sex and BMI. Age and TL was negatively correlated as expected (Spearman  $Rho = -1.66$ ,  $p = 0.080$ ). There were no statistically significant differences in TL between smokers and non-smokers, addiction levels or gender (Mann-Whitney tests,  $p > 0.10$ ). A negative association between buccal TL and tabaco smoking was not confirmed. One possible explanation can be the high turnover rate in buccal exfoliate cells relative to other cells such as lymphocytes. Although the association has not been significant with TL, the negative effect of tobacco consumption on the risk of cancer risk and respiratory alterations is largely confirmed. Future studies should include a higher number of participants. Although buccal exfoliate cells is a less invasive method, TL can be more specific using lymphocytes cells. This project was supported by a grant from Instituto Politécnico de Lisboa, ref. IPL/2018/SCITelomer/ESTeSL.

## PgmNr 2055: Modified ACMG classification criteria for mitochondrial tRNA variants.

### Authors:

T. Chen <sup>1,3</sup>; J. Wang <sup>1,4</sup>; S. Tang <sup>1,5</sup>; V. Zhang <sup>1,4</sup>; W. Craigen <sup>1,2</sup>; L. Wong <sup>1,2</sup>

Houston, Texas, USA; 3) Department of Endocrinology, Genetics and Metabolism, Children's Hospital of Soochow University, Suzhou, China; 4) AmCare Genomics Lab, Guangzhou, China; 5) WuXi NextCODE, Cambridge, Massachusetts, USA

---

### Background:

Standards and guidelines developed by ACMG and AMP have been widely used for the interpretation of nuclear-encoded protein coding variants. However, these guidelines need to be modified for the classification of mitochondrial (mt) DNA variants due to characteristics of the genome, including varying tissue-specific reliance on mt functions, heteroplasmy, and interactions between the nuclear and mt genomes. In particular, pathogenic mt tRNA variants are a common cause of maternally inherited mt disorders. Thus, the classification of mt tRNA variants is unique for mt disorders and requires substantial modifications to current ACMG guidelines that are primarily for nuclear mRNA variants.

### Purpose:

To establish criteria for the classification of variants in mitochondrial tRNA genes and to validate their clinical utility.

### Methods:

Based on the current ACMG guidelines, we included the degree of heteroplasmy, multi-system distribution, the genotypes of matrilineal relatives, functional and structural studies, (eg. ETC and muscle histopathology), variant location in the tRNA structure, and clinical phenotypes, all of which are crucial for mitochondrial tRNA variant interpretation. MitoTIP scores are used as alternative supporting criteria. We used known reported mt tRNA variants found in our database to test and validate the suitability of our criteria, followed by the use of the criteria to score VUS, outliers and novel variants, using clinical cases as examples.

### Results:

Among the 552 mt tRNA variants in our database, 463 have been reported. Among them, 59 were pathogenic (P), 22 likely pathogenic (LP), 116 VUS, 18 likely benign (LB), and 337 benign (B) using our modified criteria. In 80 previously reported pathogenic variants, we classified 48 as P, 9 LP, 9 VUS, 1 LB, 13 B. Among 89 novel variants, 5 were P, 11 LP, 54 VUS, 7 LB, and 12 B. Sequencing of mtDNA in different tissues and matrilineal relatives, degree of heteroplasmy, functional studies, and clinical

phenotypes are uniquely important classification criteria for mtDNA tRNA variants.

**Conclusion:**

Proper interpretation of mtDNA tRNA variants is crucial for accurate clinical diagnosis and genetic counseling. Testing of mtDNA in different types of tissue of probands and in matrilineal relatives, quantification of heteroplasmy, and functional studies are key evidence besides population and computational data in determining the clinical significance of mtDNA tRNA variants.

## PgmNr 2056: Drug metabolism anomalies co-segregating with familial prostate cancers and aortic aneurysms.

An 84 year old female sought the underlying cause of her complex medical history. This included numerous adverse reactions to multiple medications since childhood. She experienced staring spells and syncope beginning at an early age and persisting into adulthood, and had adverse reactions to anti-epileptic medications. She had a diagnosis of secondary porphyria due to chronic gastrointestinal complaints, sensitivity to sunlight, and venous thrombi. She was diagnosed with an ascending aortic aneurysm at age 71.

The patient had three brothers and no sisters, three sons, and one daughter. The family history is notable for aortic aneurysm (father and all brothers), prostate cancer (all brothers and one nephew), and adverse neurologic drug reactions (father, youngest brother, eldest son). Her second son carries a diagnosis of “secondary porphyria” and his son had a severe reaction to anesthetics. Her daughter experiences medication side effects, and had seizures during puberty.

The patient and her grandson were tested for variants in 19 drug metabolism genes. The patient had 10 different homozygous mutations and 2 heterozygous mutations. Seven different homozygous and 5 heterozygous mutations were identified in the grandson, 6 and 4 of which, respectively, matched those seen in the proband. The genes affected include *CYP1A2\*1F*, *CYP3A5\*3*, *VKORC1*, *SOD2*, *GSTM1*, *GSTT1*, *NAT2*, *CYBA*, *MDR1*, and *MTHFR*. The grandson likely inherited the majority of these mutations from the proband via her son. The subsequent drug metabolism pathway alternations may account for each individual’s severe reactions to medications.

No unifying factor has been found thus far to explain the patient’s clinical phenotype. Previous sequencing identified a T118M variant in the *PMP22* gene, a nonsense mutation in *FBN1*, and frameshift mutations in *SLC2A1*, *NOTCH3*, and *FECH*. An *ND4* gene alteration does not match any of the 68 known pathogenic variants. Mutational analysis for 23 genes associated with connective tissue disorders did not identify any pathogenic variants, despite the previously reported *FBN1* mutation. Upon whole exome sequencing of the patient, with a triad including her surviving brother and one of her sons, no clinically relevant alternations were reported in the exome analysis. This family illustrates in a dramatic way the increasingly appreciated phenomenon of multiple genetic disorders presenting in a single proband.

Trisomy 14 is one of the aneuploidies compatible with live in a mosaic state and has been reported in approximately 80 patients. The predominant phenotype of trisomy 14 mosaicism includes prenatal and postnatal growth failure, ear abnormalities, congenital heart disease, developmental delay and genitourinary abnormalities. Other cases of trisomy 14 include those of maternal and paternal UPD, having each disorder different characteristics. We evaluated a 1-year-old baby born from young non-consanguineous parents with pigmentary mosaicism in whirl-pooled hyperpigmentation along the body and ambiguous genitalia with no visible testicles. Karyotype and FISH results concluded 45,X/46,X der(Y)t(Y;14). However, the physical examination did not correlate with paternal UPD described in other cases. Using Whole Exome Sequencing, we identified the genes affected by the chromosomal rearrangements, therefore provided proper counseling for the patient's future, and analyzed the ethical implication of a patient with disorders of sexual differentiation.

## PgmNr 2058: Atypical nested (B-D) 22q11.2 deletion involving *CRKL* in a fetus with severe growth restriction and mother with severe systemic autoimmune disease.

22q11.2 deletion syndrome (22q11.2DS) patients present with a broad phenotypic spectrum including dysmorphic features, congenital heart defects (CHDs), T-cell deficiency, hypoplastic thymus, and hypocalcemia. We report on a prenatally diagnosed case of atypical 22q11.2DS, born to a 22-year-old with SSA+ severe systemic lupus erythematosus with cutaneous and discoid components, seronegative anti-phospholipid syndrome, lupus nephritis, chronic hypertension, and frequent infections. Due to non-reassuring antenatal surveillance, the fetus was delivered at 31wk gestation with normal cardiac imaging, leukopenia, anemia, hypophosphatemia and hypercalcemia.

At 24wk gestation, the fetus was diagnosed with severe intrauterine growth restriction (IUGR) and had an amniocentesis with FISH analysis with HIRA (TUPLE1) probes, and a chromosomal microarray analysis (CMA). FISH was normal. CMA identified a heterozygous loss of the 22q11.21 region, ~737 kb size, between low copy repeats (LCR) B and D, consistent with atypical nested 22q11.2DS. Subsequently, the mother was found to have the same deletion, which includes *CRKL* and 19 other genes but excludes *TBX1*. Echocardiogram of the mother revealed moderate concentric left ventricular hypertrophy with a decreased left ventricular ejection fraction.

Most 22q11.2DS results from a typical, non-inherited deletion between LCRs A and D (~3Mb), or A and B (~1.5Mb). The atypical deletion can be missed with a FISH screen, as in this case, and often have reduced penetrance of features and an inherited mutation from a mildly affected parent.

Deletion of *TBX1* has been implicated in causing CHD. Deletion of *CRKL* has been linked to immune deficiency. Since *CRKL* has key regulatory roles in hematopoietic cell signaling, 22q11.2DS patients may have a restricted repertoire of T-cells that leads to abnormal T-cell activation and differentiation of B-cells, with a decrease in the population of memory B-cells and an increase in transitional B-cells, explaining the decreased production of immunoglobulins and abnormal specific antibodies. This may contribute to autoimmunity, as seen in the mother.

This case highlights diagnostic pitfalls, broad phenotypic spectrum and presentation of 22q11DS, and new insight into the pathophysiology and inheritance of 22q11DS through the evaluation of parents affected with autoimmune disease. The role of *CRKL* in autoimmunity can also be investigated to understand immune deficiencies and CHD in patients with 22q11DS.

## PgmNr 2059: White matter abnormalities in the human brain of sex chromosome aneuploidies.

Sex chromosome aneuploidies (SCA) are a common group of genetic disorders (1/400 individuals) characterized by variation in the number of sex chromosomes. SCA has been associated with a wide range of behavioral and cognitive deficits and previous studies identified focal gray matter volume (GMV) alterations relative to typically developing controls using T1-weighted structural magnetic resonance imaging (sMRI) data. Here we ask whether SCA further alters regional white matter volume (WMV) in the human brain by applying deformation-based morphometry (DBM) to sMRI data from 169 typically developing controls (80 XY, 86 XX) and 137 participants with SCA (28 XXX, 58 XXY, 26 XYY, 20 XXYY, 5 XXXXY) aged 5-25 years. Genetic diagnosis of SCA was confirmed by karyotype, and all participants were scanned on a 1.5T GE scanner. A well-established DBM pipeline was applied to obtain WMV over the whole brain. We used regression models to examine X and Y chromosome dosage effects on WMV changes at each voxel controlling for total white matter volume and age. The significance level of family wise error  $< 0.05$  was set to correct for multiple comparisons across voxels. We identified significant X- and Y-chromosome dosage effects on WMV in major white matter bundles. Interestingly, these local WMV effects for X- and Y-chromosome aneuploidy converged in a similar spatial pattern, consistent with prior findings for SCA effects on regional cortical anatomy. Specifically, carriage of supernumerary X- and/or Y-chromosomes was associated with (i) WMV decreases in corona radiata, internal and external capsules, cerebral and middle cerebellar peduncles connecting cortex and striatum and brain stem, basal forebrain and cortex, and cerebellum and pons within each hemisphere, and (ii) WMV increases in genu and splenium of corpus callosum bridging two hemispheres in the frontal and posterior parts of the brain. The spatial distribution of these WMV effects was also congruent with prior reports that GMV reduces in basal forebrain, insular and subcortical areas and increases in bilateral posterior parietal cortices with mounting X- and/or Y-chromosome dosage. These data provide the first evidence that X- and Y-chromosome dosage variations influence regional white matter anatomy in humans. Together with co-occurring changes in regional gray matter, these findings specify candidate neuroanatomical substrates for the known impact of sex chromosome aneuploidy on human cognition and behavior.

## PgmNr 2060: Orofacial clefts with clubfoot phenotypes in an African population: Whole exome sequencing implicates multiple syndromes and genes.

---

Orofacial clefts (OFCs) are congenital malformations of human face and palate, presenting as either nonsyndromic or syndromic, with syndromic forms presenting with additional congenital malformations. OFCs exhibit multifactorial inheritance with both genetic and environmental factors playing crucial roles. As part of our OFC studies in Ghana, we recruited six probands that presented with cleft lip-clubfoot, and cleft lip and palate-clubfoot phenotypes, with no clinically identifiable additional malformations at the time of recruitment. Our aim was to identify causal coding variants that will help ascertain whether these OFC-clubfoot phenotypes were syndromic or that the clubfoot phenotype was just an associated anomaly by conducting whole exome sequencing of affected probands and available relatives. Analysis of exome data sought to determine rare missense, nonsense, splicing and indel variants that exhibited either autosomal dominant or autosomal recessive homozygous and compound heterozygous inheritance patterns. We highlighted variants in genes known to be associated with phenotypes related to the one being investigated using OMIM, mouse model, GWAS, HGMD and ClinVar. Implicated variants were validated by Sanger sequencing. Multiple syndromes/genes were implicated in four out of six probands. With the exception of one proband who was autosomal recessive compound heterozygote for *DIS3L2* (p.P293H and p.E524K) - Perlman syndrome, the three other probands have multiple syndromes. One proband possibly have Vici syndrome (*EPG5*: p.H532Y and p.R350C), as well as *BARX1* (p.K141N) and *MKI67* (p.R2304K) variants. Another proband possibly have either Fraser Syndrome (*FRAS1*: p.V2882L and p.L3387P), or Treacher Collins syndrome (*TCOF1*: c.2864\_2865GG) and *MKI67* (p.R2247H) variant. The last proband possibly have either Fraser syndrome (*FRAS1*: p.I3532V, p.I3869V and p.H3969Q), or Cardiomyopathy, dilated, 1LL/Left ventricular noncompaction 8 (*PRDM16*: c.T1188C;p.C396C), or CHARGE syndrome/Hypogonadotropic hypogonadism 5 with or without anosmia (*CHD7*: c.4248delA;p.T1416fs). Our results suggest that clubfoot and OFCs are two congenital anomalies that co-segregate in some syndromes with varying genetic causes. Therefore, there is a need for deep phenotyping to delineate the additional phenotypes that distinguish these cohorts from isolated OFCs and clubfoot. Our observations are crucial for syndrome diagnosis in OFC care, genetic counseling and elucidating OFC pathogenesis.

## PgmNr 2061: A case series of a mother and two daughters with a *GLI2* gene deletion demonstrating variable expressivity.

GLI2 is a zinc-finger transcription factor involved in the Sonic Hedgehog pathway, and pathogenic mutations in the gene have been reported to be in association with variable features from holoprosencephaly (HPE) to HPE features, namely facial dysmorphisms, to the milder phenotype characterized by hypopituitarism, mainly growth hormone deficiency, and post-axial polydactyly known as Culler Jones syndrome. Here we report the case of a family, two daughters and a mother, with an identical *GLI2* gene deletion with varying presentations. We also reviewed the literature and identified seven other families of at least two members that share a mutation or deletion of the *GLI2* gene, and the phenotypes frequently included anterior pituitary lobe hypoplasia, ectopic posterior pituitary lobe identified on magnetic resonance imaging, the resulting pituitary deficiencies, post-axial polydactyly, and facial dysmorphisms, most commonly cleft lip and palate. This series adds to the body of literature of families with this mutation and supports the autosomal dominant inheritance pattern and variable expressivity observed in these patients.

Table: Ratio of common features observed in *GLI2* gene mutation or deletion in study population

Affected Region	Feature	Ratio (# with feature/total patients)
Brain/Pituitary Anomalies		
	True holoprosencephaly	2/34
	Ectopic posterior pituitary	10/34
	Anterior pituitary hypoplasia	7/34
	Panhypopituitarism	8/34
	Isolated growth hormone deficiency	3/34
Facial dysmorphisms		
	Cleft lip and palate	5/34
	Hypotelorism	5/34
Limb involvement		
	Polydactyly	17/34

## PgmNr 2062: Helping solve medical mysteries: Using machine learning and systems biology to identify gene pairs that can cause digenic disease.

---

Previous efforts in clinical genetics, focused on effects on variants in a single gene, have led to the identification of the genetic causes for many diseases. However, the diagnosis of rare diseases has been a challenge. The Undiagnosed Diseases Network (UDN) was formed to address the challenges of diagnosing rare genetic diseases, and has had success in diagnosing many patients. The UDN patients undergo whole exome or genome sequencing and the team identifies genetic causes based on how dysfunction any mutated gene affects phenotype. Nonetheless, more than half of enrolled UDN patients remain undiagnosed.

Our central hypothesis is that oligogenic inheritance patterns must be considered in the analysis of rare disease genetics and that new tools are needed to enable these analyses. A database of known digenic disease causing gene pairs (DIDA) has been published previously, and it was found that it was observed that digenic gene pairs have unique biological characteristics, such as shared pathways, co-expression and protein-protein interactions.

In this study, we implemented a random forest machine learning classifier to identify pairs of genes that have the potential to cause digenic disease. We integrate combinations of gene and gene-pair features derived from systems biology and evolution to train the classifier on known digenic pairs derived from DIDA vs putative non-digenic pairs generated using several different strategies.

A classifier trained using six systems biology features performed well (mean ROC AUCs ~ 0.8) for all non-digenic gene pair sets. The addition of evolutionary features increased performance (mean ROC AUCs ~ 0.9), and additional gene level features, such as number of phenotypes, increased performance further (mean ROC AUCs > 0.95). Phenotypes, loss of function intolerance, protein age and selection pressure features were the highest weight features. We further validated the trained classifiers on additional digenic pairs not included in DIDA and synthetic lethal interaction pairs.

Our work reveals whether pairs of genes have sufficient synergy to lead a digenic disease upon co-mutation, and helps to uncover the mechanisms by which these genes functionally interact. To facilitate the impact of our work, we make digenic disease predictions available for all pairs of human

genes.

## PgmNr 2063: Increasing awareness and earlier testing for mucopolysaccharidoses to improve patient outcomes: Updated results from Simply Test for MPS™ Enzyme-Panel Program.

### Authors:

L. Clarke <sup>1</sup>; B. Deignan <sup>2</sup>; C. Raggio <sup>3</sup>; P. Solari <sup>4</sup>; T. Wood <sup>5</sup>; L. Pollard <sup>5</sup>

---

**Purpose/Background:** The subtle, non-specific signs/symptoms of mucopolysaccharidoses (MPS) often present a diagnostic challenge. Simply Test for MPS™ (ST4MPS) Enzyme-Panel Testing Program provides a no-cost MPS enzyme panel to facilitate testing for patients in the United States who present with clinical signs/symptoms consistent with MPS. The objective of this analysis is to increase awareness of non-specific signs/symptoms of MPS found through the ST4MPS program to facilitate an accurate diagnosis through earlier testing by a wide range of specialties that may encounter MPS patients.

**Methods:** Initiated in February 2017, ST4MPS provides comprehensive enzyme activity testing for all MPS disorders. Specimens are sent to Greenwood Genetics Laboratory for analysis. Results are reported.

**Results:** As of July 2018, 451 referrals for ST4MPS kits received. Since presentation of the first year program results in April 2018, there was an approximate 80% increase in the average amount of tests ordered (22 tests/month February 2017–April 2018, 40 tests/month May–July 2018) and an increased number of confirmed MPS patients through testing (n=90). Notably, of those with a positive Morquio A diagnosis (n=28), 21 were tested by a geneticist, 4 by a pediatric orthopedist, and 3 by a pediatrician. Average age at diagnosis was 16.4 years (range: 4 months–48.9 years). Of the ordering physicians that indicated signs/symptoms prompting testing (n=23; 5 missing data), all mentioned skeletal/muscular-related signs/symptoms. 46% of positive Morquio A patients were noted to have skeletal dysplasia or another skeletal condition.

**Discussion:** Increased awareness of early signs/symptoms of MPS and utilization of ST4MPS have resulted in accurate diagnoses of MPS. Broader testing by a variety of specialists that are likely to encounter MPS patients would help reduce misdiagnoses and diagnostic delays, leading to improved patient outcomes.

## PgmNr 2064: Integration of polygenic risk score with newborn metabolomics provides increased accuracy in profiling risk of infantile hypertrophic pyloric stenosis.

---

Infantile hypertrophic pyloric stenosis (IHPS) is a disease, typically appearing between two and eight weeks after birth, caused by hypertrophy of the pyloric sphincter smooth muscle. IHPS perinatal risk factors include the use of macrolide antibiotics, male sex, being first-born, preterm birth, delivery by cesarean section, and bottle-feeding. IHPS familial aggregation of 20-fold increased risk among siblings and genome-wide SNP heritability of 30% also suggest a strong genetic component. We have previously detected an association between IHPS and lipid metabolism. In this study we aimed to (1) investigate associations between IHPS and lipid-centric targeted metabolites in dried blood spots of 267 matched pairs of IHPS cases and controls taken a few days after birth, and (2) build an IHPS risk score based on the associated metabolites and polygenic risk score (PRS) from our previous IHPS GWAS.

Using the Biocrates p400 Kit, we selected 140 metabolites with valid quantification in at least 80% of the samples. Using mixed effects linear regression model with pair as random effect and adjusting for known IHPS confounders, 12 metabolites showed significantly lower levels in cases than in controls. The top two metabolites were phosphatidylcholines PC(38:4) and PC(38:3). In adults, 23% of the variance in levels of PC(38:4) and PC(38:3) and their ratio is explained by genetic variation in *FADS1* gene, which catalyzes desaturation of PC(38:3) to PC(38:4). In our data, genetic variation in *FADS1* was not associated with IHPS, suggesting that other factors influencing PC(38:3) and PC(38:4) levels underlie the association. Plasma levels of PC(38:3) and PC(38:4) are known to be lower in bottle-fed compared to breast-fed infants, and bottle-feeding is a well-known risk factor for IHPS. Also, the fact that our cases had more diagnoses for neonatal difficulty in feeding at breast (ICD-10 code P92.5) than controls (OR=4.5,  $P = 6 \times 10^{-3}$ ), supports the hypothesis that feeding practice could underlie the metabolite associations. We also evaluated IHPS risk in an independent cohort. Individuals in the highest risk quintile of PRS plus PC(38:4) had a IHPS odds-ratio of 11.4, while with PC(38:4) or PRS alone we get 2.5 and 5.3 odds-ratios, respectively.

In conclusion, we have detected lower levels of phosphatidylcholines in IHPS, possibly reflecting different feeding patterns in the first days of life. Adding the levels of PC(38:4) to PRS increased accuracy in IHPS risk profiling.

## PgmNr 2065: Integration of genome-wide association study and protein-protein interaction network data identifies novel candidate genes associated with COPD cachexia.

---

Chronic Obstructive Pulmonary Disease (COPD) is currently the third leading cause of death globally. COPD patients with cachexia have increased risk of death. As not every patient with COPD develops cachexia, we hypothesized genetic variation may be associated with increased risk. To test this, we performed genome-wide association study (GWAS) analyses among COPD subjects (defined using spirometry) with and without cachexia from 3 cohorts and integrated findings with publicly available protein-protein interaction (PPI) network data.

In ECLIPSE, cachexia was defined as weight-loss or low BMI in addition to 3 out of 5 of low 6-minute walking distance (6MWD), fatigue, anorexia, low muscle mass (FFMI) and abnormal biochemistry. In COPDGene and SPIROMICS, cachexia was defined as weight-loss or low BMI in conjunction with either low 6MWD, low FFMI, fatigue or anemia based on availability of collected information. In each cohort, logistic regression models were run on genotyped and imputed SNPs under an additive model

adjusting for age, sex and population substructure in PLINK in Non-Hispanic White (NHW) and African American (AA) COPD subjects. Gene-based tests were performed using MAGMA. Meta-analyses were performed in METAL and MAGMA. Further downstream analyses integrating genetic findings with PPI network data using dmGWAS.

No single variant was associated at a level of genome-wide significance. At the gene level, several genes were significantly associated with COPD cachexia. These included *TMEM30B* in the NHW COPD participants from SPIROMICS. *TMEM30B* encodes the transmembrane protein 30B and is involved in the hydrolysis of ATP for transport of phospholipids. Two genes (*POR* and *GNAQ*) were significantly associated with cachexia among AA in COPD Gene. *POR* encodes Cytochrome P450 oxidoreductase. *GNAQ* encodes a G Protein Q Polypeptide which was recently associated with body mass index in the UK Biobank. When the gene-based results were integrated with PPI network information, the top consensus network was found to include *SERPINB2* and *TKT*. *SERPINB2* is a protease inhibitor associated with stress response, thrombosis and cell migration. *TKT* encodes transketolase which is a thiamine dependent enzyme that channels sugar phosphotase to glycolysis. Collectively, the consensus network genes were enriched with GO Negative Regulation of Cell Death genes.

In summary, we have identified several new genes including *SERPINB2* and *TKT* associated with COPD cachexia.

---

Sporadic Inclusion Body Myositis (sIBM) is the most common form of acquired adult-onset muscle disorder in the world, with an age of onset after 45 years and affecting around 300 patients in Finland and 2500 in Europe. In the USA, the prevalence ranges from 10-71 per 1 million. However, due to high clinical variability, a number of cases remain largely misdiagnosed. Coexistence of inflammatory and muscle degenerative features result in a complicated and poorly understood molecular pathogenesis of sIBM. Additionally, there are no suitable treatments available with proven efficacy, resulting in an increasing burden of illness on patients and supporting healthcare systems.

Our primary goal is to understand the mechanism behind muscle degeneration in patients with sIBM. We performed whole transcriptome analysis on microdissected biopsies of 41 human skeletal muscle samples, including clinically and histopathologically defined sIBM, a myopathy control with clear genetic and histopathologic evidence and a non-muscle phenotype control. Our current results indicate an sIBM specific heavy inflammatory background with strong IFNG and STAT1 dysregulation and expand our understanding of the involvement of cytokines and chemokines in sIBM. Additionally, we observed differential expression of genes involved in calcium mobility in cells. These results will help us better interpret the cause of protein accumulation, immune dysfunction and consequential progressive muscle degeneration in sIBM.

## PgmNr 2067: Whole exome sequencing identifies a rare functional variant SHARPIN G186R associated with increased risk of late-onset Alzheimer's disease.

---

Late-onset Alzheimer's disease (LOAD), the most common form of dementia, is one of common diseases and is caused by contributions of many genetic factors. In spite of the recent large scale genomic approach in mainly Caucasian population, the heritability for LOAD remains mostly unknown. Comprehensive genetic studies in Caucasian have identified several rare risk genetic variants with high odds ratio for LOAD, whereas replication studies in other race, especially in East Asian including Japanese did not show certain association for these variants and LOAD. To comprehend the LOAD pathogenesis, it is important that the identification of rare variants partly contributing to the genetic architecture for LOAD in specific race. Here, we performed whole-exome sequencing (WES) analyses of 202 LOAD individuals without the *APOE* e4 risk allele, a major genetic factor for LOAD susceptibility. We identified seven candidate risk variants thorough step-by-step selection of whole-exome variants. We then conducted a case-control association study in a large Japanese cohort consisting of 4,563 cases and 16,459 controls for these seven variants, and identified a rare nonsynonymous variant, rs572750141 (NM\_030974.3:p.Gly186Arg), in *SHARPIN* associated with increased risk of LOAD (Bonferroni-corrected  $P = 8.05 \times 10^{-5}$ , odds ratio = 6.1). We also implemented *in vitro* functional analyses of the variant to reveal possible functions associated with LOAD risk. The amino acid change in SHARPIN resulted in aberrant cellular localization of the variant protein and attenuated the activation of NF- $\kappa$ B, a central mediator of inflammatory and immune responses, indicating that the identification of a rare functional *SHARPIN* variant as a previously unknown genetic risk factor for LOAD. Modest initial sample size recruited in WES, whereas the results indicate that the effectiveness of our approach to identify rare genetic variants with large effect size, and the pipeline may be applicable to fill in the puzzle for the genetic architecture associated other common diseases.

## PgmNr 2068: Genome-wide linkage analysis of Caribbean Hispanic Puerto Rican families suggests rare risk variants in the *ELAVL2* gene.

**Background:** The ancestral genetic heterogeneity (admixture) of Caribbean Hispanics (CHI) makes studies of this population critical to the discovery of ancestry-specific genetic factors in Alzheimer disease (AD). In this study, we performed whole genome sequencing (WGS) in multiplex CHI Puerto Rican (PR) families to identify rare causal variants influencing AD through linkage and segregation-based approaches.

**Methods:** As part of the PR Alzheimer Disease Initiative, WGS data were generated for 95 individuals (69 affected) from 25 Puerto Rican families. To identify the genetic loci likely to carry risk variants, we performed a multipoint linkage scan using MERLIN software. Following the linkage analysis, we identified the consensus regions (HLOD > 2), annotated variants using Ensembl Variant Effect Predictor, and combined annotation dependent depletion score (CADD). Finally, we prioritized the variants in the consensus regions based on allele frequency (< 0.01), function (CADD > 10), and complete segregation among affected individuals.

**Results:** A locus at *9p21* produced a linkage LOD score of 3.9 in the parametric multipoint model supported by 8 families. The region overlaps with a previously reported linkage peak in an independent set of non-Hispanic White families (NHW). We identified 73 rare variants that segregated with the disease in the families that supports the linkage peak on *9p21*. Remarkably, 3 rare variants in the *ELAVL2* gene segregate with disease in two families. One of the interesting variants is rs542037226 (chr9:23,827,245 G/A). It segregates with the disease in a family with 5 AD individuals (family-specific LOD = 1.2). The variant is upstream of *ELAVL2* with a rare allele frequency in the 1kGP reference data set (MAF = 0.001) and a moderate CADD score (17.36).

**Conclusions:** Linkage analysis of CHI PR families confirmed previously reported linkage to *9p21* in NHW families. Our results suggest the presence of AD risk variants in the *ELAVL2* gene. *ELAVL2* encodes a neural-specific RNA-binding protein that plays an essential role in the post-transcriptional regulations of APP, alterations of which are associated with AD. Identified putative damaging rare variants in multiplex families indicates the critical role of rare variation in AD etiology.

---

Epidemiological and genetic studies have consistently found a positive correlation between Alzheimer's disease (AD) and cardiometabolic diseases, yet the biological mechanisms behind this correlation remain elusive. One avenue to investigate the genetic etiology of this relationship is through multi-trait association studies, designed to detect single nucleotide polymorphisms (SNPs) that are associated with AD and cardiometabolic traits. We performed our multi-trait association analyses via a pairwise, bivariate genome-wide association study. Each bivariate scan was performed using summary statistics from the largest single-trait scans for AD (Jensen et al. 2019, involving 71,880 cases and 383,378 controls) paired with one cardiometabolic trait including: coronary heart disease, type 2 diabetes, blood pressure metrics, anthropometric traits, and lipid traits. In total, we performed bivariate analyses between AD and eleven cardiometabolic traits and identified three novel genome-wide significant loci, with each of the three colocating (COLOC PP4>0.85) with an expression quantitative trait locus (eQTL) for a nearby gene. One of these three loci was detected in two bivariate scans: AD with high-density lipoprotein (HDL) levels and diastolic blood pressure (DBP). The lead SNPs at this locus from both scans colocated with an eQTL for the gene *SPPL2A*, with lower expression associated with increased risk for AD and elevated HDL and DBP. In addition, we identified a second signal in the AD and DBP bivariate scan at near-genome-wide significant association in the gene *DOCK4* ( $P=8.34 \times 10^{-8}$ ). This signal implicates a low-frequency, coding variant near a 3' splice junction of *DOCK4* that is predicted to alter splicing *in silico* and warrants further functional validation. This provides a direct hypothesis for the causal variant and genetic mechanism underlying this signal.

These results emphasize the utility of multi-trait GWAS methods for (1) characterizing pleiotropy across complex human traits, (2) generating credible leads for biological and genetic mechanisms for these loci, and (3) predicting the expected phenotypes given a genetic perturbation at a locus.

## PgmNr 2070: Dissecting the local ancestry effect on *APOE* $\epsilon$ 4 and Alzheimer association in an admixed Peruvian population.

Alzheimer disease (AD) is the leading cause of dementia in the elderly and occurs in all ethnic and racial groups. Multiple AD-associated loci have been identified, mainly in participants from European (EU) backgrounds. Studies in diverse populations suggest that while there is some overlap in genetic architecture, there are also significant differences between various ethnic groups for genetic risk and protective effects.

The Peruvian population results from admixture of several Amerindian ethnic groups (~80%) and European populations (~15%). Establishing a Peruvian AD cohort will enhance discovery of novel risk/protective factors. To date, we have ascertained 72 unrelated individuals (37 AD cases; 35 cognitively intact controls) with additional ascertainment ongoing. All cases were assessed by trained neurologists following NINDS-ADRDA criteria for probable AD. Cognitively intact controls were screened using the MMSE, the Clock drawing test, and the Pfeffer functional activities questionnaire. Samples were matched for sex and age (75.8(5.5) vs 76.3(6.5), case vs control). Genotyping was performed using the Illumina GSA array; APOE genotyping was also performed. PC-AIR and model-based ADMIXTURE approach were used to infer population structure. To assess local ancestry, phasing was performed using SHAPEIT (with 1kGP reference) followed by RFMix (HGDP reference panels). Association between affection status and gene dose of the APOE  $\epsilon$ 4 allele was analyzed using logistic regression, adjusting for age, gender, PC1, and PC2.

The average genome-wide ancestry proportions in these data are estimated as 0.56, 0.37, 0.05, and 0.02 for Native American (AI), European (EU), West African, and East Asian, respectively. Logistic regression results showed a significant association between APOE  $\epsilon$ 4 allele and AD (OR=5.1, CI:1.6-22.8, p-value < 0.01). By stratifying the dataset according to the local ancestry and APOE genotypes, we observed unexpected deviation in local ancestry proportions. While individuals without the  $\epsilon$ 4 allele have local ancestry proportions (AI:0.66, EU:0.32, AF:0.02) similar to the global ancestry one, individuals with the  $\epsilon$ 4 allele showed unusual variation in ancestry proportions (AI:0.29, EU:0.56, AF:0.15). Results indicate a high frequency of EU ancestry among the  $\epsilon$ 4 risk allele carriers. This suggests that association between the  $\epsilon$ 4 allele and AD is derived through EU genetic ancestry local

to the APOE gene.

## PgmNr 2071: Utilizing CRISPR to investigate an ethnic specific deletion in *ABCA7* associated with Alzheimer's disease in African Americans.

---

Diverse populations are particularly vulnerable to Alzheimer's disease (AD); Hispanics and African Americans (AA) are 1.5 and 2 times as likely to develop AD, respectively, compared to non-Hispanic whites. We identified an ethnic specific deletion in the coding portion of *ABCA7* which significantly increases AD risk among AA ( $p=1.414 \times 10^{-5}$ , OR=1.81 [95% CI:1.38-2.37], Cukier, et al, 2016). The deletion is enriched in AA cases (15.2%) compared to AA controls (9.74%). By generating isogenic cell lines that carry the 44 base pair deletion, we aim to determine the cellular and molecular consequences on *ABCA7* function and how it may contribute to AD risk. CRISPR genome editing was performed in human embryonic kidney (HEK) cells (HEK) to remove the precise 44 base pairs in *ABCA7* in exon 14 (rs142076058) and mimic the deletion. Four guide RNAs (gRNAs) were designed that recognize protospacer adjacent motif (PAM) sequences in the region flanking the deletion through the publically available ZiFiT Targeter software (<http://zifit.partners.org/ZiFiT/>) and CRISPR Design (<http://crispr.mit.edu/>) programs. All four of the gRNAs were cloned into the pCAG-eCas9-GFP-U6-gRNA vector (Addgene), a plasmid that carries the Cas9 enzyme, gRNA and GFP tag all in one. Three of the gRNAs were verified to cut the region near the deletion in the correct manner via the Surveyor Mutation Detection kit (IDT). We transformed one of the gRNAs into HEK cells, performed fluorescence-activated cell sorting (FACS), and screened 119 unique HEK clones. Sanger sequencing confirmed that four HEK clones were generated that were heterozygous for the deletion, as well as two more clones that were homozygous for the deletion. Furthermore, RNA extracted from the HEK clones was found to be expressing *ABCA7* from both the wild type and the allele with the deletion. This demonstrates that these cell lines are an appropriate model to evaluate how the deletion may interfere with *ABCA7* function, such as cellular transport and amyloid beta processing. Utilizing CRISPR genome editing, isogenic HEK cell lines heterozygous and homozygous for the *ABCA7* deletion were created. These cell lines will be used to determine the consequences that result from this ethnic specific deletion.

## PgmNr 2072: Shared mechanisms between type 2 diabetes and Alzheimer's disease via integrative genomics analysis.

Epidemiological evidence suggests that Alzheimer's disease (AD) and type 2 diabetes (T2D) are tightly connected, and molecular pathways such as insulin signaling, growth factor pathways, protein misfolding, and inflammation are involved in both diseases. The exact causal molecular connections between AD and T2D, however, remain unclear. We hypothesize T2D may induce perturbations in biological processes that promote AD and/or the two diseases share genetically-driven pathogenic pathways. We conducted a multi-omics systems biology study that integrates human genetic association studies of AD and T2D, gene expression profiling studies of disease-relevant tissues, biological pathways, and tissue-specific gene networks to investigate the potential mechanistic links between the two diseases. Incorporation of genetic association information of both AD and T2D informed on shared tissue-specific gene subnetworks relating to immune regulation, insulin signaling, lysosome, proteostasis, cell cycle, cell adhesion, spliceosome, lipid metabolism, and extracellular matrix. AD-specific pathways were numerous and included oxidative phosphorylation, Golgi-associated vesicle biogenesis, cell-cell communication, Notch signaling, steroid hormones, and infection. For T2D, unique processes included incretin secretion, beta cell development, obesity, glycerolipid metabolism, PPAR signaling, and water homeostasis. Our systems-wide integrative genomics approach offers comprehensive molecular insights into the molecular networks connecting metabolic and neurodegenerative diseases.

## PgmNr 2073: Stratified case-control association mapping of Alzheimer's disease using family history from UK Biobank.

---

Understanding the role that genetics has in phenotypic and disease variation, and its potential interactions with other factors, is crucial for a better understanding of human biology. And it is hoped that this will lead to more successful drug development. UKBB (UK Biobank) is a Prospective cohort of 502,620 participants with deep genetic and phenotypic data. We are interested in pathways and regulators of late onset Alzheimer's disease. During the study ascertainment period at enrollment, UKBB recorded only a few hundred cases with Alzheimer disease (AD).

In this study we have conducted a genome-wide association study by proxy (GWAX) using imputed genotypes on SAIGE (Scalable and Accurate Implementation of Generalized mixed model) platform, utilizing the family history of AD from UKBB. We thus defined individuals who are not adopted and reported having at least one parent or sibling with AD as proxy cases, while the proxy controls include subjects 70 years or older who reported no parental history of AD, depression or Parkinson's disease. Also we have excluded from the control set anyone that reporting any neurological or behavioral disorders. We stratified the cases and controls based on their APOE status, by excluding all carriers of at least one *APOE4* allele from either the case or control set. We performed the GWAX analysis on 33,425 cases versus 91,259 controls. We have identified the well-known loci associated with AD, e.g., *BIN1*, *TREM2*, *INPP5D*, *CTNN3* and as well as novel loci. Many of the genes within these loci map to pathways involved in neuronal development. Currently we are validating these novel findings in genetic studies from diagnosed AD patients, such as ADNI. This study furthers substantiates the use of GWAX analysis for identifying underlying genetics of disease. These results could further serve as a valuable resource for selection of promising genes for functional follow-up experiments and may identify targets for drug development and stratification approaches.

## PgmNr 2074: A rare variant in *SYT7* and common variants in *APOE* and *LRP2* are associated with urate level in exomes of 150,000 subjects from the UK Biobank.

---

Elevated uric acid (UA) is the cause of gout, a common inflammatory arthropathy. In turn, UA is also hypothesized to exert a protective role in neurodegeneration, possibly due to its anti-oxidant properties. To better understand the genetic determinants of UA levels, we studied 150,000 individuals from the UK Biobank (UKB) with whole-exome sequencing data. We find 21 protein-altering index variants associated with UA at genome-wide significance ( $p < 5 \times 10^{-8}$ ). Among the three rare ( $MAF < 5\%$ ) index variants, the most significant one (rs747186203) is located in exon 4 of *SYT7*, changing Arg to Gly at position 132 of the protein ( $p = 5.50 \times 10^{-17}$ ,  $\beta = -0.71$ ,  $95\%CI = [-0.88, -0.55]$ ,  $MAF = 0.0005$ ). *SYT7* encodes synaptotagmin 7, a calcium sensor involved in the exocytosis of vesicles. Among common variants we interestingly find an association of UA with *APOE*. More specifically, we find an UA lowering effect for *APOE*-4 (rs429358,  $p = 4.5 \times 10^{-10}$ ,  $\beta = -0.032$ ,  $95\%CI = [-0.042, -0.022]$ ) and a weak UA increasing effect for *APOE*-2 (rs7412,  $p = 2.3 \times 10^{-2}$ ,  $\beta = 0.015$ ,  $95\%CI = [0.0021, 0.029]$ ). Because *APOE*-4 is the major risk factor for Alzheimer's disease, this association, and its molecular mechanism, may influence the correlation of UA with neurodegeneration. We further find UA being associated with a common missense variant in *LRP2* (rs2075252, Lys4094Glu,  $p = 1.9 \times 10^{-14}$ ,  $\beta = -0.033$ ,  $95\%CI = [-0.041, -0.024]$ ,  $MAF = 0.24$ ). *LRP2* (LDL receptor related protein 2) functions in reuptake of a range of ligands in the kidney, and is implicated in different forms of kidney disease. *LRP2* also is hypothesized to function in *APOE*-mediated uptake of cholesterol into neurons, as well as APOJ-mediated transport of amyloid-beta through the blood brain barrier. These studies contribute to understanding the relationship between UA levels, kidney function, and neurodegeneration, and may lead to novel therapeutic principles.

## PgmNr 2075: Using linkage analysis to identify novel gene-gene interactions in Alzheimer's disease.

Linkage analysis was a workhorse of disease gene mapping until the advent of more refined genomic scans through genome wide association studies (GWAS). However, GWAS' ability to detect gene-gene interactions is hampered by the required huge sample sizes. Whole Genome Sequencing (WGS) captures nearly all allelic variation enabling direct measurement of co-segregation with disease for each allele in a family through linkage analysis without the need to consider recombination fractions. We developed an approach integrating co-segregation data with extant biological interaction data to identify interacting genes involved in disease using WGS of multiplex Alzheimer's Disease (AD) families. Two point linkage (MERLIN) was performed on WGS of 46 AD Sequencing Project (ADSP) families. Per family, an empirical maximum LOD score (MaxLOD) was calculated. Interactions between proteins were identified by querying multiple functional/pathway databases. Variants reaching a family-specific MaxLOD were filtered by high/moderate impact (missense+stop/loss) and functional interaction. Genes of interest were defined as genes of known interaction where at least 2 biologically interacting loci per family reached a family-specific MaxLOD and were found in >1 family, creating a single shared transchromosomal locus. The transchromosomal MaxLODs were combined across multiple families sharing the same biologically interacting loci. Multiple families had biologically interacting genes with individual variants attaining a MaxLOD>1.2. One interaction of shared gene pairs/family had a transchromosomal MaxLOD across 3 families of 4.05, linking variants in SLC10A6, DHCR7, SOAT1, ABCA1 and SREBF2 in the cholesterol metabolism and lipid processing pathways. An additional 5 families had MaxLOD variants in at least one of these genes. 4 families had interacting pairs with a transchromosomal MaxLOD score >2.4 unique to the family. This approach utilizes biological interactions to identify potential disease loci despite genomic distance, thus identifying possible epistatic effects not easily observable in case-control datasets. It is easily applicable to any complex disorder having multiplex families.

## PgmNr 2076: Genetic associations with cognitive performance inform Alzheimer's disease etiology.

**Authors:**

[View Session](#) [Add to Schedule](#)

**Affiliation:** Regeneron Genetic Center, Tarrytown, New York.

---

Alzheimer's disease (AD) is a leading cause of dementia and affects over 40 million people worldwide. As AD typically develops late in life, it is challenging to perform genetic association studies with very large numbers of affected individuals. To help identify genetic risk factors for AD we analyzed a quantitative phenotype that is genetically correlated with AD case-control status ( $r_g=0.23$ ,  $P=6 \times 10^{-7}$ ) and was measured in participants of the UK Biobank study: time to complete the touchscreen questionnaire (TCQ). We analyzed 9 million common variants ( $MAF > 1\%$ ) available in 462,958 individuals, and 3.8 million rare variants ( $MAF < 1\%$ , including gene burden tests) obtained from exome sequencing of a subset of 142,360 individuals. We identified 222 variants independently associated with TCQ ( $p < 5 \times 10^{-8}$ ), 29 of which also showed at least a nominally significant association ( $p < 0.05$ ) with AD risk. Sixteen variants were in high linkage disequilibrium with a sentinel expression quantitative trait locus for a nearby gene. Overall, our results suggest that the study of phenotypes related to cognitive performance can help identify novel genetic risk factors for AD.

## PgmNr 2077: Genome-wide analyses identify novel sex-specific candidate loci for Alzheimer disease.

**Background:** Women comprise nearly two-thirds of all Alzheimer disease (AD) cases, suggesting sex-specific risk and protective factors. For example, a number of studies have established that apolipoprotein E (*APOE*) genotype contributes to risk of AD differently in men and women. To identify additional sex-specific genetic associations with AD, we meta-analyzed imputed genome-wide datasets using two complementary statistical analyses.

**Methods:** Sex-interaction and sex-stratified analyses were performed in the Alzheimer's Disease Genetics Consortium (ADGC) haplotype reference consortium (HRC) -imputed dataset (N=9,135 cases, 60% female; 9,677 controls, 60% female). Study-specific logistic regression analyses were conducted on 21 studies using Plink (sex-interaction) and SNPTest (sex-stratified). Results were meta-analyzed using inverse variance based analyses in METAL.

**Results:** We found evidence of sex-interaction effects (interaction  $P < 10^{-5}$ ) for 131 variants and 15 loci, including strong associations with opposing effect directions for intronic *BBS9* (interaction- $P = 2.51 \times 10^{-7}$ ) and *LIP1* variants (interaction- $P = 4.03 \times 10^{-7}$ ). Sex-stratified analyses identified 86 variants and 34 loci significant in one sex ( $P < 10^{-5}$ ) and not the other ( $P > 0.05$ ). Sixteen variants in the *APOE* region, the strongest AD risk locus, were associated with AD in females (top  $P = 8.95 \times 10^{-10}$ ) but not in males ( $P = 0.19$ ). Two variants in another known AD locus, *BIN1*, showed association in females (top  $P = 7.89 \times 10^{-7}$ ) but not in males ( $P = 0.08$ ). Additional associated variants in females include intronic variants in *ATE1* (female- $P = 1.19 \times 10^{-7}$ ; male- $P = 0.60$ ), *HYDIN* (female- $P = 3.32 \times 10^{-7}$ ; male- $P = 0.28$ ), and *ECE1* (female- $P = 1.37 \times 10^{-6}$ ; male- $P = 0.41$ ); and an intergenic variant near *SORD* (female- $P = 9.12 \times 10^{-7}$ ; male- $P = 0.23$ ). Male-specific variants include intronic variants in *SMOX* (male- $P = 1.43 \times 10^{-7}$ ; female- $P = 0.48$ ), *PLD1* (male- $P = 4.37 \times 10^{-7}$ ; female- $P = 0.45$ ), and *RAB10* (male- $P = 1.89 \times 10^{-6}$ ; female- $P = 0.55$ ).

**Conclusions:** We identified several sex-specific associations with AD in genes with potentially AD-relevant function including *BBS9* (hypertension, heart disease and obesity phenotypes), *LIP1* (lipoprotein metabolism), *ATE1* ( $\beta$ ?amyloid,  $\alpha$ ?synuclein, and TDP43 processing), *PLD1* (enzyme elevated in AD hippocampus), and *RAB10* (AD resilience locus). Understanding the nature of these

associations will help explain differential risk and progression for AD between the sexes.

## PgmNr 2078: Analysis and validation of tissue-specific genetic regulated expression in late-onset Alzheimer's disease in ~160,000 individuals identifies novel genes and function-based fine mapping of known regions.

---

Late-Onset Alzheimer Disease (LOAD) is the most common neurodegenerative disease, occurring in >35% of individuals age 85 years and older, and is the 6<sup>th</sup> most common cause of death in the US. Heritability of LOAD is estimated to be 40-80%, yet the numerous genome-wide studies (GWAS) conducted to date have identified risk variants that explain only 8% phenotypic variance. Many genetic mechanisms underlying LOAD remain unclear, and identifying functional genetic risk factors will likely illuminate the biological processes underlying the disease. To improve understanding of the functional genetic etiology of LOAD we used 25 GWAS datasets including 13,042 cases and 13,674 controls from the Alzheimer's Disease Genetics Consortium. These data were imputed to ~40M variants with the HRC r1.1 reference panel using Minimac3, and high quality variants with MAF>0.05 and imputation  $R^2>0.8$  were used to predict gene expression in 45 tissues using PrediXcan, an approach that infers the genetically regulated portion of gene expression from common expression quantitative trait loci identified in the Genotype-Tissue Expression Project, along with additional brain and immune cell studies. Meta-analysis across all studies was performed using METAL and identified 47 unique genes reaching Bonferroni-corrected genome-wide significance ( $p<2.5\times10^{-6}$ ) across all tissues. Top hits included APOC1 ( $p=2.3\times10^{-61}$ ), GEMIN7 ( $p=1.0\times10^{-32}$ ), and AMMECR1L ( $p=2.1\times10^{-19}$ ). In a cross-tissue model, 3 genes had significant effect, including *MRE11A* ( $p=1.1\times10^{-11}$ ), *CDHR5* ( $p=2.9\times10^{-11}$ ), and *GATAD2B* ( $p=2.7\times10^{-7}$ ). We further adjusted models using nearby previously-reported sentinel risk variants for AD. Across all tissues, 3 unique genes reached genome-wide

significance after correction for known signals: *COLCA1*, *GABPB1*, and *P2RY14*. Replication analyses and additional fine mapping were performed by MetaXcan analysis of summary statistics from logistic regression in an additional independent 11424 cases and 26277 controls. Further independent validation of identified genes was performed in 95,000 individuals in a large, electronic health record-linked DNA databank. Genes identified in our discovery analysis were enriched for associations with cerebral degeneration ( $p=1 \times 10^{-5}$ ) and memory loss ( $p=3 \times 10^{-5}$ ). In conclusion, leveraging predicted expression in ~160,000 individuals illustrates the utility of gene regulatory models in the discovery of new loci and function-based fine mapping of known regions for LOAD.

Dementia is a neurodegenerative disease with high genetic predisposition. Prior studies revealed causative and susceptible genes for both early onset (EOD) and late onset dementia (LOD). Stepwise DNA testing has been traditionally employed. This pilot study is aimed to investigate the usefulness of next generation sequencing (NGS) for dementia testing in Thailand in aspect of the diagnostic yield, correlation with clinical diagnosis, and concern in variants interpretation. Genes included in the NGS panel are those responsible for Alzheimer's disease (AD) (*APP ABCA7 ITM2B PSEN1 PSEN2 SORL1 TOMM40 TREM2*), Frontotemporal Dementia (FTD) (*ALS2 ANG C9orf72 CHMP2B DCTN1 FUS GRN MAPT MATR3 OPTN PFN1 SETX SOD1 SPG11 SQSTM1 TARDBP TBK1 UBQLN2 VAPB VCP*), Dementia with Lewy bodies (DLB) (*SNCA SNCB*) and other dementia conditions (*CSF1R NOTCH3 SERPINI1 TFG TYROBP UBE3A VPS35*). NGS was performed on an Ion S5XL sequencer. Variant annotation and filtering were done using Ion Reporter™, wANNOVAR server, and Variant Effect Predictor. Selected variants with minimum read depth of 30x and minor allele frequency lower than 0.01 were interpreted with ACMG2015 guideline. Samples were from 45 *PSEN1* and *PSEN2* negative AD, 10 FTD, 3 DLB, and 5 unclassified dementia patients diagnosed by neurologists or geriatricians. These were also classified into EOD or LOD, and sporadic or familial (having at least one 1st degree relative with dementia) groups. In AD group, among 103 identified variants, 6 pathogenic/likely pathogenic (p/lp) variants and 28 variants of uncertain significance (VUS) were found (34/103 = 33%). Detection rate of p/lp variant were 13% and 21% in sporadic and familial early onset AD. For FTD group, 28 variants were found included 2 p/lp variants and 3 VUS (5/28 = 18%). Detection rate of p/lp variant were 25% and 33% in sporadic and familial early onset FTD. No p/lp variants were found in DLB group. In unclassified dementia, 13 variants were found included 1 p/lp variant and 6 VUS (7/13 = 54%). Detection rate of p/lp variant was 20% in unclassified dementia. Surprisingly, 2 out of 6 p/lp variants in AD group were indeed causative for FTD and DLB. Overall detection rate of p/lp variant or VUS in Thai *PSEN1* and *PSEN2* negative dementia patient was 68% (43/63 probands). The magnitude of clinical and molecular diagnostic discrepancy should be further explored. This study demonstrated usefulness of mutation screening with NGS over traditional stepwise testing in EOD patient.

## PgmNr 2080: Genome wide meta- and mega-analysis for identifying genes modifying age-at-onset of Alzheimer disease in the ADGC cohorts.

Genetic predispositions of age-at-onset (AAO) of Alzheimer disease (AD) was first demonstrated by linkage studies (Daw et al. 1999, Li et al. 2002). In the era of genome wide association study (GWAS), the Alzheimer Disease Genetics Consortium (ADGC) has previously conducted a meta-analysis of 14 cohorts for AAO of AD (Naj et al. 2014), and reported several variants in known risk genes as well as novel AAO variants. Here we re-examine AAO in the ADGC dataset with additional cohorts and improved genome-wide imputation data by both meta- and mega-analysis. A total 6642 unrelated AD cases with AAO data from 20 ADGC cohorts were investigated. Imputation was performed for each dataset based on the Haplotype Reference Consortium reference panel through the Michigan Imputation Server. Consistent quality control procedures were applied to each dataset. Variants with allele counts < 10 in each dataset or overall MAF < 0.01 were excluded. We tested allelic dosage association with AAO by multivariable linear regression models. For meta-analysis, we performed association tests for each dataset with covariate adjustment of sex and three principal components (PCs), where PCs were computed for each dataset. Meta-analysis was followed using the METAL program. For mega-analysis, we used QCTOOL to merge genotype data of 20 cohorts. PCs were generated from the merged data. Covariate adjustment includes sex, 4 PCs, and cohort. Variants meeting  $p < 10^{-5}$  in either methods were examined. The average AAO ranged from 72.2 to 86.1 years among AD cases in the 20 datasets. Meta-analysis revealed 11 regions (meta-regions) associated with AAO with  $p < 10^{-5}$ , but only the chromosome 19 APOE region reached genome wide significant ( $p < 5 \times 10^{-8}$ ). On the other hand, mega-analysis identified 14 regions (mega-regions) with 10 regions reaching  $p < 5 \times 10^{-8}$ . APOE and chr1p36.31 intra-genic regions were identified by both methods with. In addition, 7 meta-regions still maintain nominal significance in mega-analysis except with smaller effect sizes. However, eight mega-regions were not detected by meta-analysis ( $p > 0.05$ ). While more detailed investigation is underway, our results imply that meta-analysis are likely influenced by within-cohort sample size and data normality, which may explain some of the discrepancy. When feasible, mega-analysis would be preferable. By using both approaches, we identified several genetic loci for AAO of AD.

## PgmNr 2081: The genetic and phenotypic overlap between human herpesvirus and Alzheimer's disease risk in the UK Biobank.

---

Human herpesvirus (HHV) is a family of nine viruses known to cause a range of common diseases including mononucleosis, chickenpox, and shingles. It has been suggested that HHV infection in the brain may increase the risk of developing late onset Alzheimer's disease (AD). While these studies highlight the involvement of viral activity in the brain and amyloid beta, there is a lack of understanding on the role of genetics in susceptibility to viral infection and AD.

Using data from the UK Biobank, we sought to examine whether there is an association between HHV-related phenotypes and AD risk, and the extent to which genetic factors explain such associations. After constructing a general HHV phenotype using data from medications, ICD9, ICD10, and self-reported categories, we assessed the phenotypic overlap between individuals with HHV and AD, as well as AD family history. We performed a GWAS using BOLT-LMM on a general HHV cohort (10,559 cases, 397,606 controls). We used DEPICT and DAPPLE to identify pathways and PPI networks between our HHV and an AD risk GWAS. Finally, we generated polygenic risk scores (PRS) from the general HHV GWAS summary statistics and tested whether the PRS was as associated with AD/AD family history.

We found that individuals with a general HHV phenotype are 2.6 times more likely to have been diagnosed with AD ( $P=5.95e-26$ ) and 1.4 times more likely to have a family history of AD ( $P=7.08e-25$ ) than those without an HHV phenotype. We identified one genome-wide significant locus for the general HHV GWAS, rs3903160 ( $P=6.2e-9$ , OR=1.09), which falls within the HLA region on chromosome 6. Pathway and PPI analysis identified common gene sets that are nominally enriched in HHV and AD GWAS, including immune-related, lipid binding, apoptotic and cell-cell adhesion, as well as pathways previously reported in AD, such as INPPL1 and PLCG2 protein-protein interaction subnetworks. Finally, the HHV susceptibility PRS was significantly associated with AD ( $P=2.94e-4$ ) and AD family history ( $P=8.92e-8$ ), suggesting some shared genetic basis between HHV and AD risk. While the HHV phenotype is not the most well-defined and is difficult to interpret, our findings are consistent with other literature on HHV infection and AD and suggest a genetic overlap between the two. Future studies with better defined HHV phenotypes could further elucidate this relationship, and could potentially fuel drug development decisions and resulting therapies for AD.

---

Dementia is a brain disorder caused by the aging which obstructs social life and interpersonal relationships due to cognitive dysfunction such as memory impairment, consciousness impairment, and slowed ability to judgment. In Japan, about 30% of elderly people aged 65 over were reported to have some types of dementia or mild cognitive impairment (MCI), and the number of affected people is expected to increase as the population aging. The most common form of dementia is late-onset Alzheimer's disease (LOAD), whereas vascular dementia (VaD), dementia with Lewy bodies (DLB), frontotemporal dementia (FTD) and normal pressure hydrocephalus (NPH) are also known as certain types of dementia. The pathogenesis of dementias is affected by environmental and genetic factors and is often misdiagnosed among dementias because of similar symptoms. Dementias are highly heritable, especially in LOAD (58~79%), therefore identification of the genetic factors for dementias contributes to elucidate the pathogenesis and eventually lead to developing the novel diagnosis, prevention, and medicine. Recently, multiple genetic loci associated with dementia have identified in the Genome Wide Association Study (GWAS) in Caucasian subjects. Here, we conducted an ethnicity specific GWASs for LOAD, DLB, VaD, FTD and NPH to clarify the genetic architecture for dementias using an ethnicity specific whole genome genotyping array, Japonica (Affymetrix), which constructed based on whole-genome sequences of 1,070 Japanese individuals, with approximately 7,100 Japanese population recruited at National Center for Geriatrics and Gerontology (NCGG) biobank. We replicated the *APOE* locus (rs429358,  $P$ -value  $\leq 5.0 \times 10^{-8}$ ) for LOAD and DLB and found convincing associations for 4 known LOAD loci, *CLU*, *PICALM*, *ABCA7*, *SORL1*. We further identified new candidate risk loci for these types of dementia. We have also investigated the differences in the susceptible loci identified in the GWASs among dementias.

## PgmNr 2083: Utilizing Massively Parallel Reporter Assays to identify protective functional variants in the *ApoE* region.

---

The risk for late-onset Alzheimer disease (AD) in *ApoEε4* carriers differs between ethnic groups with risk decreasing from Japanese over Europeans to Africans. Ancestry analyses in *ApoEε4* carriers of African-American and Puerto Rican admixed populations showed significant interaction of risk with local ancestry (LA); i.e. ancestry of genomic region surrounding *ApoE* (Rajabli et al, 2019). Reduced risk was observed for African LA *ApoEε4* carriers versus European LA *ApoEε4* carriers. Identification of the protective variant on the African LA haplotype will lead to greater insights into the mechanism with which *ApoEε4* leads to AD.

1000 Genomes variants with significant frequency difference between African and Japanese or European LA haplotypes in the topologically associated domain surrounding *ApoE* (chr19:45375500-45431600) were selected for functional analysis. All these variants are noncoding. Massively parallel reporter assays (MPRA) were used to assess, first, the regulatory potential of these variants and their surrounding regions to present with enhancer activity and, second, the effect size of these variants on enhancer activity, in immortalized SHY-SY5Y neuronal cells, U-118 microglial and HMC3 astrocytes.

We selected variants with significant frequency differences ( $p < 1 \times 10^{-5}$ ) between Japanese or European and African *ApoE* LA ancestry for MPRA. We generated ~900bp PCR fragments surrounding these variants, representing candidate regulatory elements (CRE), in heterozygous carriers to ensure equal representation of alleles. We pooled the amplicons and cloned them into a library of enhancer reporter vectors (pGL4.24) tagged by over 15M different barcodes in the 3'UTR. Subassembly linking APOE fragments to unique barcodes has been completed and has identified >250k unique barcode:fragment links. The vector library was transfected in all three cell lines in duplicate. Analyses of differential expression driven by opposite alleles at the positions of interest are ongoing.

## PgmNr 2084: Integrative genome and transcriptome analysis reveals link between complement pathway and APOE e2 protective mechanism for Alzheimer's disease.

The  $\epsilon 4$  allele of apolipoprotein E (*APOE*) is the major genetic risk factor for late onset Alzheimer disease (AD), while the  $\epsilon 2$  allele is known to mitigate disease risk. Mechanisms underlying the protective effect of  $\epsilon 2$  are largely unknown. To investigate the genomic basis of the influence of  $\epsilon 2$  on AD risk, we evaluated gene expression data obtained from the dorsolateral *prefrontal cortex* area of 545 human autopsied brains (including 32 AD and 39 controls with the e23 genotype) that were donated to the Religious Orders Study and Memory and Aging Project (ROSMAP). Expression data obtained from 153 autopsied brains (including 4 AD and 12 controls with the e23 genotype) from the Mayo Clinic Study of Aging (MAYO) were used for replication. Expression levels for each gene were compared between cases and controls within *APOE* genotype groups in the ROSMAP sample. Results obtained from the ROSMAP for significantly differentially expressed genes (DEGs) were combined with results from MAYO by meta analysis. We also constructed co-expressed gene-networks separately in cases and controls for each *APOE* genotype subgroup using Weighted Co-expression Network Analysis (WGCNA). Preserved networks in both datasets ( $Z_{summary} > 10$ ) were further validated using integrative gene enrichment analysis that included the top-ranked DEGs and genes previously implicated in AD by GWAS. Among *APOE* e23 subjects, significant DEGs ( $P < 10^{-5}$ ) were identified including *GFAP* ( $Z_{score} = 4.55$ ,  $P = 6 \times 10^{-6}$ ) and *C4A* ( $Z_{score} = 4.45$ , and  $P = 9 \times 10^{-6}$ ). These DEGs were transcriptome-wide significant in all subjects combined ( $P < 5 \times 10^{-8}$ ). Other complement pathway genes, *C6* ( $Z_{score} = 2.90$ ,  $P = 0.004$ ) and *CR1* ( $Z_{score} = 2.61$ ,  $P = 0.009$ ), were nominally significant DEGs in the e23 subgroup. A network module containing these and AD risk genes was significantly enriched ( $P = 5 \times 10^{-4}$ ). Our findings demonstrate a biological link between the *APOE*  $\epsilon 2$  protective mechanism(s) and complement pathway in AD. Together with a recent report of protein interaction between *APOE* and C1q, our study also suggests that further research aimed at understanding how complement pathway genes interact with *APOE*  $\epsilon 2$  may lead to a potential novel therapeutic target for AD.

## PgmNr 2085: Blood-based transcriptional risk scores predict neuroimaging biomarkers for Alzheimer's disease.

Dysregulated gene expression associated with genetic loci influencing Alzheimer's disease (AD) risk could possibly reflect the pathophysiological status of AD. Here we calculated blood-based transcriptional risk scores (TRS) by integrating genome-wide association study (GWAS) summary statistics and expression quantitative trait locus (eQTL) data to predict MRI-based biomarkers for AD. First, we selected 188 independent SNPs with  $p < 1 \times 10^{-5}$  from a large-scale GWAS (Jansen *et al.* 2019) and then identified 31 candidate genes significantly associated with these SNPs in blood-based eQTL database (Westra *et al.* 2013) (FDR-corrected  $p < 0.05$ ). To identify pathogenic genes among the 31 genes, we performed GWAS summary-based Mendelian randomization (SMR) ( $p < 8.4 \times 10^{-6}$ ) and a Bayesian test for colocalization ( $H_4 > 80\%$ ) (Marigorta *et al.* 2017) using summary-level GWAS and eQTL data, which yielded the identification of 3 pathogenic genes (*CD33*, *CTSH*, *PILRA*). Finally, we calculated TRS by summing z scores of the 3 pathogenic genes' expression levels using peripheral-blood microarray gene expression data from two independent cohorts (661 and 674 participants from the Alzheimer's Disease Neuroimaging Initiative (ADNI) and the AddNeuroMed cohorts as discovery and replication samples, respectively). We evaluated whether TRS was associated with diagnosis (AD vs. cognitively normal control) and MRI-based biomarkers (hippocampal volume and entorhinal cortical thickness). In ADNI, TRS was significantly associated with diagnosis ( $p = 1.69 \times 10^{-3}$ ; Odds ratio (OR) = 1.21), hippocampal volume ( $p = 2.11 \times 10^{-3}$ ;  $t$  value = -3.09), and entorhinal cortical thickness ( $p = 2.47 \times 10^{-3}$ ;  $t$  value = -3.04). In AddNeuroMed, TRS was significantly associated with diagnosis ( $p = 1.28 \times 10^{-4}$ ; OR = 1.19) and entorhinal cortical thickness ( $p = 2.07 \times 10^{-2}$ ;  $t$  value = -2.33). The expression of *CD33* on immune cells is known to be increased in AD and to be associated with inhibition of phagocytosis of A $\beta$ . Cathepsin H, encoded by *CTSH*, is one of the lysosomal cysteine proteases which clear accumulated materials including A $\beta$  by proteolytic processing or autophagy. Paired immunoglobulin-like type 2 receptor alpha, encoded by *PILRA*, is a cell surface inhibitory receptor and is known to be a negative regulator of microglia and neutrophils. Blood-based TRS predicted neuroimaging biomarkers for AD with biological plausibility and replication in an independent cohort.

---

Late onset Alzheimer's disease (AD) is caused by a complex polygenic and environmental mechanism. It is the 6<sup>th</sup> leading cause of death in the United States. Women are at twofold risk for AD with a more rapid neurodegeneration.

With the arrival of whole genome-sequencing studies, family-based designs enable sex-specific analysis approaches that can be applied to only affected individuals and are completely robust against the effects of population substructure. These advantages make the family-based association tests (FBATs) especially suited for the analysis of diseases such as Alzheimer's Disease (AD). However, the application of FBATs to assess sex-specific effects can require additional filtering steps, as sensitivity of FBATs to sequencing errors is amplified in this type of analysis.

Here, we illustrate the implementation of robust analysis approaches and additional filtering steps that can minimize the chances of false positive-findings due to sex-specific sequencing errors. FBAT framework is used to model sex-specific effects separately and perform a joint analysis of the main genetic effect and the sex-specific effect. We apply this approach to two family-based datasets consisting of 558 multiplex AD families. We identify three novel genetic loci showing sex-specific association with AD risk. Following strict quality control filtering, the strongest candidate was *ZBTB7C*, conferring increased risk for AD in females and protection in males. *ZBTB7C* encodes the Zinc Finger and BTB Domain Containing 7C, a transcriptional repressor of membrane metalloproteases (MMP), including members of this family implicated in AD neuropathology.

## PgmNr 2087: Using the lens of local ancestry to focus risk in Alzheimer disease.

### Background:

Alzheimer disease occurs in all ethnic and racial groups. Genetic studies across populations have shown differences in both risk effect size (e.g., *APOE*, *ABCA7*) and risk variants (e.g., *ABCA7*). While the role of genetic “local” ancestral effects for *APOE* is rapidly unfolding, the role of local ancestry at other AD genetic risk/protective factors has not been assessed. This study examines the effect of genetic ancestral backgrounds in admixed African-American (AA) and Caribbean Hispanic Puerto Rican (PR) populations for AD genes identified in non-Hispanic Whites.

### Methods:

Genome-wide genotyping was performed in 5,506 AA (1,776 cases, 3,730 controls) and 1,132 PR (255 cases, 877 controls) individuals. Quality control analyses were done using software PLINK v.2. Global ancestry for each population was estimated by performing Principal Components Analysis (using GENESIS). Local ancestry (LA) was calculated using SHAPEIT (with 1kGP reference) followed by RFMix (using HGDP reference panels). We performed genotype-based logistic regression tests, testing for the interaction between genetic ancestral background and known AD risk/protective variants.

### Results:

Results showed that two genes (*CD33* (rs3865444g): p-value=0.03, *CASS4* (rs7274581): p-value=0.03) in AAs and one gene (*EPHA1* (rs11771145): p-value=0.02) in PRs were significantly associated with AD in the presence of LA. All variants were significantly associated with the European (EU) background around the genes. The main effect for *CD33* and *CASS4* in AAs were not significant, whereas the *EPHA1* main effect was significant for the variants in PRs. The global proportion of European (EU) ancestral background in PRs (~67%) and AAs (~20%) likely explains the difference in

the significance of the main effects among the populations.

**Conclusion:**

These results demonstrate that individuals with an EU genetic region at the *CD33*, and *CASS4* genes in AAs and *EPHA1* gene in PRs have different risk of AD from those who inherited an African local ancestral background. This suggests that genetic risk/protective factors in admixed populations are correlated with the local genetic ancestry emphasizing the need to consider LA when determining risk in admixed groups. Identification of population-specific variation could lead to the development of ancestry-specific AD therapies. This would improve treatments and help reduce health disparities.

## PgmNr 2088: Association of short tandem repeats with neuropathological features in late-onset of Alzheimer's disease brains.

Sergievsky Center Columbia University, New York, NY, USA; 3) The Department of Neurology, College of Physicians and Surgeons Columbia University, New York, NY, USA; 4) Rush Alzheimer's Disease Center, Rush University Medical Center, Chicago, Illinois; 5) Department of Neurological Sciences, Rush University Medical Center, Chicago, Illinois; 6) Department of Pathology, Rush University Medical Center, Chicago, Illinois; 7) Center for Translational and Computational Neuroimmunology, Columbia University Medical Center, New York, New York

**Background:** Late-Onset Alzheimer's Disease (LOAD) is characterized by genetic heterogeneity and there is no single model explaining the genetic mode of inheritance. Short tandem repeats (STRs), which are hyper-mutable sequences in the human genome could explain some of the missing heritability in LOAD. STRs are involved in several neural-degenerative disorders such as Huntington disease. We systematically evaluated the impact of STRs on neuropathological LOAD features.

**Methods:** We used whole-genome sequencing (WGS) data in for 1,134 unrelated individuals of European ancestry from Religious Orders Study (ROS) and Rush Memory and Aging project (MAP) cohorts to identify genome-wide STRs. WGS was generated from DNA extracted from blood and brain tissues. We used hipSTR to perform STR calling and genotyping with human genome build 19 as reference. For, quality control, we excluded monomorphic STRs, STRs with depth<10 or missing rate>20%. We tested the association of STRs with a) neuropathological LOAD status, b) beta-amyloid levels, c) neurofibrillary tangle (NFT) burden and d) global measure of pathology based on the scaled scores of 5 brain regions. Regression models adjusting for age, sex and first three principal components were used to test association and Bonferroni correction was used to establish significance.

**Results:** Post QC filtering, we identified 917,298 STRs genome-wide. Two STRs within *APOE* gene (19:45423986 and 19:45412779) were associated with global pathology score ( $p=4.5E-17$ ,  $p=3.9E-12$ ), beta-amyloid levels ( $p=6.3E-08$ ,  $3.6E-07$ ) and pathological AD status ( $1.7E-07$  and  $8.2E-07$ ) but not with tangle counts. We found a novel association for a STR (18:7901364) in the *PTPRM* gene with tangle counts ( $p=6.9E-08$ ). The STR has "T" as the repeat motif and an average length of 17. Additionally, *rs6506544* in *PTPRM* which is 0.1 MB from the associated STR, is an expression quantitative trait loci ( $p=9.73E-05$ ).

**Conclusions:** *PTPRM*, tyrosine phosphatase receptor-type mu, is a signaling molecule that regulates various cellular processes such as cell growth and differentiation. *PTPRM* was identified as a 5-Hydroxymethylation-associated epigenetic modifier of Alzheimer's disease that modulates Tau-induced neurotoxicity. The proximity of eQTLs near the associated STR suggests a regulatory role.

*PTPRD*, from the same gene family, has been associated with NFT burden in the same cohort. The results indicate STRs could explain some of the missing heritability in LOAD.

---

Substantial inter-individual variability exists in the disease trajectories of Alzheimer's disease (AD) patients, some of which is likely due to genetics. We describe a genome wide association study to examine rate of cognitive decline in a sample of AD patients with longitudinal measures of cognition. We tested for interactions between genetic variants and time since AD diagnosis to predict a composite measure of global cognitive performance in a sample of 3,946 AD cases from eleven cohorts and performed pathway analysis on the top genes identified. Suggestive associations ( $p < 1.0 \times 10^{-6}$ ) were observed in a large region on chromosome 15 that includes DNA polymerase- $\gamma$  (*POLG*) (rs3176205,  $p = 1.11 \times 10^{-7}$ ), on chromosome 7 (rs60465337,  $p = 4.06 \times 10^{-7}$ ) in contactin-associated protein 2 (*CNTNAP2*), in lincRNA RP11-384F7.1 on chromosome 3 (rs28853947,  $p = 5.93 \times 10^{-7}$ ), and family with sequence similarity 214 member A (*FAM214A*) on chromosome 15

(rs2899492,  $p=5.94 \times 10^{-7}$ ); as well as intergenic regions on chromosomes 16 (rs4949142,  $p_{GEE}=4.02 \times 10^{-7}$ ), and 4 (rs1304013,  $p=7.73 \times 10^{-7}$ ). One variant (rs1476679,  $p_{AD}=5.6 \times 10^{-10}$ ) in previously established AD risk gene *ZCWPW1*, was significantly associated with rate of decline ( $p_{decline}=3.07 \times 10^{-6}$ ). Ten genes (*APBA1*, *BANK1*, *KCNH5*, *NEGR1*, *PDE4D*, *PTPRN2*, *RBFOX1*, *SGCZ*, *SLC17A3*, and *ZCCHC4*) significantly associated with intelligence were also among the top results. Several significant pathways were identified including ones related to neuronal development and function (Gαq signaling, ephrin signaling, synaptic long term depression, axonal guidance signaling), neuronal apoptosis (Huntington's disease signaling, phospholipase C signaling), memory (CREB signaling in neurons, protein kinase A signaling), and inflammation and immunity (CXCR4 signaling, thrombin signaling). These results suggest that pathways related to AD, intelligence, and neurological function all determine rate of cognitive decline, while the previously identified AD risk variants, including ApoE, do not have a major impact.

## PgmNr 2090: Multiomic data integration in Alzheimer's disease using deep learning.

Despite intense investigation into preclinical Alzheimer's Disease (AD) models, there are currently no approved disease-modifying drugs. Genome-wide association studies have proposed a number of genes significantly associated with AD across different pathways, however these genes explain a fraction of disease heritability. The prevailing view of AD as a singular disease with one driving genetic mechanism is oversimplified and does not consider the extensive phenotypic heterogeneity observed. While almost all patients present the hallmark b-amyloid plaque and neurofibrillary tangle neuropathology, there is significant variability in severity of cognitive symptoms, age of onset, and neurophysiology across patients. This suggests that there are likely multiple different genetic mechanisms and pathways in the patient population driving disease to the commonly observed neurodegeneration. High-throughput studies have revealed that AD is a result of complex interactions within and between the genome, transcriptome, epigenome, and proteome. Given that univariate association methods are unable to detect such nonlinear interactions, in this study we interrogate the complex genetic architecture of AD by using a deep learning framework to integrate multiomics data for AD case-control individuals. Using prior biological knowledgebases, we mapped gene-level multiomics data to pathways and aggregated the data to generate "pathway scores". Using a neural network approach, we combined pathway scores from each omic data type to determine models of candidate AD pathways that best explain disease status. Preliminary analysis from this study uses multiomics AD data from Religious Orders Study and Memory and Aging Project. We integrated RNA-sequencing and methylation data pathway scores to identify pathway models with accuracy of 0.71 and area under the curve of 0.69. Pathways known to be associated with AD from the literature such as amino acid synthesis, vesicular transport, and DNA damage repair were identified in our models, in addition to novel innate immunity pathways not previously associated with AD such as NOD-like receptor signaling and leishmaniasis infection. These results reveal there is remaining complex AD biology that can be identified only through simultaneous evaluation of multiomics data. Our study addresses the larger challenges in data dimensionality reduction and data integration, and contributes to the identification of novel disease pathway models.

## PgmNr 2091: Circadian-relevant gene *PERIOD3* is related to autism spectrum disorder and has function neuronal development.

---

Synaptic dysfunction is considered to be a part of pathology for autism spectrum disorder (ASD) since many genes associated with synaptic function were detected as candidates for ASD. On the other hand, 44-83% of children with ASD have sleep problems and some circadian-relevant genes such as *PER1* and *MTNR1A/B* have been reported to be associated with ASD. Previously, we detected mutations in several circadian-relevant genes and revealed that *NR1D1* contributed to ASD and had the role on neural network formation. This time, we focused on *PERIOD3* (*PER3*) to analyze for the mutations in ASD patients and also the contribution to neuronal development. *PER3* that is located on 1p36.23 with 25 exons belongs to the period family. However, exact function is not well understood. (Methods) We screened Japanese ASD patients for *PER3* mutation by Sanger sequencing analysis. After obtained informed consent from parents, genomic DNA was extracted from lymphocytes, amplified each exon and its neighboring introns by PCR, and subjected to sequence. We also analyzed the role of *Per3* on the brain during embryogenesis by using in utero electroporation in the mouse. In utero electroporation, *Per3* was suppressed using RNAi on embryonic day (E) 14.5 and the brain was analyzed after birth.

(Results) We analyzed only up to 100 patients until now, but detected 13 kinds of miss sense base changes. Among them, six mutations were judged as damaging in polyPhen-2 analysis, and four of them, p.V134M, p.A264D, p.A554T and p.Q1085K, were not reported as SNPs previously. Acute knockdown of *Per3* with in utero electroporation caused abnormal positioning of cortical neurons, which was rescued by RNAi-resistant *Per3*. *Per3*-deficient cells showed abnormal migration phenotypes, impaired axon extension and dendritic arbor formation.

(Discussion) High incidence of rare mutations affecting the gene function suggested the relation of *PER3* to ASD. And also, *Per3* was found to play a pivotal role in corticogenesis via regulation of excitatory neuron migration and synaptic network formation. Addition to our previous results of *NR1D1*, it is suggested that the circadian related genes closely related to ASD, and had function on neuronal development and synaptic network formation besides the circadian rhythm formation.

## PgmNr 2092: Assessment of the ancestral origin of multiple sclerosis risk within the major histocompatibility complex in a large Hispanic patient cohort.

---

The Major Histocompatibility Complex (MHC) demonstrates the strongest genetic association with multiple sclerosis (MS), with additive and dominant effects at 32 independent alleles explaining ~20% of the estimated heritability within European populations. Despite the importance of the region for understanding the etiology of MS, the complex genomic structure has made it difficult to comprehensively identify risk alleles across populations. We therefore sought to characterize the MHC within a Hispanic cohort consisting of 1298 MS cases and 1354 controls. Dense genotype data across the MHC were available from a custom Illumina array, termed the MS Chip. Classical HLA alleles were imputed using HIBAG, and logistic regression was used to assess the association of each SNP and classical allele with MS after adjustment for global ancestry. A forward stepwise approach was used to identify independent signals. In order to assess the ancestral origin of risk, several approaches were utilized. First, admixture mapping identified regions within the MHC of differential local ancestry between MS cases and controls. Second, risk allele and haplotype frequencies for MS cases and controls were compared to those frequencies observed in the 1000 Genomes populations. Lastly, principal components analysis was used to compare the Identity by Descent distances between the Hispanics and 1000 Genomes samples; first using markers within the MHC and then using ancestry informative markers (AIMs). Greater variability was observed with the MHC than with the AIMs components, due to regionally high levels of selection within the MHC. Differential clustering of MS cases and controls in the MHC only analysis indicated ancestral specific risk haplotypes. Collectively these analyses provided insight into the ancestral origins of MHC alleles conferring MS risk in our Hispanic cohort.

## PgmNr 2093: Genome-wide association of myasthenia gravis.

---

Myasthenia gravis is a chronic disease of the neuromuscular junction causing fluctuating weakness of the skeletal muscles and, in more serious cases, the respiratory muscles. It is an underdiagnosed autoimmune condition affecting 14 to 20 persons per 100,000 in the general population and can occur at any age. Epidemiological studies show a bimodal pattern of incidence where early onset cases are predominantly females under the age of 40 years, but appears to affect both sexes equally after the age of 50 years. Due to aging of the world's population, it is expected that the number of individuals living with this disease will also increase in the coming years.

Although the disease is mediated by circulating auto-antibodies against proteins at the neuromuscular junction, the exact pathogenesis triggering disease onset is unclear. To understand the mechanism underlying this autoimmune condition, we have undertaken a genome-wide approach using a cohort of ~2100 cases and ~46000 healthy controls of European descent to identify genetic variants that alter the risk of myasthenia gravis or drive onset- and sex differences. We replicated previous association signals at *PTPN22* (chr1), *HLA-DQA1* (chr6), and *TNFRS11A* (chr18). We also identified seven new loci on chr2, chr5, chr7, chr8, chr13, and chr14. Additionally, we identified several novel loci that were distinct in male versus female or early versus late onset cases, suggesting that the mechanisms underlying age at onset and risk based on gender may be different. Having the knowledge of which genes or mutations cause or modify MG will facilitate disease modeling and enable the design and testing of new targeted therapeutics tailored to the gender or age at onset of the patient. Thus, the identification of new genes that cause MG is of great significance.

---

Parkinson's disease (PD) is a complex neurodegenerative disorder with a strong genetic component, where most disease associated genetic elements are single nucleotide variants (SNVs) and Indels. The role of more complex and larger genomic events, such as short tandem repeats (STRs) have only been studied for candidate genes, therefore their genome-wide contribution to the disease remains unknown. Here we present a genome-wide association analysis (GWAS) of STRs for PD. We have used a GWAS dataset from the International Parkinson's Disease Genomic Consortium (IPDGC) composed of 15,368 individuals (5,333 PD cases and 10,035 controls) that were recruited from different academic health centers across the US and Europe. The dataset includes 547,364 genotyped SNPs, that served as proxies for STR imputation using a recently published STR reference panel built on the 1000 genome project. Imputation was performed using BEAGLE v.5.0. Case control association analysis was done using logistic regression in PLINK, controlling for gender and population structure. We have successfully imputed 17,465 good quality autosomic STRs ( $R^2 > 0.3$ ,  $MAF > 1\%$ ). The association analysis with PD revealed 28 STRs surpassing the genome-wide significance threshold of  $5 \times 10^{-8}$ , with the strongest signal located in the known PD locus of *MAPT* ( $p=2.43 \times 10^{-20}$ ,  $OR=1.35$ , C.I. 95%= 1.27-1.43), depicted as 5 repetitions of a GAAT motif. We also observed significant STRs in other known PD genes: *KANSL1* ( $p=2.88 \times 10^{-18}$ ,  $OR=1.33$ , C.I. 95%=1.41-1.25), *GAK* ( $p=1.04 \times 10^{-12}$ ,  $OR=1.58$ , C.I. 95%=1.39-1.78) and *IFNAR1* ( $p=3.34 \times 10^{-10}$ ,  $OR=1.20$ , C.I. 95%=1.14-1.28). We identified STRs mapping to genes not previously related to PD: *GNL1* ( $p=3.79 \times 10^{-19}$ ,  $OR=1.38$ , C.I.

95%=1.29-1.48), *CNTLN* ( $p=6.78 \times 10^{-10}$ , OR=1.23, C.I. 95%=1.15-1.32), *TEX14* ( $p=9.52 \times 10^{-10}$ , OR=1.19, C.I. 95%=1.13-1.23), *MSH3* ( $p=1.33 \times 10^{-9}$ , OR=1.22, C.I. 95%=1.14-1.30), *SRSF12* ( $p=1.08 \times 10^{-8}$ , OR=1.21, C.I. 95%=1.13-1.29) and *ZNF723* ( $p=1.42 \times 10^{-8}$ , OR=1.31, C.I. 95%=1.19-1.44). Interestingly, *GNL1*, *CNTLN* and *MSH3* have previously been associated to neurodegenerative disorders, linking at their possible functional roles in PD. These results show that STRs in known and novel associated genes could be involved in the pathogenesis of the disease. Study of multiallelic events, gene-sets and pathway enrichments, heritability contribution and replication in independent populations are currently underway with the aim to expand and confirm our findings.

### Background

Migraine is a complex neurological disorder with high heritability. Associations between human leukocyte antigen (*HLA*) genes and migraine remained uncertain. We aimed to evaluate the association of *HLA* variants with migraine or headache in clinic and community-based settings.

### Methods

The study included 772 clinic-based migraine patients in a tertiary medical center and 10,019 population-based participants in Taiwan Biobank (TWB). All study subjects were aged between 30-70 and were examined by Axiom Genome-Wide SNP Arrays. The diagnosis of clinic-based cases was ascertained by headache specialists and the individuals in TWB were interviewed by a structured questionnaire including their history of headache and migraine. Single nucleotide polymorphism-based imputation for *HLA-A*, *B*, *C*, *DPA1*, *DPB1*, *DQA1*, *DQB1* and *DRB1* were performed by R package HIBAG with an Asian reference group. After quality control, 605 clinic-based cases remained eligible for subsequent analyses, while 2,394 self-reported headache cases, including 911 with self-reported migraine, were identified in TWB. 6,055 TWB subjects free of self-reported headache or migraine were the control group. We used likelihood ratio tests to examine *HLA* associations with migraine and logistic regressions to estimate odds ratios (OR) and 95% confidence intervals (CI) for *HLA* alleles.

### Results

*HLA-B* and *C* were significantly associated with migraine in clinic-based patients (FDR q-value < 0.05). We found *HLA-B\*39:01*, *HLA-B\*51:01*, *HLA-B\*58:01* and *HLA-C\*03:02* to be significantly associated with migraine, with age and sex-adjusted OR (95% CI) of 1.80 (1.28-2.53), 1.50 (1.15-1.97), 1.36 (1.14-1.62) and 1.36 (1.14-1.62), correspondingly. Among the clinic-based patients, the odds of chronic migraine (CM) with medication-overuse headache (MOH) but not that of CM without MOH were significantly ( $p < 0.05$ ) higher than episodic migraine if patients carried *HLA-A\*33:03*, *HLA-B\*58:01* or *HLA-C\*03:02*. *HLA-A\*33:03*-*HLA-B\*58:01*-*HLA-C\*03:02* was the most common haplotype, found 9.74% in the control population. Individuals carrying the haplotype had 1.44 (1.20-1.73) likelihood of clinical migraine. The attributable fraction of the haplotype was 8%. However, no *HLA* genes were associated with self-reported headache or migraine in community-based cases.

### Conclusion

*HLA* class I genetic variants confer risk of migraine in clinic but not population-based cases and may contribute to medication overuse-related migraine chronification.

## PgmNr 2096: Nanopore sequencing of the glucocerebrosidase (*GBA*) gene in a New Zealand Parkinson's disease cohort.

---

**Introduction:** Mutations in the gene for glucocerebrosidase (*GBA*) cause Gaucher disease, an autosomal recessive lysosomal storage disorder. *GBA* mutation carriers are at greatly elevated risk of Parkinson's disease (PD) or dementia with Lewy bodies (DLB) compared with non-carriers. Large studies have shown that ~ 7% of PD cases will carry *GBA* mutations, and these patients may also experience an earlier age of onset and more aggressive disease.

**Methods:** Comprehensive analysis of *GBA* mutations is technically challenging, due to the presence of a closely related pseudogene, and complex structural mutations that can occur at this locus. Using a targeted long PCR step can largely overcome the pseudogene problem, and recently a nanopore sequencing method for complete analysis of this long PCR amplicon was published (Leija-Salazar et al. 2019). We examined *GBA* variants in a large, longitudinal cohort of PD, which includes extensive neuropsychological and clinical assessment. We established the nanopore sequencing method for *GBA* amplicons and analysed samples on a GridION platform (Oxford Nanopore Technology, UK). Sequencing was carried out on R9.4 flow cells, with barcoding and pooling of samples in each run. Guppy base caller was used, and alignment was carried out with Minimap2 and NGMLR software.

**Results:** *GBA* amplicon sequencing revealed 19 mutations in 17 PD cases. All variants were confirmed by Sanger sequencing. Mutations known to be associated with risk of PD included p.E365K (rs2230288) in 10 cases, p.N409S (rs76763715) in one case and R78C (rs146774384) in one case. Mutations possibly associated with PD included D179H (rs147138516) in one case, who had E365K on the same allele, and p.T408M (rs75548401) in six cases, one of whom had p.E365K on the other allele. One potentially novel mutation, p.L335= (C>T), was also detected, which is predicted to impact splicing of *GBA* transcripts.

### Conclusions:

We have further confirmed the utility of nanopore sequencing of *GBA* as a means to identify variants in multiple patient samples. In a large New Zealand PD cohort we found multiple known *GBA* mutations, and several variants of unclear significance. This work may contribute to a better understanding of the effects of these mutations on disease presentation or progression, and potentially to the development of more targeted treatments.

---

Amyotrophic lateral sclerosis (ALS) is a fatal neurodegenerative disease that is characterized by upper and lower motor neuron loss. This neuronal degeneration leads to loss of voluntary muscle movement and eventual death 3-5 years after symptom onset. The molecular mechanisms that cause neuronal demise in ALS are not well understood. ALS can be classified into familial and sporadic forms. Familial ALS (FALS), which accounts for 10% of ALS cases, is defined by a case having a first or second-degree relative that is also affected. Sporadic ALS (SALS) accounts for the remaining 90% of cases and has a heritability estimate of ~0.60. However, only 17% of SALS cases have a pathogenic variant in a known ALS-causing gene, suggesting that additional causal genes remain to be elucidated. To investigate the potential role of *de novo* mutations in SALS causation, we used ALS family trios to detect potential ALS risk variants present in probands, but absent in both unaffected parents. Two trios were selected from a large cohort of ALS cases on whom whole-genome sequencing (WGS) was carried out at an average coverage of 60x. BWA and GATK (v3.3) were used to perform read alignment and variant calling. To identify candidate ALS risk genes, the pedigree-Variant Annotation Analysis and Search Tool (pVAAST) software was used. The software first calculates logarithm of odds (LOD) scores to estimate linkage between the identified variants and disease. It then combines LOD scores with VAAST scores, which identify genes that are more burdened with deleterious, rare (MAF<0.01) variants in case genomes compared to 96 WGS controls. After removal of false positives, the pVAAST analysis identified *PRPF40B* as a top candidate risk gene with a proband having the deletion chr12:50026795\_50026796delAG. Interestingly, this mutation is not present in the gnomAD database and is predicted to disrupt transcript splicing. *PRPF40B* codes for pre-mRNA-processing factor 40 homolog B protein, which functions in mRNA splicing. We find this intriguing because other known-ALS genes encode for proteins that function in RNA binding. Additionally, *PRPF40B* knockdown increases cell apoptosis. Future experiments include determining if the deletion renders the protein nonfunctional. These results indicate that ALS trio analysis can help to identify novel candidate ALS risk loci.

## PgmNr 2098: A unified framework for global and local genetic correlation analysis.

---

Genetic correlation analysis based on summary statistics from genome-wide association studies (GWASs) has quickly gained popularity in the past few years and provided fundamental new insights into the shared genetic architecture of many diseases and traits. However, most applications only report the global genetic correlation, a metric that quantifies the overall genetic sharing between two phenotypes. Although it is of great interest to identify and understand specific genetic regions contributing the most to the overall genetic similarity, existing analytic tools face several major technical challenges including complex linkage disequilibrium (LD) in local regions and pervasive sample overlap across GWASs. Due to these issues, existing methods provide biased estimates for local genetic correlations with inflated rates of false findings. Here, we introduce SUPERGNOVA, a unified framework for diverse types of genetic correlation analyses. Through extensive simulations and analyses of real data, we demonstrate that SUPERGNOVA provides statistically rigorous and computationally efficient inference for both global and local genetic correlations. Additionally, our approach only uses GWAS summary statistics as input, and is robust against overlapping GWAS samples when the shared sample size is unknown. Compared to existing methods, SUPERGNOVA provides comparable estimates on global genetic correlations but substantially outperforms all methods when applied to local genetic regions. We applied SUPERGNOVA to investigate the shared genetic basis of two neurodevelopmental disorders, attention deficit/hyperactivity disorder (ADHD;  $n=53,293$ ) and autism spectrum disorder (ASD;  $n=46,351$ ). Consistent with the literature, we confirmed a positive genetic correlation between ADHD and ASD ( $\text{cor}=0.27$ ,  $p=5.5\text{e-}4$ ). Further, we identified six specific regions showing significant local genetic correlations after correcting for multiple testing, including chromosomes 20p11.22 ( $p=1.5\text{e-}22$ ; *KIZ*), 17q21.31 ( $p=5.6\text{e-}9$ ; *MAPT*), 10q25.1 ( $p=2.1\text{e-}7$ ; *SORCS3*), 4q24 ( $p=5.8\text{e-}7$ ; *MANBA*), 5q21.2 ( $p=1.4\text{e-}6$ ; intergenic), and 1p21.3 ( $p=7.0\text{e-}6$ ; intergenic). Among these regions, 1p21.3 is the only locus implicated in GWASs for both ASD and ADHD. 10q25.1 was identified for ADHD and 20p11.22 is a known ASD locus. The other three loci are novel findings for ASD and ADHD. Taken together, SUPERGNOVA is a major advancement in genetic correlation analysis and has wide applications in complex trait research.

## PgmNr 2099: Prioritization of ALS and PD causal genes from GWAS using protein-protein network analysis.

---

**Background:** Amyotrophic Lateral Sclerosis (ALS) and Parkinson's disease (PD) are neurodegenerative disorders with complex genetic architecture. Mutations in genes, including genes coding for RNA-binding proteins (RBPs), account for less than 20% of the cases. Genome-wide association studies (GWAS) have identified many genomic loci with strong associations with ALS and PD. However, the functional consequences of the causal SNPs are yet to be determined, which limits the ability to translate the GWAS hits into actionable therapeutic hypothesis.

**Methods:** The Disease Association Protein-Protein Link Evaluator (DAPPLE) is a tool developed to prioritize genes in the linkage disequilibrium (LD) block containing the causal SNP, using protein-protein interaction (PPI) networks. A PPI network was constructed by expressing 160 RBPs in HEK293T cells, followed by immunoprecipitation and mass-spec. All baits were selected because they cause genetic forms of neurodegeneration in humans. The network was constructed using CompPASS developed by Harvard. InWeb (combined network of inWeb3 and inWeb\_IM, licensed from Intomics) network was also used. The RBP network is dense, composed of 1,843 proteins and 5,433 interactions.

**Results:** DAPPLE based on GWAS SNPs only was unable to prioritize any genes. For this reason, eQTLs and known disease genes were spiked in, to create eDAPPLE (enhanced DAPPLE) with markedly improved results. For example, for ALS, eDAPPLE identified 13 direct interactions compared to 0 identified by DAPPLE. Known genes had the biggest effect on eDAPPLE predictions, while eQTLs alone had variable effect. Combination of RBP network with InWeb network identified significantly more interactions than InWeb or RBP only network, for both ALS and PD subnetworks. Common interactors between ALS and PD were also identified by using this combined network.

**Conclusion:** The curated RBP PPI network, although considerably smaller than the inWeb, significantly improved eDAPPLE performance, presumably because it consists of disease-specific interactions. The addition of eQTLs and known ALS and PD genes was necessary to allow DAPPLE to identify new disease modules and prioritize genes for further studies. Functional validation of interactions will be done by network perturbation in animal models and/or iPSCs. Common interactors between diseases indicated that the shared pathways may be affected and supporting the hypothesis that a common drug may ameliorate symptoms of both.

## PgmNr 2100: Rare genomic variants impacting neuronal functions modify the Dup7q11.23 phenotype.

---

**Background:** Duplication of the 7q11.23 region (Dup7) results in a complex neurodevelopmental disorder. Common characteristics include distinctive craniofacial features, abnormal neurological findings, low-average intellectual ability and Social Anxiety Disorder. Interestingly, Dup7 is one of the most frequent (0.2%) recurrent copy number variants (CNVs) in individuals with Autism Spectrum Disorder (ASD). However, only 19% of Dup7 carriers have ASD, suggesting that additional genetic factors may be necessary to manifest the ASD phenotype.

**Methods:** To assess the contribution of additional rare variants to the phenotype of individuals with Dup7, we conducted systematic whole-genome sequencing (WGS) analysis of 24 Dup7 carriers: 12 with ASD (Dup7-ASD) and 12 without ASD (Dup7-non-ASD). We analyzed microarray and WGS data through burden, functional and pathway enrichment analyses, and correlated the results with categorical and quantitative phenotypic measures.

**Results:** We identified three variants of clinical significance: a pathogenic loss-of-function (LoF) frameshift deletion variant in *EP400* in one Dup7-ASD individual, and two rare deletions which disrupt *IMMP2L* at the 7q31.1 locus in one Dup7-ASD and one Dup7-non-ASD individual. No findings differentiated the Dup7-ASD group from the Dup7 Non-ASD group. When analyzing the Dup7 cohort as a whole, we found that adaptive behaviour scores (measured by SIB-R) were negatively correlated with an enrichment of rare likely damaging missense variants in genes expressed in the prenatal human brain ( $p=0.004$ ). In addition, intellectual ability (measured on DAS-II) was positively correlated with an enrichment for rare CNVs (non-Dup7) impacting genes with a low to medium mutation intolerance ( $p=0.002$ ) and in structural molecular activity pathways ( $p=0.0001$ ). Lastly, intellectual ability was negatively correlated with an enrichment for rare likely damaging LoF variants in nervous system development ( $p=0.002$ ) and membrane component pathways ( $p=0.001$ ).

**Conclusion:** Overall, WGS characterization of Dup7 carriers suggests that in the presence of the same primary pathogenic Dup7 variant, there are additional genetic variants which tend to have low penetrance and act additively to the overall Dup7-related phenotype. This study highlights the power of pathway analyses and the correlation of quantitative traits towards understanding how additional rare variants in the genetic background modulate neurodevelopmental phenotypes.

## PgmNr 2101: Creating a phenome risk score to identify developmental stuttering in electronic health records.

---

**Introduction:** Developmental stuttering is a speech disorder that typically begins around age 3 and is characterized by syllable repetitions and prolongations. Despite population prevalence of 1%, no population-based genetic studies of stuttering have been conducted and few, if any, studies have utilized DNA database-linked electronic health records (EHRs). Given stuttering is diagnosed by speech pathologists, not physicians, information regarding diagnosis is not consistently noted in EHRs. Rather than relying on ICD 9/10 codes, medications, or other typical approaches to defining phenotypes in EHRs, text-based keyword searches prove more helpful in defining behavioral phenotypes like stuttering. However, manually reviewing files following keyword search is impractical due to the number of records returned. Therefore, the purpose of this project is to develop a phenome risk score to identify likely cases of developmental stuttering in EHRs; enabling use of large-scale DNA biobank resources for well-powered GWAS and epidemiological studies of stuttering.

**Method/Results:** A keyword text search for stuttering terms within the Synthetic Derivative (SD), a de-identified EHR database at Vanderbilt University Medical Center, returned ~14,000 individuals with at least one keyword mention in their records. Files were manually reviewed by an expert in speech pathology who identified 50 confirmed cases of developmental stuttering and an additional 50 files were confirmed as *not* cases of developmental stuttering. A text mining word cloud algorithm was developed to identify stuttering cases and found that the frequency of mentions of *stuttering*, *mother*, *school*, and *childhood* distinguished the stuttering cases from the exemptions. Five percent of the 14,000 files were manually reviewed to test the PPV of the text mining algorithm. We then examined ICD 9/10 codes, labs, and other values associated with developmental stuttering in the SD. Results show enrichment for a variety of comorbid disorders; some were expected based on previous population studies (anxiety, ADHD), others were previously unidentified (constipation, anemias). From this data, we created a phenome risk score by extracting weights for each comorbidity to identify likely cases of stuttering. We applied the phenome risk score in BioVU, VUMC's biorepository of DNA linked to de-identified medical records, and report results from the first GWAS study of quantitative risk scores for developmental stuttering.

## PgmNr 2102: The role of copy number variants in the genetic architecture of common, complex epilepsies.

### Authors:

E.P. Almanza Fuerte; H.C. Mefford; Epi4K Consortium

[View Session](#) [Add to Schedule](#)

**Affiliation:** Department of Pediatrics, University of Washington, Seattle, Washington.

---

**Background:** Epilepsy is a group of neurological disorders characterized by recurrent, unprovoked seizures. Major classes of epilepsy include focal epilepsy, generalized epilepsy and epileptic encephalopathies. While the encephalopathies are largely due to de novo genetic and genomic mutations, the more common focal and generalized epilepsies appear to be due to complex genetic inheritance. Copy number variants (CNVs) are known to contribute to the genetic etiology of epilepsy and can act as de novo pathogenic variants or inherited risk variants. Here we investigate the role of CNVs in multiplex families with focal or generalized epilepsy. **Methods:** We performed CNV analysis using exome data from 303 multiplex families with at least 3 individuals with non-acquired seizures, at least 2 of which had a diagnosis of one or more of the common epilepsy syndromes. Detailed phenotyping was previously performed for each affected individual, and exome sequence data was generated for at least two affected individuals in each family. To identify potential CNVs, we analyzed exome data with CoNIFER; recurrent CNVs and CNVs involving epilepsy-related genes were prioritized for follow-up studies. High-priority CNVs were validated using array comparative genomic hybridization (aCGH). Segregation studies were performed when possible for all validated CNVs. **Results:** We validated 11 CNVs in 9 (3%) families. In two cases, the CNVs are likely pathogenic deletions of known epilepsy genes: de novo deletion of HNRNPU in one subject from a family, and deletion of the DEPDC5 gene in affected siblings and an unaffected parent of another family. In five families, we identified recurrent deletions known to be associated with increased risk of epilepsy and developmental disorders: 15q11.2 deletion (3x), 15q13 deletion, and 16p13 deletion. Four CNVs are variants of unknown significance: 15q13.2 duplication, 18q deletion, CHRNA7 duplication, and a duplication of the entire SCN1A gene. Notably, the duplication of SCN1A, a known epilepsy gene, was inherited from an unaffected parent. None of the CNVs we identified segregated perfectly with disease in all affected individuals of a family. **Conclusion:** CNVs contribute to the complex genetic architecture of the common epilepsies. Analysis of exome data for contributing single nucleotide variants in these same families is ongoing.

---

Focal epilepsies (FE) comprise a clinically and genetically heterogeneous group of disorders. An array of comorbid neurological and psychiatric disorders contribute to the clinical heterogeneity of FE. The cause of FE can be acquired or non-acquired (idiopathic). Common causes for acquired forms of FE include stroke, traumatic brain injuries, brain tumors, central nervous system infections, or vascular insults. Recently, it has been shown that common genetic variants can confer risk for focal epilepsy. These variants, combined into FE-Polygenic risk scores (FE-PRS) can identify FE patients with a higher genetic burden for FE compared to population controls. Currently, large research studies explore potential clinical applications for FE-PRS - for example, assessing the risk of developing FE after a first seizure. The goal of this study was to determine if the predictive power of FE-PRS differ across subtypes of FE. We generated genotype data for 430 patients with FE ascertained at the Cleveland Clinic. We subgrouped FE patients and compared the FE-PRS burden against >20k ethnically matched controls for which genetic data were available. FE patient groups were selected based on individual clinical variables (acquired/non-acquired epilepsy, early/late seizure onset, occurrence/no occurrence of psychiatric comorbidities) or combined using a computational clinical data clustering approach. We observed that individuals with non-acquired FE and/or an early seizure onset (<21 years) showed higher FE-PRS compared to controls. In contrast, individuals with acquired FE, defined by the presence of a possible cause (stroke, traumatic brain injuries, brain tumors, central nervous system infections, or vascular insults) are not different from population controls. The highest mean FE-PRS was observed in a group defined by the clustering approach, enriched for individuals with non-acquired FE and early seizure onset. In summary, we observe a heterogeneous burden of PRS in different focal epilepsy subtypes defined by deep clinical phenotyping and clustering analysis. Particularly, the current available FE-PRS have the most predictive power in young FE patients of unknown etiology.

**Purpose:** Rare genetic variants can cause epilepsy, and genetic screening has been widely adopted for severe, pediatric-onset epilepsies. The phenotypic consequences of common genetic risk burden for epilepsies and their potential future clinical applications have not yet been determined.

**Method:** Using polygenic risk scores (PRS) from a European-ancestry genome-wide association study in generalized (GE) and focal epilepsy (FE), we quantified common genetic burden in people with GE or FE from two independent non-Finnish European-ancestry cohorts (*Epi25* Consortium, N=5,705; *Cleveland* Clinic Epilepsy Center, N=620; both compared to 20,435 controls). One Finnish-ancestry population isolate (*Finnish-ancestry Epi25*, N=449; compared to 1,559 controls), two European-

ancestry biobanks (*UK Biobank*, N=383,656; *Vanderbilt biorepository*, N=49,494), and one Japanese-ancestry biobank (*BioBank Japan*, N=168,680) were available for additional explorations.

**Results:** Across 630,603 individuals, we found significantly higher GE-PRS in people with GE compared to people with FE (*Epi25*:  $P=1.64 \times 10^{-15}$ ; *Cleveland*:  $P=2.85 \times 10^{-4}$ ; *Finnish-ancestry Epi25*:  $P=1.80 \times 10^{-4}$ ) or population controls (*Epi25*:  $P=2.35 \times 10^{-70}$ ; *Cleveland*:  $P=1.43 \times 10^{-7}$ ; *Finnish-ancestry Epi25*:  $P=3.11 \times 10^{-4}$ ; *UK Biobank* and *Vanderbilt biorepository* meta-analysis:  $P=7.99 \times 10^{-4}$ ). FE-PRS were significantly higher in patients with FE compared to controls in the non-Finnish, non-biobank cohorts (*Epi25*:  $P=5.74 \times 10^{-19}$ ; *Cleveland*:  $P=1.69 \times 10^{-6}$ ). European-ancestry derived PRS did not predict GE or FE status in Japanese-ancestry people. We observed significant 4.63-fold and 4.47-fold enrichments of people with GE compared to controls in the top 0.5% highest GE-PRS of the two non-Finnish European-ancestry cohorts, respectively. Finally, in 383,197 European-ancestry individuals from the UK Biobank without epilepsy, high GE-PRS or FE-PRS were associated with low educational attainment and several personality/mood traits.

**Conclusion:** Focal and generalized epilepsy common variant burden is associated with specific epilepsy types and neuropsychiatric phenotypes. As sample sizes and PRS accuracy continues to increase with further common variant discovery, PRS could complement established clinical biomarkers and become valuable tools for patient classification, comorbidity research, and potentially targeted treatment.

## PgmNr 2105: Whole exome sequencing in patients with *gba1* mutations may identify pathways implicated in Parkinson disease.

---

While it is known that mutations in *GBA1*, the gene mutated in the lysosomal storage disorder Gaucher disease, are an important risk factor for the development of Parkinsonism, the majority of patients with Gaucher disease (GD) and *GBA1* carriers never develop Parkinson disease (PD). To explore other factors contributing to Parkinson pathogenesis in these individuals, Whole Exome Sequencing (WES) was performed on 125 subjects evaluated at the NIH Clinical Center with informed consent. The cohort included 35 patients with Parkinsonism (29 with GD and 6 carriers) and 40 without PD, but with a strong family history of Parkinsonism (25 with GD, 9 carriers and 4 non-carrier family members). WES data was analyzed using three different approaches. Rare probands with both GD and PD where parental DNA was available were evaluated as trios. In addition, sequence from nine sets of GD sib pairs where only one sib had PD were compared. Lastly, candidate genes implicated in lysosomal pathways and known PD genes were explored in patients with and without PD. Thus far, few interesting leads have uncovered in exonic and canonical splice variants in genes related to endolysosomal pathways, and these are currently being validated and will be discussed in meeting. However, few are present in multiple families, suggesting that many different PD risk allele or genetic modifiers will be involved. These subjects provide a rich cohort for the identification of further alleles that enhance or lessen the risk of developing Parkinsonism.

## PgmNr 2106: Association of expression quantitative trait loci in blood with ischemic stroke.

---

Several single nucleotide polymorphisms (SNPs) have been associated with ischemic stroke (IS). It is also known that expression of many genes changes after ischemic stroke. However, SNPs that are associated with changes of gene expression in blood after ischemic stroke are largely unknown. Thus, we studied the association of common genetic variants with changes in mRNA expression levels (i.e. expression quantitative trait loci; eQTL) in blood after ischemic stroke.

RNA and DNA were isolated from blood samples collected from 137 ischemic stroke patients and 138 vascular risk factor controls (VRFC). Gene expression of all protein-coding transcripts was quantified by Affymetrix HTA 2.0 microarrays and SNP variants assessed by Axiom Biobank Genotyping microarrays. In order to identify ischemic stroke diagnosis-dependent eQTL, a linear model with a genotype (SNP) × diagnosis (IS and VRFC) interaction term was fit for each SNP-gene pair.

We found several SNP-gene pairs associated with the magnitude of gene expression change after IS. Some of the strongest cis-eQTLs were rs56348411 related to expression of neurogranin (NRGN), rs78046578 related to expression of chemokine (C-X-C motif) ligand 10 (CXCL10) and rs975903 related to expression of SMAD family member 4 (SMAD4). CXCL10 is involved in blood-brain barrier (BBB) breakdown following stroke and SMAD4 is a cause of hereditary hemorrhagic telangiectasia syndrome and modulates N-cadherin expression in endothelial cells to stabilize the BBB. Regarding trans-eQTL, we found SNP rs148791848 significantly affected the expression of anosmin-1 (ANOS1) in a disease-specific manner. ANOS1 is key in developmental processes including neural cell adhesion and axonal migration and might play a similar role after stroke.

This study describes the importance of genetic variants in the expression of genes that relate to post-ischemic stroke injury and/or recovery. Understanding the mechanisms used by these eQTLs illustrates patient heterogeneity and could lead to the development of a novel strategy to treat stroke. Further work examining these relationships will help with establishing personalized treatment strategies to improve stroke outcome.

## PgmNr 2107: A new case of nonepileptic neurodevelopmental disorder due to a novel GRIN2A mutation.

---

The GRIN2A gene codes for the GluN2A subunit of N-Methyl-D-aspartate receptors (NMDARs). Inherited and de novo GRIN2A mutations are usually associated with different forms of epilepsy from moderate to severe (i.e. Landau-Kleffner syndrome, continuous spike and wave during slow-wave sleep syndrome, atypical rolandic epilepsy), and speech impairment. Recently, some authors suggested that the phenotypic spectrum of GRIN2A-related disorders may also include neurodevelopmental and movement disorders without seizures.

Here we report the case of a 10-year-old girl coming from southern Italy born to non consanguineous, healthy parents after full-term and uneventful pregnancy by vaginal delivery. Her birth weight and length were 3980 g and 50 cm, respectively, and her Apgar score was 9/10. She displayed retarded psychomotor development, with delayed acquisition of language and motor milestones (sitting at 19 months, walking at 30 months, 2-word phrases at 4 years, and 3-word phrases at 6-7 years). The patient exhibited insomnia with frequent awakenings and stereotypic movements of upper limbs (right predominance) with mild problems in fine motor coordination.

However, she has never experienced a seizure, and repeated EEG recordings have revealed an absence of epileptiform abnormalities.

At 8 years of age, to establish a diagnosis, targeted next-generation sequencing analysis of a panel of genes associated with neuropediatric diseases was performed. The heterozygous variant c.2539 C>T, which promotes the amino acid change p.Arg847Ter, was identified in the GRIN2A gene. The variant was not present in either parents.

Our findings reinforce the association between GRIN2A mutations and neurodevelopmental and movement disorders but not necessarily associated with seizures and emphasize the importance of molecular analyses in undiagnosed patients.

## PgmNr 2108: Genetic basis for blood pressure associations with migraine.

### Authors:

Y. Guo<sup>1</sup>; P.M. Rist<sup>1,2</sup>; I. Daghlas<sup>2</sup>; F. Giulianini<sup>1</sup>; T. Kurth<sup>1,3</sup>; D.I. Chasman<sup>1,2</sup>

### Affiliations:

1) Division of Preventive Medicine, Brigham and Women's Hospital, Boston, MA 02215; 2) Harvard Medical School, Boston, MA 02115; 3) Charité – Universitätsmedizin Berlin, Institute of Public Health, Charitéplatz 1, 10117 Berlin

**Background:** Blood pressure (BP) has been inconsistently associated with migraine and the biological mechanism of BP-lowering medications in migraine prophylaxis is not clear. We aimed to gain insight into mechanistic links between BP and migraine using genetic approaches.

**Methods:** We leveraged the most recent large-scale GWAS summary-statistics for migraine ( $N_{\text{cases}}/N_{\text{controls}}=59,674/316,078$ ) and BP ( $N=757,601$ ) and genetic methods to i) estimate global and local genetic correlation, ii) identify shared genetic components, iii) discover new migraine loci, and iv) infer the potential causality and directionality between BP and migraine.

**Findings:** There were positive overall genetic correlations of migraine with diastolic BP (DBP) ( $r_g=0.11$ ,  $P=3.56 \times 10^{-06}$ ) and systolic BP (SBP) ( $r_g=0.06$ ,  $P=0.01$ ), but not pulse pressure (PP) ( $r_g=-0.01$ ,  $P=0.75$ ). Local genetic correlations were experiment-wide significant at three known migraine loci (*FHL5*, *C7orf10*, and *PLCE1*) ( $P<0.05/1703$ ). Cross-trait meta-analysis revealed 14 shared loci novel to migraine ( $P_{\text{CPASSOC}} \leq 5 \times 10^{-08}$ ), nine of which were replicated in the UK Biobank ( $P<0.05$ ). Transcriptome-wide association studies (TWAS) identified 12 novel genes for migraine shared with one or more of the BP traits in expression data from artery, nerve, skin, esophagus mucosa, and whole blood. SNPs at five of these shared genes (*ITGB5*, *SMG6*, *ADRA2B*, *ANKDD1B*, and *KIAA0040*) were also significant in the cross-trait meta-analysis revealing important roles of vascular development, endothelial function, and calcium homeostasis as biological mechanisms shared by migraine and BP regulation. Specifically, *ADRA2B* associations highlight effects of glutamate, serotonin (5-HT), and calcitonin gene-related peptide (CGRP). Additionally, we found stronger genetic instrumental estimates (per 10mm Hg) of elevated DBP (OR [95%CI]=1.20 [1.15-1.25];  $P=5.57 \times 10^{-25}$ ) on migraine than elevated SBP (1.05 [1.03-1.07];  $P=2.60 \times 10^{-07}$ ) or decreased PP (1.09 [1.05-1.14];  $P=3.65 \times 10^{-07}$ ). Conditional instrumental analysis suggested that effects of elevated SBP on migraine may be explained by effects of DBP. By contrast gene-based influences of SBP were dominant to DBP for migraine comorbidities CAD and stroke in parallel analyses.

**Interpretation:** The findings prioritize a more prominent role of DBP than SBP in migraine susceptibility. Shared genetic components provide insights into biological mechanisms linking migraine and BP, and potentially into migraine treatment.

## PgmNr 2109: Genetic profile of a multiplex Hirschsprung disease family.

---

Hirschsprung disease (HSCR), also known as congenital megacolon, is characterized by the absence of enteric ganglia in the hindgut. HSCR is a rare multigenic neurocristopathy with receptor tyrosine kinase, *RET*, being the major HSCR gene. Increasing evidence from genetic studies suggests that a sensitized genetic background of reduced *RET* expression conferred by the regulatory HSCR-associated common variant is critical for the phenotypic expression of HSCR. We performed a whole-genome sequencing study of a multiplex HSCR family with two affected siblings, one with more severe long-segment HSCR (LHSCR) while another with the common form of short-segment HSCR (SHSCR). A truncating *de novo* mutation of *KIF26A* was identified in the LHSCR patient where knockout of *kif26a* in mice was shown to present with hyperganglionosis and megacolon. We hypothesized that *KIF26A de novo* mutation acts as a genetic modifier contributing to the increased severity and there exists other causal variants or genetic modifiers shared between the affected siblings for the phenotypic expression. Combined with the approach of polygenic risk score, we delineated the relationship between the sensitized genetic background of common variants and constellations of rare DNA changes, including copy number variations, with respect to risk of HSCR. Latest results of the genetic profile of the family will be presented.

---

**Background:** The processing and production of complex spoken and written language are traits that are unique to humans. Decades of family and twin studies established that these traits are highly heritable. Nonetheless, the relevant genetic architecture is complex, heterogeneous, and multifactorial, and yet to be explored in well-powered studies. The GenLang consortium is facilitating larger studies on the genetic underpinnings of spoken and written language.

**Methods:** Here, we performed a genome-wide association study (GWAS) for quantitative reading- and language-relevant traits: word reading, spelling, nonword reading, phoneme awareness, nonword

repetition and rapid automatized naming. The phenotype data were collected across different languages (primarily English, and also Dutch, Spanish, German, Finnish, French and Hungarian) and ages (range 5 to 18 years) in 17 GenLang cohorts. Uniform pipelines were established for consistent quality control and association analysis across cohorts. Univariate, inverse variance-weighted meta-analyses for each trait were performed in METAL, and multivariate analyses with N-weighted GWAMA. Functional mapping was performed in FUMA, and genetic correlation analyses with LDSC.

**Results:** We reached sample sizes of more than 6,000 to 22,000 individuals. A single genome-wide significant locus was discovered for word reading, spelling and phoneme awareness. A multivariate meta-analysis of the four highly correlated traits: word reading, nonword reading, spelling and phoneme awareness, identified further significant loci. Initial functional enrichment analyses revealed an enrichment in brain-expressed genes.

**Discussion:** These efforts by GenLang discovered multiple genome-wide significant loci for reading and language traits, and will open up novel avenues for deciphering the biological underpinnings of spoken and written language. Language-related phenotypes pose special challenges for genetic analysis, due to the labour-intensive nature of assessment and additional heterogeneity caused by different assessment tools and languages. Therefore they have yet to fully benefit from advances in large-scale genomic screens.

## PgmNr 2111: Febrile seizures GWAS identifies 7 new loci implicating genes involved in fever response and neuronal excitability.

Hans, Mental Health Services, Capital Region Denmark, Roskilde, Denmark; 5) Epilepsy Research Centre, Department of Medicine, University of Melbourne (Austin Health), Victoria, Australia; 6) Danish Headache Center, Department of Neurology, Rigshospitalet-Glostrup, Denmark; 7) Novo Nordisk Foundation Center for Protein Research, University of Copenhagen, Copenhagen, Denmark; 8) Clinical Epidemiology Division, Department of Medicine, Solna, Karolinska Institutet, Stockholm, Sweden; 9) Novo Nordisk Foundation Center for Basic Metabolic Research, University of Copenhagen, Copenhagen, Denmark; 10) National Centre for Register-Based Research, Department of Economics and Business Economics, Aarhus BSS, Aarhus University, Denmark; 11) Department of Neurology, Aarhus University Hospital, Aarhus, Denmark; 12) Department of Clinical Immunology, Copenhagen University Hospital, Rigshospitalet, Denmark; 13) Department of Medicine, Stanford University School of Medicine, Stanford, California, USA

**Introduction:** Febrile seizures affect 2-5% of children in western countries including Denmark with an incidence peak around 16 months of age. While usually benign, in a minority of cases febrile seizures precede development of epilepsy.

**Methods:** We conducted a GWAS meta-analysis of febrile seizures with a total of 4,304 cases and 48,290 controls in the discovery stage, all sampled from the Danish National Biobank. The analysis was based on 8.5 million variants imputed from the 1000 genomes project phase III reference panel, using logistic regression on imputed SNP dosages for association testing. Replication testing was carried out in independent Danish and Australian cohorts (3,235 cases, 40,519 controls).

**Results:** Seven novel robustly associated loci (replication  $P < 0.05$ , combined  $P < 5 \times 10^{-8}$ ) were detected harboring genes related to fever response (*PTGER3*, OR=1.14,  $P=2.2 \times 10^{-11}$ ; *IL10*, OR=1.14,  $P=3.1 \times 10^{-8}$ ), GABA-signaling (*GABRG2*, OR=1.28,  $P=1.9 \times 10^{-15}$ ), neurotransmitter release (*BSN*, OR=1.15,  $P=4.9 \times 10^{-12}$ ; *ERC2*, OR=1.30,  $P=1.8 \times 10^{-12}$ ; *HERC1*, OR=1.20,  $P=3.3 \times 10^{-12}$ ), and MAP kinase signaling (*MAP3K9*, OR=1.13,  $P=1.5 \times 10^{-10}$ ). Fine-mapping and analysis of exome sequencing data at these loci is ongoing. The four previously known febrile seizures loci (*SCN1A*, *SCN2A*, *ANO3*, 12q21.33) were also confirmed, and collectively the 11 loci explained 3.3% of the variation in liability to febrile seizures. Subsequent genome-wide enrichment analysis using MAGMA suggested that presynaptic cytomatrix proteins are implicated in seizure etiology ( $P = 0.039$ ). Looking at variants

with a minor allele frequency  $>1\%$  across the genome and comparing with GWAS summary statistics from the International League Against Epilepsy Consortium on Complex Epilepsies, we found positive genetic correlations with focal epilepsy ( $r_g = 0.44$ ,  $P = 0.04$ ), genetic generalized epilepsy ( $r_g = 0.17$ ,  $P = 0.03$ ), and all epilepsies combined ( $r_g = 0.31$ ,  $P = 0.002$ ).

**Conclusion:** Our study identified novel genetic associations with febrile seizures implicating genes involved in neuronal excitability and fever response. We also found positive genetic correlations between febrile seizures and complex epilepsies.

---

Migraine is a common brain disorder typically characterized by disabling episodes of severe headache accompanied by nausea and hypersensitivity to light, sound and smell. Its lifetime prevalence is 15-20% worldwide and family and twin studies estimate a heritability of about 40%. To date, 41 migraine susceptibility loci have been identified from the genome-wide association studies (GWAS), and these loci are suggested to be enriched for genes highly expressed in vascular and smooth muscle tissues.

In this meta-analysis, we increase the largest published migraine meta-analysis (Gormley et al. Nat Gen 2016) sample size by 71% by adding to it 22,644 new cases from 23andMe, 10,881 cases from the UK Biobank, 7,801 cases from the HUNT Study and 1,084 cases from the GeneRISK Study. This takes our total sample size to 102,084 cases and 771,257 controls.

In a fixed-effects meta-analysis, we identify 124 independent ( $r^2 < 0.1$ ) genome-wide significant ( $P < 5 \times 10^{-8}$ ) autosomal single-nucleotide polymorphisms (SNPs) that are at least 250kb apart from each other. Of these 124 loci, 91 are reported here for the first time. We report enrichment of GWAS signal in 5 central nervous system and 3 cardiovascular cell types, and in single cell types of digestive system, musculoskeletal/connective tissue and ovary (FDR 5% from LDSC-SEG).

Among the 91 new loci, we report the first evidence from GWAS at *CALCA-CALCB* locus (lead SNP

rs1003194,  $P=2.43 \times 10^{-10}$ ) encoding calcitonin gene-related peptide (CGRP). Recently approved monoclonal antibodies (mAbs) targeting CGRP or its receptor are a first major breakthrough for the migraine specific treatments since the development of the triptans over two decades ago. This indicates that also other drugs targeting genes from our GWAS could be excellent candidates for new ways to treat migraine. While also a mAb (erenumab) targeting the CGRP receptor has proven efficient against migraine, we report that none of the central genes coding the receptor proteins (*CALCRL*, *RAMP1* or *RCP*) show a clear association to migraine ( $P > 10^{-4}$ ).

To conclude, we report the largest migraine GWAS to date with 91 new susceptibility loci. The enrichment of association signal in both central nervous system and cardiovascular system reflects the heterogeneous genetic background of migraine. The first genetic evidence for CGRP association in migraine provides a new route to further develop the recent breakthroughs in migraine therapeutics that target the CGRP pathway.

## PgmNr 2113: Whole genome sequencing analysis of gastroparesis.

### Authors:

M. Keefe; J. Carlin; S. Smieszek; C. Xiao; C. Polymeropoulos; G. Birznieks; M. Polymeropoulos

[View Session](#) [Add to Schedule](#)

**Affiliation:** Vanda Pharmaceuticals Inc., 2200 Pennsylvania Ave, Suite 300E, Washington, D.C. 20002

Gastroparesis is a disorder characterized by delayed gastric emptying of solid food in the absence of a mechanical obstruction of the stomach, resulting in the cardinal symptoms of early satiety, postprandial fullness, nausea, vomiting, belching and bloating. To ascertain the genetic risk factors for gastroparesis we conducted the first to date whole genome sequencing (WGS) study of gastroparesis cohort. We investigated the frequency and effect of rare loss-of-function (LOF) variants in patients with idiopathic and diabetic gastroparesis enrolled in a clinical study, VLY686-2301. The dataset consisted of 119 WGS samples.

Among rare LOF variants, we report an increased frequency of a frameshift mutation within Motilin Receptor (MLNR) gene, variant rs562138828. Motilin is a 22 amino acid peptide hormone expressed throughout the gastrointestinal (GI) tract. The protein encoded by this gene is a motilin receptor which is a member of the G-protein coupled receptor 1 family. We have shown an increased frequency of a frameshift mutation with MAF 0.01 as compared 0.0009 AF in GNOMAD ( $P$ -value = 0.01) with Odds Ratio of 21.9. We detect 4/119 Gastroparesis patients carry the variant of interest that results in p.Leu202ArgfsTer105. Noteworthy is the fact that the 4 cases were equally split among idiopathic and diabetic, so this possible gastroparesis risk factor appears to be agnostic as to condition. The finding may be of direct relevance to treatment as individuals with the identified mutation may respond differently to gastroparesis treatments especially those targeting MLNR. Among other rare LOF, we identified a case of CHD7 discussed in literature in gastro-related context and a case of CFTR duodenal stenosis pathogenic variant. The CFTR variant has been seen in pancreatitis and is likely causative of Cystic Fibrosis Gut which is characterized by increased mucous viscosity and development of intestinal inflammation, dysbiosis and dysmotility.

Whole genome sequencing of Gastroparesis patient samples showed enrichment for rare variants in the MTLR in cases compared with controls. The identified LOF variants within the region can serve as risk factor for disease as well as inform treatments, especially given the knowledge of different response to treatment.

## PgmNr 2114: Automated genetic and functional fine-mapping of Parkinson's disease loci.

---

A recent large-scale GWAS of Parkinson's Disease (PD) by Nalls et al. (2019, BioRxiv) identified 78 independent loci containing PD-associated SNPs. However, for any given locus the SNP with the smallest p-value may merely be a proxy for the true causal SNP (or set of causal SNPs) due to linkage disequilibrium (LD). Fine-mapping aims to identify the causal SNP(s), which can greatly reduce the number of false-positive genetic associations and thus accelerate the identification of mechanisms causal for the disease. We fine-mapped all 78 loci by developing echolocatoR, an open-access R package that enables automated end-to-end statistical and functional fine-mapping in a single line of code. By integrating multiple fine-mapping tools (FINEMAP and SuSiE), we reduced the average number of candidate SNPs from ~5,000 to 8 per locus. In 56% of loci, multi-tool consensus converged on 1-4 SNPs (i.e. consensus SNPs) that had the highest posterior probability of being causal. In 71% of loci the lead SNP was within the credible set, suggesting this approach does more than simply recapitulate the SNP with the lowest GWAS p-value. Specifically, within the *LRRK2* locus, rs7294619 was the most probable causal SNP for PD. Using eQTL data from monocytes, we found that rs7294619 has cis-QTLs in the *IFN* ( $\beta=0.917$ , FDR<1.34e-05) and *LPS* 24-hour ( $\beta=0.983$ , FDR<1.34e-05) stimulated data, but not in the *CD14* or *LPS* 2-hour, suggesting context-dependent regulatory effects. Within the *BST1* locus, 6,227 SNPs were refined to a credible set of 9, and a single consensus SNP (rs4613561). Both consensus SNPs in the *BST1* and *LRRK2* loci are located within monocyte enhancers (HaploReg) and have histone marks in blood and brain (ROADMAP). As both *LRRK2* and *BST1* are involved in innate immune function, these results further support the hypothesis that genetic dysregulation of the immune system is an important causal factor in PD risk. We also identified potentially causal missense variants at in the *TRIM40* (rs1265096, rs2233952), *RPS12* (rs41286192), and *CD19* (rs7140) loci. We are now validating these findings through Bayesian epigenomic data integration and functional experiments (genome editing, allele-specific protein binding and differential enhancer assays). Overall, these results demonstrate that echolocatoR robustly and rapidly identifies functionally relevant variants that have a statistically higher probability of being causal for PD and thus targets of therapeutics development.

## PgmNr 2115: Characterization to the genomic landscape in SMS with whole genome sequencing.

### Authors:

---

Smith-Magenis syndrome (SMS; OMIM #182290) is a rare complex genomic disorder resulting from haploinsufficiency of *RAI1*. It is associated with decreased total nighttime sleep for age, frequent and prolonged nocturnal awakenings, early morning sleep offset, and excessive daytime sleepiness.

We conducted whole genome sequencing analysis to explore the genomic landscape of the SMS population with confirmed *RAI1* aberration. We investigated 41 individuals with confirmed diagnosis of SMS. We detect 1x stopgain (novel) 727723, *RAI1*:NM\_030665:exon3:c.C2878T:p.R960X. 39 patients have a haploinsufficiency detected as stretches of ROH across whole coding sequence of *RAI1*, missense patient.

*RAI1* is a dosage-sensitive gene expressed in many tissues and highly conserved among species. Many studies have demonstrated that *RAI1* and its homologs acts as a transcriptional factor implicated in embryonic neurodevelopment, neuronal differentiation as well as behavioral functions and circadian activity. Patients with *RAI1* pathogenic variants show some phenotypic differences when compared to those carrying the typical deletion. This deletion encompasses *RAI1*, whose haploinsufficiency is considered the primary cause for most of the SMS features including aberrant clock activity via its effect on *CLOCK* (ChIP-Chip and luciferase data suggest that *RAI1* binds, directly or in a complex, to the 1st intron of *CLOCK* enhancing transcriptional activity).

Interestingly since *COPS3* is located within the common deletion interval, most individuals with SMS are haploinsufficient for *COPS3*. Within the core SMS region on chromosome 17, the gene *COPS3* encodes subunit 3 of the COP9 related to the 26S proteasome regulatory complex. The latter has been associated with control of the rate-limiting step in melatonin metabolism by N-acetyltransferase. Altogether, 34 cases have *COP3* haploinsufficiency, 2 have LOF variants, and 2 do not. It may be that the joint *COPS3* haploinsufficiency is more tightly linked to the clinical phenotype of disrupted sleep in SMS patients.

In addition, we have conducted a GWAS on SMS patients and a set of matched controls. MDGA2 MDGA2:NM\_001113498:exon4:c.C502A:p.R168R, variants on chromosome 17, HDAC7 and PLEKHA7 (10-8) though these may rather be risk factors, given the incidence of the disorder. Investigation of the landscape not only reveals the fundamental cause and the pathophysiology but helps delineate risk factors and comorbidities in this already complex disorder.

## PgmNr 2116: Integration of genomic and gene expression profiles from normal appearing white matter tissue in multiple sclerosis reveals novel candidate genes and inferences of pathogenesis.

---

Multiple sclerosis (MS) is a neuroinflammatory disorder characterized by demyelination and tissue degeneration of the central nervous system. Pathological changes taking place in the normal appearing white matter (NAWM) remain poorly understood. Genome-wide association studies (GWAS) have detected genetic loci associated to MS. Disease-related tissue expression data can aid in better interpreting the nature of disease-associated variants. In this study, a recent GWAS of 68,379 MS cases and controls was integrated with gene expression profiles derived from MS NAWM post-mortem brain tissue. Tissue samples collectively included 38 MS NAWM cases and matched controls from two datasets: RNA sequencing reads of NAWM microglia and microarray profiles of active perilesional NAWM. These datasets were independently studied in network-based analyses considering the human protein interactome as the reference network. We integrated MS GWAS summary statistics (node weight) with MS NAWM tissue co-expression (edge weight) and searched signal-enriched modules with our in-house tool: Edge Weighted Dense Module Search of GWAS (EW\_dmGWAS). Among the top 100 modules we identified, surprisingly, we found several MS FDA drug target genes: *HDAC1*, *IFNRA1*, *KEAP1* and *RELA*, which were not reported by original GWAS or gene expression studies. A subsequent dual evaluation anchored by the MS GWAS considered microglia NAWM profiles as the discovery set and perilesional NAWM profiles as the evaluation set. It yielded 19 resulting modules containing 55 non-redundant genes. This gene set was enriched in the Gene Ontology Biological Process terms “Fc-gamma receptor signaling pathway involved in phagocytosis” (adjusted p-value =  $6.87 \times 10^{-3}$ ) and “intracellular transport of virus” (adjusted p-value = 0.02), among other relevant functional terms. We pinpointed the genes *CCNB2* (p-value =  $4.08 \times 10^{-3}$ ), *CDK3* (p-value =  $6.56 \times 10^{-4}$ ), *HSPA1L* (p-value =  $1.58 \times 10^{-14}$ ), *MORF4L1* (p-value =  $5.10 \times 10^{-5}$ ), *TEC* (p-value =  $2.11 \times 10^{-6}$ ) and *VAV1* (p-value =  $7.21 \times 10^{-4}$ ) as novel MS candidate genes for their presence in top MS NAWM gene networks. Genes enriched for phagocytic activity give insight to MS pathogenesis in NAWM. Furthermore, functional terms related to virus transport pathways supported the involvement of viral infection in MS etiology. In summary, the results from our novel network analysis provided better understanding of the mechanisms underlying MS and several novel genes that warrant further investigation.

## PgmNr 2117: Responder analysis to melatonin agonist, in a whole genome sequencing study of major depression disorder.

Major Depression Disorder (MDD) can severely impact patients in terms of excess morbidity and mortality, disability and diminished functioning. Circadian rhythm disruption may be involved in the etiology of MDD. Interestingly, differences were previously observed in the expression of circadian timing system between African Americans (AA) and Caucasians. Melatonin agonist Tasimelteon 20 mg was shown to improve symptoms of depression in African American patients with MDD. This may further reiterate a circadian component in the etiology and treatment of Major Depression.

We have conducted a large whole genome sequencing study of MDD to examine the genetic underpinnings of those differences. Participants included patients between the ages of 18-65 with primary diagnosis of MDD. The cohort included 166 AA patients assessed with Hamilton Depression Scale. Timing of the onset of melatonin was measured (the pineal melatonin rhythm is considered the most reliable marker of the circadian timing system). To ascertain the genetic underpinnings of response to melatonin agonist, we conducted whole genome sequencing association analysis using responders and non-responders in the AA population.

We detect a significant association with a NTF3 variant rs11063714 (MAF 0.10) 19/2 and OR of 15.6. The allele is a marker of higher response (AA). The protein encoded by this gene is a member of the neurotrophin family that controls survival and differentiation of mammalian neurons. NTF3 variants have been previously associated with insomnia in a meta-analysis study of AA insomnia. The variant is located downstream in a highly regulatory region of the gene as assessed with Haploreg (ENCODE). Of potential interest, we identify an association with variants in ANO2, which is immediately adjacent to NTF3 that harbors an insomnia associated SNP among AA subjects.

Clinically, at 8 weeks AA MDD patients treated with tasimelteon improved by 9.9 points on the HAMD scale as compared to 6.9 points for the placebo treated patients (p-value =0.018).

In a responder analysis, 59% of tasimelteon treated AA patients improved as compared to 30% of placebo treated AA patients (p-value =0.0019). Interestingly previous data have shown that NTF3 rapidly modulates the activity of NPO neurons involved in REM sleep and that cholinergic neurons in the LDT and PPT contain NTF3. Taken together these results support the hypothesis that NTF3 may be involved in the control of naturally occurring REM sleep.

## PgmNr 2118: Longitudinal positron emission tomography of dopamine synthesis in subjects with *GBA1* mutations.

Mutations in *GBA1*, the gene mutated in Gaucher disease (GD), are the most common known genetic risk factor for Parkinson disease (PD) and dementia with Lewy bodies. However, the majority of *GBA1* mutation carriers never develop parkinsonism. To test for early signs of PD in this at-risk population, we performed <sup>18</sup>F-fluorodopa PET imaging on *GBA1* mutation carriers, with and without PD, to identify patients with evolving loss of dopamine prior to the development of overt symptoms. While we previously published PET results in a smaller cohort, we have extended the study to include more participants, many of whom were studied longitudinally, representing 117 scans performed on subjects with *GBA1* mutations, including 41 patients with GD and 20 *GBA1* heterozygotes, as well as 98 controls, all seen at the Clinical Center of the National Institutes of Health between 2006-2016.

PET studies were performed on a GE Advance 3D scanner, and presynaptic dopamine synthesis was measured with <sup>18</sup>F-fluorodopa. Drugs that might impact the results were tapered appropriately. Sixty minutes before scanning, participants received carbidopa (200 mg) to reduce peripheral <sup>18</sup>F-fluorodopa metabolism and increase tracer availability in the brain. A bolus dose of <sup>18</sup>F-fluorodopa of 15±2 mCi was administered intravenously and 27 frames collected over 90 minutes. Longitudinal studies were performed on 33 subjects with *GBA1* mutations and 15 controls.

Seventeen patients with clinical evidence of parkinsonism showed diminished striatal dopamine synthesis, particularly in the putamen, as expected. Six had 2-3 subsequent scans. The study also followed 43 patients (27 with GD and 16 *GBA1* carriers) who did not show clinical evidence of parkinsonism at their first evaluation, including 38 with a strong family history of PD. Sixteen had one scan, but 27 were followed longitudinally. Twelve had two scans, 12 completed three scans and 3 completed four scans, with an interval between 1-7 years between scans, and clinical follow-up has continued. Only one of the 43 has subsequently been diagnosed with PD, and his sole PET study, performed 12 months prior to symptom onset appeared normal.

The analysis revealed that over time, as a whole, the PET studies in patients without PD did not show a marked decline in striatal dopamine synthesis capacity and were comparable to the results seen in controls. Thus, close clinical monitoring may be as effective as costly <sup>18</sup>F-fluorodopa imaging for this at-risk group

## PgmNr 2119: Detection of somatic CNVs in SNCA and genome-wide in the brains of synucleinopathies (multiple system atrophy and Parkinson's disease).

Parkinson's disease (PD) and multiple system atrophy (MSA) are synucleinopathies, progressive neurodegenerative disorders of partly unexplained aetiology. Somatic mutations can be found in neurons. We recently used FISH to detect somatic *SNCA* (alpha-synuclein) CNVs in substantia nigra, where they were commoner in dopaminergic (DA) neurons in disease. To further investigate somatic CNVs, focusing mainly on MSA, we performed additional FISH for *SNCA*, combined in selected experiments with markers for oligodendrocytes, neurons and alpha-synuclein, and low coverage single-cell whole genome sequencing (scWGS) for CNVs.

1) **FISH:** We analysed the nigra in 15 MSA cases (10 striatonigral- SND, 5 mixed). *SNCA* gains were present in 3.3% of DA neurons, and 3.1% of other cells, notably 9.4% of oligodendrocytes in 3 cases. CNVs and inclusions often occurred in the same cells in a disease-relevant pattern: DA neurons in Lewy body (LB) cases (1 PD, 4 incidental;  $p=0.004$ ), and other cells in SND MSA ( $n=7$ ;  $p=0.001$ ), mostly oligodendrocytes in 2 of 3 cases. Most cells with CNVs did not, however, have detectable inclusions, and vice versa.

In the cingulate cortex (12 PD, 6 MSA, 9 controls to date), there was a clear difference in the fraction of cells with CNVs between all groups / cell types ( $p=0.001$ ), with higher levels in neurons (MSA 4.3%, PD 2.8%, controls 1.4%).

We investigated possible correlations of the fractions of cells with CNVs. In the nigra, there was a possible negative correlation in non-DA cells with onset age in SND MSA ( $r=-0.6$ ,  $p=0.07$ ). In the cingulate, there was a clear correlation with age of death in non-neuronal cells in controls ( $r=0.9$ ,  $p=0.002$ ).

2) **scWGS:** We performed nuclear isolation and whole genome amplification by Picoplex Gold followed by scWGS. We obtained successful results so far from 9 neurons and 12 other cells from the pons of a case with MSA, with sequencing of an additional 250 cells from MSA brain underway. Among 5 neurons with nuclear a-syn inclusions, 3 had somatic gains, one of which was in the *SNCA* vicinity. Apparent neuronal multiple chromosomal losses were also seen, and gains in a non-neuron.

**Conclusion:** We demonstrate that somatic *SNCA* CNVs are commoner in MSA, and also occur in the cingulate. *SNCA* CNVs and inclusions often occur together, in a cell-type specific pattern, suggesting a functional role, supported by the possible negative correlation with age of onset in SND MSA. Ongoing scWGS will provide more details on CNVs detected.

## PgmNr 2120: *TLR* gene polymorphisms and susceptibility to Guillain-Barré syndrome: A study from India.

Guillain Barre Syndrome (GBS), the commonest cause of acute neuromuscular paralysis, is a post-infectious autoimmune disorder of peripheral nerves. The innate immune-molecule Toll-like receptors (TLRs) have emerged as an important mediator of inflammatory and autoimmune diseases including GBS. The impact of genetic variations within *TLR* genes on the risk and clinical phenotypes of GBS is inadequately known. Therefore, we investigated the role of *TLR* gene polymorphisms in GBS.

A total of 150 patients with GBS and 150 healthy subjects were assessed for Insertion/Deletion and single nucleotide polymorphisms (SNPs) within *TLR2* (rs3804099 and rs111200466), *TLR3* (rs3775290 and rs3775291) and *TLR4* (rs1927911 and rs11536891) genes by the polymerase chain reaction and restriction fragment-length polymorphism (PCR-RFLP). Haplotype analysis was performed by SHEsis, a web-based interface. Interactions among variants were determined by multifactor dimensionality reduction (MDR), a machine learning tool. Influence of genotypes on clinical features was analyzed using SPSS 20.

The most significant finding was 24-fold increased risk ( $p < 0.001$ ) to GBS in individuals with Insertion/Insertion (I/I) genotype of rs111200466 of *TLR2* gene. Specific genotypes of rs3804099, rs1927911 and rs11536891 were also associated with the risk of GBS. However, polymorphisms of the *TLR3* gene were not associated with GBS. The haplotype TC ( $p = 0.0001$ ) of *TLR4* SNPs confers 2.5-fold risk for GBS compared to controls. Specific haplotypes of *TLR2*, *TLR3* and *TLR4* variants have also imposed the risk of GBS. Two-way interaction between rs111200466 of *TLR2* and rs1927911 of *TLR4* selected as the best predictor of disease, having the highest average testing accuracy (0.67) and CVC value (4/5). The interaction dendrogram indicates a synergistic effect among rs111200166 and rs3804099 SNPs of *TLR2* and rs1927911 of *TLR4*. Patients with demyelinating subtypes with TT homozygosity had significantly higher MRC sum scores at admission ( $p = 0.0285$ ) and higher creatine kinase (CK) level ( $P = 0.0137$ ) compared with heterozygous CT genotype of rs3804099.

In conclusion, *TLR2* polymorphisms could influence genetic susceptibility to GBS and can emerge as a potential genetic marker of GBS. Leverage in CK level in demyelinating subtypes with TT homozygosity in rs3804099 is intriguing. Further studies in ethnically diverse populations may provide more insights on the role of *TLR* gene in pathogenesis and pathophenotypes of GBS.

## PgmNr 2121: Unbiased genome-wide screen identifies new ALS risk variants within gene-regulatory elements.

---

**Background:** Amyotrophic lateral sclerosis (ALS) is a universally fatal and relatively common neurodegenerative disease; lifetime risk is 1/350 in the UK. Currently there is no effective disease modifying therapy. 10% of ALS is autosomal dominant, but even in sporadic ALS observed broad-sense heritability is 61%. Currently, described genetic risk factors for ALS are found in <10% patients. Genome-wide association studies suggest the majority of missing ALS heritability is distributed throughout non-coding chromosomal regions. Enhancers are cis-acting DNA sequences that modulate expression of target genes primarily through binding of transcription factors.

**Methods:** Enhancers were associated with genes using manually curated data including (i) tissue-specific co-expression correlation between genes and enhancer RNAs, and between genes and transcription factors; (ii) expression quantitative trait loci (eQTL) for variants within enhancers; (iii) capture Hi-C; and (iv) gene-enhancer genomic distances. Genetic variants within enhancers were prioritised for further analysis if they were rare (MAF<0.01) and evolutionary conserved (LINSIGHT score >0.8).

Whole genome sequencing data was obtained from whole blood for 4,495 ALS patients and 1,925 controls. Reads were aligned to the hg19 human genome and SNP QC was performed using PLINK. Enhancers were grouped according to their target gene(s), and a rare variant burden test was conducted for ALS-association within grouped enhancers.

**Results:** A genome-wide screen of genetic variation within enhancers grouped around individual genes (n=15,603) revealed two new ALS genes with genome-wide significant disease-association: *METTL8* (SKAT-O, p=6.05E-07) and *CAV2* (p=1.28E-06). Association within *CAV1*-enhancers was near genome-wide significant (p=1.02E-05). Interestingly rare genetic variation within coding and promoter regions of *CAV1* is also significantly associated with ALS (Firth logistic regression, p<0.05). Genetic variation within all three regions could conceivably impair *CAV1* function; consistent with this immunoblotting for *CAV1* protein in patient-derived lymphoblastoid cells carrying two identified ALS-associated *CAV1*-enhancer variants revealed reduced protein expression.

**Conclusion:** An unbiased genome-wide screen for ALS-associated genetic variation within enhancer elements has identified new risk variants. Our work highlights new disease biology and new

methodology that could be applied in other disease areas.

---

Neurodegenerative diseases are characterized by cognitive decline and motor dysfunction as a result of neuronal loss and are estimated to affect over 50 million people worldwide (GBD 2016 Collaborators, 2017, *The Lancet*). Although substantial effort has been expended to genetically characterize these diseases, many studies have focused on identifying single nucleotide polymorphism associations, each with only a small effect size. We aim to elucidate the rare genetic landscape of neurodegeneration using targeted next-generation sequencing (NGS). In total, 519 participants were enrolled with one of five neurodegenerative diseases: 1) Alzheimer's disease and mild cognitive impairment (AD/MCI); 2) amyotrophic lateral sclerosis (ALS); 3) frontotemporal dementia (FTD); 4) Parkinson's disease (PD); and 5) vascular cognitive impairment (VCI). We sequenced participants and 189 cognitively normal controls using a custom NGS panel that covers 80 genes previously associated with neurodegeneration. We used rare variant association analysis burden testing to identify disease cohorts with an increased frequency of rare variants and

disease-associated genes with greater burdens of variants.

The ALS cohort had a significant burden of rare candidate variants in primary ALS genes compared to controls (OR 4.65 [1.46–14.8]  $P=0.0092$ ). Further, the AD/MCI and PD cohorts had significantly increased burdens of rare candidate variants in secondary AD/MCI and PD genes, respectively, compared to controls (OR 2.18 [1.10–4.32]  $P=0.0260$  and OR 2.81 [1.21–6.56]  $P=0.0166$ , respectively).

Using an Optimized Sequence Kernel Association Test custom script we only identified *PARK2* in the FTD cohort to have a significant burden of rare variants compared to controls ( $P=0.0127$ ). However, other genes approached significance, and further analysis confirmed a rare variant burden. The genes included *PARK2* in AD/MCI and VCI (OR 13.8 [1.65–114.6]  $P=0.0153$  and OR 13.1 [1.52–113.2]  $P=0.0194$ , respectively) and *PINK1* in AD/MCI and VCI (OR 7.65 [1.59–36.89]  $P=0.0113$  and OR 6.46 [1.26–33.1]  $P=0.0252$ , respectively).

Although the study has a relatively modest sample size, these pilot results indicate a genetic contribution by rare variants to neurodegeneration, which can now be further elucidated. Additionally, the burden of rare variants in *PARK2* and *PINK1* across multiple disease phenotypes suggests they could be contributing to overlapping features of diseases, which warrants further investigation.

## PgmNr 2123: Mid-life ethanol intake and cognitive decline: A gene x environment interaction study.

---

**Background:** Previous studies of the relationship between ethanol intake and cognitive decline have been inconsistent, yet possible interaction between ethanol intake and genetic susceptibility on the risk of cognitive decline has often not been considered. **Objective:** To investigate if unweighted genetic risk scores (GRSs) based on ethanol intake-associated single nucleotide polymorphisms (SNPs) modify the relationship between weekly ethanol intake in mid-life and 15-year rate of decline in general cognitive performance from mid-to-late life among African-American and European-American adults. **Methods:** A total of 9,183 participants (n=1,733 African-Americans and n=7,540 European-Americans) of the Atherosclerosis Risk in Communities (ARIC) study completed an interviewer-administered questionnaire and two neurocognitive examinations at 1996 and 2013. Twenty ethanol intake-associated SNPs for African-Americans and 11 for European-Americans were combined, separately, to create unweighted GRSs, uGRS<sub>20</sub> and uGRS<sub>11</sub>, respectively. Multivariable linear regression was used to assess modification of the ethanol intake-cognitive decline association by uGRS<sub>20</sub> and uGRS<sub>11</sub>. Multiple imputations by chained equations (MICE) were used to account for attrition. **Results:** Ethanol intake in mid-life was not associated with 15-year decline in general cognitive performance from mid-to-late life (African-American:  $\beta = -0.011$  (95% CI: -0.052, 0.031), European-Americans: -0.010 (-0.021, 0.002)). The uGRS<sub>20</sub> and uGRS<sub>11</sub> did not modify the association of ethanol intake in mid-life with 15-year change in general cognitive performance from mid-to-late life among African-Americans (P= 0.811) and European-Americans (P= 0.847), respectively. **Conclusions:** Ethanol intake in mid-life is not associated with cognitive decline from mid-to-late. There is no indication that an association between ethanol intake and cognitive depends on genetic susceptibility to ethanol intake among African-American and European-American adults.

---

Parkinson disease (PD) is a genetically heterogeneous condition; both single nucleotide variants (SNVs) and copy number variants (CNVs) are important genetic risk factors. Here, we examined the utility of combining exome sequencing (ES) and genome-wide array-based comparative genomic hybridization (aCGH) for identification of PD genetic risk factors. We performed ES on 110 subjects with PD and a positive family history; 99 of these subjects were also evaluated using genome-wide aCGH. We interrogated ES and aCGH data for pathogenic SNVs and/or CNVs at Mendelian PD gene loci, respectively. All SNVs were confirmed via Sanger sequencing. All CNVs were confirmed using orthogonal experimental approaches including a custom-designed high-density array comparative genomic hybridization (aCGH), droplet digital PCR, and breakpoint sequencing. Based on ES, we discovered individuals with known pathogenic SNVs in *GBA* (p.E365K, p.N370S, p.T408M, p.L444P) and *LRRK2* (p.R1441G and p.G2019S). Two subjects were each double heterozygotes for variants in *GBA* and *LRRK2*. Using aCGH to identify CNVs, we additionally discovered 1 *SNCA* duplication and a heterozygous intragenic *GBA* deletion. Five additional cases harbored both an SNV (p.N52fs, p.T240M, p.P437L, p.W453\*) and a likely disrupting CNV at the *PARK2* locus, consistent with compound heterozygosity. In nearly all cases, breakpoint sequencing revealed microhomology; mutational signatures consistent with CNV formation due to DNA replication errors. Integrated ES and aCGH yielded a genetic diagnostic rate of 21.1% of our PD cohort. Our analyses also highlight potential mechanisms for *SNCA* and *PARK2* CNV formation, uncover multilocus pathogenic variation, and identify novel SNVs for further investigation as potential PD risk alleles.

---

Parkinson's disease (PD) is a genetically complex disorder. Multiple genes have been shown to cause monogenic PD, and currently 90 independent risk loci have been identified by genome-wide association studies. Thus far, a number of genes have been shown to be pleomorphic risk loci, containing variability across a spectrum of frequency and effect, from rare highly penetrant variants to common risk alleles; these include *SNCA*, *LRRK2*, *VPS13C*, and *GBA*.

*GBA*, encoding the enzyme glucocerebrosidase, contains variants associated with PD. These variants, which reduce or abolish enzymatic activity, confer a spectrum of disease risk, from 1.4- to ~5-fold. An outstanding question in the field is whether there are genetic factors that influence *GBA*-associated disease risk, and whether these overlap with known PD risk variants. Using multiple, large case-control datasets (including IPDGC and UK Biobank), totaling 217,165 individuals including: 22,757 PD cases, 13,431 PD proxy cases, and 180,355 controls, we performed a genome-wide association study and analyzed the most recent PD-associated genetic risk score (GRS) to detect genetic influences on *GBA* risk and age at onset including in total 1,772 *GBA*+ cases, 711 *GBA*+ proxy cases and 7,624 of *GBA*+ controls.

We identified that the PD GRS modifies risk for disease and lowers age at onset in carriers of *GBA* variants. Notably, this effect was consistent across all tested *GBA* risk variants. Dissecting this signal demonstrated that variants in close proximity of *SNCA* and *CTSB* are the most significant contributors. Additional analyses suggest that there is might be a potential genetic interaction between *CTSB* and *GBA* and that the likely functional mechanism of disease risk is a difference of expression of *CTSB*.

These data provide a genetic basis for modification of *GBA* parkinsonism risk and age at onset and support the hypothesis that variability at genes implicated in lysosomal dysfunction exert the largest effect on *GBA* associated risk for disease. The finding of a link between PD associated GRS with *GBA*

associated PD indicates that *GBA* linked PD may not simply be an etiologic subtype of disease but rather that *GBA* and lysosomal dysfunction are more general features in etiopathogenesis of certain forms of alpha synucleinopathies. Further, these results have important implications for selection of *GBA* carriers for therapeutic interventions. HiC

---

Genetic analyses of complex neurodegenerative syndromes have become more advanced with the development of whole genome sequencing (WGS) technologies. In this project, we assembled and profiled genomes from ~3,000 samples from Lewy body dementia (LBD) alongside ~2,000 neurologically-healthy controls. This project is the largest WGS effort for this common age-related dementia syndrome. PCR-free DNA libraries were sequenced on the Illumina HiSeq X10 system to study the genetic architecture underlying these two heterogeneous dementia syndromes. Here, we present analyses on both common and rare variant discovery testing. In addition, we applied modern data-driven approaches, such as the construction of polygenic risk scores, applying machine learning to determine which features are explaining the variance, gene and pathway analyses, and two-way Mendelian randomization to better understand the complex genetic composition of these dementia syndromes. All data from this initiative will be made available on the Accelerating Medicines Partnership - Parkinson's Disease (AMP-PD) platform as a public resource, so that other researchers can access, analyze, and combine these genomes with their own cohorts for downstream analyses. With this sequencing initiative, combined with the online platform available for collaboration, we aim to gain a better understanding of the genetic underpinnings of LBD.

## PgmNr 2127: Genetic analysis of risk alleles associated with frontotemporal dementia in a group of Colombian patients.

**Introduction:** Frontotemporal Dementia (FTD) is a common type of dementia in people younger 65 yo, with strong genetic basis. FTD encompasses distinct clinical symptoms including progressive changes in behavior, language, executive and motor function. The FTD clinical spectrum includes a behavioral variant (bvFTD), a non-fluent/agrammatic variant primary progressive aphasia (nfvPPA), and a semantic variant (svPPA). There are risk loci and causative mutations associated with FTD that have been identified by Genome-Wide Association studies. These genes include *C9orf72*, *GRN*, *MAPT*, and *TMEM106B* among others. **Methodology:** We studied 104 patients clinically diagnosed with FTD with a Pan-Neurodegenerative Disease-Oriented Risk Allele (PANDORA) panel that was performed on a mass ARRAY instrument. The panel was designed by University of Pennsylvania as a method for genotyping common single nucleotide polymorphism (SNP) risk alleles for common neurodegenerative disorders: Alzheimer Disease (AD), Parkinson Disease, FTD and Amyotrophic lateral sclerosis. We analyzed 56 SNPs, calculated minor allele frequencies and Hardy-Weinberg (HW) law for each SNP. All patients had neuropsychological evaluations (Stroop, ineco frontal screening, Rey-Osterrieth complex figure etc). We analyzed data to look for associations between these tests and the risk alleles in each SNP. **Results:** 28 patients were classified with nfvPPA, 60 with bvFTD, and 16 with svPPA. Median age of diagnosis was 61 yo. All SNPs related to FTD genes reached HW. The following SNPs related to AD did not reach HW: rs7412 in *APOE* gene ( $p=0.029$ ); rs6656401 in *CR1* gene ( $p=0.024$ ), and rs983392 in *MS4A6A* gene ( $p=0.009$ ). rs1411478 in *STX6* gene, related to progressive supranuclear palsy, didn't reach HW ( $p=0.014$ ). We found low performance in Total IFS test when the allele A for rs5848 (*GRN* gene) was present (OR: 13 [1.47,115.34],  $p=0.021$ ); low performance in SDMT test when allele A in rs1020004 (*TMEM106B* gene) was present (OR:3.4 [1.06,10.89],  $p=0.039$ ). Other alleles in SNPs of *TMEM106B* gene were also significant associated with low performance in Stroop test. **Discussion:** a pleiotropic effect is seen in FTD, meaning that multiple loci have small additive effects for increasing its risk. Having any of these SNPs, should not be considered as a necessary factor to develop FTD. More studies are needed to determine if having one or several SNPs confers additional risk for the development and severity of FTD.

## PgmNr 2128: Genetic differences between neuropathologically confirmed pure dementia with Lewy bodies and Parkinson's disease dementia.

### Objectives

Parkinson's disease dementia (PDD) and dementia with Lewy bodies (DLB) are differentiated based on the temporal onset of parkinsonism versus cognitive impairment. The disorders share classical Lewy pathologies and may be neuropathologically indistinguishable. We sought to identify genetic differences between the disorders.

### Methods

PDD (n=54) Caucasian subjects presented with parkinsonism and pure DLB (pDLB; n=78) subjects presented with dementia. Both groups were defined by the neuropathologic criteria. Coding regions were screened for 27 causative AD, PD, or neurodegeneration-related genes: sample libraries were constructed and enriched for these genes using xGEN custom probes; >100X mean sequence coverage was generated per sample (Illumina); and sequences were aligned to hg19 (Burrows-Wheeler Aligner) and variants were called and annotated with custom Genome Analysis Tool Kit and ANNOVAR, respectively. To evaluate disease specificity, variants of interest identified in the PDD and DLB patients were screened in the 2237 Alzheimer disease (AD) cases and 2207 controls of the 1st data release of the AD Sequencing Project.

### Results

883 SNPs from 27 genes passed QC filters and were advanced to the analyses.

We compared frequencies of variants with MAF <5% between the pDLB and PDD groups using the gene burden tests (SKAT-O) for all 27 genes. We found significant differences in only 1 gene, *LRRK2*. We found that the burden of rare missense variants in *LRRK2* (not known to be pathogenic) were significantly higher in PDD compared to pDLB ( $p = 0.003$ ). Both groups also harbored unique *LRRK2* variants (7 for PDD; 8 for pDLB). Of the unique MS variants, only 2 were observed in the ADSP; making p.M712T and p.T776M very rare and specific to pDLB and PDD respectively). p.N2081D was previously reported in gnomAD NFE (1.7%) and subsequently identified in both AD cases and controls in the ADSP. Interestingly, p.R1941H is extremely rare in gnomAD NFE, but was identified in 8 AD and 6 controls of the ADSP; all of Hispanic descent.

**Conclusions:** Genetic differences in *LRRK2* exist between neuropathologically confirmed pDLB and

PDD. These findings suggest that genetic signatures may differentiate PDD from DLB. Though we identified some variants specific to PDD and pDLB, 1 of the rare variants also appears in Hispanic AD and controls, confirming that the inclusion of subjects from the same ethnicity is crucial to fully understand the underlying genetics to disease.

## PgmNr 2129: Neuropsychiatric features differ in individuals of African and European descent with Alzheimer disease (AD).

P.R. Mena <sup>1</sup>; J. Ramos <sup>1</sup>; K. Celis <sup>1</sup>; L.D. Adams <sup>1</sup>; A. Scott <sup>1</sup>; T. Stark <sup>2</sup>; F. Lacroix <sup>1</sup>; J.L. Haines <sup>3</sup>; C. Reitz <sup>4</sup>; G. Beecham <sup>1</sup>; G.S. Byrd <sup>2</sup>; M.A. Pericak <sup>1</sup>; J.M. Vance <sup>1</sup>; M.L. Cuccaro <sup>1</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) John Hussman Institute of Human Genomics, University of Miami, Miami, Florida.; 2) Department of Biology, North Carolina A&T State University, Greensboro NC; 3) Department of Population and Quantitative Health Sciences, Case Western Reserve University, Cleveland OH; 4) Taub Institute, Columbia University, New York, NY

**Background:** There is evidence that genetic risk for AD differs between African Americans (AA) and individuals of European descent (EU). However, whether these differences in genetic risk for AD translate into phenotypic differences between the groups is not known.

We investigated neuropsychiatric phenotypes in our AA and EU groups. Prior studies indicate that these phenotypes may vary by race and ethnicity in AD. Understanding neuropsychiatric phenotypes in AD may provide insights into genetic mechanisms.

**Methods:** Participants were enrolled in genetic studies of AD and met criteria for mild cognitive impairment or AD. Self-reported race was confirmed by genetic analysis. Neuropsychiatric features were assessed using the 12-item Neuropsychiatric Inventory Questionnaire (NPI-Q). NPI-Q items (e.g., agitation and depression) are scored as present/absent and summed to create a total score (higher scores=more problems).

Our primary hypothesis was that our AA and EU groups would differ on NPI-Q outcomes. To test this, we compared mean NPI-Q total scores for our groups using an independent samples t-test and performed logistic regression to identify those NPI-Q items that differentiate AA and EU cases.

**Results:** We had 675 cases (EU=53%; AA=47%) with complete NPI-Q data. Our groups did not differ on age of onset of AD ( $p=0.13$ ) or distribution of CDR scores ( $p=0.79$ ). Mean NPIQ total scores were nominally significantly higher in our AA group ( $p=0.04$ ). Our logistic model was significant ( $p<0.001$ ) and the odds of being in the AA group was 3.1 times greater (95% CI 2.0, 4.8) when agitation was present while the odds of being in the EU group was 2.2 time greater (95% CI 1.5, 4.4) when anxiety was present and 1.7 times greater (95% CI 1.2, 2.5) when apathy was present.

**Conclusions:** We identified differences in our AA and EU groups on select neuropsychiatric features. Among EU, there was a greater likelihood of anxiety and apathy (i.e., apprehension or indifference) while our AA group showed a greater likelihood of agitation (i.e., resistant, uncooperative behavior). While our findings may be explained by non-genetic causes (e.g., SES), the presence of distinctive neuropsychiatric problems may be phenotypically and genetically relevant to AD in these populations.

## **PgmNr 2130: Longitudinal analysis of 4500 whole blood transcriptomes across over 1500 whole-genome sequenced individuals within the Parkinson's Progression Markers Initiative.**

Transcriptome analyses of whole blood samples from normal healthy control subjects and patients with Parkinson's disease (PD) have the potential to uncover biological pathways disrupted by disease processes. Detectable changes in the transcriptome of a readily accessible biofluid, such as blood, have the potential to be valuable biomarkers. Moreover, integration of transcriptomic data with genomic whole-genome sequencing data has the potential to give insight to variants of unknown significance and previously identified genetic loci. In this study, we report transcriptome profiling of whole blood from 4,600 samples longitudinally collected from over 1,600 individuals who also have whole genome DNA sequence, as part of Michael J. Fox Foundation's Parkinson's Progression Markers Initiative (PPMI) cohort. Paxgene derived whole-blood samples were sequenced at baseline and at months 6, 12, 24, and 36 to a depth of over 200 million reads, with many individuals having over 1 billion reads over the time series. Longitudinal analysis was conducted using across a series of clinical variables, examining clinical phenotypes, carrier status, and therapeutic drug usage. We analyzed expression data with existing whole-genome sequencing data, reporting on the robustness of expression quantitative loci (eQTL) over the 3 year period, examining both novel and known eQTLs in PD associated genes. We detail the utility of longitudinal analysis and will present on differentially expressed transcripts between PD and normal controls, as well as transcript changes associated with time. Finally, we describe a series of resources to enable other researchers, including a series of tools for querying and searching through the clinical/genomics data via an analysis portal.

## PgmNr 2131: Differential gene expression analysis of CD8<sup>+</sup> T cells from multiple sclerosis patients and healthy controls.

### Authors:

---

### Introduction

Through recent genome-wide approaches the adaptive immune system has been implicated as a major contributor to the risk for developing multiple sclerosis (MS). Furthermore, post-mortem analysis of MS lesions has pointed out that CD8<sup>+</sup> T cells may be involved in the disease processes. A detailed insight in the activity of genes involved in the MS processes will contribute to a better understanding of disease mechanisms and may provide valuable markers for disease and disease activity.

### Materials and methods

CD8<sup>+</sup> T cells were purified from whole blood from 20 MS patients and 20 controls. RNA was extracted and sequenced in 12-plex 75-basepair paired-end reads on an Illumina NextSeq sequencer in order to get detailed insights in gene expression. The raw reads were mapped using the program Kallisto. The per-sample-per-gene read count matrix was imported into DeSeq2 for differential expression analysis. We included surrogate variable analysis to account for hidden confounders.

### Results

After correction for multiple testing according to Benjamini and Hochberg we identified 73 genes with significant differential expression. These genes may provide valuable insights in which biological pathways are affected in CD8<sup>+</sup> T cells in MS patients.

### Discussion and conclusion

CD8<sup>+</sup> T cells from MS patients show differential gene expression compared to healthy controls. Further analysis of the differentially expressed genes in a pathway analysis may provide a much-needed insight in how these cells contribute to MS disease processes. Furthermore, by analysis of the RNA sequencing dataset in the perspective of the large-scale genome wide association studies by the international MS genetics consortium (IMSGC) may provide additional clues to which genes in CD8<sup>+</sup> T cells are driving or marking MS disease processes.

## **PgmNr 2132: Single-cell transcriptomics analyses of cells from a novel tri-culture model of HIV neuropathogenesis reveals cellular heterogeneity and inflammatory gene expression signatures.**

---

HIV-Associated Neurocognitive Disorders (HAND) affect 55% of HIV-infected individuals worldwide. While antiretroviral treatments have reduced the severity of HAND, the prevalence has increased due to increased life expectancy. In addition, little progress has been made in developing therapeutics to reduce the prevalence of HAND. While the major pathological manifestation of HAND is synaptodendritic damage, the full, underlying mechanism is unknown partly since there is no in vitro model to study the direct interactions between HIV-infected macrophages/microglia and neurons. In order to address this problem, we developed a human-induced pluripotent stem cell (HiPSC) based model; whereby, we separately differentiate HiPSCs into glutamatergic-like neurons, astrocytes, and microglia and create a co-culture of the three cell types with or without HIV-infection. We used single-cell RNA-sequencing (scRNA-seq) to understand gene expression changes under four separate conditions including during HIV infection in the presence or absence of Efavirenz (EFZ), an antiretroviral treatment that prevents integration of the HIV virus into host cells. The cellranger pipeline (10x Genomics, v.3.0.1) was used for initial analysis and aggregation of samples. Secondary analysis was performed using the Seurat package in R. After QC, 31,177 cells (39,227 post-normalization mean reads per cell, 2,165 median genes per cell) were characterized from the separate conditions (6,564 cells from control condition, 7,431 from HIV infected, 7,111 from HIV infected+EFZ, and 10,071 from control+EFZ). Automated clustering generated 16 distinct cell clusters. Cells were identified into one of the 3 cell populations based on canonical gene markers in each cluster. Inflammatory pathways were altered in all HIV infected cell types compared with uninfected controls, suggesting that each cell type may play a role in HIV mediated neuropathogenesis. The upregulation of the inflammatory gene signature was most pronounced in HIV infected microglia, indicating that neuroinflammatory roles of each cell type may not be equal. Additionally, a markedly different gene expression profile between infected and infected with antiretroviral treatment conditions was observed, suggesting different mechanistic drivers of damage between pure HIV infection and a combination of HIV infection with antiretroviral treatment.

## PgmNr 2133: Human iPSC-derived microglia are genetically relevant to Alzheimer's disease.

Microglia are the primary innate immune cell type in the brain that have been implicated in the pathogenesis of neurodegenerative disorders such as Alzheimer's disease (AD) and neuropsychiatric disorders such as schizophrenia. Microglia generated from human-induced pluripotent stem cells (hiPSCs) represent a promising *in vitro* cellular model for studying the neuroimmune interactions involved in AD. Among several methods of generating hiPSC-derived microglia (iMG)—varying in duration and resultant purity—a recent protocol by Brownjohn et al. is particularly simple and efficient. However, the replicability of this method, transcriptomic similarity of these iMG to primary adult microglia, and their genetic relevance to AD remain unclear. Using two hiPSC lines, we demonstrated that Brownjohn's protocol can rapidly generate iMG that morphologically and functionally resembled microglia. The iMG cells we generated were found to be transcriptionally similar to previously reported iMG lines, as well as fetal and adult microglia. Furthermore, by using cell type-specific gene expression to partition disease heritability, we showed that iMG cells are genetically relevant to AD. Across a range of neuronal and immune cell types we found only iMG, primary microglia, and microglia-like cell types exhibited a significant enrichment for AD heritability. Our results thus support the use of iMG as a human cellular model for understanding AD biology and underlying genetic factors, as well as for developing and efficiently screening new therapeutics.

## PgmNr 2134: Longitudinal behavioral characterization of Gaucher-associated Parkinson murine models.

Mutations in the glucocerebrosidase gene, *GBA1*, impart an increased risk for Parkinson disease. Murine models created to elucidate the link between *GBA1* and Parkinson vary widely in mutation type and severity and have been evaluated at different ages, complicating comparative analyses between different mouse models. As *GBA1*-associated Parkinson is an age-related disorder, elucidating age-dependent alterations in behavior in mouse models can provide an appropriate timeline for future therapeutic studies. We crossed mice overexpressing the mutated human  $\alpha$ -synuclein transgene (*SNCA*<sup>A53T</sup>) with a heterozygous *GBA1* knockout mouse (*gba*+/-), and the behavior of the corresponding WT/WT, *gba*+/+//*SNCA*<sup>A53T</sup> and *gba*+/- mice were initially analyzed at 18 months and then monthly for four consecutive months. We then tested younger groups of mice at eight months and re-tested them every other month for six months. Three phenotypes were tested: memory by the novel object recognition test, olfaction by the buried pellet test, and motor coordination by the beam walk test. Gait, assessed by a tunnel-guided gait walk, also provided a qualitative comparative measure. The collected data were analyzed in GraphPad Prism 8.

The study revealed mild, age-associated differences between experimental groups on the behavioral tasks. Over-expression of *SNCA*<sup>A53T</sup>, regardless of genotype, resulted in impaired motor coordination starting from 10 months of age ( $p = 0.037$ ). Olfaction and memory were well-preserved throughout this time span in all mice, regardless of genotype, although *gba*+/+//*SNCA*<sup>A53T</sup> mice exhibited a trend suggestive of impaired memory after age 12 months. Physiological parameters assessed in *gba*+/-//*SNCA*<sup>A53T</sup> mice at 22 months showed decreased weight ( $p < 0.05$ ) and reduced glucocerebrosidase (GCase) activity in brain tissue ( $p < 0.05$ ), confirming the late-onset physiological effects of combining *gba* and *SNCA* mutations.

This study indicates that even prior to the development of symptoms, *gba*+/-//*SNCA*<sup>A53T</sup> mice model the age-dependent decline in motor behavior seen in Parkinson disease from as early as 10 months of age. These results suggest that motor coordination in *gba* haploinsufficient mice can be utilized as an efficacy endpoint for testing novel therapeutics at different timepoints.

## PgmNr 2135: Spinocerebellar ataxia STRs identified in Mexican Americans families show association with decreased cerebellum volume and decreased working memory.

---

Short-tandem repeats (STRs) are a typically uncharacterized but clinically relevant form of genetic variation (DNA repeat expansions) that have been shown to cause over 40, primarily neurological, disorders. We used two methods for STR detection (ExpansionHunter and exSTRA) to profile 21 clinically relevant STRs in short-read Illumina WGS from 1159 individuals from the Genetics of Brain Structure and Function Study (GOBS); a randomly ascertained, pedigree-based cohort of Mexican Americans from San Antonio, Texas that also includes comprehensive neuroimaging and neurocognitive assessments.

We identified 4 individuals with expansions at the SCA8 locus (*ATXN8*) and 16 carriers of a SCA10 (*ATXN10*) expansion. These STRs are responsible for the development of autosomal dominant spinocerebellar ataxia 8 and 10, respectively. GOBS does not specifically record clinical ataxias but this disease may be undiagnosed in this clinically underserved minority group. To date, SCA10 expansions have only been observed in ataxia patients with apparent Amerindian ancestry, supporting our findings. Our ExpansionHunter estimates suggest the SCA8 carriers have an expansion in the pathogenic range of >74 repeats, whereas the SCA10 carriers are expanded beyond the normal range with >30 repeats, but not within the pathogenic range (>500 repeats). We therefore hypothesized that, in the absence of overt ataxia diagnoses, we would detect association with ataxia related quantitative phenotypes in STR carriers.

To test for association with quantitative phenotypes we used variance components modelling in SOLAR. This incorporates the non-independence of related individuals in this cohort into the analysis

to identify mean unit differences in phenotypes in variant carriers versus non-carriers. For carriers of the SCA8 expansion we identified 1.19 and 0.89 standard deviation unit (SDU) decreases in the left and right cerebellum cortex volumes ( $P=0.002$  and  $0.02$  respectively) and a 1.05 SDU decrease in bilateral cerebellum cortex volume ( $P=0.006$ ). For carriers of the SCA10 expansion we did not detect cerebellum size changes however a 0.5 SDU decrease in response time to a spatial capacity test as a measure of working memory was identified ( $P=0.009$ ).

STRs have been posited as a potential source for some of the 'missing heritability' of complex disease. Here we show that two clinically relevant STRs are associated with spinocerebellar ataxia relevant quantitative phenotypes.

## PgmNr 2136: *De novo*/shared mutations identified for autism in the US Hispanic population.

---

**Introduction:** Autism, a complex neurodevelopmental disorder with a prevalence rate of 1% worldwide, has been seen to have varying etiologies, trajectories and has been found to affect everyone differently. ASD has been found to deficits in communication, repetitive behavior, abnormal social functioning, etc. Autism has been found to be caused by the interactions between genetic factors and environmental factors such as exposure to toxic chemicals, advanced parental age, and preterm birth among other factors. Although there have been recent advancements in the molecular techniques used for the discovery of causative variants for multiple diseases, there has not been much progress in the discovery of causative variants for Autism. The limited studies conducted for the discovery of causative variants has been conducted on a predominantly Caucasian population. Very few studies have been performed on the US Hispanic/Latino population.

**Material and Method:** Whole exome sequencing (WES) was used for the discovery of causative mutations in nine affected children and one affected parent from five families.

**Results:** We identified two genes/mutations in the AR gene and the ACOXL gene, where the mutation found in the AR gene is a *de novo* mutation and the mutation found in the ACOXL gene is a mutation found to be shared between an affected child and affected parent from the same family. Gene information such as expression in the central nervous system, the function, and if they were previously reported was gathered and used to identify these mutations. These variants will then go through PCR and will be sent to a biotech company for Sanger Sequencing for further confirmation.

**Conclusion:** This WES led to the discovery of additional causative mutations in the US Hispanic population; however, future validation using a large sample are needed to confirm the current findings.

## **PgmNr 2137: Assessment of frequency and pathogenicity of loss-of-function and missense variants in candidate genes of autistic spectrum disorders.**

Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder that affects around 1-2% of the world's population. The etiology of ASD is still not fully understood, however, many advances have been made to understand its genetic component. Next generation sequencing pointed that rare alterations of loss-of-function (LoF) and missense changes with high *in silico* prediction of damage in neurodevelopment genes are contributing to the mechanism of the disease. Whole exome sequencing (WES) of 48 individuals with TEA and 119 controls were evaluated, 11 lists of genes of relevance for TEA ranging from 23 to 7764 genes were evaluated. The number of rare variants (frequency less than 0.01) and singleton variants were counted for each individual. There was no difference (measured by Chi-Square test) in the number of LoF variants found in individuals with ASD and controls in any of the scenarios tested. The missense variants were ordered for their pathogenicity by the SPRING software and the distribution of the variants compared in the interest groups. There was no difference in the mean of non-synonymous variants per individual, nor in the degree of pathogenicity in individuals with ASD and controls in any of the tested scenarios. Due to the small sample size, the results of this study should be interpreted with limitations, and it is necessary to replicate this scenario in other databases. However, these findings suggest that the choice of candidate genes for ASD may increase the number of false positives in clinical reports and the determination of causative variant must be accompanied by further investigations other than WES.

## PgmNr 2138: Whole exome sequencing of a monozygotic triplet with autism spectrum disorder identifies two homozygous mutations in genes involved in neuronal development.

Autism spectrum disorder (ASD) is a neurodevelopmental disorder that affects 1-1.5% of individuals and characterized by impairments in social interaction and communication, along with repetitive and restrictive behaviors. ASD is usually accompanied by heterogeneous phenotypic comorbidities, such as mild to severe intellectual disability and epilepsy. ASD is highly heritable with complex genetic architecture where both rare and common genetic variations contribute to its etiology. Rare genetic variations in many genes have been identified in ASD patients and genome-wide association studies have identified multiple common genetic risk variants for ASD. In this study, we performed whole exome sequencing of a consanguineous middle-eastern family in which a monozygotic triplet was affected with ASD. The Autism Diagnostic Interview-Revised scores for the proband were consistent with ASD diagnosis with developmental delay and epileptic seizures. Exome capture was performed using SureSelect Human all exon v6 followed by sequencing on Illumina platform. Identity by state analysis confirmed monozygosity of the triplet.

Results showed a homozygous missense mutation in the *VPS13B* gene. Both parents were heterozygotes for this mutation and all three ASD patients were homozygotes. The mutation was very rare in the gnomAD database (MAF=0.00002, homozygous count=0) and predicted to be pathogenic by functional prediction tools. Current evidence indicates an important role for *VPS13B* in normal growth and development of neurons. Mutations in *VPS13B* have been reported in patients with Cohen syndrome, a rare autosomal recessive disease characterized by intellectual disability, dysmorphism, and microcephaly.

Sequencing results also revealed a homozygous missense mutation in the *PIGN* gene in the three ASD patients. The mutation was rare in the gnomAD database (MAF=0.0007, homozygous count=1) and predicted to be pathogenic. The *PIGN* protein is involved in glycosylphosphatidylinositol (GPI)-anchor biosynthesis and homozygous mutations in *PIGN* have been reported in patients with multiple congenital anomalies including delayed psychomotor development, hypotonia, and seizures.

Our data reveal the complex genetic architecture of ASD and identify two homozygous mutations in genes involved in neuronal development. The mutation in *PIGN* could explain the observed seizures in the patients but further functional studies will be required to confirm this finding.

## PgmNr 2139: Bioinformatics analysis of GWAS for autism spectrum disorders and related traits.

Autism Spectrum Disorders (ASDs) are neuropsychiatric conditions affecting communication skills and social interactions. They feature related traits such as restricted and repetitive behaviors and have an onset prior to 3 years of age. ASDs, with a 4 male:1 female sex ratio has current prevalence estimate of 1/37 in males. The consensus is that ASDs are polygenic, with as many as 1,000 predisposing genes. Robust detection of these common risk genes having small effect sizes is contingent upon the development of large study samples that permit well-powered GWAS. A recent GWAS meta-analysis of approximately 45,000 Danes that identified 5 loci for ASDs at  $p < 5e-8$  provides a marked improvement over previous studies, however, this sample is still smaller than those for other complex disorders with robust findings. To address robustness using a different approach, we conducted a bioinformatics analysis aimed at detecting associations for ASDs and related traits from published GWAS using 2 publicly available databases with different inclusion criteria. We hypothesized that associations meeting stringent criteria in both GWAS databases are more likely to be robust, and searched for concordance between the Simons Foundation Autism Research Initiative SFARI Gene-Human Gene Module database and the NIH/NHGRI GWAS Catalog (GC) for ASDs and related traits. These databases apply markedly different approaches to curation. SFARI employs a panel of scientists who score the published evidence for GWAS results on an ordinal scale (score) ranging from 1 to 6, with 1 representing the most stringent criterion. GC reports all genes published in the GWAS literature along with their p-values and other relevant information. When we applied a score threshold of 3 for SFARI and a p-value of  $5e-8$  for GC the analysis identified 822 GC and 18 SFARI genes. Their overlap consisted of 3 genes: (*GRIN2A* ( $p=2e-9$ ,  $score=3$ ), *MACROD2* ( $p=4e-8$ ,  $score=2$ ) and *PHB* ( $p=7e-9$ ,  $score=3$ )). There was a .4% concordance in the results. Similar patterns were observed with a GC criterion of  $p < 5e-8$  and SFARI thresholds of 2 and 4. These analyses 1) illustrate the feasibility of identifying robust GWAS results using publicly available databases, 2) illustrate that different methods of curation allow the application of diverse criteria, and 3) provide additional support for *GRIN2A*, *MACROD2*, and *PHB* as risk genes for ASDs and their related traits.

---

Although autism spectrum disorder is phenotypically and genetically heterogeneous, clinical morphology classification can help stratify ASD heterogeneity to resolve genotype-phenotype relationships in ASD. Using microarray and whole-exome sequencing, we previously determined a molecular diagnostic yield (MDY) of 15.8% in 95 ASD cases, with the yield higher in the complex (more dysmorphic) ASD subtype (Tammimies *et al*, JAMA, 2015). Here, we aimed to examine the MDY in a larger ASD cohort (n=327), and to dissect the genes and pathways involved in different ASD subtypes using whole genome sequencing (WGS), with the advantage of detecting a full size spectrum of variants in a single experiment. A total of 327 children with ASD from Newfoundland, Canada were enrolled using a population-based recruitment strategy. Standardized dysmorphology assessments were used to stratify the cohort into 193 essential (non-dysmorphic), 57 equivocal, and 77 complex ASD cases. We identified clinically significant single nucleotide variants, short insertions/deletions and copy number variants in 15.0% of ASD cases. The yield was higher in the complex subgroup (39.0%; 30/77) compared to the essential subgroup (6.7%; 13/179) ( $p=7.61 \times 10^{-10}$ ). Clinically significant variants included 16p11.2 microdeletion and microduplication, and variants impacting *SHANK3* and *CHD8*. Two ASD cases (~0.6%) had two clinically significant and/or ASD-risk variants. By performing a global burden analysis, we found a significant enrichment of rare deletions impacting genes in ASD cases with more dysmorphologies ( $p=7.03 \times 10^{-4}$ ). Via gene-set enrichment analysis, cases with more dysmorphologies had a difference in burdens of rare deletions and duplications in genes responsible for neuronal function (e.g., neurotransmission,  $p=4.25 \times 10^{-4}$ , FDR=0.02) and expressed specifically in brain ( $p=9.30 \times 10^{-3}$ , FDR=0.1), respectively. Moreover, the number of dysmorphologies was positively correlated with the number of missense variants in genes responsible for neuronal (e.g., neurogenesis,  $p=4.32 \times 10^{-4}$ , FDR=0.03) and mental function ( $p=4.48 \times 10^{-4}$ , FDR=0.02). Our findings show that WGS captures clinically significant variants with different size spectra for molecular diagnosis of ASD. By using a combination of rich genome-wide

data and extensive clinical data, we also dissect the specific brain and neuronal functions that are impacted by rare variants in ASD cases with more dysmorphologies.

## PgmNr 2141: Microbiome-wide analysis of children with autism spectrum disorder and their neurotypical siblings identifies numerous differentially enriched taxa.

---

Despite the surge in genome-wide association studies (GWAS) in the past decade, no genotype-to-phenotype models currently exist for most complex diseases. One potential explanation is that GWASes ignore an important component of genetic diversity: - the trillions of microbes living in the human gut, which cumulatively contain more than 3 million genes. Autism Spectrum Disorder (ASD) is one such disease for which GWASes have struggled to find the causal genes. Microbial therapy has decreased ASD symptoms in mouse models, hinting that the microbial genes in the gut microbiome may play a significant role. Moreover, several human studies have found differences in the gut microbiomes of ASD and neurotypical children, despite being underpowered and struggling with the many confounding variables that influence gut microbiota. We present one of the largest microbiome-association studies to date across children with ASD and their neurotypical siblings, and identify 50 operational taxonomic units (OTUs) as well as 16 genera that are differentially enriched between children with ASD and their neurotypical siblings.

We performed 16s rRNA sequencing of 115 ASD-neurotypical sibling pairs over 3 timepoints, achieving an average read depth of on over 100,000 reads/sample after quality filtering. We sequenced across multiple timepoints to control for quality and stability, and took advantage of similarities of lifestyles between siblings as well as measured over 100 lifestyle related variables, such as diet, birth mode, and medication usage to control for confounders. We highlight three key findings: (1) Lifestyle factors such as diet, birth mode, and medication use can explain much of individual variation in higher level taxonomic features such as diversity and abundances of certain phyla, but (2) children with ASD and their neurotypical siblings differ with respect to which specific lower level taxa are present. We identified 50 OTUs and 16 genera differentially present in ASD vs neurotypical children, primarily composed of members of the of Lachnospiraceae, Ruminococcaceae, and Veillonellaceae families. (3) We show that pairwise statistical testing yields more powerful results than non-paired tests, and the implications for metagenome-wise association studies (MWAS), outlining a framework and bootstrapping methods for such future studies.

Autism spectrum disorders (ASD) are complex neuropsychiatric conditions with an important genetic core. Over 1000 genes are estimated to be involved in outlining the pathological phenotype. Its genetics basis is extremely variable from point mutation to chromosomal abnormalities. The contribution of comparative genomic hybridization based on microarray (aCGH) in identification of small rearrangements and of new candidate genes, was valuable for defining the genetic architecture of ASD.

Our study includes 200 cases with ASD investigated by aCGH and CGH+SNP array in combination with classical cytogenetic methods (karyotype, FISH). The phenotype of our ASD children encompassed also intellectual disability, speech delay, epilepsy, dysmorphic features.

The genomic profile obtained in our patients ranged from benign to pathogenic variants. Some pathogenic variants are already associated with ASD, such as: Xq28 duplication (including *MECP2* gene), 22q11.2 deletion, 22q13.3 deletion (including *SHANK3* gene), 9q34.1 (contained *TSC1* gene) and 1q21.3q22 (including *POGZ* gene). Several rare variants were identified as well: deletion of the region 8p11.2p21.2 (only two autistic patients described so far), 9p13, 3p26.3 (including *CHL1* gene - 15 patients reported), and duplications of 2q13 (including *NPHP1* and *MALL* genes - ten patients described earlier), 4p16.1p16.3 (including *MRT54* and *PPP2C* genes- 4 patients reported), and 13q14.13q34 (3 patients have been described).

The genomic investigation in our group of patients led to delineation of disease etiology with a strong impact in management of the patients and in counselling of their families.

## PgmNr 2143: Naturally-occurring mutations in *CHD8* and *KDM6B* in rhesus macaques are associated with differences in social behavior.

---

Nonhuman primates (NHPs) provide models of social behavior and social interaction that offer enormous potential for the study of autism and other behavioral disorders in humans. Rodent models are useful for investigating some mechanistic aspects of genotype-behavior relationships, but NHPs provide models of social behavior and social interaction with greater translational value. Although NHPs have long been critical to studies of developmental psychobiology, investigation of the genetic basis of intra-species variation in behavioral traits among NHPs is in its early stages. We conducted two analyses of individual variation in social behavior among juvenile rhesus macaques (*Macaca mulatta*). We used a well-established and broad behavioral ethogram as well as a novel downward extension of the macaque Social Responsiveness Scale (mSRS) to characterize social behavior among 209 juvenile macaques living in large social groups at the Yerkes National Primate Center. We performed whole exome sequencing on 91 of these animals to identify genetic variation among them. Using FaST-LMM, we then performed quantitative trait association analyses restricted to 87 genes, selected based either on published studies or high scores in SFARI Gene. A missense mutation in *CHD8* that has a CADD score of 26 (predicting a major effect on protein function) is significantly associated ( $p < 3 \times 10^{-9}$ ) with a behavioral phenotype (exploratory factor score) in which “social play” and similar variables have high loadings. This gene has been associated with risk for autism in children and is a strong candidate for direct effects on measures of sociality. A missense variant in *KDM6B* is associated with the same macaque factor score ( $p < 2 \times 10^{-8}$ ). While this gene has also been associated with autism spectrum disorder, the specific variant showing association has a low CADD score. For the *CHD8* variant, three other macaque behavioral phenotypes show p-values  $< 4 \times 10^{-6}$ . For *KDM6B* four other phenotypes produce p-values  $< 5 \times 10^{-6}$ . Two study animals each carrying both genetic variants displayed high levels of atypical behavior. These studies implicate these alleles as determinants of social behavior in macaques although do not yet provide definitive evidence for genotype-phenotype effects. Whole exome sequencing is in progress for the remainder of the 209 study animals and will provide additional information about this potential primate model of specific gene effects on complex social behavior.

## PgmNr 2144: Regional variation in transcriptional dysregulation and patterning in postmortem cerebral cortex in ASD.

---

Autism Spectrum Disorder (ASD) is a highly heritable and common neurodevelopmental disorder characterized by deficits in social communication and repetitive behaviors. Previous work has identified transcriptomic alterations in frontal and temporal cortex in ASD, characterized by the upregulation of genes expressed in astrocytes and microglia, downregulation of genes associated with synaptic activity, and attenuation of cortical patterning. Here, we expand upon this work using RNA-sequencing to identify gene expression changes in a total of 808 samples across eleven cortical brain areas from 58 subjects with ASD and 54 neurotypical controls (on average, seven regions per individual). While we replicate previous patterns of glial up-regulation and synaptic signaling down-regulation, we also observe regional gradients in the severity of the pattern, with the greatest changes occurring in the occipital cortex, followed by parietal regions and the auditory cortex. We confirm previous observations of less regional differences in gene expression in ASD, identifying pervasive deficits in patterning throughout the cortex, driven by a strong attenuation of typical anterior-posterior transcriptomic gradients in ASD. Co-expression network analysis (WGCNA) connects both widespread and region-specific ASD dysregulation to specialized biological pathways within the previously observed 'synaptic' and 'glial-immune' functional categories. These findings suggest that although the dysfunction of convergent molecular pathways is widespread in the ASD cerebral cortex, it is regionally variable, possibly reflecting an increasing gradient of severity from anterior to posterior. Whether this is due to biological or technical factors at this point cannot be determined definitively. However, we note that there is a positive relationship between the strength of the changes in a given region and neuronal density determined in previously published studies in primates.

Neurodevelopmental disorders (NDDs) such as attention deficit hyperactivity disorder (ADHD) and autism spectrum disorder (ASD) are illustrative examples of clinical cases exhibiting phenotypes that often undergo exhaustive diagnostic odyssey due to lack of definitive corroborating genetic information. ASD and ADHD have complex genetic associations implicated by rare recurrent copy number variations (CNVs). Diseases associated with similar organ impairments are hypothesized to share similar biological etiologies. Platforms aimed at investigating genetic-based associations, such as high-density microarray technologies, have allowed for the application of groundbreaking techniques in fields aimed at elucidating the underlying disease biology associated with NDDs and related psychiatric diseases. Previous studies investigating NDDs have uncovered CNVs associated with genes within shared candidate genomic networks. In this study we investigated 1,400 ADHD and 1,059 ASD cases using 7,526 controls with the study design of identifying CNVs that increase susceptibility in both diseases in order to better elucidate shared disease biology across NDDs. Cases and controls were matched for Illumina chip subversions and observed vs. expected frequency in association was calculated. Quality control through visual inspection of genotype and intensity was undertaken to ensure CNV confidence prior to association studies. In order to assess the implication of metabotropic glutamate receptor (mGluR) network functions underlying the disease biology of NDDs, we exhaustively queried patients with ASD and ADHD for CNVs associated with 273 genomic regions of interest within the mGluR network. We saw CNTN4 deletions in 190 cases and 50 controls ( $P = 8.15E-73$ ,  $OR = 11.91$ ). Additionally we saw NPY2R deletions in 10 cases and 0 controls ( $P = 8.15E-7$ ,  $OR = \text{infinity}$ ). Together, these results suggest that disruption in neuronal cell-adhesion pathways confers significant risk to multiple NDDs and showcase that rare recurrent CNVs in CNTN4 and NPY2R are overrepresented in both ADHD and ASD cases.

---

Autism spectrum disorders (ASD) are neurodevelopmental disorders that are characterized by difficulties in communication, social interactions and stereotyped behaviors. ASD has a heritability of 64 – 91% indicating a high genetic component. We previously reported a rare *de novo* mutation in *FOXN1* gene in an individual with autism through exome sequencing. *FOXN1* gene encodes a transcription factor essential for the development of the thymus which knockout mouse is known as Nude/SCID. Not much information is known regarding its expression in human brain except for two human SCID fetuses reported with severe neural tube defects such as anencephaly and spina bifida. We used ChIP-Seq technique to identify possible genome-wide targets of the transcriptional factor *FOXN1* in CNS tissue from mouse embryonic brain (E13) and adult brain piriform cortex (P40). Control samples, not treated with anti-*FOXN1* antibody, were also sequenced for both tissues. Data was processed according to the guidelines for analysis of ChIP-Seq data by Bailey, *et al.* Sequences in DNA from embryonic mouse tissue include target genes that have been associated with ASD such as: contactin associated protein, thioredoxin-related transmembrane protein and vomeronasal receptor. Transcription factor DNA motifs for *FOXN1* include high homology for the *FOXP1* (p=0,0001) and *FOXK2* (p=0,001) genes as well as other members of the Forkhead family of transcription factors. The findings in this study confirm that *FOXN1* plays an important role in the development of the CNS during its early stages and will enable a better understanding of early stage neural pathways involved in ASD.

---

Autism spectrum disorder (ASD) is a collection of neurodevelopmental disorders characterized by restrictive interests and/or repetitive behaviors and deficits in social interaction and communication. Studies have shown that individuals with ASD have a higher global burden of rare copy number variations. We have previously demonstrated a shared genetic etiology for autism and a specific language impairment (SLI) phenotype characterized by individuals who do not show other neurological or psychological impairments. We conducted an analysis of copy number variations (CNV) in our familial dataset collected as part of the New Jersey Language and Autism Study (NJLAGS). We have SNP genotyping microarray data for 570 individuals genotyped with Affymetrix and Illumina arraycards. The individuals are spread across 117 families with a median n of 4 members per family. The data consists of individuals affected by ASD, individuals affected by SLI and unaffected individuals. Comparative studies on algorithms to detect copy number variations have shown that there is greater variability but lower concordance and reproducibility among algorithms. This necessitates careful assessment of experimental design and stringent data curation in discovery studies. We therefore employ multiple algorithms (PennCNV, QuantiSNP, iPattern, GenomeStudio, Axiom CNV Summary Tools) to analyze intersection of results from at least 3 CNV callers for each sample. Extensive quality control with strict cutoffs for parameters like CNV length (10kb - 7.5 Mb) and probe count (>4) is carried out to investigate CNVs detectable by SNP genotyping arrays. Using families allows us to identify de-novo CNV calls that are observed only in ASD affected sibling and not in the unaffected siblings. Our preliminary results indicate greater number of CNVs in our ASD affected individuals (mean n=16.6) when compared to unaffected individuals (mean n=15.1). We also observe a greater number of CNVs in ASD affected individuals compared to SLI affected individuals (mean n=14.1). These results are statistically significant with p values 0.046 and 0.007 respectively. We did not see a statistically significant difference in number of CNVs in SLI affected and unaffected individuals. We have also identified previously reported CNVs associated with ASD suggesting that our samples share significant genetic etiology with previously reported samples.

## **PgmNr 2148: Non-additive genetic effects in autism spectrum disorder and specific language impairment on reading achievement and symptoms of the broader autism phenotype.**

We examined traits associated with Autism Spectrum Disorder (ASD) and Specific Language Impairment (SLI) using quantitative genetic and linkage analysis to determine the effects of these disorders on reading achievement and social aptitude.

Nuclear and extended families (N=179) in which at least 1 member had a diagnosis of ASD and at least 1 member had a diagnosis of SLI were recruited as part of the New Jersey Language and Autism Genetics Study and given behavioral rating scales on a variety of topics, including the Social Responsiveness Scale, Second Edition (SRS-2; Constantino, 2012). Social subscales of interest were those of awareness, cognition, communication, motivation, and restricted interests and repetitive behaviors. Reading data were also collected using the Gray Oral Reading Test-Fourth Edition (GORT-4; Wiederholt & Bryant, 2001), specifically within subdomains of reading rate, accuracy, fluency, and comprehension.

Heritability ( $h^2$ ) estimates present the proportion of genetic variation that influences phenotypic variation within a specific group in a specific environment. Univariate heritabilities and bivariate genetic correlations were modeled with the Sequential Oligogenic Linkage Analysis Routines package v4.3.1 (Almasy & Blangero, 1998). We compared the heritability estimates of ASD symptoms and reading in the full sample (N=687), containing families with both ASD and SLI, to heritability estimates when participants with ASD were statistically removed. In a comparison analysis, individuals with SLI were statistically removed.

Heritability of the SRS-2 subscales significantly changed when participants with ASD were removed, while few changes were apparent when participants with SLI were removed. This may be evidence for non-additive genetic effects on social aspects of ASD, specifically for awareness ( $\Delta h^2_r=31.6\%$  to  $37.0\%$ ,  $p<.01$ ), communication ( $\Delta h^2_r=16.7\%$  to  $24.8\%$ ,  $p<.05$ ), and restricted interests and repetitive behaviors ( $\Delta h^2_r=30.9\%$  to  $38.7\%$ ,  $p<.01$ ). Few substantial changes in heritability were found on the GORT-4 subscales when either participants with ASD were removed or participants with SLI were removed. Notably, however, a non-linear effect was observed in oral reading rate when SLI participants were removed from the sample, supporting the influence of language impairment on this trait ( $\Delta h^2_r=43.7\%$  to  $52.8\%$ ,  $p<.01$ ). Ongoing genetic linkage analyses investigate the relation of ASD

and SLI to reading and social ability throughout families.

## PgmNr 2149: Identification of common variants associated with risk for autism spectrum disorder in the SPARK dataset.

---

Autism spectrum disorder (**ASD**) is a highly heritable neurodevelopmental disorder characterized by deficits in social interaction and communication as well as repetitive and restrictive behaviors. Although current research has identified hundreds of *de novo*, likely gene-disrupting ASD rare variants, these variants do not explain a large component of inherited risk. Recently, a genome-wide association study (GWAS) including 18,000 individuals with ASD identified five ASD susceptibility loci (Grove *et al*, *Nat. Genet.* 2019). Given SNP-based heritability estimates of around 50% (Gaugler *et al.*, *Nat. Genet.* 2014), many more common variants are expected to impact risk for ASD. Identification of additional common genetic risk factors may aid understanding of biological mechanisms underlying risk for this behaviorally defined disorder.

In order to detect additional common variants associated with ASD risk, and to replicate previously identified associations in an independent dataset, here we perform a GWAS study on 6,376 trios from **SPARK** (Simons Foundation Powering Autism Research for Knowledge) genotyped on a Illumina Infinium Global Screening Array. Since most participants in SPARK are families (35% and 29% are complete quads and trios, respectively), we applied a case-pseudocontrol strategy which compares allele frequencies between transmitted versus untransmitted alleles to a proband from his/her parents. Genotype imputation was performed on Michigan Imputation Server using TOPMed reference panel.

The primary SPARK GWAS identified one novel genome-wide significant (GWS) locus (rs552214748,  $P < 5e-8$ ) and one suggestive locus (rs16887378,  $P < 1e-6$ ). In particular, rs16887378 (near the gene **FGFR1**) overlaps with a GWS locus identified from a cross-disorder meta-analysis of ASD and schizophrenia (The Autism Spectrum Disorders Working Group, *Mol. Autism.* 2017). This signal was replicated in Grove *et al* ( $P = 0.007$ ; OR=0.96), although the combined p-value after meta-analysis did not reach genome-wide significance ( $P = 1.9e-6$ ). Meta-analysis with Grove *et al.* identified four additional loci including a **KANSL1** locus that was previously found by a more lenient gene-based analysis (Grove *et al.*, *Nat. Genet.* 2019).

Collectively, SPARK GWAS recapitulates previously reported ASD GWAS signals. We now work on the functional interpretation of these findings using chromatin interaction, chromatin accessibility, expression, and brain structure QTL data.

## PgmNr 2150: Scoring neurotypicals for autism polygenic risk reveals the underlying genetic architecture of the autism spectrum.

Common inherited variation explains the majority of liability for autism spectrum disorder (ASD), a phenotypically heterogeneous neurodevelopmental disorder of increasing public health urgency. As such, many ASD risk alleles are also found within the general population of unaffected individuals ("neurotypicals") and contribute to a polygenic architecture composed of a multitude of common variants each having a small effect towards modulating overall ASD liability under a threshold model that includes rare and *de novo* mutations.

We reasoned that studying the effects of common, polygenic risk for ASD in neurotypicals would uncover shared mechanisms of disease amongst the overlapping ASD endophenotypes and comorbid conditions. Specifically, we hypothesized that downstream molecular targets of common, polygenic risk for ASD will have altered gene expression in neurotypicals in a tissue-specific manner.

Here, we estimated polygenic risk score (PRS) effects on gene expression to identify ASD PRS expression quantitative trait loci (PRS-eQTL) within the Genotype-Tissue Expression (GTEx) cohort. European-specific effect size estimates from a recent ASD GWAS (Grove 2019) were used to score neurotypicals of European-American descent (n=527). Normalized RNA-Seq expression estimates from post-mortem tissue samples were then modeled as a function of the ASD PRS along with confounding covariates, including latent factors captured through probabilistic estimation of expression residuals (PEER).

A tissue-by-tissue analysis of 48 tissues revealed nine tissues that had  $\geq 1$  ASD-specific PRS-eQTL at a tissue-specific FDR  $\leq 10\%$ , including three tissues sampled from the brain (cortex, caudate basal ganglia, and substantia nigra). Five genes were associated with an ASD PRS at tissue-specific Bonferroni significance, including an antisense RNA *RP11-342K6.3* ( $p = 2.07 \times 10^{-6}$ ;  $q\text{-value} = 0.045$ ; effect size = -0.60 normalized units of expression) in brain substantia nigra (SN) at the *GCFC2* locus, which has been previously associated with dyslexia and language impairment and replicated in ASD. A random effects meta-analysis of an ASD PRS effect on *GCFC2* expression across 13 brain regions revealed that the concomitant effects on *GCFC2* expression were in the opposite direction for all regions and the strongest in the SN. Combined, these results suggest the presence of a shared ASD genetic etiology and molecular mechanisms of disease driven by common inherited variation.

## PgmNr 2151: Autism spectrum disorder in the Amish: Exome sequencing unveils a novel missense variant in EvC ciliary complex subunit 1 (*EVC*), a known regulator of the sonic hedgehog signaling pathway.

**Purpose:** To date, sequencing efforts to identify genetic determinants of autism spectrum disorder (ASD) have focused largely on *de novo* copy number variants and loss-of-function (LOF) variants in severely affected children. In this study, we evaluated exonic variants for association with quantitative measures of social impairment within the autism spectrum among adult subjects.

**Methods:** The Social Responsiveness Scale™, Second Edition (SRS-2), Adult Self-Report Form was administered to 357 generally healthy Amish adult research participants of the University of Maryland Amish Research Clinic. The SRS-2 is an objective measure of symptoms associated with ASD, with a higher Total T-score correlating with increased severity. The SRS-2 also generates scores for five treatment and two DSM-5-compatible subscales. Using exome sequencing data, an exome-wide association analysis (ExWAS) of each SRS-2 score was performed using the MMAP program, adjusting for age, sex, and relatedness. Results were limited to exonic variants in HWE ( $P \geq 0.05$ ) with a MAC  $\geq 5$ .

**Results:** SRS-2 Total T-Score ranged from 36-75 with a mean of  $48.9 \pm 6.4$  (SD). A missense variant in EvC ciliary complex subunit 1 (*EVC* c.550G>A, p.D184N, rs41269549; MAF=0.7%) showed the strongest association with Total T-Score, reaching near exome-wide significance ( $\beta=14.5$ ,  $P=2.1 \times 10^{-6}$ ). In addition, *EVC* p.D184N demonstrated exome-wide significant associations with scores for Repetitive and Restrictive Behaviors (RRB,  $\beta=15.8$ ,  $P=3.3 \times 10^{-8}$ ) and Social Motivation (Mot,  $\beta=16.3$ ,  $P=7.7 \times 10^{-7}$ ). LOF variants in *EVC* are associated with Weyers acrofacial dysostosis and Ellis-van Creveld Syndrome, for which ASD is not a characteristic feature; however, the clinical significance of *EVC* p.D184N remains uncertain in ClinVar. *EVC* regulates the Sonic hedgehog signaling pathway which is involved in body and CNS patterning, providing mechanistic plausibility for this novel association.

**Conclusions:** We evaluated adults across the full spectrum of ASD-related behavioral traits, and through ExWAS, identified a germ-line variant in *EVC* associated with SRS-2 Total T-Score, as well as RRB and Mot scores. Possible explanations for this association include pleiotropy, incomplete dominance, and/or *EVC* p.D184N representing a gain-of-function variant. This work has potential to identify disease pathways and therapeutic targets for ASD, while highlighting the power of founder populations and the importance of deep phenotyping for gene discovery.

## PgmNr 2152: Whole genome sequencing and homozygosity mapping in a consanguineous cohort identifies new candidate genes for autism spectrum disorder.

---

Autism spectrum disorder (ASD) is a neurodevelopmental disorder characterized by deficits in social communication and restricted, repetitive patterns of behavior or interests. The current estimate of prevalence for ASD is 1 in 59. ASD is one of the most highly heritable neuropsychiatric conditions, but is extremely genetically heterogeneous, reducing the power to identify causative genes. Here we utilized the enriched homozygosity in a consanguineous cohort with ASD to identify disease variants. In collaboration with the MSSNG Consortium we performed whole genome sequencing (WGS) in 68 individuals from 22 families. On average, each individual had 3.6-4.4 million variants after filtering for genotype quality  $\geq 99$  and read depth  $\geq 10$ , 160,000-220,000 of which were rare ( $MAF \leq 1\%$  in 1000 Genomes, ExAC, and gnomAD databases). Out of these rare variants, each proband had an average of 1,305 homozygous, 17 compound heterozygous, 164 X-linked, and 25,838 *de novo* variants. Focusing on coding nonsynonymous variants left 0-17 homozygous, 6-30 compound heterozygous, 0-6 X-linked, and 7-53 *de novo* variants per proband. Next, we identified runs of homozygosity (ROHs) in probands using a sliding window analysis of common SNPs ( $MAF \geq 5\%$ ) in PLINK, allowing for no more than 3 heterozygous SNPs in every 10 consecutive SNPs. We restricted our analysis to ROHs with  $\geq 75\%$  homozygosity. The largest ROH detected was over 17 Mb, consistent with expectations for multiple generations of consanguineous unions. For Sanger validation we selected rare coding nonsynonymous variants that were located either within an ROH or present in a SFARI-annotated ASD gene. Out of the 59 candidate variants (0-7 variants for each proband), 40 were in 35 SFARI-annotated ASD genes including *ANK2*, *ARID1B*, *SHANK1*, *SHANK3*, and *VPS13B*. The remaining 19 novel candidates included genes associated with neurological disorders such as epilepsy (*XIRP2*), intellectual disability (*ZNF721*), and Joubert syndrome (*CC2D2B*, *PIBF1*), as well as genes involved in cytoskeletal (*KIF26A*, *NEK3*) and transmembrane (*ABCC12*, *GPR142*) signaling, mitosis (*ANAPC1*, *CDK10*), and protein synthesis (*AARS*, *SMG7*). We combined homozygosity mapping with WGS to identify candidate ASD variants. Our data illuminate important biological pathways underlying ASD and emphasize the importance of leveraging shared ancestry to map disease variants in complex neurodevelopmental disorders.

## PgmNr 2153: The influence of common and rare variation on risk for autism spectrum disorders.

---

Heritability estimates for autism spectrum disorder (ASD) range between 64-91%, a substantial fraction of which is explained by common polygenic variation. Parent to child transmission of polygenic risk for ASD is highly complex, and may depend on factors such as cognition and sex of the affected individual. Here, we aim to understand common polygenic transmission in subgroups of individuals with ASD, and its affect on ASD heterogeneity.

Polygenic risk scores (PRS) for four traits (ASD, schizophrenia (SCZ), educational attainment (EA), and ADHD) were estimated for ASD probands and their unaffected parents in three independent cohorts – the Simons Simplex Collection (SSC, N=2580), Psychiatric Genomics Consortium (PGC)-AGRE (N=1478), and PGC-TASC (N=807). PRS were also calculated for unaffected siblings from the SSC cohort. We used the polygenic transmission disequilibrium test (pTDT) to examine the influence of each PRS in ASD cases. The difference between proband and average parent PRS scores was calculated for each affected child across the four traits, and split by sex and IQ. Overtransmission of a PRS is observed when the mean proband PRS exceeds the mean PRS of the probands' parents, and suggests that the common polygenic variation indexed by a PRS has contributed to risk of case status.

We found significant ( $p < 1 \times 10^{-7}$ ) overtransmission of common polygenic risk for ASD in all three cohorts, as previously reported. Consistent and significant overtransmission was also found for common polygenic risk for SCZ. For the first time, we found significant points of heterogeneity in common variant influence. In all cohorts, overtransmission of the ASD PRS to female probands was between 1.7- 2.0 times that of male probands, consistent with a female protective effect against ASD. While overtransmission of the EA PRS was highly significant in SSC ( $p = 1.84 \times 10^{-10}$ ) and PGC-TASC ( $p = 3.47 \times 10^{-7}$ ), there was no evidence of this in PGC-AGRE. Further analyses will be necessary to determine whether these between cohort effects could relate to AGRE being a multiplex cohort and SSC and TASC being simplex cohorts. Further, average polygenic influence differed by probands' mean level of cognition.

Addressing the heterogeneity of common polygenic risk for ASD will allow it to be used more profitably in downstream analyses. It will also highlight groups of ASD cases more etiologically similar, nominating potentially more homogeneous groups for treatment trials.

## PgmNr 2154: Affected sib-pair analyses identify signaling networks associated with social behavioral deficits in autism.

---

Autism spectrum disorders (ASDs) are characterized by deficits in three core behavioral domains: reciprocal social interactions, communication, and restricted interests and/or repetitive behaviors. Several hundreds of risk genes for autism have been identified, however, it remains a challenge to associate these genes with specific core behavioral deficits. In multiplex autism families, affected sibs often show significant differences in severity of individual core phenotypes. We hypothesize that a higher mutation burden contributes to a larger difference in the severity of specific core phenotypes between affected sibs. We tested this hypothesis on social behavioral deficits in autism. We sequenced synaptome genes (n=1,886) in affected male sib-pairs (n=274) in families from the Autism Genetics Research Exchange (AGRE) and identified rare (MAF $\leq$ 1%) and predicted functional variants. We selected affected sib-pairs with a large ( $\geq$ 10; n=92 pairs) or a small ( $\leq$ 4; n=108 pairs) difference in total cumulative Autism Diagnostic Interview-Revised (ADI-R) social scores (SOCT\_CS). We compared burdens of unshared variants present only in sibs with severe social deficits and found a higher burden in SOCT\_CS $\geq$ 10 compared to SOCT\_CS $\leq$ 4 (SOCT\_CS $\geq$ 10: 705.1 $\pm$ 16.2; SOCT\_CS $\leq$ 4, 668.3 $\pm$ 9.0;  $p=0.025$ ). Unshared SOCT\_CS $\geq$ 10 genes presented only in sibs with severe social deficits are significantly enriched in the SFARI gene set. Network analyses of these genes using InWeb\_IM, MSigDB, and GeNetMeta identified a significant enrichment for PI3K-AKT-mTOR (eScore P-value=3.36E-07; n=8 genes) and NGF (eScore P-value =8.94E-07; n=9 genes) networks. These studies support a key role for these signaling networks in social behavioral deficits and present a novel approach to associate risk genes and signaling networks with core behavioral domains in autism.

## PgmNr 2155: Phenotype-to-genotype approach reveals head-circumference-associated genes in a Chinese autism cohort.

### Authors:

**Background** The genotype-first approach has been successfully applied and has elucidated several subtypes of autism spectrum disorder (ASD). However, it requires very large cohorts because of the extensive genetic heterogeneity. We investigate the alternate possibility of whether phenotype-specific genes can be identified from a small group of patients with specific phenotype(s).

**Methods** To identify novel genes associated with ASD and abnormal head circumference using a phenotype-to-genotype approach, we performed whole-exome sequencing on 93 families with ASD and abnormal head circumference.

**Results** Clinically relevant pathogenic or likely pathogenic variants account for 25.4% of patients with microcephaly or macrocephaly, and 76.5% of those variants or genes are head-size associated. Significantly, recurrent pathogenic mutations were identified in two macrocephaly genes (*PTEN*, *CHD8*) in this small cohort. *GIGYF1* was implicated as a novel gene associated with the increased head circumference. *De novo* mutations in several candidate genes (*UBN2*, *BIRC6*, *SYNE1*, and *KCNMA1*) were detected, as well as two new candidate genes (*TNPO3*, *PPP2R2B*) implicated in ASD and related neurodevelopmental disorders.

**Conclusions** We identify genotype-phenotype correlations for head-size-associated ASD genes and novel candidate genes for further investigation. Our results also suggest a phenotype-to-genotype strategy would accelerate the elucidation of genotype-phenotype relationships for ASD by using phenotype-restricted cohorts.

Copy number variations (CNVs) are implicated across many neurodevelopmental disorders (NDDs) and contribute to their shared genetic etiology. Multiple studies have attempted to identify shared etiology among NDDs, but this is the first genome-wide CNV analysis across autism spectrum disorder (ASD), attention deficit hyperactivity disorder (ADHD), schizophrenia (SCZ), and obsessive-compulsive disorder (OCD) at once. Using microarray (Affymetrix CytoScan HD), we genotyped 2,691 subjects diagnosed with an NDD (204 SCZ, 1,838 ASD, 427 ADHD and 222 OCD) and 1,769 family members, mainly parents, from the province of Ontario, Canada. We identified rare CNVs, defined as those found in less than 0.1% of 10,851 population control samples. We found clinically relevant CNVs

(broadly defined) in 284 (10.5%) of total subjects including 22 (10.8%) among subjects with SCZ, 209 (11.4%) with ASD, 40 (9.4%) with ADHD, and 13 (5.6%) with OCD. Among all NDD subjects, we identified 17 (0.63%) with aneuploidies and 115 (4.3%) with known genomic disorder variants. We searched further for genes impacted by different CNVs in multiple disorders. Examples of NDD-associated genes linked across more than one disorder (listed in order of occurrence) are *NRXN1*, *SEH1L*, *LDLRAD4*, *GNAL*, *GNG13*, *MKRN1*, *DCTN2*, *KNDC1*, *PCMTD2*, *KIF5A*, *SYNM*, and long non-coding RNAs: *AK127244*, *NRON*, and *PTCHD1-AS*. We demonstrated that identical CNVs or genes could potentially contribute to the etiology of multiple NDDs. The CNVs identified will serve as a useful resource for both research and diagnostic laboratories for prioritization of variants and clinical interpretations.

## PgmNr 2157: Rare variants involved in risk of suicide death identified from targeted genome-wide array analysis.

Suicide kills >47,000 Americans annually, and rates have risen over 33% in the last decade. With estimated heritability at 50%, only a small fraction of the genetic variance contributing to risk of suicide death has been accounted for. Here we focus on the role of rare, functionally relevant, SNPs in suicide death using the large genetic resources available in the Utah Suicide Genetic Risk Study (USGRS). The USGRS has collected >6,000 de-identified DNA samples through a two-decade collaboration with the Utah Department of Health's centralized Office of the Medical Examiner. Genome-wide data from the Infinium PsychArray were available for >4,300 population-ascertained suicide deaths. Our study involved three stages. Stage 1: we performed a targeted discovery analysis of 30,377 rare PsychArray SNPs with potential functional gene consequences, in 2,672 USGRS suicides of non-Finnish European (NFE) ancestry and >50,000 NFE controls from gnomAD. Variants were selected for analysis if they passed rigorous QC filters and if variant annotation tools (SIFT, Polyphen, CADD) predicted that the variant has a high-impact effect on gene function. Allele frequencies were compared between cases and controls using Fisher's exact test (Bonferroni adjusted significance  $P < 1.69 \times 10^{-6}$ ). Stage 2: an analysis with stage 1 cases and independent controls was used to prioritize variants further. Stage 3: an analysis with 1,522 independent Utah suicide cases of mixed ancestry and 114,707 gnomAD mixed ancestry controls was performed. We identified nine novel, high-impact, rare SNPs with significant associations with suicide death in NFE individuals in both stage 1 and stage 2. These risk variants included loss-of-function variants in *LILRB1* and *PLEKHA4* and missense variants in *SNAPC1*, *TNKS1BP1*, *ADGRF5*, *PER1*, *ESS2*, *SLC25A41* and *SPRED1*. Both *PER1* and *SNAPC1* have other supporting gene level evidence of suicide risk. The SNP in *LILRB1* also replicated in our stage 3 mixed ancestry analysis. Rare variants identified from the PsychArray were validated in sequence data. Our study suggests an important role for rare variants in suicide risk. Furthermore, we highlight the utility of genotyping arrays in rare variant discovery.

## PgmNr 2158: Genetic variants within *HCRT1* are associated with nighttime eating behavior in Southwestern American Indians.

---

Night eating syndrome (NES) is an eating disorder whose prominent feature is excess food intake during the evening and night. Prior studies have suggested a heritable component for this disorder. Affected individuals are prone to weight gain; therefore, our study focused on identifying genetic determinants of nighttime eating (NE) behavior in American Indians who are at elevated risk for obesity. We performed whole-genome sequencing on 23 individuals with NE behavior and 27 controls, who were all from the same Southwestern American Indian community. These individuals had been clinically characterized over a 3-day period as inpatients in our Clinical Research Center, and NE status was determined based on the occurrence of food intake on any of the 3 nights between 11 pm and 5 am recorded by a computerized vending machine. Among sequence data from these individuals, 4.3 million high quality SNPs with minor allele frequencies  $\geq 0.05$  were detected. As expected with this small sample size, no variant achieved genome-wide significance for NE in a case/control analysis. Therefore, 24,125 SNPs with a nominal association with NE ( $P < 0.01$ ) were queried in the GIANT dataset ( $N \approx 235,000$  Europeans) for evidence of association with BMI. Eleven of these SNPs, which represented 2 linkage disequilibrium groups, were directionally associated with BMI in the GIANT dataset ( $P < 1 \times 10^{-4}$ , where the risk allele for NE associated with higher BMI), and all mapped to a 72 kb region on chromosome 1. Among them, 2 tag SNPs ( $r^2 = 0.46$ ) were further genotyped in an additional 32 American Indians informative for NE (13 cases and 19 controls) and 2,679 American Indians characterized for BMI. Both associated with NE in an expanded sample of 82 subjects (rs3753612:  $P = 1.5 \times 10^{-3}$ ; rs4949459:  $P = 2.7 \times 10^{-4}$ ) while only one, rs3753612 (C/G) also associated with BMI in the 2,679 American Indians ( $\beta = 0.017$ ;  $P = 7.8 \times 10^{-3}$ ). The G allele carriers were found to consume a significantly higher fraction of their total calories during nighttime ( $P = 0.013$ ). The rs3753612 variant is an eQTL for *HCRT1* (GTEx Portal), where the risk (G) allele for NE and higher BMI associated with increased *HCRT1* expression in the pituitary. *HCRT1* is involved in the regulation of sleep and food intake and is an excellent candidate gene for NE behaviour and possibly NES. We hypothesize that genetic variants in the *HCRT1* locus may lead to increased wakefulness and nocturnal eating in Southwestern American Indians.

## PgmNr 2159: Alcohol consumption and health outcomes: New evidence from Mendelian randomization of China.

Alcohol consumption has been shown to be associated with more than 60 diseases, and recent debates have challenged the conventional view that low-to-moderate alcohol drinking has a protective effect on health conditions. In this study, we investigate the causal influence of drinking behavior on various health outcomes by utilizing a Mendelian randomization (MR) on the genetic variation of aldehyde dehydrogenase 2 gene (*ALDH2*). The genetic basis of the MR approach relies upon the random allocation of genes at meiosis in humans, which likely resembles the random assignment into treatment groups in randomized controlled trials (RCT).

Through collaboration with WeGene, a leading personal genetics company in China, we conducted an online survey of alcohol drinking behavior to the participants with online consent since December 2018. The latest survey contained 1,534 respondents from mainland China with drinking behavior linked to genotyping data. A special variant of the *ALDH2* genotype that is common in Chinese (affecting about 35-45% of East Asians, but less than 1% of Caucasians) is known to cause the alcohol flushing response and adverse alcohol reaction (e.g. nausea, headache after drinking) due to decreased acetaldehyde metabolism, thereby plays a strong protective role against heavy drinking behavior and can be used as an instrumental variable (IV) to disentangle environmental confounders, which are otherwise very difficult to fully account for in observational studies.

Our results confirmed an adverse relationship between the presence of *ALDH2*\*2 allele (rs671) and general drinking frequency (-0.312,  $P < 0.01$ ), drinking times during the past 30 days (-1.903,  $P < 0.01$ ), binge drinking frequency (-0.968,  $P < 0.01$ ), as well as the maximum number of drinks consumed on a single occasion (-2.376,  $P < 0.01$ ). By using *ALDH2*\*2 allele as a genetic IV for drinking behavior, we found that higher alcohol consumption is causally associated with increased risks of chronic liver diseases ( $P < 0.1$ ). On the other hand, the IV point estimates of drinking behaviors on self-evaluated healthfulness, asthma, cancer, cardio cerebral diseases, diabetes, fatty liver, gout, and hypertension revealed no substantial associations. These findings were also robust with the pleiotropy-robust Mendelian randomization (PRMR) method. Our results highlighted the practicability of using genetic information to gain new insights into the long-term health outcomes of alcohol drinking behavior.

## PgmNr 2160: Mechanisms of parent-child transmission of tobacco and alcohol use with polygenic risk scores: Evidence for a genetic nurture effect.

### Authors:

G. Saunders; M. Liu; S. Vrieze; M. McGue; GWAS & Sequencing Consortium of Alcohol and Nicotine use (GSCAN)

[View Session](#) [Add to Schedule](#)

**Affiliation:** Department of Psychology, University of Minnesota, Minneapolis, MN.

---

Parent-child substance use similarity is a function both of genetic (transmitted alleles) and environmental transmission (e.g., modeling of parent behavior). An additional possibility is that alleles not transmitted to offspring may drive parental behavior, thereby affecting the rearing environment of the child. Measuring genetic risk for substance use directly, through polygenic risk scores (PRSs), provides a way to test for an effect of the non-transmitted parental genotype on offspring outcome, termed a “genetic nurture” effect. In the current study we 1) evaluate the accuracy of tobacco and alcohol polygenic scores across developmental age and parent vs. offspring generation and 2) use these PRSs to test for a genetic nurture effect in a longitudinal, parent-offspring sample. Polygenic risk scores, with weights derived from the GWAS & Sequencing Consortium of Alcohol and Nicotine use, for smoking initiation ( $N = 1,232,091$ ), cigarettes per day ( $N = 337,334$ ), and drinks per week ( $N = 941,280$ ), were used to predict alcohol and tobacco consumption in a sample of 3,012 twins, assessed prospectively from age 17 to age 29, from the Minnesota Center for Twin and Family Research. Mixed effects models were used to test for a genetic nurture effect whereby parental PRSs predict offspring substance use after controlling for offspring’s own PRS. We find within-substance predictive accuracy of all polygenic scores (pseudo- $R^2$  ranging from 2.3%-4.1%) and cross-substance prediction for SI scores (pseudo- $R^2 = 2.2\%-3.6\%$ ). The predictive accuracy of scores remains relatively stable across adolescence and young adulthood, as well as over generation (parent vs. offspring). Parental smoking initiation PRS predicts offspring cigarettes per day at ages 17 and 24, and alcohol use at age 17, independent of shared genetics, consistent with a genetic nurture effect of parental smoking on adolescent tobacco and alcohol consumption. The parental effect attenuates to near zero after additionally controlling for parental education and occupation. Using genetic analysis tools, we find evidence of a genetic nurture effect on offspring tobacco and alcohol use in late adolescence and early adulthood. The parental genotype effect, through non-transmitted PRSs, is environmentally mediated by parental educational attainment and occupational status, suggesting a potentially causal environmental effect of rearing socioeconomic status on offspring substance use in late adolescence.

## PgmNr 2161: Investigation of the genetic modifiers of smoking-related environmental risks.

### Authors:

---

Smoking is considered to be the leading cause of preventable death in the United States. It has been strongly linked to the development of a variety of diseases, including heart disease, stroke, and cancer. However, there are populations of smokers, however, who do not develop such diseases. We hypothesize that individuals may contain genetic variants which modify the risk associated with smoking for the development of these diseases.

To investigate this hypothesis, we utilized the UK Biobank, a large biorepository containing phenotypic and genotypic data from ~ 500,000 individuals. We identified individuals with a history of cancers associated with smoking (lung, pharyngeal, stomach, bladder, etc.), heart disease, and stroke. The number of cigarettes per day (CPD) they smoked was used as a measure of smoking intensity. We seek to study the potential interactions between genetics and CPD, as a way to identify genetic modifiers for individuals with exposures to environmental risk factors. We performed logistic regression with the disease status as the response variable, CPD, genetic variants, the interaction term between CPD and genetic variants, age, sex, and ancestry measures as the predictors. To improve the robustness of the results in the presence of measurement errors for the environmental exposure, we utilized a sandwich-type estimator. The improved estimator yielded well-calibrated type I errors, while the standard score statistics from logistic regression produced many seemingly spurious associations.

Our results have identified genes which may modify smoking-related disease risk, such as: XKR4, a caspase-activated scramblase important for autophagy; DAPP1, a phospholipid binding protein; and PCDH20, an extracellular matrix protein in the brain. These genes modify the risk of cancer, heart disease, and stroke, respectively. Identified genes will be further analyzed to determine the most likely variants to cause such interaction effects. Our findings support the trend within the medical community toward personalized medicine, improving understanding of the variance of diseases within smoking populations. Such findings may provide insights into the etiology of these diseases, thereby identifying new therapeutic avenues for prevention.

## PgmNr 2162: Examining pleiotropic factors that jointly contribute to anxiety and depressive phenotypes in the UK biobank data.

### Authors:

B. Verhulst <sup>1</sup>; J. Hettema <sup>3</sup>; J. Pritikin <sup>2</sup>; M. Neale <sup>2</sup>; S. Clark <sup>1</sup>

---

Comorbidity between anxiety and depressive traits is substantial (Kessler et al. 2005; CDG-PGC, 2013), implying pleiotropic genetic factors may be shared between the phenotypes. To understand the both the comorbidity and the pleiotropy, we must explicitly model the correlation between the two phenotypes when testing association between a SNP and either comorbid phenotype. This type of analysis cannot be directly specified in current GWA methods as it requires a GWAS method that directly uses structural equation modeling (SEM). Accordingly, we will use GW-SEM (Verhulst et al. 2017) to estimate a two-factor latent variable model where both the anxiety and depression factors are simultaneously regressed on to each SNP, while accounting for the correlation.

We will use data from the UK biobank study to examine the comorbidity and pleiotropy for anxiety and depressive phenotypes (N ~ 375,000). In contrast with alternative GWAS methods that rely on listwise deletion and thus complete phenotypic data, the GW-SEM internally accounts for missing data. The anxiety factor will be assessed with 5 items that examine the individual's recent feelings of "annoyance or irritability", "nervousness or anxiety", "concentration", "foreboding", and "inability to stop or control worrying". The depression factor will be assessed with 4 items that assess the individual's feelings of "sadness/depression", "un-enthusiasm/disinterest", "tenseness/restlessness", and "tiredness/lethargy." Because we explicitly account for the correlation between the latent factors, it is possible to distinguish whether the SNP association contributes to the comorbidity between traits by examining the associations of each phenotype with the SNP and the change in the correlation between the phenotypes controlling for the SNP. The results for this study will be particularly useful for a more complete understanding of the comorbidity between internalizing phenotypes.

## PgmNr 2163: Prenatal alcohol exposure increases risk for ADHD after accounting for genetic liability.

**INTRODUCTION:** Attention deficit hyperactivity disorder (ADHD) is a common, heritable disorder with high prevalence rates in children of alcoholics and in children with prenatal alcohol exposure (PAE). An often overlooked issue in research is the compounded risk due to the likelihood that mothers who are alcohol dependent are more likely to drink during pregnancy (and risk of prenatal alcohol exposure is increased in alcohol dependent mothers). Polygenic risk scores (PRS) for ADHD were computed using summary data from the Psychiatric Genomics Consortium (PGC) in: (1) offspring in the Collaborative Studies on the Genetics of Alcoholism (COGA, N=1,498), and (2) participants in the Collaborative Initiative on Fetal Alcohol Spectrum Disorders (CIFASD, N=366). Parental ADHD and alcohol dependence were collected as part of COGA but were not available in CIFASD.

**METHODS:** Probability of being ADHD was examined, and significant covariates were identified separately in COGA and CIFASD data. PAE was included in all analyses (COGA: # drinks during the entire pregnancy; CIFASD: heavy vs minimal/none). COGA analyses included maternal alcohol dependence (mom-AD) and mom-AD\*PAE. Family history of alcohol dependence (FHAD = yes/no) was used in CIFASD. Maternal (mom-ADHD) and paternal ADHD (dad-ADHD) were included to assess which (or both) predicted ADHD in the offspring. PRS were included in both datasets to account for genetic liability in the absence of parental diagnosis.

### RESULTS:

COGA: Dad-ADHD increased risk of ADHD, independent of PAE ( $p < 0.0001$ ). There was an increased risk if mom-AD=yes ( $p = 0.0065$ ), which increased with higher levels of PAE (PAE\*mom-AD  $p = 0.07$ ). PRS increased risk if dad-ADHD=no. If dad-ADHD=yes, the PRS increased the risk of ADHD in individuals with low levels of PAE (# drinks < 76), which was reduced at high levels of PAE (# drinks > 266).

CIFASD: Having a FHAD increased risk for ADHD ( $p = 0.045$ ). PRS ( $p = 0.088$ ) and PAE\*PRS ( $p = 0.068$ ) modestly increased the risk for ADHD. PRS increased risk for ADHD if there was no PAE, but had minimal effect on individuals with PAE.

**CONCLUSION:** In the absence of PAE: PRS, dad-ADHD and mom-AD contributed to risk for ADHD. With PAE, genetic contribution was diminished and risk associated with PAE increased. These results indicate potentially different etiologies of ADHD in individuals with and without PAE.

---

Over the last decade, genome wide association studies (GWAS) of increasing sample sizes have associated many loci to schizophrenia, with the largest study to date having found 145 loci passing genome wide significance. To better understand the etiology of this complex trait, several omics resources were recently generated. Gene expression data in large cohorts of post-mortem brain allowed generation of expression quantitative trait loci (eQTL) libraries and differential expression signatures, leading to fine-mapping for some of these loci; ChipSeq and Hi-C data have started to address epigenetic control and three dimensional (3D) structure of chromatin; and further fine-mapping is being done using gene expression imputation methods from large GWAS datasets. While these efforts have provided many results implicating central nervous system development and the immune system as components of the disease, causal chains defining disease mechanisms remain to be established.

To interpret GWAS results in the broader context of the network of gene expression and 3D structure of the genome, we used Bayesian regulatory networks (BN) to integrate genetic and gene expression datasets from two large cohorts of post-mortem samples with or without schizophrenia (Common Mind Consortium data, N = 594 and Human Brain Collection Core data, N = 386). This enabled us to model causal interactions between genes, as well as the genetic control of their expression by incorporating eQTLs and GWAS loci. To gain power to identify disease signatures, we used schizophrenia diagnosis as well as schizophrenia polygenic risk score as a continuous trait in our differential expression analyses. To focus our networks on disease-relevant signals, we used co-expression network analyses and identified modules enriched for differential expression and GWAS signatures to generate a list of input genes into our BN models. We took advantage of our flexible framework to integrate information from prior studies, including chromosome conformation capture derived topologically associated domains, to define genes and locus interactions as structure priors boosting power to infer causal relationships and increase network model accuracy. This enabled us to identify master regulators of disease signatures and of genetic loci associated to disease, and prioritize potential mechanisms of action and therapeutic targets for schizophrenia.

## PgmNr 2165: Identification of *de novo* mutations and structural variants in brain development-associated genes in Chinese schizophrenia families.

---

Schizophrenia (SCZ) is a severe psychiatric disorder with a strong genetic component. It is associated with a marked reduction in fecundity, leading to the hypothesis that alleles with large effects on risk might often occur *de novo*. In this study, eight families from Taiwan, with whole-genome-sequenced SCZ-free parents, SCZ patient(s) and family-matched healthy sibling(s) and four to six family members each, were kept after kinship analysis. To reliably identify *de novo* mutations and structural variants, only *de novo* events consistently called by multiple independent software tools were retained in downstream analyses. *De novo* mutations (DNM) were confirmed by checking with Integrative Genomics Viewer and *de novo* structural variants with LowResBam2Raster visually. DNM rate per nucleotide per year was consistent with previous studies. Two stop-gain loss-of-function DNMs in genes *GJC1* and *HIST1H2AD* were identified in SCZ patients. No loss-of-function DNM was identified in healthy siblings. Because of limited occurrence of *de novo* structural variant (DNSV), only DNSVs occurred multiple times in SCZ patients but not in healthy siblings were considered detrimental DNSVs. One *de novo* deletion covering the gene *SKA3* was found in two SCZ patients but not in the matched healthy sibling in the same family. To explore if the *de novo*-implicated genes *GJC1*, *HIST1H2AD* and *SKA3* were involved in brain development, the expression data from prefrontal cortex (PFC), the most affected cerebral cortical region in SCZ, from BrainCloud (n = 269) were leveraged. We found the expression of the three genes was significantly higher in prenatal than in postnatal stages ( $P = 1.92 \times 10^{-21}$  for *GJC1*,  $P = 6.02 \times 10^{-18}$  for *HIST1H2AD* and  $P = 3.30 \times 10^{-20}$  for *SKA3*). The involvements of the three genes in brain developments were preserved across multiple cortical regions and conserved across species. To explore the functions of *de novo*-implicated genes in brain, we performed enrichment analyses by leveraging the genes coexpressed with the *de novo* target in PFC. Interestingly, the *GJC1*-coexpressed genes were found to be involved in SCZ-associated pathways and drug targets. Furthermore, the *de novo*-implicated genes were within or close to the loci enriched with GWAS signals ( $P < 1 \times 10^{-5}$ ) of SCZ, intelligence, cognitive performance and educational attainment. Our results revealed potential *de novo* mutations and structural variants in Asian population with the potential risk to schizophrenia.

## PgmNr 2166: Identification of candidate genes for alcohol use disorder by gene set enrichment and pathway analyses of RNA-seq data.

---

Alcohol use disorder (AUD) is a chronic psychiatric disease with a complex genetic etiology. AUD is characterized by compulsive drinking patterns that lead to damaging consequences. Excessive alcohol consumption in the form of binge drinking is common among adolescents and young adults and is associated with an increased risk of developing AUD. Using a rodent model of binge drinking (adolescent intermittent ethanol (AIE)), we identified candidate genes and pathways that may contribute to long-term changes in brain function and the development AUD. We analyzed RNA-seq data from Sprague Dawley rats (*Rattus norvegicus*) to investigate temporal variations in hippocampal gene expression. At postnatal day (PND) 30 (adolescence), rats received chronic intermittent ethanol (5g/kg intragastrically (i.g.) 10 times across 16 days). Hippocampal tissue was collected at three time points: 1) 24 hours after 4th dose (PND35), 2) 24 hours after last dose (PND46), and 3) 24 days after last dose (PND70; adult). We processed the RNA-seq data using TrimGalore and compiled gene counts using HTSeq. We employed the R/Bioconductor package DESeq2 for differential expression analysis. We performed gene set enrichment analysis (GSEA) to identify differentially regulated pathways and gene ontology terms for various comparisons based on ethanol exposure and the three time points. At PND35, genes and pathways encoding negative regulators of cellular component organization and metallopeptidases, and those involved in mitochondrial function were identified as enriched. At PND46, ethanol exposed rats showed enrichment for genes encoding potassium channels, synaptic transmission, and synaptic organization. Interestingly, immune response genes were downregulated. At PND70, ethanol exposed rats showed highly enriched gene sets involved in cytoskeletal remodeling. These results provide detailed insight into how hippocampal gene expression changes during development and in response to AIE. To identify subnetworks of genes enriched by higher interaction, we used the Markov CLustering Algorithm (MCL) as implemented by the clusterMaker app of the Cytoscape pathway analysis package on the differential expression data. We compare and contrast the results and identify genes enriched in both analyses, which may facilitate determination of the underlying mechanism for acute and long-term effects of AIE exposure that increase risk of developing AUD.

## PgmNr 2167: A trans-ethnic two-stage polygenetic scoring analysis detects genetic correlation between osteoporosis and schizophrenia.

---

The patients with schizophrenia (SCZ) have increased risk of osteoporosis. The biological mechanism remains elusive now. Our study aim to explore the genetic correlation between SCZ and osteoporosis. We conducted a trans-ethnic two-stage genetic correlation analysis of osteoporosis and SCZ, totally invoking 2,286 Caucasians subjects in discovery stage and 4124 Chinese subjects in replication stage. The BMD and bone area values of ulna & radius, hip and spine were measured using Hologic 4500W dual energy X-ray absorptiometry machine. SCZ was diagnosed according to DSM-IV criteria. Genotyping was conducted using Affymetrix SNP 6.0 array. Polygenetic risk scoring analysis was conducted by PRSice software. Multi-trait analysis of GWAS (MTAG) was performed to detect novel candidate genes for osteoporosis and SCZ. In the Caucasians discovery samples, significant genetic correlations were observed for ulna & radius BMD vs. SCZ ( $P$  value = 0.010), ulna & radius area vs. SCZ ( $P$  value = 0.031). In the Chinese replication samples, we observed significant correlation for ulna & radius area vs. SCZ ( $P$  value = 0.019). MTAG analysis identified several novel candidate genes, such as CTNNA2 (MTAG  $P$  value =  $2.24 \times 10^{-6}$ ) for SCZ and FADS2 (MTAG  $P$  value =  $2.66 \times 10^{-7}$ ) for osteoporosis. Our study results support the overlapped genetic basis for osteoporosis and SCZ, and provide novel clues for elucidating the biological mechanism of increased osteoporosis risk in SCZ patients.

## PgmNr 2168: Protective effects of N-acetylorlithine on psychiatric and neurocognitive traits.

Brain disorders with extensive categories exhibit similar symptoms and share common genetic underpinnings, however, their shared biological processes remain largely unknown. Blood metabolites, which are known as functional intermediate phenotypes and capture genetic heritable traits, can be potentially used to uncover the etiology influencing brain disorders. Here, we examined the potential causal effects of 363 blood metabolites on 44 brain related traits (11 psychiatric disorders, 12 neurological disorders, 7 brain structures and 14 neurocognitive quantitative phenotypes) by using the three module of Mendelian Randomization (MR) methods: (i) The GSMR as the primary approach was performed with summary-level data from genome-wide association studies, (ii) the summary data-based MR approaches were applied for complement that comprising inverse variance-weighted (IVW) method, weighted median method, and MR-Egger, and (iii) confirmed the significant results using polygenic risk score (PRS) prediction with individual genotype data. Converging evidence showed that some metabolic exposures were causally associated with psychiatric and neurocognitive outcomes, whereas none causation appeared on neurological disorders. N-acetylorlithine, an endogenous metabolite of ornithine to participate in arginine-proline metabolism, was the most significant metabolite which had a protective effect against schizophrenia ( $P = 3.74 \times 10^{-10}$ ) with a 27% decrease in risk and 6% positively increase in intelligence ( $P = 2.48 \times 10^{-6}$ ) after adjustment of multiple testing. Further, we conducted morphology statistics of fluorescence microscopy from N-acetylorlithine supplementation in neonatal mouse cortical primary culture experiments, which indicated that N-acetylorlithine promoted neuronal differentiation with longer neurite length, more dendrite branches, higher density of spines and higher cell viability. To explore the potential molecular mechanism of N-acetylorlithine on neurodevelopment, we conducted Bayesian fine-mapping method to identify 39 causal SNPs and 3 of the 15 putative effector genes (EXOC6B, NOTO and DCTN1) that potentially act as neuron-related functional genes for N-acetylorlithine via integrating gene mapping and animal-model strategies. Our results highlight the importance of N-acetylorlithine as a predicted biomarker for brain neurodevelopmental related traits and provide a novel insight into mechanisms by which metabolites affect brain disorders.

## PgmNr 2169: Novel mutation in PPEF2 reported in a family affected with schizophrenia: Whole genome sequencing study.

Schizophrenia is a complex genetic disorder with a multifactorial mode of inheritance that affects about 1% of the population. Genetic studies have implicated many different genes and pathways, but much of the genetic liability is still unaccounted for. Nonetheless, leading theories of the pathophysiology of schizophrenia include the glutamate and dopamine pathways. We performed whole genome sequencing analysis of 7 individuals diagnosed with schizophrenia and 1000 controls.

We report a novel rare stopgain in PPEF2 in a family with 3 affected individuals. The LOF PPEF2:NM\_006239:exon3:c.G135A:p.W45X has a MAF of 2.83E-05 in EXAC and has a CADD score of 37, (~1/30000 carrier).

Intriguingly, all 3 affected individuals in this pedigree share a stopgain variant in PPEF2. PPEF2 encodes a neuronally expressed protein phosphatase that binds calmodulin furthermore influencing mGluR5 levels. Specifically, it has been previously shown that HEK293 cells transfected with *PPEF2* demonstrated increased levels of mGluR5 in the presence of the mGluR5 agonist suggesting that disturbance of *PPEF2* could lower mGluR5 membrane levels. Previously a missense substitution in this gene was reported for a single affected family.

The three affected individuals are all men and developed schizophrenia early on at 9, 11, and 17 years of age. The strong genetic predisposition for schizophrenia can be seen in the early-onset of the disorder. In fact, two out of three developed schizophrenia before age 13, which it is extremely rare, with a prevalence rate of approximately 1/10,000.

Whole genome sequencing delineated a novel deleterious variant in *PPEF2* as a likely genetic risk factor for schizophrenia. Furthermore, additional genomic screens that stratify patients based on the affected genetic pathways may better guide the most effective treatments.

## PgmNr 2170: Molecular characterization of postpartum depression using genomic, methylomic, transcriptomic, and endocrine data.

---

**INTRODUCTION:** Postpartum depression (PPD) is a severe perinatal form of major depressive disorder. It is one of the most frequent complications of childbirth (prevalence 10-15%) and leading cause of maternal death due to suicide. PPD is an under-studied health concern and its biological underpinnings are not well understood.

**METHOD:** We recruited 1,517 ancestrally diverse women (549 cases, 968 controls) at six weeks postpartum. PPD status was determined using diagnostic interview. Levels of estradiol (E2), progesterone (P4), BDNF, and oxytocin (Oxt) were assayed in serum/plasma. DNA and RNA from whole blood was used to generate data with three omic platforms. Genotyping was done on the Illumina Multi-Ethnic Genotyping Array which, after imputation and quality control (QC), left 12.5 million SNPs. DNA methylation was measured using the Illumina 450k array. A new QC pipeline was developed to prevent test static inflation across 374K CpGs. RNA-seq reads were annotated using ENSEMBL Release 92 resulting in 108,474 transcripts for association testing. Cell proportions were derived using methylation references and complete blood counts. Cell type proportion allowed for association tests within constituent populations of T-cells/B-cells/monocytes/granulocytes. Associations were determined for the outcomes case status and its interaction with assayed hormones. Analyses were performed in RAMWAS.

**RESULTS:** Associations with PPD were seen across platforms ( $P < 5e-08$ ), notably within CD8T, CD4T, and B cell populations and interaction analyses of PPD and P4. Top genotype signals showed significant overlap with both the top methylation and transcription findings (P range: 0.02-6.00E-04), and that the top methylation findings showed significant overlap with the gene expression findings (P range: 0.01-6.86E-03). Pathway analyses suggest processes linked to dysregulation of gene expression. Lastly, we used a machine learning algorithm with 10-fold cross validation to condense all association information for bulk and the cell types into a single risk score for each outcome tested. When combined, these risk scores correlate 0.3 with case status with the main predictors being methylation and gene expression in bulk.

**DISCUSSION:** Convergent evidence across three omic platforms suggests differential responses to hormones, namely P4, characterizes PPD. Biomarker risk scores suggest methylation and expression data can be used along with clinical data to better anticipate PPD onset.

## PgmNr 2171: GWAS for handedness indexes: Support a role of microtubule in brain asymmetries and neurodevelopmental disorders.

### Authors:

[View Session](#) [Add to Schedule](#)

**Affiliation:** School of Medicine, University of St Andrews, St Andrews, Fife, United Kingdom

---

**Background:** Worldwide, ~10% of individuals are left-handed with twin studies showing a 25% heritability. Increase of non-right handedness frequency has been reported in neurodevelopmental conditions including dyslexia and schizophrenia. These findings highlight the potential to use behavioural lateralised traits to investigate neurodevelopmental disorders. To date, very few genes have been associated with hand skill (*PCSK6*) or hand preference (*MAP2*, *MAPT*, *TUBB*), with the latter genes being linked to brain disorders and microtubule-related processes.

**Methods:** Here we performed and compare GWAS analyses of four quantitative handedness measures and we perform the first GWAS of foot and eye preference. All analyses were performed in SNPTEST while functional mapping on FUMA. Genetic correlations and SNP heritability were computed with LDSC and PRS for neurodevelopmental disorders were performed with PRSice.

**Results:** With a sample size of ~ 8,000 children, we did not find genome-wide significant hits. However, SNPs in the proximity to genes being associated with neurodevelopmental disorders (Schizophrenia, Usher, Autism), microtubule functions and axonal growth were highlighted. Pathway-analyses shows enrichment of inflammatory pathways, while locomotory behaviour and neuronal-related pathways have been highlighted.

**Discussion:** Handedness is highly influenced by social factors which, together with the heterogeneity of phenotypes in the literature, hinder genetic analysis. The behavioural correlation across the handedness traits is low, suggesting that the tests explore different cognitive skills, and this is reflected by different genetic profiles. The markers highlighted in the current study strengthen the current understanding that behavioural laterality, brain asymmetries and neurodevelopmental disorders are linked. Top hits close to genes involved in tubulin and cytoskeleton are present, in line with the literature. Despite the modest sample size, these findings highlight the importance of the phenotype definition, including for a trait like handedness intuitively straightforward

## PgmNr 2172: Gene ontology derived candidate gene analysis for reading disability.

---

While prior studies have demonstrated high heritability for reading disability (RD), commonly called dyslexia, small sample sizes have hindered identification of associated genes and variants. To balance limited sample sizes with our goal to discover novel genes, candidate genes for RD were selected based on connection to gene ontology (GO) terms. The primary sample was drawn from the Genes, Reading, and Dyslexia study (GRaD), a cohort of 1,331 Hispanic American and African American children 9 – 14 years of age. GRaD combines a comprehensive battery of reading and language measures, as well as genotyping with over 2,300,000 SNPs on the Illumina HumanOmni 2.5 array. We chose a highly-vetted endophenotype for reading and language disorders called Rapid Automatized Naming of objects (RAN objects), which taps into underlying cognitive processing speed and recently produced genome-wide significant results in GRaD (Truong et al. 2019). Subjects were separated into ancestry groups according to clustering with 1000 Genomes Project AMR superpopulation and ASW population. For the primary analysis in 865 GRaD Hispanic subjects, SNP variants were assigned to genes identified with GO terms, and gene-wise association determined with MAGMA applied to RAN-objects performance, controlling for sex, a SES composite measure derived from participation in social assistance programs, 2 ancestry derived PCs, subject age at testing, and highest year of education for the primary caretaker. *RUNX1* showed a suggestive p-value of  $4.9 \times 10^{-5}$ , though this p-value did not meet the Bonferroni adjusted threshold of  $2 \times 10^{-5}$ . *RUNX1* is a transcription factor associated with early neural development. This gene has previously not been associated with RD, supporting the value of this approach in connecting new genes to RD. While no single gene achieved statistical significance when correcting for multiple testing, the top 10 genes from the primary GRaD analysis were selected for replication in the Hispanic subset of the New Haven Lexinome Project, a longitudinal cohort of 360 (to date) students in the New Haven Public School District. Replication results and analysis of the African American subset of both datasets are forthcoming.

## PgmNr 2173: Contribution of polygenic risk score for psychiatric disorders in consanguineous Pakistani pedigrees.

---

**Introduction:** Large-scale genome-wide association studies (GWAS) in Caucasian case-control cohorts have shown that schizophrenia (SCZ) and bipolar disorder (BPD) are highly polygenic in nature and numerous loci with small effects may contribute to these mental disorders. Polygenic risk scores (PRS), which aggregate the effects of variants across the genome at various thresholds, have been used to estimate heritability, to infer genetic overlap between traits and to predict phenotypes based on the genetic profile in additional samples. In this study, we aimed to estimate the contribution of PRSs from the GWASs of Caucasian samples in large consanguineous Pakistani pedigrees with SCZ and BPD.

**Samples and Methods:** 124 cases (SCZ or BPD) and 151 controls from ten large consanguineous pedigrees plus 34 unrelated healthy individuals, recruited from Sindh Province of Pakistan, were genotyped by Illumina Human OmniExpress Bead Chip. The summary statistics from the latest Psychiatric Genomics Consortium SCZ and BPD GWAS studies were used, and markers were pruned in each dataset with p-value-informed LD clumping (using LD pruning parameters of  $r^2=0.1$  over 500 kb windows) and collapsed to the most significant marker. After standard QC and imputation on the Pakistani family genotype data, PRS was calculated using PRSice-2 software, including all genetic variants with minor allele frequency  $\geq 5\%$ .

**Results:** Preliminary results showed that PRS generated from the PGC SCZ and BPD GWAS datasets were able to explain a maximum variance in our Pakistani family dataset at the p-value significance threshold of  $5e-08$  and  $0.1$ , respectively. Estimating the respective heritability and exploring PRS from GWAS summary statistics of other related psychiatric phenotypes in our family dataset are underway.

## PgmNr 2174: The genetics of addiction in a large Northern Nevada cohort of the Healthy Nevada Project.

---

Addiction, particularly to opioids, has reached epidemic levels in the U.S. By merging the genetics of a large population with comprehensive Electronic Health Records (EHR), socio-economic, geographic, and environmental data, the Healthy Nevada Project (HNP) aims to identify disease associations specific to local communities. Here we use Helix Exome+ sequencing of 20,000 HNP participants to examine genetic and phenotypic associations of substance addiction. The current control cohort contains 650 participants carefully selected as users of opiates, other illicit drugs, or alcohol, but who do not exhibit dependence or addiction. The case cohort consists of 1,000 participants with at least one addiction diagnosis in the last 12 years. A genome-wide association study (GWAS) was performed across cohorts using 2.5 million high-quality variant calls (GQ>20) obtained after applying additional thresholds (90% SNP call rates, 85% individual call rates, Hardy-Weinberg  $p > 1 \times 10^{-6}$ ). PLINK v. 1.9 performed logistic associations with age, gender, and principal components to control for population stratification as covariates, and the standard log-additive genetic model. Two phenome-wide analyses (PheWAS) were performed: the first PheWAS examined associations between significant SNPs identified in the GWAS and EHR phenotypes based on ICD codes; the second identified associations between incidence of addiction and ICD-based diagnoses. Of the 10 strongest associated SNPs ( $p < 1 \times 10^{-5}$ ), four are in genes reported in prior genetic studies of addiction. Two genes, *ITPR2* and *GABBR2*, have functional relevance in opioid, cocaine, alcohol and nicotine addiction pathways. A third association in the HNP cohort lies in *ITGA9*, a gene down-regulated in long-term oxycodone use in mice and linked to human drug abuse. A fourth variant identified is in *PARK2*, a gene often linked to Parkinson's Disease, supporting the notion that the molecular mechanisms of neurodegeneration of the two disorders are similar. The strongest association in our cohort is a variant in the geneless region 20q11.2 not yet affiliated to addiction. PheWAS results show strong clinical links with addiction: tobacco use disorder ( $p < 1 \times 10^{-55}$ ), mood disorders, depression, and anxiety ( $p < 1 \times 10^{-10}$ ). SNPs associated with addiction in the HNP are linked to alcoholism, tobacco use disorder, emphysema, and lupus. This study shows prior identified and possible novel genomic associations with substance addiction in a large HNP cohort.

## PgmNr 2175: Applying reverse linkage as a method in 1,589 Finnish migraine families.

---

Migraine affects up to 15% of the population and is shown to have a heritability of up to 57% (PMID:14624726). In addition to the 38 common loci published in a genome-wide association meta-analysis (PMID:27322543), rare variants may provide a deeper understanding of underlying etiology of migraine. Previous linkage studies on rare hemiplegic migraines have identified variants in *CACNA1A*, *SCN1A*, and *ATP1A2*: however, the role of these genes in common forms of migraine has not been established. Rare variants are more enriched in isolate populations e.g. Finland. Hence, we hypothesize increased chances in identifying rare variants by studying large Finnish migraine families. In traditional linkage analysis, all families are analyzed together by summing LOD (logarithm-of-odds) scores across families in a given locus. A signal from a highly penetrant rare variant which appears in a subset of families may be missed, resulting in a loss of power to detect linkage. We propose to define a quantitative method by integrating linkage analysis and whole genome sequencing (WGS) data -- the reverse-linkage method. First, we joint called WGS data from 631 migraineurs: 184 index patients and 447 family members. We applied a strict QC criteria and annotated the filtered variants. Variant and family selection were based on the index patients with the assumption that variants identified would segregate in respective families. We filtered for variants which were shared in  $\geq 2$  families, rare, and damaging variants: missense ( $\text{gnomAD}_{\text{FIN}} < 0.05$ ,  $\text{CADD} > 10$ ) and loss-of-function (LOF) variants. Our QC and filtering resulted in 7836429 variants: 12966 missense and 745 LOF variants. Upon comparing damaging:synonymous variants ratio, results indicate a low damaging load (1:1.2). Subsequently, we ran parametric linkage analyses on markers near the variants identified in the WGS using the migraine collection of 8,319 Finns in 1,589 families. The resulting partial LOD scores for families carrying the proxy marker were then used for computing sum-of-LODs ( $\text{LOD}_v$ ). With a filter of  $\text{LOD}_v > 2.0$ , we identified 6 variants. These variants were investigated for possible phenotype etiological association in 96,499 Finns (FINNGEN project) against 1,122 phenotypes constructed from registry data. The results showed that the 6 variants identified were of low effect sizes ( $p > 10^{-4}$ )

towards constructed phenotypes. Our results suggest that highly penetrant variants are not major genetic contributors to migraine.

## PgmNr 2176: Case-only exome analysis of severe alcohol dependence using a multivariate hierarchical gene clustering approach.

Background: Variation in genes involved in ethanol metabolism has been shown to influence risk for alcohol dependence (AD) including the inactivating rs671 in *ALDH2*; rs671 heterozygotes show only 20-40% of wild type enzymatic activity due to the homotetrameric structure of mature ALDH2. When ethanol is consumed, the reduced enzymatic activity leads to the accumulation of acetaldehyde, the first product of ethanol catabolism, and unpleasant symptoms including flushing. This variant is common in east Asian populations and associated with lower rates of alcohol abuse/dependence. Given the existence of protective loss of function alleles in ethanol metabolizing genes, we hypothesized that people with severe alcoholism would have less rare functional variation than expected.

Objective: Test this hypothesis using a case only design and Whole Exome Sequencing (WES) data from a collection of 195 severe alcoholic cases from Ireland.

Methods: A novel case only analysis method to compare sets of hypothesized candidate genes to matched sets of controls genes was developed and applied. Briefly, multivariate hierarchical clustering was used to match genes of interest (GOI) with sets of control genes using gene-level summary features obtained from the gnomAD database. After identifying sets of control genes for each GOI, multivariable logistic regression was used to test if GOI were different from control genes for the number of synonymous, missense, and LOF variants. This approach was applied to two separate gene sets, first using 15 *ADH* and *ALDH* alcohol-metabolizing genes and second using a published set of 357 genes (including the 15 from the previous set) shown to alter ethanol response in invertebrate models.

Results: Results from the analyses of the first set of 15 genes showed no significant difference in number of synonymous, missense, or LOF variants between GOI and control genes while analysis of the second, larger set of genes found slightly elevated counts of synonymous variants in alcohol-related genes of interest as compared to control genes. With this analysis, we have demonstrated a viable, computationally and statistically reasonable approach for genetic analyses of case-only data.

## PgmNr 2177: Transcriptomic signature of the 16p11.2 duplication in cultured neurons and brain.

---

The 650 kb duplication copy number variant (CNV) on chromosome 16p11.2 confers substantial risk for autism, schizophrenia, bipolar, and other neuropsychiatric disorders, but little is known about how resulting differences in gene dosage lead to pathogenic changes in the transcriptome, function, or structure of the developing brain. We have ascertained a proband with schizoaffective bipolar disorder who was found to carry the 16p11.2 duplication after SNP array analysis of DNA extracted from peripheral blood. Digital droplet PCR of fibroblasts obtained from the proband and 5 available relatives confirmed the duplication and revealed 2 additional carriers, along with 3 non-carriers. Fibroblasts were reprogrammed into induced pluripotent stem cells (iPSC) with a Lentivirus vector, then differentiated into neurons by use of published protocols. Neuronal identity was established through immunostaining and morphology. After 6 -7 wk of neuronal differentiation, high-quality RNA was depleted of ribosomal RNA (Ribo-Zero Gold) and used to prepare stranded libraries that were pair-end sequenced on the Illumina NovaSeq 6000. A total of 100 million reads per sample were mapped to 26,363 Ensemble genes. Differential gene expression between carriers and non-carriers was analyzed with DESeq2. As expected, many (14/27) genes within the duplicated region showed increased expression, with mean fold-change values of 1.5-2.5. Genome-wide, 152 genes were differentially expressed (DE) at FDR<5%. DE genes were enriched for pathways involved in neuronal development and migration, synaptic transmission, and neurite growth. Consistent with these results, 7-8 wk neuronal cultures from 16p11.2 carriers showed decreased dendritic arborization, increased neurite length, and decreased expression of the post-synaptic density protein, PSD95. DE genes were disproportionately expressed across 59 brain regions mapped by the Allen Brain Atlas. Comparison with published reports of brain morphologic differences in people with 16p11.2 CNVs (Martin-Brevet et al. 2018) revealed striking overlaps between anatomical and gene expression differences, especially in the right insula. This study demonstrates for the first time that patient-derived neurons carrying the 16p11.2 duplication display concordant transcriptomic and cellular phenotypes that overlap with dosage-sensitive anatomical differences in brain regions thought to underlie attention, emotion, and reward.

## PgmNr 2178: Evaluating the phenotype of the 15q13.3 deletion using clinical MRI data.

The 15q13.3 deletion (breakpoints 4-5; 15qdel) occurs in approximately 1 of 40,000 individuals worldwide and encompasses six known genes, including *CHRNA7*. The 15qdel exhibits variable expressivity with clinical phenotypes that range in severity. The most common clinical diagnoses associated with 15qdels include intellectual disability, epilepsy, schizophrenia, and other neuropsychiatric disorders. Previous studies of this deletion have focused on pediatric populations with severe phenotypes, while adults and individuals with milder 15qdel phenotypes have not been well characterized. In this study, we identified 55 individuals with a 15qdel (mean age = 44.96 years) from 92,455 patient-participants in the Geisinger-Regeneron DiscovEHR project, which includes exome and electronic health record (EHR) data from Geisinger. Of the 55 individuals with the deletion, 17 had at least one clinical brain MRI in their EHR as a result of epilepsy, migraine, and/or meningioma diagnoses. Therefore, the aim of this study is to evaluate clinical MRI reports to characterize the phenotype of the 15qdel as reflected in brain imaging findings. Radiologist reports that were entered into the EHR at the time of the scan were exported into a database and findings from each report were summarized. Overall, there were 2 with reported meningioma, 10 individuals with reported scattered white matter hyperintensities (WMH), 7 with reported sinus abnormalities, and 2 with brain volume loss. The incidence of meningioma in these patients is higher than expected, with an annual incidence of approximately 2 cases per 100,000 individuals. Importantly, some of these findings may reflect variation in clinical reporting terminology, particularly those that are more common, such as in the sinuses and WMH. In ongoing analyses, we will assess whether radiological findings are different using a rubric-based consensus review by neuroradiologists, as well as comparing volumetric brain measurements with a matched control group. This is the first study of its kind to assess the phenotype of the 15qdel using radiologist report summaries and provides insight into the variable neurological manifestations of 15qdel.

## PgmNr 2179: Studying the role of short tandem repeat variants in schizophrenia risk.

Genome-wide association studies (GWAS) have successfully identified thousands of genetic loci associated with a range of complex traits. However, GWAS based on common single nucleotide polymorphisms (SNPs) still fail to explain the majority of heritability for most traits, even with sample sizes of up to several hundred thousand individuals. One compelling hypothesis explaining this is that complex variants, such as multi-allelic repeats not in strong linkage disequilibrium (LD) with common SNPs are important drivers of complex traits. We focus on the role of Short Tandem Repeats (STRs), a highly polymorphic class of repeats consisting of 1-6bp repeating motifs present at more than 1.5 million loci in the human genome. STRs have been implicated in more than 30 Mendelian disorders and a variety of complex traits. Intriguingly, most repeat disorders identified to date have involved neurological or psychiatric phenotypes.

Here, we present the first STR-based GWAS of schizophrenia, a highly polygenic trait which has been robustly associated with more than 100 genomic loci. We first used our published phased reference haplotype panel to impute STRs into more than 60,000 samples from Psychiatric Genomics Consortium (PGC) schizophrenia dataset. We used imputed genotypes to test more than 450,000 STRs for association with schizophrenia. We next performed simulation analyses on case-control cohorts to obtain an empirical estimate of the genome-wide significance threshold for STR association testing. Our GWAS identified 1740 STRs that passed the genome-wide p-value threshold estimate of  $1.11 \times 10^{-5}$ . We applied LD-based clumping to identify independent association signals using SNP and STR summary statistics and used CAVIAR to perform fine-mapping of each signal.

Preliminary results suggest 11 of the 108 previously associated signals are potentially driven by underlying STRs. Candidate loci will be validated using orthogonal cohorts. Overall, we anticipate that incorporation of STRs and other complex variant types into GWAS will identify additional causal variants and ultimately lead to improved understanding of the genetic architecture and biological processes driving complex traits.

## PgmNr 2180: Genome-wide study of speech-sound disorder identifies ties to regulatory elements controlling neurological development and function.

---

The sound system of language forms the basis for most human communication, and disorders that affect speech have a lifelong adverse impact. The known neural basis of speech resides in Broca's and Wernicke's areas of the brain, but the presence of speech and language dysfunction in several neurodevelopmental disorders suggests a broader genetic foundation. Speech-pathologist diagnosed families (N=435 children from 148 families) in the Cleveland Family Speech study (CFS) were assessed for 16 variables representing 6 domains (oral motor function, phonological memory and awareness, reading decoding, spelling, expressive and receptive language and vocabulary). We examined the genetic basis of non-syndromic childhood speech sound disorder (SSD) via a genome-wide association study (GWAS) using RVtests for >8.5M SNPs (MAF>5%). For replication, we obtained data from the Avon Longitudinal Study of Parents and Children (ALSPAC), a birth cohort containing children with similar endophenotypes and available genetic data (max N=6203), in which mothers of 4% of children self-reported problems with speech. Although genetic correlations between measures are high (range: 0.56-0.99), there is considerable familial discordance in inheritance of identical phenotypes between sibs, suggesting that cross-trait replication across any pair of assessments between CFS and ALSPAC may provide more consistent conclusions. We thus identified 163 significantly associated SNPs in CFS ( $p < 1 \times 10^{-5}$ ), which replicated in correlated ALSPAC traits ( $p < 0.05$ ), residing in 32 novel loci, with 18 SNPs having combined  $p < 10^{-8}$ . We annotated SNPs using HaploReg, RegulomeDB, and FUMA-GWAS as they were mostly intergenic (74%) or intronic (23%). Many lead SNPs or LD-tags (80%) either mapped to brain eQTLs or were enriched for neuronal promoter/enhancer elements. For example, rs856380 (combined  $p = 2.1 \times 10^{-6}$ ) is an eQTL for DACT1, highly expressed in the substantia nigra, and an enhancer for the language processing temporal region of the brain. In CFS alone, we replicated previously associated genes ATP2C2 ( $p = 7.7 \times 10^{-8}$ ) and CNTNAP2 (CFS  $p = 5.2 \times 10^{-6}$ ). Using gene set enrichment analysis, regulation of gene expression and molecular function were top GO pathways overrepresented by our mapped genes ( $p = 1 \times 10^{-6}$  and  $1.7 \times 10^{-7}$ ). This evidence suggests that the genetic influence on SSD is primarily in the regulation of neural and brain pathways, and that these pathways may be common with other neurological disorders.

## PgmNr 2181: Genetics of severe mental illness in a Colombian population isolate.

---

Our current classification system divides most severe mental illness (SMI) into dichotomous diagnostic categories; psychotic disorders and mood disorders. However, these categories overlap clinically, and are genetically correlated. We are ascertaining and phenotyping a Colombian sample of 8,000 SMI individuals across diagnostic categories, and 2,000 demographically matched controls. In this sample, we will attempt to identify symptom-level and quantitative phenotypes that better represent the biological underpinning of SMI than do the diagnostic categories alone.

Recruitment of cases takes place primarily at a single psychiatric hospital serving the state of Caldas, a large catchment area within the “Paisa” region of Colombia, characterized by a high level of cultural and genetic homogeneity. Through high quality electronic health records (EHR), patients across the full range of severe mood and psychotic disorders are ascertained in a diagnosis-naïve way. Phenotyping is performed in a deep and uniform manner, and includes diagnostic interview (NetSCID), symptom assessment (SA45) and a neurocognitive battery (PennCNB).

Here, we will provide an overview of the first 3,000 cases, representing SMI across diagnoses in Colombia, and highlight some initial results from the “Paisa project”.

The diagnostic breakdown of the SMI sample is as follows: 38% bipolar disorder (BD) type I, 13% other BD, 33% major depressive disorder and 13% schizophrenia. This surprisingly high proportion of cases with BD matches that of hospitalized patients as a whole as well as that for other hospitals in the Paisa region.

Our genetic analyses of the Paisa population highlight strong characteristics of isolation, even relative to the Finnish population. Exploring the relationship between genome-wide significant SMI-associated variants and specific symptoms of SMI in our cohort, our data provides a replication of a locus previously associated with BD, which in our sample has a much larger effect size than those observed in published psychiatric GWAS.

Finally, using NLP-based machine learning approaches, we are leveraging EHR data on >70,000 cases collected over a period of 14 years from the hospital to extract phenotypic constructs such as diagnostic features and substance use phenotypes.

Our cohort provides unique opportunities for the (genetic) characterization of SMI that may ultimately lead to novel approaches for disease classification.

## PgmNr 2182: Association between polygenic liability for schizophrenia and substance involvement: A nationwide population-based study in Taiwan.

---

**Background:** Schizophrenia and substance involvement, from use to severe dependence, frequently co-occur in the same individual. A growing number of studies have investigated shared genetic liability between schizophrenia and a range of substance involvement, including alcohol drinking, tobacco smoking, and substance use disorder, but these studies provided conflicting evidence. This study investigated the genetic overlap between schizophrenia and substance involvement, including phenotypes in relation to tobacco, alcohol, and betel nut use. **Methods:** The study subjects were recruited from the Taiwan Biobank, and genome-wide genotyping data was available in 18327 individuals without schizophrenia. We calculated the Psychiatric Genomics Consortium-derived polygenic risk score (PRS) for schizophrenia, the cumulative additive effect of disease-associated variants across the genome, in each individual, and the PRS was normalized to a Z score. The significance of the schizophrenia PRS associated with a wide range of substance involvement was evaluated by regression models with adjustment for sex, age, and population stratification components. The modified effect of sex or birth decade on the association between schizophrenia PRS and substance involvement was also explored. **Results:** The schizophrenia PRS was positively associated with lifetime tobacco smoking in women (OR in per SD increase in PRS=1.12 with 95% CI 1.04-1.20, p=0.002), but not in men (OR=0.99 with 95% CI 0.95-1.04, p=0.74), and the sex-PRS interaction reached significance (p=0.006). The strength of association, OR, between PRS and lifetime tobacco smoking increased with birth decade (p of birth decade-PRS interaction=0.0002). In women, OR increased from 0.97 (p=0.85) for birth decade before 1950 to 1.21 (p=0.04) for birth decade after 1980; in men, the corresponding OR increased from 0.88 (p=0.04) to 1.13 (p=0.11). There was no association between schizophrenia PRS and alcohol/betel nut use phenotypes. **Conclusions:** This study provided evidence for the genetic overlap between schizophrenia and tobacco smoking in women, and such overlap was stronger in later birth decade. However, the shared genetics may not reflect real biological pleiotropy, further studies are required to explore the influence of potential confounders/mediators.

## PgmNr 2183: Revisiting schizophrenia from an evolutionary perspective: An association study between recent evolutionary markers and schizophrenia.

---

Recent investigations suggest that abnormalities that arise during central nervous system development and subsequently exacerbated during cerebral maturation in adolescence and early adulthood may underlie schizophrenia. SZ persisted in human populations despite high morbidity and reduced fertility and thus it may likely be a by-product of key evolutionary events. Human brain has evolved into much larger and highly complex organ since the divergence from Chimpanzee. These evidences suggest that genomic components, attributable to human-specific brain development may have been favoured by natural selection and also predispose to SZ. Comparative genomics has led to the discovery of genomic regions namely Human Accelerated Regions (HARs) that are highly conserved among non-human species but have experienced accelerated substitutions in the human genome, serving as a marker of human-specific evolution since our divergence from chimpanzees. 93.1% HARs are present in the non-coding region and act as enhancers and/or repressors regulating expression around them. Of note, previous studies have shown that SZ genes are closer to HARs than would be expected by chance, but these are limited to a subset of HARs present near the known SZ candidate genes. To reassess the association of HAR SNPs in a hypothesis free manner, we have systematically selected 43 SNPs from all the HARs identified till now, genotyped and tested their association with SZ, using a two-stage study design comprising discovery and replication cohorts (n=1012 cases; n=1049 controls). Significant association of two SNPs (rs764453; P-value=7.7e<sup>-06</sup>, OR=1.5; CI=1.1-1.8 & rs3801844; P-value=0.0002, OR=1.4, CI=1.1-1.5) was observed. As these SNPs are intergenic, gene mapping was done using - i) positional, ii) eQTL and iii) chromatin interactions approaches and 26 genes were mapped. Pathway analysis of these genes revealed significant (P-value=2.30e-02) overrepresentation of developmental processes. Of these, previous knock-out mouse studies of six most relevant novel genes namely *DLX5*, *DLX6*, *CHN2*, *HOXA1*, *SKAP2* and *SLC25A13* have shown abnormal brain development, behavioral anomalies and increased anxiety related response and were also reported to be differentially expressed in SZ cases vs controls in the largest meta-analysis of gene-expression microarray studies of neuropsychiatric disorders. Further investigations of these novel HAR influenced genes may provide additional insights for SZ etiology in humans.

## PgmNr 2184: Exome variation in ethanol metabolizing enzyme genes in Irish severe Alcohol Dependence (AD) cases.

---

Common variants do not account for all the genetic risk for complex traits like AD. For some traits, part of this 'missing heritability' has been shown to be due to the influence of rare variation. Rare functional variants that reduce AD risk are well documented, but the question of whether rare variants that increase AD risk exist has remained largely unexplored. We sequenced the exomes of 195 Irish AD cases, and variants were selected for further study based on minor allele frequency (MAF) differences between 195 cases and 3757 UK10K Project controls and bioinformatic assessment of the putative functional impact of variants. We focused initially on variants with MAF <0.01 in 10 genes encoding enzymes with a known role in ethanol metabolism (*ADH1A-C*, *ADH4-7*, *CYP2E1*, *CAT* and *ALDH2*). We identified 23 variants with predicted functional impact in these 10 genes that were more common in case exome data than in UK10K controls. Selected variants were then directly genotyped in 906 Irish AD cases and 2000 Irish controls using SNaPshot assays, to increase overall sample size and to ensure that differences were not due to Ireland-UK population differences. An ethnically homogeneous sample from Ireland is well-suited to the study of rare exome variation because of the differences observed in rare variant frequencies and distribution across European populations. Genotyping of the first panel is complete and no significant differences in frequency between Irish cases and Irish controls were observed. Two additional panels of variants in these 10 genes (including all the prioritized loss of function variants), are being genotyped currently.

## **PgmNr 2185: De novo missense mutations revealed by whole-exome sequencing in monozygotic twins are associated with schizophrenia.**

### **Authors:**

L. Guan <sup>1,2</sup>; N. Lv <sup>1</sup>; B. Wu <sup>1</sup>; H. Ma <sup>1</sup>; X. Yu <sup>1</sup>

---

### **Objectives:**

The genetic risk of schizophrenia is conferred by a large number of alleles, including common alleles of small effect and rare alleles of highly penetrance. Despite high heritability, a large fraction of cases with schizophrenia do not have a family history of the disease. Recent large-scale genomic studies have revealed a polygenic burden of rare disruptive mutations in schizophrenia and de novo mutations may account for a significant fraction of sporadic cases. Availability of next-generation exome sequencing permits the study of de novo mutations, especially in the coding regions. Monozygotic (MZ) twins, as natural control of each other, have been widely studied to dissect the relative contributions of genetics and environment. This study aim to identify novel variants and genes in sporadic cases of schizophrenia.

### **Methods:**

We collected three typical MZ twins families which has no history of psychiatric disorders except for the twins themselves. Standardized questionnaires and tools were administered to make schizophrenia diagnosis according to DSM-IV criteria and record the demographic details, developmental history as well as clinical and cognitive assessment. We sequenced the whole exomes of 14 subjects on Illumina HiSeq2500 platform. 13 SNVs and 8 indels in three families were selected to undergo the validation through Sanger sequencing.

### **Results:**

We identified two de novo missense mutations in two families. One mutation was found in the affected proband in a discordant twin pair. The other mutation originating from the germline was found to exist in both of the concordant twin pair. The two mutations both induce a disruptive amino acid change and are evaluated to be damaging and evolutionary consensual using SIFT, PolyPhen-2 and GERP++. Additionally, the two loci were absent in our in-house sample of 2,516 healthy individuals. The gene indentified with the germline mutation is highly expressed from the early fetal stages in human brain, including the hippocampus, substantia nigra, brain cortex, white matter, and ventral thalamus, which are regions implicated in the pathogenesis of schizophrenia.

### **Conclusions:**

Our study implicates novel genes in the etiology of schizophrenia and supports the notion that de novo mutations may account for some of the heritability reported for schizophrenia. Follow-up studies are needed to investigate the function of mutant protein.

## PgmNr 2186: Family based whole exome sequencing identifies novel genetic susceptibility loci in Han Chinese schizophrenia patients.

---

Schizophrenia (SCZ) is a highly heritable psychiatric disorder that affects approximately 1% of population around the world, causing life-long treatment and substantial social burden. However, our knowledge of the genetic mechanisms of SCZ still remains incomplete and early relevant studies did not reach clear conclusions, suggesting that additional susceptibility loci that exert significant influence on SCZ are yet to be revealed. Family-based designs are particularly well suited for analysis of rare variants and transmission information from parents to offspring in a relatively small sample size. So, in order to identify novel susceptibility genes that account for the genetic risk of SCZ, we performed a systematic family-based study using whole exome sequencing (WES) in 65 Han Chinese families. The analysis of 51 SCZ trios with both unaffected parents identified 22 exonic and 1 splice-site *de novo* mutations (DNMs) on a total of 23 genes, and showed that 12 genes carried rare protein-altering compound heterozygous mutations in more than one trio. In addition, we identified 26 exonic or splice-site single nucleotide polymorphisms (SNPs) on 18 genes with nominal significance ( $P < 5 \times 10^{-4}$ ) using a transmission disequilibrium test (TDT) in all the families. Moreover, TDT result confirmed a susceptibility locus on 3p21.1, encompassing the multigenetic region *NEK4-ITIH1-ITIH3-ITIH4*. Through comprehensive evaluation, we revealed 4 previous discovered susceptibility genes (*TSNARE1*, *PBRM1*, *STAB1* and *OLIG2*) and 3 novel susceptibility loci (*TLR5*, *MGAT5B* and *SSPO*) in Han Chinese SCZ patients. In summary, we identified a list of putative candidate genes for SCZ using a family-based WES approach, thus improving our understanding of the pathology of SCZ and providing critical clues to future functional validation.

## PgmNr 2187: Cell-type specific expression quantitative trait loci during human neocortical differentiation.

Genome wide association studies (GWAS) indicate that common non-coding variants have major impact on many human phenotypes, including neurodevelopmental disorders. One potential function of these variants is to regulate the cis expression genes. We performed an expression quantitative trait locus (cis-eQTL analysis) to map the effect of genetic variation on gene expression. As eQTLs can vary by cell type, we performed RNA-seq (rRNA depleted library preparation) on a homogeneous population of primary human neural progenitor cells (n = 89 donors) and their 8-week differentiated, virally labeled, and sorted neuronal progeny (n=75 donors). Each donor cell line was also genotyped on a dense array (Illumina Omni 2.5+Exome) and imputed to a common reference panel (1000 Genomes).

We performed proximal-eQTL analysis by evaluating association between each gene's expression and variants within  $\pm 1$  Mb window of transcription start site of each gene by implementing linear mixed model associations. We analyzed ~5.56 million variants and 15,848 protein coding, 2,219 lncRNA and 2,600 antisense RNA genes. From the eQTL analysis, 8,154 eSNPs displayed significant association with 3,666 eGenes in progenitors, and 4296 eSNPs were significantly associated with 2,196 eGenes in neurons at an FDR of 5%. Although 1,531 eQTLs were shared between progenitor and neurons, we also detected cell-type specific eQTLs. As an example of a cell-type specific eQTL, a locus previously associated with intracranial volume was found to regulate the expression of the gene *CENPW* in progenitors (rs9401883;  $p = 6.03e-07$ ), but not in neurons. To identify cell-types and genes impacted by disease GWAS loci, we further assessed coincidence of significant eQTLs with loci showing significant associations for schizophrenia. 24 eQTLs in progenitors and 28 eQTLs in neurons were coincident with schizophrenia GWAS SNPs, where the index SNP was shared with the GWAS and eQTL. For instance, index GWAS variant rs73058052 ( $p = 2.74e-08$ ) was also identified as lead eQTL SNP ( $p = 7.8e-06$ ) for schizophrenia related gene *NOSIP* in only progenitor eQTLs. Importantly, both these two eQTL examples were not significant in adult brain eQTLs from GTEx.

Here, we demonstrate a platform to explore the cell-type specific genetic basis of gene regulation during a critical time period of brain development, cortical neurogenesis, which complements existing post-mortem brain eQTL approaches.

## PgmNr 2188: Sequencing of chromosome 1 and chromosome 13 identifies damaging variants linked to verbal trait disorders.

---

**Purpose:** Verbal trait disorders (VTD) describe a wide range of conditions that impair ability to communicate, and include deficits in speech, language, reading, spelling, and writing. We previously identified a 30Mb region of chromosome 13q14-q21 (LOD=4.35) that segregates with poor nonword repetition (NWR)—a robust endophenotype for VTD—in a six-generation extended family of European ancestry with a history of VTD (Truong et al., 2016). However, the chromosome 13 linkage signal does not fully explain all observed cases of VTD in this family. We hypothesize that there are additional genetic loci harboring damaging mutations segregating with other verbal trait domains in this family.

**Method:** We used a genome-wide multipoint variance component linkage analysis to identify chromosomal regions that segregate with self-reported problems in reading, spelling, speech, and/or language in school within the family. We then performed whole exome sequencing and targeted deep sequencing of candidate loci to identify damaging mutations segregating in 20 informative family members. ANNOVAR was used to predict functional variants that were likely pathogenic.

**Results:** The linkage analysis identifies a region on chromosome 1p22.3-22.1 with max LOD=3.98 between 122.5 and 123 cM, spanning approximately 900kb that segregates with a history of spelling problems in school. Whole exome sequencing of this region identifies two variants in predicted promoter regions—one for *TMED5*, the other, *FNBP1L*. Whole exome sequencing and targeted deep sequencing of the initial chromosome 13 linkage signal also identifies 17 predicted functional and deleterious variants in six genes that segregate with poor NWR. All eight genes associated with the chromosome 1 and 13 linkage and sequencing analyses are expressed in developing human brain, with 10 of the variants located in regions of predicted gene regulation. Eleven of the 19 variants are in *DIAPH3*, a gene associated with auditory processing. We also show that variants implicated in the regulation of *DIAPH3* are also associated with poor NWR performance in an independent general population cohort.

**Conclusions:** The often-overlooked non-coding genome may play a critical role in the etiology of VTD. Findings from this study highlight the importance of the non-coding genome in the regulation of genes relevant to the development of the brain, and verbal trait performance.

## PgmNr 2189: Genome-wide association study of opioid cessation.

---

In the U.S, opioid use disorder (OUD) related deaths are rising. While studies have identified several loci that are associated with OUD risk, the genetic basis for the ability to discontinue opioid use has not been investigated. We performed a genome-wide association study (GWAS) of opioid cessation in the Yale-Penn study, including 1,130 African Americans (AAs) and 1,859 European Americans (EAs) recruited for genetic studies of opioid, cocaine, or alcohol use disorders and who met DSM-5 criteria for mild to severe OUD. Opioid cessation was defined as abstinence from opioids for at least one year before the interview date in the context of lifetime OUD. We examined the association of opioid cessation status genome-wide (GW) using a regression model that included terms for imputed single nucleotide polymorphism (SNP) dosage, sex, age and the first five principal components of ancestry that used generalized estimating equations to correct for correlations among related individuals. Association tests performed separately within each population were combined by GW meta-analysis with summarized results obtained from the Comorbidity and Trauma Study, which included a European-ancestry only Australian sample (N=1,060). Although there were no genome-wide significant associations, we found suggestive associations with three independent loci: rs1535677 in *PTPRD* ( $p=6.44 \times 10^{-8}$  in AAs and EAs combined), rs2865688 located 0.7kb downstream of *MINAR1* ( $p=5.96 \times 10^{-7}$  in EAs), and rs72330536 in *KCNQ5* ( $p=7.77 \times 10^{-7}$  in AAs and EAs combined). Pathway analysis identified significant functions related to glutamate signaling, cell-mediated immunity and cell cycle. We also found evidence ( $p<0.005$ ) of shared genetic underpinnings between opioid cessation and other substance use disorder such as cocaine, cessation of smoking and drinking, and chronic back pain in the UK Biobank by evaluating the association of polygenic risk scores constructed from summary statistics of these phenotypes with opioid cessation. These results provide evidence of genetic influences on opioid cessation and suggest genetic overlap with other relevant traits.

## PgmNr 2190: Whole genome sequencing determines contributions of rare and common genetic variants to risk for schizophrenia.

**Objective:** Schizophrenia (SCZ) is a highly heritable mental disorder affecting ~1% of the population. Heterogeneity of SCZ challenges the identification of its underlying genetic risk. Rare (with the predominant role of copy number variants) and common genetic variants have both been shown to contribute to the etiology of SCZ. We aimed to determine the contribution of rare/common variation to SCZ and provide a more comprehensive estimation of genetic underpinnings in this disorder through the application of advanced genomic technologies to capture various genetic variants.

**Methods:** Here, we used whole genome sequencing (WGS) to study 259 unrelated adults with SCZ, a subset of a well-characterized community-based cohort previously assessed with chromosomal microarray, and by design enriched for those with rare CNVs. We assessed rare genetic variants for clinical relevance, including single nucleotide variants (SNVs), small insertions and deletions (indels), copy number variants (CNVs), and structural variants affecting genes or previously reported to be associated with schizophrenia and related disorders. In addition, we estimated SCZ liability from common genetic variants (single nucleotide polymorphisms, SNPs) using polygenic risk scores (PRSs). We also identified genes that were recurrently impacted by ultra-rare loss of function (LoF) variants.

**Results:** WGS detected all 28 pathogenic CNVs previously reported by microarray in this cohort, accounting for a likely genetic diagnosis in 10% (n=26) of the 259 cases. Rare clinically relevant SNVs and indels alone, likely contributing to the phenotype, constituted 3.5% (n=9) of individuals with no other identified relevant variant, e.g. CNVs. Common variants were responsible for 9.4% of the variance in SCZ liability, and significantly enriched in individuals with a family history of SCZ.

However, analysis of PRS quantile indicated these confer relatively small overall risk for pathogenicity even considered the top PRS quantile (odds ratio: 2.7, 95% confidence interval: 1.1-6.6]. Analysis of ultra-rare LoF variants suggested *ZMYM2*, a gene associated with transcription repression, as a novel SCZ-relevant gene candidate.

**Conclusions:** These results support the power of WGS to delineate the contributions of a variety of

genetic variants to SCZ liability. Our findings support the feasibility of using WGS as a potential single comprehensive genetic test for SCZ.

## PgmNr 2191: Inverse pleiotropic effects of the nicotine metabolizing gene *CYP2A6*.

**Introduction:** Smoking behaviors are contributors to lung cancer. Various genome-wide association studies (GWAS) have implicated shared and unique genetic loci with either smoking-related behaviors or lung cancer. For example, the chromosomal region 19q13.2 encompassing *CYP2A6*, which metabolizes nicotine, has been associated with cigarettes smoked per day, smoking cessation, and lung cancer. In this study, we examine the genetic correlations and interconnectedness between smoking-related phenotypes.

**Methods:** Genetic data consisted of GWAS summary results from previously published studies. SNP heritability and genetic correlations were estimated using linkage disequilibrium (LD) score regression software. Z-score-z-score (ZZ) plots were generated by comparing z-scores of each SNP between pairwise comparisons of each outcome. Chromosomal region 19q13.2 including *CYP2A6*, the primary nicotine metabolizing gene, is highlighted.

**Results:** The overall genetic correlations between increased cigarettes smoked per day, failed smoking cessation, and increased lung cancer risk are strong (cigarettes smoked per day – lung cancer:  $r = 0.59$ ; failed smoking cessation – lung cancer:  $r = 0.49$ ; cigarettes smoked per day – failed smoking cessation:  $r = 0.43$ ). The chromosomal region 19q13.2 shows a positive correlation between increased cigarettes smoked per day and lung cancer. The effect allele-C of the lead SNP (rs56113850) within *CYP2A6* is associated with an increased risk of lung cancer (z-score = 8.91;  $p = 5.02 \times 10^{-19}$ ) and increased cigarettes smoked per day (z-score = 19.2;  $p = 1.10 \times 10^{-81}$ ). Surprisingly, this variant is associated with successful smoking cessation (z-score = -8.17;  $p = 2.52 \times 10^{-26}$ ).

**Conclusion:** Genome-wide, there are strong, positive genetic correlations between all smoking-related phenotypes. Interestingly, the chromosomal region 19q13.2 encompassing the gene *CYP2A6* is not only associated with increased cigarettes smoked per day and elevated risk of lung cancer but also with successful smoking cessation. This inverse relationship highlights the need for additional analyses to determine how *CYP2A6*, which metabolizes nicotine, could increase smoking cessation yet increase risk of lung cancer likely through increased cigarettes smoked per day.

## PgmNr 2192: Association between a genetic variant in the *PDE9A* gene and the risk of idiopathic hypersomnia.

---

Idiopathic hypersomnia (IHS) is a rare sleep disorder characterized by excessive daytime sleepiness, great difficulty in awakening, and prolonged sleep time. The exact prevalence of IHS is unknown, but it has been estimated to be approximately 0.005%. In contrast to narcolepsy type 1 which is a well-recognized hypersomnia, the etiology of IHS has been poorly understood. No susceptibility loci for IHS have also been identified, although familial aggregations have been observed among patients with IHS. Narcolepsy type 1 is tightly associated with *HLA-DQB1\*06:02*. However, no significant associations were observed between IHS and HLA alleles. We performed a genome-wide association study and replication studies involving a total of 412 Japanese patients with IHS and 5,345 Japanese healthy individuals to identify genetic variants influencing IHS susceptibility. Genome-wide SNP genotyping was performed with the Affymetrix Genome-Wide Human SNP Array 6.0. The genomic inflation factor of the GWAS was 1.01, suggesting that the effect of population stratification was negligible. Although no SNPs reached the genome-wide significance threshold in the present study, a genetic variant (rs2250870) within an intron of *PDE9A* was suggestively associated with IHS ( $P = 3.0E-05$ ; odds ratio = 1.5). rs2250870 showed a significant association with expression levels of *PDE9A* ( $P = 7.8E-09$ ). The leading SNP in the *PDE9A* region was the same in associations with both IHS and *PDE9A* expression levels. *PDE9A* is a potential target for treatment of diseases, such as depression or stress-induced heart disease. Further, inhibitors of *PDE9A* have been developed as a new potential drug of Alzheimer's disease. Since higher expression levels of *PDE9A* were found in the risk allele of rs2250870 for IHS, *PDE9A* inhibitors and the related compounds might contribute to develop new treatment for IHS.

Cigarette smoking is a leading cause of morbidity and mortality worldwide. Each phase—initiation, regular smoking, nicotine dependence (ND), and cessation—is a heritable trait, but knowledge of the specific genetic loci is incomplete. We performed a 1000 Genomes-imputed genome-wide association study (GWAS) meta-analysis for ND, defined by the Fagerström Test for Nicotine Dependence (FTND), using the largest sample size to date: 58,000 smokers of European (EUR) or African ancestry from 23 cohorts. We identified two novel genome-wide significant associations with ND, *TENM2* (chr5, lead SNP rs1862416,  $P=1.5 \times 10^{-8}$ ) and *MAGI2/GNAI1* (chr7, lead SNP rs2714700,  $P=2.3 \times 10^{-8}$ ), while replicating associations at three known loci. Rs1862416-T and rs2714700-C were associated with increased ND risk across ancestries. For independent testing, we used 33,791 smokers from the UK Biobank with the heaviness of smoking index (HSI), which is based on two FTND items that explain much of the variance in the full 6-item FTND. Rs2714700-C was associated with higher HSI ( $P=0.014$ ), but rs1862416 was not associated ( $P=0.39$ ). Testing specific FTND items in our GWAS cohorts showed rs1862416 associations with items not captured by the HSI, suggesting that the composite ND phenotype enhanced power for discovery but limited its detection in the UK Biobank. Next, using LD score regression on EUR-specific GWAS results, we estimated the common SNP-based heritability of ND (8.6%) and found 13 traits genetically correlated with ND at  $P < 0.0012$  ( $\alpha=0.05/43$  tests): other smoking traits ( $r_g=0.40$ – $0.95$ ), lung cancer ( $r_g=0.66$ ), alcohol dependence ( $r_g=0.56$ ), depression

symptoms ( $r_g=0.40$ ), years of schooling ( $r_g=0.33$ ), coronary artery disease ( $r_g=0.32$ ), neuroticism ( $r_g=0.28$ ), and schizophrenia ( $r_g=0.16$ ). We also applied stratified LD score regression to test genetic correlations with 205 gene expression datasets from brain and other tissues/cell types. We found that genes spanning ND-associated SNPs were significantly enriched for expression in cerebellum ( $P < 1.4 \times 10^{-4}$ ,  $\alpha = 0.05/205$  tests). Our results show the utility of the FTND as a composite measure to expand genetic knowledge of smoking, as the novel loci were not detected in much larger GWAS of single component smoking traits (e.g., ever vs. never smoking with  $N > 1$  million). Also, the genetic correlation of ND with cerebellum-specific expression highlights a potential role for this brain tissue, which is often overlooked in studying the etiology of ND.

Autism Spectrum Disorder (ASD) is a neurodevelopment disorder with consistently high heritability estimates. However, the genetic architecture of inherited ASD risk remains elusive despite many studies with several thousand individuals. A plausible explanation for this lack of discovery is that ASD encompasses several disorders, each with distinct genetic etiology. This work presents a novel statistical framework and computational method (Structured Causal Model PCA; SCMPCA) to rigorously evaluate and further decompose the ASD phenotype into distinct dimensions that are consistent measures of genetic liability. We evaluated current clinical ASD behavioral scoring algorithms under this framework, and fit a set of novel phenotype scoring algorithms (termed Synthetic Genetic Liability (SGL) scores) directly from behavioral data using SCMPCA. Notably, this method can be applied to any complex genetic trait with recurrence in families.

ASD is typically defined by three sub-phenotypes: social interaction deficits, communication deficits, and restricted and repetitive behavioral patterns. Using a Structured Causal Model (SCM), we derived a criterion to assess if a given sub-phenotype scoring algorithm gives a consistent measure of genetic influence. We applied this criteria to the Autism Diagnostic Interview Revised (ADIR) behavioral instrument data in the AGRE/iHART collection (largest WGS multiplex autism dataset: 4242 full siblings, 172 DZ, 192 MZ twins) of 1004 families with multiple children with ASD. We found that the 'Reciprocal Social Interaction' (RSI) score is a consistent measure of genetic influence, whereas the 'Restricted, Repetitive, and Stereotyped Patterns' (RRSP) score is not a consistent measure of genetic influence. The 'Communication' (C) score is a consistent measure of genetic and non-genetic influences. Supporting this finding, genetic similarity between dizygotic twins is very highly correlated with RSI similarity, but not correlated with C or RRSP scores. Strikingly, this finding is supported by recent human biomarker studies from the Karen Parker lab (Oztan, O. 2018) that show high correlation of CSF vasopressin with ADIR RSI, but no correlation with RRSP. Finally, we used the SGL scores fit by SCMPCA to partition the iHART families into phenotypically distinct sub-groups that may reflect shared genetic etiology.

Oztan, O., et al. (2018) 'Cerebrospinal fluid vasopressin and symptom severity in children with autism', *Annals of Neurology*

## PgmNr 2195: The effects of natural selection on the persistence of common genetic risk for physiologic and pathologic traits of the human brain.

Genome-wide association studies (GWAS) have identified common genetic variants underlying many brain-related phenotypes, including physiologic and pathologic traits. Different functional categories of genomic variation contribute disproportionately to trait heritability. Common genetic variation underlying several neuropsychiatric phenotypes, such as schizophrenia and autism spectrum disorder, has demonstrated influence by natural selective pressures. It is unclear how universally these pressures influence the heritability across brain-related phenotypes. Investigating 73 brain-related traits analyzed in large-scale GWAS including up to 766,345 individuals of European descent, we detected widespread enrichment of variants in mutation-intolerant regions of the genome and variants under background selection in psychiatric disorders (maximum loss-of-function (LoF) intolerance enrichment: *Tourette syndrome*, 2.11-fold,  $p=3.08 \times 10^{-5}$ ; maximum background selection enrichment: *bipolar disorder*, B-statistic (a measure of nucleotide diversity reduction due to purifying selection), 3.03-fold,  $p=2.87 \times 10^{-5}$ ), brain imaging phenotypes (maximum LoF enrichment: *caudate volume*, 1.87-fold,  $p=0.007$ ; maximum background selection enrichment: *caudate volume*, B-statistic, 3.64-fold,  $p=0.039$ ), and internalizing behavioral traits (maximum LoF enrichment: *recent easy annoyance*, 2.25-fold,  $p=1.25 \times 10^{-5}$ ; maximum background selection enrichment: *recent restlessness*, B-statistic, 5.79-fold,  $p=0.007$ ) and externalizing behavioral traits (maximum LoF enrichment: *recent low energy*, 2.08-fold,  $p=4.81 \times 10^{-6}$ ; maximum background selection enrichment: *frequency of drinking alcohol*, B-statistic, 3.92-fold,  $p=0.002$ ) after correction for multiple testing. Several caudate nucleus imaging phenotypes (i.e., caudate nucleus measured in five out of the six brain imaging phenotypes available for heritability partitioning) robustly demonstrated these signatures at multiple thresholds of background selection dichotomization (i.e., top 2%, top 1%, and top 0.5% of genome-wide scores), supporting its pathological role in development of schizophrenia, bipolar disorder, and alcohol use, and its physiological contribution to educational attainment and cognitive performance. These findings reveal the widespread influence of background selection to remove mutations with large deleterious effects on fitness thereby enriching for variants with small effects now observed as common risk loci for neuropsychiatric traits.

Accumulating evidence suggests that inflammation plays a part in several neuropsychiatric disorders. Yet the underlying transcriptomic relationships of the individual diseases to neuroimmunity remains clouded. To understand the role of immunologic changes to these disorders, we assessed gene expression changes related to neuroimmunogenic systems in post-mortem brain samples of individuals with schizophrenia (SCZ), bipolar disorder (BD), autism spectrum disorder (ASD), alcoholism (AAD), major depressive disorder (MDD), Alzheimer's disease (AD) and Parkinson's disease (PD).

Using data from 2540 brain samples, we calculated differential gene expression (DGE) using a linear mixed-effects model. In 1256 immune-related genes collected from databases, we identified differential expressed immune genes to each disorder (AD: 631, ASD: 273, BD: 56, MDD: 26, AAD: 51, PD: 95, SCZ: 216). Meanwhile, we also found immune-related genes fold changes showing significant sex differences in ASD (FDR  $q < 0.05$ ) and MDD (FDR  $q < 0.05$ ). In differential pathway analysis, we found specific immune pathways to each disorder. In one instance, we found highly enriched virus-response related genes only in the AD samples (GO:0009615 Response to virus, FDR  $q = 1.88e-20$ ). To test for immune transcriptome similarity between disorders, we used correlation analysis of immune gene changes across disorder pairs. Results showed significant positive correlation between BD and SCZ ( $\rho = 0.77$ , FDR  $q < 0.05$ ). Whereas, results showed negative correlation between AD and other disorders: SCZ ( $\rho = -0.27$ , FDR  $q < 0.05$ ), BD ( $\rho = -0.33$ , FDR  $q < 0.05$ ), ASD ( $\rho = -0.37$ , FDR  $q < 0.05$ ). Meanwhile, we found that immune gene fold changes were significantly correlated with genetic correlations across the same disease pairs (Pearson'  $r = 0.54$ ,  $p = 0.014$ ). Lastly, we placed individual genes into networks using Weighted Gene Co-Expression Network Analysis (WGCNA), identifying 11 co-expression modules and 3 modules enriched for immune genes. These three modules were also enriched for neuronal development functions, with one enriched for schizophrenia and intelligence GWAS signals.

Our study identified shared changes and disease-specific changes in the immune process across different neuropsychiatric disorders at the transcriptome level. These findings provide new insights into immunogenic systems alterations at transcriptome level in major neuropsychiatric disorders.

## PgmNr 2197: A pilot study of the association between the gut microbiota, sleep quality, and the risk of depression among elderly Taiwanese.

Among the trend of aging globalization, the major depressive disorder has become one of the most important topics of public health. A community-based study revealed that association between the score of the geriatric depression test and the feature of microbiota composition. The gut microbiota associated with the risk of geriatric depression via the mechanism of the gut-brain axis. The prevalence of the geriatric depression was around 16-25% in Taiwan; however, there was no study in the field of the mechanism between the gut microbiota and the geriatric depression in Taiwan. The present study aimed to explore the association analysis between the risk of geriatric depression and gut microbiota. We recruited 14 participants over 65 years old from Day Care Center, Nursing home and Intermediate Care Center. The questionnaires 15-item Geriatric Depression Scale (GDS) and the Pittsburgh Sleep Quality Index were used to understand the depressive status and subjective sleep parameters, respectively. The fecal samples were examined by Illumina Miniseq or Miseq platform for 16s rRNA sequencing of microbiota features. Linear discriminant analysis effect size (LEfSe) and random forest (RF) procedures were applied to examine the feature of the microbiota composition for geriatric depression. There were 4 (28.6%) participants with depressive status, and the participant who cannot get to sleep within 30 minutes more than once a week was significantly increased the risk for depressive status, showing odds ratio (95% confidence interval) was 4.45 (1.16-17.10). After the RF procedure, Families Mogibacteriaceae and Turicibacteriaceae were the top two feature ranks in contributions for classification accuracy of depressive participants and control. The LEfSe revealed that the relative abundance of Family Prevotellaceae significantly increased in the participants who had trouble pain sleeping more than once a week. Our study indicated the association between the gut microbiota features, sleep quality, and the risk of depression among elderly Taiwanese.

Religious experience is a transformative force that shapes the positive and negative social interactions of individuals and societies. The relationship between self and other, whether beings or dieties, shapes social science and religious philosophy but has common neural circuitry has been elusive. Therefore, the brain systems mediating these may overlap, suggesting the social neuropeptides oxytocin (OT), arginine vasopressin (AVP) and their receptors, the *OXTR* and the *V1a*, respectively, were also involved in the brain networks of religious experience. In our prior studies, we have shown that endogenous OT, but not AVP, was associated with BOLD activation in anterior and posterior cingulate cortex, ventromedial prefrontal cortex and anterior insula, the hubs of default mode and paralimbic networks that are involved in self-awareness and self-other, when individuals felt the spirit. In this report, we explored the hypothesis that the genetic variance of the receptors, *OXTR* and *AVPR1A*, might be independently associated with specific brain substrates in response to three religiously evocative tasks (Quotations Initial, Scripture Reading and Quotations Final), in a cohort of individuals trained to report spiritual responses. Our results showed that DNA polymorphisms of *OXTR* (rs2254298, rs2268498) were associated with left dorsolateral prefrontal cortex, right inferior parietal and left posterior cingulate cortex. The *AVPR1A* promoter-region microsatellite repeat length of RS3 was associated with right ventrolateral orbitofrontal cortex. These brain substrates were also involved in default mode network, self-other and high cortical processes, suggesting the genetic variance, present for birth, possibly acting throughout development, and the other, reflecting the variable interaction and results of a spectrum of developmental and experiential events. Putting together with our prior studies, these results indicate that both the original state of the receptors, and the endogenous peptide, are involved in religious experience, most strongly in regions involved in early developing brain systems but also with the later appearing brain systems for the more complex aspects of self involving others.

---

SUPER is a nationwide study conducted in Finland, where health care system is publicly funded and supported housing facilities are accessible to every citizen. National health care registers cover every hospital visit since 1969 and prescription drug purchase since 1995. Data on education, employment and cause of death can be also drawn from registers and linked to other information based on an individual national social security number.

Subtle changes in cognitive performance and social behavior can be observed years before onset of psychosis. Different aspects of functional capacity are poorly correlated, suggesting that they might have different etiological backgrounds. Functional deficiencies are refractory to antipsychotic therapy, further suggesting that they are independent from mechanisms causing psychotic behavior.

To evaluate biological basis of functional deficiencies in patients with a psychosis, we used polygenic risk scores (PRSs) for various neurodevelopmental disorders. Risk scores were derived using LDpred software and summary statistics from recent genome-wide association studies. SUPER recruited

10,382 individuals (age  $46.7 \pm 14.9$  years, 49.5% females) with a history of at least one psychotic episode. Functional capacity was assessed with a structured interview, which contained questions regarding past school difficulties, current employment, housing and relationship status. Genotyping with Illumina Global Screening Array has so far been performed for 7,310 subjects. Imputation was performed using the population-specific SISu panel as a reference panel.

PRS for schizophrenia (SCZ) was associated with need for supported housing at the time of study visit (OR 1.08, 95% CI 1.02-1.14,  $P=4.9 \times 10^{-3}$ ), whereas it had no association with subjective difficulties at school. However, subjective difficulties at school were associated with PRS for intelligence (OR 0.87, 95% CI 0.83-0.91,  $P=4.7 \times 10^{-8}$ ). Subjects who had both subjective difficulties at school in childhood and needed supported housing in adulthood had lower PRS for intelligence and higher PRS for SCZ compared to those with constantly good community functioning.

In conclusion, the poor lifelong functional capacity in subjects with a history of psychosis is associated with an unfavorable polygenic profile for two distinct neuropsychiatric traits. We will further confirm these findings using registry data.

## PgmNr 2200: Biobank-based genome-wide analysis for post-traumatic stress disorder.

Biobanks that integrate electronic health records (EHR) with genome-wide data create vast growing resources for genetic research. Here, we leveraged Partners HealthCare Biobank, which links EHR with genome-wide data, to perform genome-wide analyses for posttraumatic stress disorder (PTSD). We identified 637 PTSD cases ( $\geq 2$  PTSD ICD9 codes) and 18,295 controls (0 PTSD codes) of European ancestry. We first genetically validated EHR-based PTSD against 2 external PTSD GWAS from UK Biobank ( $N=123,794$ ) and Psychiatric Genomic Consortium (PGC;  $N=9,954$ ). Using LD-score regression, we showed that EHR-based PTSD has SNP-based heritability ( $h^2_g$ ) similar to conventionally-ascertained PTSD ( $h^2_g=0.11$ ,  $p=1.04 \times 10^{-6}$ ), and substantial genetic correlation ( $r_g$ ) with external PTSD samples ascertained by diagnosis/systematic interview ( $r_g=0.53$  for PGC PTSD GWAS,  $p=0.03$ ), but lower  $r_g$  with PTSD identified through self-report survey ( $r_g=0.37$  for UKBB PTSD GWAS,  $p=0.0004$ ). Using external GWAS summary statistics, we also confirmed significant  $r_g$  between EHR-based PTSD and other psychiatric traits, such as ADHD ( $r_g=0.40$ ,  $p=2.63 \times 10^{-6}$ ), depression ( $r_g=0.39$ ,  $p=2.01 \times 10^{-5}$ ), schizophrenia ( $r_g=0.22$ ,  $p=0.0004$ ), educational attainment ( $r_g=-0.30$ ,  $p=1.29 \times 10^{-7}$ ), and cognitive performance ( $r_g=-0.30$ ,  $3.88 \times 10^{-7}$ ). Second, we used UK Biobank and PGC PTSD GWAS meta-analysis to generate polygenic risk scores for PTSD ( $PRS_{PTSD}$ ) in Partners Biobank with 2 methods: 1) LD-clumping with association p-value thresholding and 2) Bayesian regression with continuous shrinkage priors (PRS-CS). We showed that PRS-CS with causal variant proportion parameter set to 10% gives the best prediction ( $R^2=0.009$ ,  $p=5.21 \times 10^{-11}$ ). We also showed that patients with top 5%  $PRS_{PTSD}$  have a 1.69-fold increased risk for PTSD (95% CI=1.25-2.29), compared with the rest of the patient population. Finally, we performed a phenome-wide association study (PheWAS) to explore the capacity of  $PRS_{PTSD}$  to predict a range of EHR-based health outcomes using 853 PheWAS codes derived from ICD codes.  $PRS_{PTSD}$  significantly predicts the risk of mood disorders, depression, anxiety disorders, substance addiction, and chest pain. For the first time, we showed that PTSD patients identified through diagnostic codes from EHR are genetically comparable to conventionally-ascertained PTSD patients. Furthermore, we showed potential applications of PRS in a real-world clinical system to identify patients with higher risk of PTSD and other comorbidities of PTSD.

---

Mood disorders affect 10-20% of the population, ranging from brief, mild episodes to severe, incapacitating conditions that markedly impact lives. Multiple approaches have shown considerable sharing of genetic risk factors between unipolar and bipolar mood disorders.

We used genome-wide association study results for major depression and bipolar disorder to investigate the molecular basis of the shared genetic liability to mood disorders. We meta-analysed the latest results from the Psychiatric Genomics Consortium (PGC) major depression and bipolar disorder cohorts, along with an additional major depressive disorder cohort from UK Biobank (185,285 cases, 439,741 controls, non-overlapping N = 609,424). 73 loci reached genome-wide significance in the meta-analysis, with additional loci significant in subtype and depression-only analyses. More genome-wide significant loci from the PGC analysis of major depression (39/44, 89% of the loci) than from the PGC analysis of bipolar disorder (4/19, 21%) reached genome-wide significance in the meta-analysis. Genetic correlations calculated between major depression and bipolar disorder subtypes revealed that type II bipolar disorder correlates strongly with major depression. Integrating the results with systems biology information, we implicated pathways and neuronal subtypes that highlight similarities but also potential differences between major depression and bipolar disorder.

Our results reflected major depression more than bipolar disorder, perhaps due to the larger sample size for major depression, but also perhaps because depression is the predominant common feature of mood disorders. Overall, these results provide evidence for a genetic mood disorders spectrum.

## PgmNr 2202: Common and rare damaging variants both contribute to familial form of bipolar disorder and explain difference in clinical manifestations in multiplex families.

---

Bipolar disorder (BD) is a severe psychiatric disorder with a complex pattern of inheritance. Genome wide association studies have revealed an additive polygenic contribution of common low risk alleles, explaining up to 25% of the overall genetic variance in the heritability of BD. Rare high penetrant variants might partly explain this missing heritability and family studies with a high density of illness are of particular relevance for such study.

To estimate the contribution of common and rare variants in BD vulnerability, we combined both whole exome sequencing and genotyping arrays in 8 multiplex families with BD (39 subjects, of whom 22 were affected). We showed a higher BD polygenic risk scores (PRS) in multiplex families when compared with 1,636 individuals of general population, but no difference was observed between affected and unaffected subjects. When extending this analysis to a cohort of 445 BD patients, no difference in BD PRS was observed between individuals with or without family history of BD. However, we reported a higher schizophrenia (SZ) PRS in familial cases of BD than in unfamilial ones.

The analysis of rare damaging variations in constraint genes shared by affected subjects in multiplex families revealed a single interaction network enriched in neuronal and developmental biological pathways, as well as in the regulation of gene expression. We sequenced 241 additional patients with BD and compared the rare mutation frequency for these genes with the 21,071 individuals from the non-Finnish and non-psychiatric European subjects of the Exome Aggregation Consortium (ExAC) cohort. Four genes showed a higher mutation rate in patients with BD than in the ExAC population after correction for multiple testing, including three involved in epigenetic regulations. Interestingly, these patients showed a specific clinical manifestation. Furthermore, we computed a score combining information from BD and SZ PRS and showed a significant negative correlation of this score with rare damaging variations specifically in unaffected individuals of multiplex families.

Altogether, our results suggest that common and rare genetic variants both contribute to the familial aggregation of BD and that this genetic architecture may explain the heterogeneity in clinical manifestations in multiplex families.

## PgmNr 2203: Genes regulated by BCL11B during T-cell development are enriched for *de novo* mutations found in schizophrenia patients.

---

Schizophrenia (SCZ) is a common but severely debilitating adult-onset mental illness characterized by hallucinations, delusions, and a lack of desire to accomplish goals or form social relationships. Cognitive deficits (affecting memory, IQ or attention) are also a core feature of SCZ. However, these deficits are not effectively targeted by current treatments, primarily owing to a lack of understanding of the shared biology of SCZ and cognition. Abnormal neurodevelopment contributes to SCZ risk but there is also evidence to support a role for immune dysfunction in SCZ. *BCL11B* is associated with SCZ in genome-wide association studies (GWAS) and is a transcription factor involved in regulating the differentiation and development of cells in both the central nervous system and the immune system. Here, we use functional genomics data from studies of *BCL11B* to investigate the contribution of neuronal and immune processes to SCZ pathophysiology. We generated three gene-sets that contain the targets of BCL11B in (i) brain striatal cells (n=220 genes), (ii) Thy3 developing T-cells (n=74 genes) and (iii) Thy4 developing T-cells (n=560 genes). For each gene-set, the BCL11B targets were identified using an integrated analysis of differential gene expression data and ChIP-seq binding data. We tested each gene-set for enrichment of genes associated with SCZ or cognition using MAGMA gene-set analysis (GSA) and summary statistics from GWAS. Enrichment of SCZ *de novo* mutations was tested in our gene-sets with denovolyzeR using data from multiple studies that have identified genes containing *de novo* mutations through exome sequencing of SCZ probands and their parents (n=1,024 trios). GSA of GWAS did not identify evidence of enrichment of SCZ or cognition genes in our gene-sets. Analysis of *de novo* mutations did identify that the Thy4 gene-set was enriched for genes containing protein altering mutations (p=0.0007). When this gene-set was divided up into genes that were either up- or down-regulated upon *BCL11B* knockout, the enrichment signal was coming from the up-regulated genes (p=0.0002). Pathway analysis of these up-regulated genes identified 'Interferon alpha/beta signaling' and 'Cytokine signaling in immune system' as biological pathways that are enriched for these genes. These analyses, leveraging a GWAS-identified SCZ risk gene and functional genomics datasets, indicate that *de novo* mutations in immune pathways contribute to SCZ risk.

---

Genome-wide association studies (GWAS) for psychiatric disorders have been extremely successful. Interpretation of most GWAS findings is complicated by the presence of many significant and highly correlated associations, mainly located in non-coding regions. Chromatin conformation capture methods enable the identification of 3D chromatin interactions *in vivo* and can clarify GWAS findings. We have generated high-resolution 3D chromatin interactome of adult and fetal cortex using “easy Hi-C” (eHi-C), a variation of Hi-C that yields high quality Hi-C libraries using a much lower input. To aid interpretation of the eHi-C readouts, we generated or assembled RNA-seq, ATAC-seq, and ChIP-seq data from adult and fetal cortex. We used in-house pipelines for the analysis of compartment A/B, to call frequently interacting regions (FIREs), and to identify topologically associated domain (TAD) boundaries and chromatin interactions. Our Hi-C readouts agreed with external datasets and captured key biological processes of adult and fetal brain. We focused our analysis on high-confidence regulatory chromatin interactions (HCRCI), which involve enhancers or promoters, and we used these 3D data to functionally connect genetic results for multiple psychiatric disorders and brain traits to specific genes. Finally, we systematically compared how HCRCI fared against other established methods for connecting single nucleotide polymorphisms (SNP) to specific genes. Our data suggests that location- based approaches provide a limited view of the complexity of psychiatric GWAS

findings, and provide support for the idea that, following genetic identification of a locus for a complex disease like schizophrenia, it is essential to incorporate knowledge of chromatin interactions in a disease-relevant tissue.

## PgmNr 2205: The genetic overlap between body composition, glycemic, and psychiatric traits is age- and sex-dependent.

Alterations in appetite regulation, energy intake, and physical activity are key symptoms of psychiatric disorders. Negative and positive genetic correlations between anorexia nervosa and attention-deficit/hyperactivity disorder (ADHD) with body mass index implicate a shared genetic etiology. Additionally, psychiatric disorders show sex differences with more females being affected by major depressive disorder and anorexia nervosa and more males by schizophrenia and autism. The body mass compartments, such as fat mass and fat-free mass, also differ between the sexes. We generated sex-specific GWAS of fat-free mass and fat mass in a healthy and medication-free subsample of the UK Biobank (all N = 155,961), the MAGIC consortium supplied GWAS of glycemic traits (N = 140,583), and the Psychiatric Genomics Consortium and others of 17 psychiatric disorders and behavioural traits (up to N = 217,568). We then calculated sex-specific genetic correlations across all these traits using bivariate linkage disequilibrium score regression. Two notable patterns emerged: (1) anorexia nervosa, schizophrenia, obsessive-compulsive disorder, and education years were negatively associated with body fat % and fat-free mass, and, (2) ADHD, alcohol dependence, insomnia, and heavy smoking were positively associated with body fat % and fat-free mass. Anorexia nervosa showed a significantly stronger genetic correlation with body fat % in females than in males, whereas education years showed a stronger genetic correlation with fat mass in males than in females. Most genetic correlations were significant with GWAS of body composition traits in late adulthood, whereas only ADHD showed a genetic correlation with obesity in childhood. Mendelian randomization analyses indicated evidence consistent with schizophrenia, anorexia nervosa and more years of education causing decreased fat mass while, in contrast, that higher body fat % may be a causal risk factor for ADHD and heavy smoking. These findings generate new hypotheses for targeted preventive strategies.

## PgmNr 2206: GWAS of anxiety disorders in pediatric-enriched cases.

---

Anxiety disorders as a group are the most prevalent mental health condition worldwide, with approximately one in nine people meeting relevant diagnostic across a 12-month period. Relevant disorders include agoraphobia, generalized anxiety disorder, panic disorder, phobias, selective mutism, separation anxiety disorder, and social anxiety disorder. While heritability estimates for anxiety disorders broadly range from ~30–50%, susceptibility loci have not been reliably validated. In collaboration with our colleagues at the electronic medical records and genomics (eMERGE) consortium, we developed an electronic algorithm for identifying anxiety cases and controls across the pediatric-adult spectrum. We conducted a genome-wide association study on 2,529 European individuals with anxiety and 3,414 ancestry-matched controls selected from eMERGE. Whole genome imputation was performed by the Michigan Imputation Server, while association between single nucleotide polymorphisms (SNPs) and anxiety was tested by SNPTTEST using linear regression, adjusting for age, gender, site, and ancestry principal components (PC).

Although no tested SNP surpassed the traditional genome-wide significance threshold, we report that 1q23.3 (rs7526815,  $3.5 \times 10^{-6}$ ), 7q36.1 (rs855738,  $5.4 \times 10^{-7}$ ), 8p23.2 (rs10503346,  $1.5 \times 10^{-6}$ ), 16p23.2 (rs73574279,  $1.3 \times 10^{-6}$ ) were nominally associated with the risk of anxiety. Further analysis of eQTL data from GTEx indicated that genotypes of rs7526815 were significantly associated the expression level of *VANGL2* in tissue from cerebellum ( $6.5 \times 10^{-9}$ ). It has been reported that products of *VANGL2* may be involved in the development of the neural plate, and associated with several neurological disorders.

## PgmNr 2207: Schizophrenia polygenic risk score analysis in 22q11.2 deletion syndrome.

---

**Background:** ~25% of individuals with 22q11.2DS develop schizophrenia (SZ), which is >20 times the SZ risk in the general population. As for other genetic conditions that are not fully penetrant, there may be a contribution by other genetic variants. Polygenic risk score (PRS) analysis examines the collective contribution by common genetic variants to risk, and has shown that SZ in the general population has a polygenic component explaining ~7% of variance on the liability scale. The present study used PRS methods to investigate a role for common variants in SZ among patients with 22q11.2DS.

**Methods:** Whole genome sequencing (WGS) data were available from 432 patients with 22q11.2DS of European descent (212 SZ cases; 220 non-psychotic controls). Additional European data were obtained from a general population SZ case-control study (10,791 CLOZUK cases; 24,391 WTCCC controls) to compare PRS between 22q11.2DS and general population samples (utilizing genotypes imputed from array data). PRS were constructed using the PGC SZ GWAS (SCZ2) summary results as training data. When CLOZUK/WTCCC samples were included among the target samples, the PGC SCZ2 dataset excluding CLOZUK/WTCCC samples was used as training data. Associations between phenotype and PRS were examined using logistic regression adjusting for sex and ancestry.

**Results:** PRS analysis of the 22q11.2DS WGS data showed that PRS explained 7.7% of variance in SZ on the observed scale ( $p=6.73 \times 10^{-6}$ ), with one standard deviation increase in PRS yielding a 1.77 increased odds of SZ (95% CI: 1.41-2.22). Comparison of idiopathic SZ cases with 22q11.2DS SZ cases revealed idiopathic cases to have higher PRS (OR=1.31; 95% CI: 1.10-1.55;  $p=0.012$ ).

**Discussion:** 22q11.2DS patients with SZ have significantly greater PRS, consisting of common SZ risk alleles, as compared with 22q11.2DS non-psychotic controls, suggesting variants outside the 22q11.2 deleted region contribute to SZ risk in 22q11.2DS, much like in the general population. In addition, lower PRS among patients with 22q11.2DS and SZ compared with idiopathic cases indicates that individuals with this large SZ-associated copy number variant may require lesser contribution by common genetic variants for SZ to develop. These findings contribute to understanding the

mechanisms underlying SZ, both among individuals with 22q11.2DS and within the general population.

## PgmNr 2208: Genome-wide admixture mapping of DSM-IV alcohol dependence in African American population.

### Authors:

---

The prevalence of alcohol dependence is significantly lower in African Americans (AA) as compared with European Americans (EA). In addition to sociocultural and contextual factors that might contribute to this population difference, there is known genetic heterogeneity as well. For example, rs2066702 in *ADH1B* gene has been linked to AD in AA only, while rs1229984, which is amongst the single strongest contributors to AD in EAs, is not found in AA. However, studies searching for AA-specific AD genes are limited. Furthermore, due to their African Ancestry, AA have more variants and faster decay of linkage disequilibrium across physical distance, resulting in the need for more tag variants to achieve genomic coverage. Principle components (PCs) while accounting for global ancestry may not fully account for local ancestry in such recently admixed populations. Admixture mapping has been successfully applied to test the association between local ancestry and ancestry-specific disease etiology. Here, using AA samples from the Collaborative Study on the Genetics of Alcoholism (COGA, 875 AD cases and 940 controls) as a discovery sample, we performed genome wide (632,882 SNPs) admixture mapping of AD. Two independent AA samples, Study of Addiction: Genetics and Environment (SAGE, 400 cases and 341 controls), and Alcohol Dependence GWAS in European and African Americans (Yale-Penn, 1552 cases and 491 controls), were used for replication. SHAPEIT2 was used to phase haplotypes, then RFmix (v1.5.4) was used to infer local ancestry. At each locus, association between AD and African ancestry allelic count was tested with study specific covariates (sex and birth cohorts for COGA and SAGE, sex and age for Yale-Penn). Genome wide significant threshold was determined as 1.83E-04 after adjusting 273 effective ancestry blocks estimated using autocorrelation method. One region on chromosome 11 (84,844,920-85,623,607 bp,  $p=1.2E-04$ ) was significant and replicated in SAGE ( $p=0.03$ ) but not in Yale-Penn ( $p=0.42$ ). In this region, having African ancestry increases the risk of AD. Studies have linked this region to Schizophrenia, Attention Deficit/Hyperactivity Disorder. Multiple genes (e.g. *DLG2*, *SYTL2*, etc.) are located in this region and further study is needed to pinpoint the causal gene. The finding of this study wasn't nominated by any previous genetic studies of AD in AA and highlighted the importance of performing admixture mapping in admixed populations.

## PgmNr 2209: Identifying cognitive genes for nootropic drug repurposing.

### Authors:

M. Lam<sup>1,2,3,4</sup>; T. Lencz<sup>1,2</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

---

**Background:** Cognitive traits have been demonstrated to be strongly genetic correlated with psychiatric disorders and physical traits. In the last 2 years, several cognitive GWASs have been reported, identifying more than 200 loci across 300,000 individuals in the population. Here, we aim to consolidate GWAS evidence for cognitive performance, and perform novel downstream analysis that aims to identify candidate genes for downstream drug re-purposing.

**Methodology:** We leverage on two large-scale GWASs in the recent literature (PMID 29844566 & 29942086), which reported 148 and 205 genome-wide significant loci, respectively. Summary statistics were harmonized and meta-analyzed using Multi-Trait Analysis of GWAS [MTAG] and METAL 2.0, which is optimized for handling sample overlaps. Independent loci were identified, and downstream analysis was carried out using MAGMA pathway analysis and S-Predixcan/SMultixcan Transcriptomic Wide Analysis (with GTEx 7.0 brain samples as reference). Significant TWAS and MAGMA genes were looked up in multiplem chemoinformatic databases (DGI, KI, and a review on 'druggability' (PMID 28356508).

**Results:** A total of 264 genome-wide significant loci were identified after harmonizing across the two input GWAS; meta-analysis and QC filtering procedures identified 200 loci that could be followed up for downstream analysis. After Bonferroni correction, 558 genes and 444 genes were significant in the MAGMA and TWAS analysis respectively. The intersection of significant GWAS loci, MAGMA and TWAS genes yielded 81 high-confidence genes associated with cognition that could be searched in drug repurposing databases. Of these, 24 genes (~30%) were found to be promising candidates for drug repurposing.

**Discussion:** Preliminary data analysis suggest that the following genes -- CYP2D6, MST1, IL27, MST1R, SULT1A2, GPX1, SEMA3F, NEK4, BTN3A2, SULT1A1, CHST10, ITIH3, SREBF2, DAG1, ITIH4, NAGA, ATP2A1, ITIH1, CAMKV, ALMS1, NDUFS3, RBL2, PBRM1, PSMC3 -- identified in large-scale GWAS meta-analysis for cognition may be candidates for nootropic drug repurposing. Further work is necessary to further identify biological properties of these candidate genes.

## PgmNr 2210: Sex-stratified genome-wide association study of smoking behavior identified sex-specific genetic loci and functional regions in the brain.

### Authors:

---

With great efforts made by large research consortia, recent genome-wide association studies (GWASs) of smoking have identified hundreds of associated loci. However, the distinct genetic architecture of smoking behavior between women and men remains understudied. We analyzed sex-stratified GWASs of smoking initiation (smkInit) and smoking cessation (smkQuit) in the UK Biobank (women N~180,000, men N~156,000). We identified 81 genetic loci significantly associated with smkInit in the combined-sex GWAS, 22 loci in the female GWAS, and 21 loci in the male GWAS. Twelve loci were sex-specific, including 5 female-specific loci (5q14.3, 10q26.13, 15q26.1, 16p11.2, and 18q21.2) mapped to *TMEM161B-AS1*, *TACC2*, *RGMA*, *ZNF689*, and *DCC* by the nearest location, and 7 male-specific loci (2p16.3, 2q37.3, 4q34.3, 10p12.31, 12q24.13, 1p21.3, and 13q31.1) mapped to *NRXN1*, *OTOS*, *TENM3*, *CASC10*, *RBM19*, *LOC101928241*, and *LINC01068*. These sex-specific loci were not identified to be significant in the combined-sex or the opposite sex, hinting at sex-specific genetic variants of smoking initiation for women and men. Four sex-specific loci were novel in comparison to recent GWAS results reported in Liu et al. (2019) and Linnér et al. (2019). To better understand the biological mechanism underlying different genetic risks of smoking behavior, we estimated the overall and partitioned SNP-based heritability of smkInit for female and male. The estimated heritability was comparable among combined-sex ( $h^2=0.09$ ,  $se=0.003$ ), female-specific ( $h^2=0.10$ ,  $se=0.005$ ), and male-specific ( $h^2=0.11$ ,  $se=0.005$ ) GWASs. Partitioned heritability analysis identified brain cingulate gyrus ( $p=2.5E-04$ ) as a female-specific region significantly enriched for the heritability of smkInit. Brain dorsolateral prefrontal cortex ( $p=5.2E-06$ ), angular gyrus ( $p=1.4E-04$ ), and hippocampus middle ( $p=6.4E-04$ ) were identified as male-specific regions. Brain anterior caudate was significantly enriched for both women ( $p=2.2E-04$ ) and men ( $p=2.9E-04$ ). These regions are functionally involved in decision-making. Combined-sex GWAS identified 5 loci for smkQuit and none was sex-specific. Results from the sex-stratified genetic study highlighted possibly distinct genetic architecture of smoking initiation between women and men. While we appreciate the power gain of meta-analysis, we stressed the importance of uncovering biologically interpretable associations and distinct mechanisms accounting for heterogeneity within the population.

## PgmNr 2211: Examining mtDNA variants and sleep disturbances in major depressive disorder.

### Authors:

L. Melhuish Beaupre<sup>1,2</sup>; V. Goncalves<sup>1,3</sup>; J. Kennedy<sup>1,2,3</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Molecular Brain Sciences Research Department, Centre for Addiction and Mental Health, Toronto, Canada; 2) Institute of Medical Sciences, University of Toronto, Toronto, Canada; 3) Department of Psychiatry, University of Toronto, Toronto, Canada

---

**Background:** Major depressive disorder (MDD) is a debilitating mood disorder that affects 11-14% of the global population. A core symptom of MDD is sleep disturbance, mainly insomnia and hypersomnia, affecting approximately 75% of individuals. Sleep disturbances might constitute a biotype of MDD. Unfortunately, MDD with accompanied sleep disturbances poses a substantial problem associated with a poorer course of the disease, and a substantial economic burden. Although it is a heritable feature, the genetics of these sleep disturbances is poorly understood. Thus far, only a select number of core circadian genes in the nuclear genome have been investigated, with positive findings for *CLOCK* and *TIMELESS*.

There is compelling evidence that mitochondria play a role in sleep-wake regulation, probably adjusting energy metabolism for day/night periods. To the best of our knowledge, nobody has investigated variants in the mitochondrial genome (mtDNA) thus far. Based on the above, we hypothesize that variants in mtDNA are associated with sleep disturbances in MDD.

**Method:** We selected a subset of depressed individuals from the CAMH IMPACT study, which had sleep disturbance measures available. We had N=135 mtDNA variants on the Illumina Omni microarray genotyped in this sample. All participants had a Beck Depression Inventory (BDI) score greater than 19. Sleep disturbances were measured using the BDI #1.6 (change in sleep), and Udvalg for Kliniske Undersogelser Side Effect Rating Scale (UKU) #1.7 (increased sleep) and #1.8 (decreased sleep). We performed a binary logistic regression for association testing. All individuals (N=293) were genetically of European descent.

**Results:** The top findings from our data were for SNPs from *MT-ND4* ( $p=0.004$ ) and *MT-ND6* ( $p=0.006$ ) and altered sleep as well as a variant found in the mtDNA control region with altered sleep ( $p=0.01$ ) and increased sleep ( $p=0.01$ ).

**Discussion:** We were unable to detect any mtDNA variant that survive multiple hypothesis testing. However, our data is suggestive that variants in mtDNA may play a role in sleep disturbances in MDD. Overall, given the risks associated with MDD and concurrent sleep disturbances, it is vital we gain a better understanding of the genetics underlying them so that we can improve diagnosis and treatment regimens for these individuals. As such, further research in a larger sample is warranted.

## PgmNr 2212: Presence of copy-number variants in the metabotropic glutamate receptor gene network and psychiatric comorbidities of attention deficit hyperactivity disorder.

### Authors:

A.I. Nesbitt<sup>1</sup>; H.S. Hain<sup>1</sup>; I. Slaby<sup>1</sup>; F. Mentch<sup>1</sup>; J.T. Glessner<sup>1</sup>; H. Hakonarson<sup>1,2</sup>

---

Psychiatric comorbidities are commonly observed in attention deficit hyperactivity disorder (ADHD) and autism spectrum disorders (ASD) including anxiety, depression, impulse control, and mood disorders. This poses a challenge regarding treatment regimens addressing all co-occurring disorders as stimulant drugs, the first-line ADHD therapy, often worsen comorbid symptoms. Several studies have linked metabotropic glutamate receptors (mGluR) with psychiatric disorders. We previously demonstrated that copy-number variants (CNVs) in the mGluR network of 273 genes were associated with both ADHD and ASD (Elia *et al*, 2011; Hadley *et al*, 2014). This led to the study of fasoracetam (NFC-1), a non-stimulating mGluR modulator, demonstrating its effectiveness at treating symptoms of ADHD and its comorbid traits in individuals with CNVs in the mGluR genes (Elia *et al*, 2018). In an effort to tie together mGluR gene association with several psychiatric disorders, we evaluated the comorbidities of these disorders in individuals with both ADHD and mGluR CNVs, as these individuals may benefit the most from mGluR modulating drugs. From the Center of Applied Genomics' pediatric biobank, over 50,000 individuals were genotyped on SNP-arrays that were amenable to CNV analysis. Phenotypic information was obtained from electronic medical records with manual record validation. Variant calls were analyzed using ParseCNV. As part of our initial review of findings, we evaluated CNV calls in mGluR genes with previous ADHD associations and observed response to NFC-1: *GRM1*, *GRM5*, *GRM7*, *GRM8* and the GRM interactor gene, *CNTN4*. When compared to individuals with no CNVs in the 273 mGluR network gene set, we uncovered significant ( $p < 0.001$ ) enrichment of these 5 mGluR genes for ADHD, aggressive behavior (including conduct disorder) and mood disorders. Further, in individuals with either ADHD or ASD, greater comorbidity with aggression was observed in the presence of *CNTN4* CNVs ( $p = 0.014$ ). This study extends our previously published results demonstrating that rare recurrent CNVs in mGluR genes that associate with ADHD and autism are also associated with their comorbid traits. Studies to determine the optimal patient cohort responsive to NFC-1 treatment are in the planning, including a basket study to explore the potential benefit on ADHD, autism, anxiety, mood and depression both individually and in ADHD patients with these comorbid symptoms where there is significant unmet medical need.

## PgmNr 2213: Nightmares: Genetic variants and risk of psychiatric disorders.

### Authors:

H.M. Ollila <sup>1,2,3,4</sup>; N. Sinnott-Armstrong <sup>3</sup>; K. Kantojarvi <sup>5</sup>; T. Palviainen <sup>4</sup>; C. Hublin <sup>6</sup>; K. Valli <sup>7</sup>; N. Sandman <sup>7</sup>; E. Kronholm <sup>7</sup>; K. Kaprio <sup>4,5</sup>; T. Paunio <sup>5</sup>; R. Saxena <sup>1,2</sup>

---

Nightmares are dreams that can inflict intense fear, sadness or anxiety. However, why we experience nightmares has remained unknown. To address this question, we examined the phenotypic and genetic underpinnings of nightmares in 28,596 individuals from Finland and from the United States. Here we show that nightmares associate strongly with sleep and psychiatric traits at epidemiological level; awakenings during the night ( $p=1.93e-11$ ), depression ( $p<2e-16$ ) and alcohol use ( $p=6.32e-12$ ). Similarly, we describe a strong genetic correlation between the frequency of nightmares and personality, psychiatric disorders and sleep-related traits; neuroticism ( $rg=0.59$ ,  $p=8e-7$ ), major depressive disorder ( $rg=0.68$ ,  $p=7e-4$ ), schizophrenia ( $rg=0.23$ ,  $p=0.02$ ), insomnia ( $rg=0.50$ ,  $p=1.87e-5$ ) and tiredness ( $rg=0.62$ ,  $p=1e-6$ ). Analysis of directionality using mendelian randomization showed a significant effect from psychiatric traits to nightmares ( $p<0.01$ ) with no evidence of pleiotropy and no evidence of nightmares predisposing to psychiatric problems. Finally, we identified individual genetic variants that predispose to nightmares near *MYOF* ( $rs701873$ ,  $p=2.18e-8$ ) and *PTPRJ* ( $rs11039471$ ,  $p=3.7e-8$ ) - the latter representing a locus previously associated with sleep duration. These findings are the first evidence showing individual genetic associations with nightmares. Furthermore, while nightmares are caused by unique genetic risk factors, a substantial effect in nightmares is conveyed through underlying psychiatric traits.

The NIMH Center for Collaborative Genomic Studies on Mental Disorders, now known as the NIMH Repository and Genomics Resource (NRGR), was established through the NIMH Human Genetics Initiative in 1998 to leverage and increase the value of human genetic samples and data produced through NIMH funded research. NRGR plays a key role in facilitating psychiatric genetic research by providing collections of well characterized, high-quality patient and control samples from a wide-range of mental disorders. The NRGR maintains clinical data, genetic data, and biomaterial samples from over 200,000 well characterized individuals with a range of psychiatric illnesses, their family members, and unaffected controls. Clinical data include overall diagnoses and, in many cases, item-level data from assessment instruments. Biomaterials include DNA on virtually all subjects and lymphoblastoid cells lines or cryopreserved lymphocytes on most subjects; plasma, RNA, fibroblasts, and iPSCs are available on subsets of the collection. Genome-wide SNP or sequence data is available for many NRGR subjects. For many subjects, additional data is available through dbGaP and NDA, collaborating data repositories. Given the size of the NRGR collection and the diversity of data available, new tools were required to facilitate research using this resource. To this end, the NRGR recently partnered with a user experience design company and developed an enhanced website that streamlines access to data, provides more powerful search features, and improves the overall user experience. The new website was developed in concert with ongoing processes of enhanced curation of the underlying data to improve uniformity and harmonization across individual studies, including harmonization of diagnoses for comparison across studies and collections, and improved linkage of subject IDs at collaborating repositories. Highlights of the improvements to the website and data will be presented to assist interested researchers in using this resource, including a new query interface for identifying individuals satisfying desired demographic, phenotypic, genetic, and biosample characteristics, and a new web-based interactive data submission pipeline with numerous quality control checks to enhance data curation. Please visit the improved website at [www.nimhgenetics.org](http://www.nimhgenetics.org) to explore our available data and resources, and contact [help@nrgr.on.spiceworks.com](mailto:help@nrgr.on.spiceworks.com) with feedback and/or questions.

## PgmNr 2215: Association between maternal depression symptoms and child telomere length: Evidence from growing up in New Zealand.

---

The biological mechanisms that explain how early life events influence adult disease risk are poorly understood. One proposed mechanism is via accelerated biological ageing, for which telomere length is understood to be a useful and valid biomarker. We aimed to determine if maternal depression pre and post-partum was associated with telomere length in children at 4 years of age (n~ 4,000). Mothers completed questionnaires during pregnancy, at nine months and at 54 months that included an assessment of their depression symptoms. Linear regression was used to investigate the relationship between telomere length and maternal depression at each time-point. Child telomere length was longer if their mothers depression score was higher at nine months of age (coefficient 0.003, SE 0.001, P=0.01) or 54 months of age ((coefficient 0.003, SE 0.002, P=0.02). Although these findings seem paradoxical, it suggests that early life stressors may result in adaptive responses in the child, leading to increased telomere length. We propose several testable hypotheses to explain these results and suggest further research is required to determine if the positive association between depression and telomere length is a developmental adaptation or an indirect consequence of environmental factors.

## PgmNr 2216: Integrative analysis of omics summary data prioritize susceptibility genes underlying alcohol consumption.

### Authors:

H. Zhang; S.P. Chou

[View Session](#) [Add to Schedule](#)

**Affiliation:** NIH/NIAAA, Rockville, Maryland.

---

Access and use of alcohol are associated with risk of abuse and alcohol use disorder, both are prevalent and serious mental health conditions. A genome-wide association study (GWAS) of up to 1.2 million individuals discovered hundreds of genetic variants for alcohol consumption (Nat Genet. 2019;51(2):237-244). In order to prioritize genes identified in this study for the following functional studies, we used summary-data-based Mendelian randomization method (SMR) to re-analyze the summary GWAS results underlying alcohol consumption. Among the genetic variants (SNPs) reaching the genome-wide significant threshold ( $P < 5 \times 10^{-8}$ ), we discovered 12 genomic loci (*FUT2*, *GCKR*, *IZUMO1*, *KANSL1*, *MAPT*, *NSF*, *PLEKHM1*, *RASIP1*, *SPPL2C*, *STH*, and two intergenic loci (rs1260333, rs4788084)) pleiotropically associated with both alcohol consumption (volume of alcohol consumption per week) and Methylation QTL(mQTL) in brain tissue (SMR P value  $< 1 \times 10^{-10}$ ). In addition, there are 11 genomic loci (*CRHR1*, *FUT2*, *KLB*, *NSF*, *PLEKHM1*, *RASIP1*, *RFC1*, *SH2B1*, *SLC39A8*, intergenic rs2726033, and intergenic rs4788084) discovered in the same method using mQTL expression data in blood lymphocytes and 1 gene (*CRHR1*) using eQTL expression data in peripheral blood tissue (SMR P value  $< 1 \times 10^{-10}$ ). The results indicated that the effects of these susceptibility genes on alcohol consumption are mediated by the expression level of the corresponding gene. It also suggested that the Mendelian randomization method using summary GWAS is effective and efficient in identifying and prioritizing candidate loci for the downstream functional studies.

## PgmNr 2217: A large schizophrenia family with a highly penetrant, rare, non-synonymous functional variant in the NRXN1 interactant CASKIN1.

### Authors:

---

Schizophrenia is a highly heritable (estimated at 60-80%), common, and severe psychiatric disorder that affects ~1% of the population worldwide. The first episode of psychosis typically occurs in early adulthood, and the course of disease varies among individuals. In most cases, disease risk is conferred by many common genetic variants with additive effects, where each variant makes small contributions to the risk. However, rare variants of high penetrance also contribute to the disease prevalence. These variants include both copy number variants (CNVs) and single nucleotide variants (SNVs). We have identified a 3 generational Greek family where schizophrenia (SZ) appears to be inherited in an autosomal dominant fashion, suggesting the presence of a causative rare variant of high penetrance. The pedigree includes 4 individuals with SZ, one with schizoaffective disorder and one with bipolar disorder as well as 8 unaffected individuals (for which we have DNA). The presence of two obligate carriers in the family suggests high but incomplete penetrance. We sequenced the exome of the 4 affected individuals and found only two rare, non-synonymous variants (<1% in dbSNP, ExAc and gnomAD databases) that were present in all and are in genes that are expressed in the brain. Both variants were bioinformatically predicted to be damaging and were completely absent from all variation databases. Genotyping of other individuals in the family by Sanger sequencing showed that one of the variants (D1204N in CASKIN1) was segregating with psychosis and linkage analysis gave the highest possible LOD score of 2.2 for the family at a penetrance of 0.75. D1204N has high intolerance scores and is in the Proline rich region of the protein CASKIN1. CASKIN1 interacts directly with NRXN1 at the synapse through tripartite complexes. Neurexins interact across the synapse with neuroligins promoting synapse formation. The *NRXN1* gene encoding neurexin 1 in particular is disrupted by the only known single-gene SZ CNV, making CASKIN1 an excellent candidate as a causative highly penetrant variant in this family. We are currently introducing this variant into induced pluripotent stem cells using CRISPR Cas9 to identify phenotypic and transcriptomic changes after differentiation into neuronal cells. Identifying and characterizing a high penetrance SZ variant in the neurexin-neuroligin signaling at the synapse will improve our understanding of the role of the synapse in SZ development.

## PgmNr 2218: Transcriptome analysis to identify co-expressed gene networks as a molecular signature for childhood trauma-related mood disorders.

---

Bipolar Disorder (BD) and Major Depressive Disorder (MDD) are common and severe psychiatric diseases which can be devastating for the patients, resulting in higher risks of suicide, drug abuse, and shorter life expectancy. Despite the heterogeneous etiology of these illnesses, ranging from genetic predisposition to environmental factors, recent studies showed significant associations between childhood trauma (CT), the severity of symptoms and early onset of BD and MDD. Furthermore, patients who experienced adversity during childhood have been found less responsive to Lithium, the standard mood-stabilizer. Acknowledging that the prognosis of both BD and MDD strongly depends on thymic relapses, understanding their risk factors and underlying mechanisms is, hence, a major challenge to target patients requiring more intensive care.

In this study, we aim to identify a transcriptomic signature of CT in both BD and MDD patients whose experiences during youth have been carefully assessed using the standardized childhood trauma questionnaire (CTQ). First, at the gene level, we conducted a differential expression analysis on: 1) RNA-seq data of lymphoblastoid immortalized cell lines generated from 37 BD patients and 20 healthy controls; and 2) RNA-seq data of peripheral blood leukocytes, generated from 30 MDD patients and 34 controls. Then, at a system level, we performed a weighted gene correlation network analysis (WGCNA), to detect specific or common modules and hub genes amongst both disorders. The expression of all genes within each module was summarized as eigengene to test association between module expression and CT.

Our preliminary results indicate interesting enrichments, with up-regulated genes involved in immune response in both BD and MDD, and down-regulated genes implicated in neuronal development among BD patients. Further characterization of genes whose expression is modified by the exposure to CT might provide a more comprehensive pathophysiological pathway leading from CT exposure to a higher severity in BD and MDD.

## PgmNr 2219: RNA sequencing reveals transcriptomic changes in individuals with insomnia.

### Authors:

---

**Purpose:** Insomnia affects 10-20% of the population and is associated with negative health and psycho-social sequelae. In addition, disruption in sleep homeostatic processes results in higher stress vulnerability. In this study, we examined differentially expressed genes in 15 individuals with chronic insomnia and age- and sex-matched good sleepers (n=15).

**Methods:** We performed RNA-sequencing on total of 150 whole blood samples (five samples per participant) by using Illumina's NovaSeq-6000 sequencer. We used STAR for alignment to hg38 reference genome. Differential gene expression analysis was performed using DESeq2.

**Results:** Based on the RNA-sequencing of samples withdrawn at time point 1 (0 hours) and timepoint 5 (42-44 hours), insomnia patients showed 2516 dysregulated genes compared to controls. Those dysregulated genes include CSMD1, IMPA1, and MIR1244-2. Particularly, CSMD1 gene is 4.4 fold down-regulated in insomnia patients, which is also reported to be related to Schizophrenia.

**Conclusion:** This first study of understanding transcriptome changes in individuals who suffer from insomnia, may provide future direction for understanding pathways and identifying targets for drug and intervention studies.

## PgmNr 2220: Genome-wide association study in multiplex consanguineous Pakistani pedigrees with schizophrenia and bipolar disorder.

### Authors:

---

**Introduction:** Genome wide association studies (GWASs) in additional diverse populations are essential to test the generalizability of the previous GWAS findings, to extend our understanding of the disease etiologies, and to identify the population-specific genetic risk in addition to common factors. Particularly no such studies have been performed in South Asian populations, one of the largest parts of the world population with distinctive population history and genomic characteristics.

**Samples and Methods:** Ten large consanguineous pedigrees (124 affected with SCZ or BPD and 151 unaffected individuals) and 34 unrelated healthy individuals were recruited from Sindh Province of Pakistan. Genotyping was performed using Illumina HumanOmniExpress BeadChip. After the standard QC and genotype phasing and imputation, we performed family-based GWAS using DFAM implemented in PLINK1.07 and FUMA for post-GWAS annotations.

**Results:** We've identified one locus (chr2:11,237,350, rs541513649;  $P$  value  $5.52e^{-08}$ ) associated with the broad psychiatric phenotype and 14 other independent loci showing suggestive statistical evidence of association ( $P$  value  $< 10^{-5}$ ). Out of 15 loci, 10 loci also showed nominal association ( $P$  value  $< 1.00e^{-3}$ - $2.31e^{-11}$ ) in the previously reported psychiatry and/or related GWASs, e.g., a locus on chr7: 68,977,045-69,825,163, (rs12698811,  $P$  value  $8.75e^{-07}$ ) was previously reported associated with cognition (rs12112638,  $P$  value  $2.31e^{-11}$ ; Lee et al., 2018) and intelligence (rs12698891,  $P$  value  $1.22e^{-09}$ , Savage et al., 2018). Functional annotation of these loci using FUMA have also identified a number of interesting disease relevant genes, including *KCNF1*, *ROCK2*, *GABRA4*, *GABRB2*, *AUTS2*, *IGF1* etc.; which showed supporting evidence from the previous genetics and functional studies.

## PgmNr 2221: Structural variant in the RNA binding motif protein, X-linked 2 (*RBMX2*) gene found to be linked to bipolar disorder.

Bipolar disorder (BD) is a phenotypically and genetically complex neurological disorder that affects 1% of the worldwide population. There is compelling evidence from family, twin and adoption studies supporting the involvement of a genetic predisposition with estimated heritability up to ~ 80%. The risk in first-degree relatives is ten times higher than in the general population. Linkage and association studies have implicated multiple putative chromosomal loci for BD susceptibility, however no disease genes have yet to be identified.

Here, we have fully characterized a ~12 Mb significantly linked (lod score=3.54) genomic region on chromosome Xq24-q27 in an extended family from a genetic isolate that was using long-read single molecule, real-time (SMRT) sequencing. The family segregates BD in at least 4 generations with 16 individuals out of 61 affected. Thus, this family portrays a highly elevated reoccurrence risk compared to the general population. It is expected that the genetic complexity would be reduced in isolated populations, even in genetically complex disorders such as BD, as in the case of this extended family.

We selected 16 key individuals from the X-chromosomally linked family to be sequenced. These selected individuals either carried the disease haplotype, were non-carriers of the disease haplotype, or served as married-in controls. We designed a Nimblegen capture array enriching for 5-9 kb fragments spanning the entire 12 Mb region that were then sequenced using long-read SMRT sequencing to screen for causative structural variants (SVs) explaining the increased risk for BD in this extended family. Altogether, 192 SVs were detected in the critically linked region however most of these represented common variants that could be seen across many of the family members regardless of the disease status. One SV stood out that showed perfect segregation among all affected individuals that were carriers of the disease haplotype. This was a 330bp Alu deletion in intron 4 of the RNA Binding Motif Protein, X-Linked 2 (*RBMX2*) gene that has previously been shown to play a central role in brain development and function. Moreover, Alu elements in general have also previously been associated with at least 37 neurological and neurodegenerative disorders. In order to validate the finding and the functionality of the identified SV further studies like isoform characterization are warranted.

## PgmNr 2222: Sex differences and tissue-specific gene expression across psychiatric disorders.

Prevalences of psychiatric disorders differ between males and females; for example autism spectrum disorders and substance use are more prevalent in males, whereas anxiety and depression are more prevalent in females. Twin and family studies showed that vulnerability to psychiatric disorders are partially explained by genetic factors. Genetic correlations between sexes are generally very high ( $>.9$ ), which indicates that the genetic factors are largely the same for males and females.

Differences in gene expression are a plausible mechanism underlying sex-differences in psychiatric disorders. In this project we will investigate sex differences in a large sample of gene expression data. By mining Gene Expression Omnibus (GEO) data repository we will extract two Affymetrix chip human gene expression data (GPL96 and GPL570). We will re-analyze these pooled data to extract sex specific patterns of gene expression, separately for brain ( $N \approx 300$ ) and blood ( $N \approx 2000$ ) samples. We will focus on autosomes as well as on the X chromosome. We will then integrate our findings with summary statistics obtained in large genome-wide association studies. This will allow us to facilitate our understanding of mechanisms that underlie sex differences in psychiatric disorders.

## PgmNr 2223: Discovery of novel genetic risk loci for acute central serous chorioretinopathy and genetic pleiotropic effect with age-related macular degeneration.

---

Central serous chorioretinopathy (CSC) is a severe and heterogeneous chorioretinal disorder and shares certain clinical manifestations with age-related macular degeneration (AMD), suggesting common pathophysiologic mechanisms between two diseases. To advance the understanding of genetic susceptibility of CSC and further investigate genetic pleiotropy between CSC and AMD, we performed genetic association analysis of 38 AMD-associated single nucleotide polymorphisms (SNPs) in a Chinese CSC cohort, consisting 464 patients and 548 matched healthy controls. Twelve SNPs were found to be associated with CSC at nominal significance ( $p < 0.05$ ), and four SNPs on chromosomes 1 (rs1410996 and rs1329428), 4 (rs4698775), and 15 (rs2043085) showed strong associations whose evidences surpassed Bonferroni-corrected significance. While the genetic risk effects of rs1410996 and rs1329428 (within the well-established locus *CFH*) are correlated (due to high LD), rs4698775 on Chr4 and rs2043085 on Chr15 are novel risk loci for CSC. Three independent SNPs were also found to be associated with clinic manifestations of CSC patients. PRS constructed by using three SNPs showed highly significant association with CSC ( $p = 2.10 \times 10^{-7}$ ), with the top 10% of subjects with high PRS showing 6.39 times higher risk than the bottom 10% of subjects with lowest PRS. In addition, the comparison of the genetic effects (ORs) of these 38 SNPs revealed significant, but complex genetic pleiotropic effect between CSC and AMD. By discovering two novel genetic risk loci and revealing significant genetic pleiotropic effect between CSC and AMD, the current study has greatly advanced the biological understanding of CSC.

---

The involvement of genetic factors in the pathogenesis of KC has long been recognized but the identification of pathogenic variants has been challenging. In this study, we selected 34 candidate genes for KC based on previous Whole Exome Sequencing (WES) and literature, an resequenced them in 745 KC patients and 810 ethnically matched controls. Data analysis was performed using a single-SNP association test on the variant level, as well as gene-based mutation burden and variance components tests.

In our study, we detected enrichment of genetic variation across multiple gene-based tests for the genes *COL2A1*, *COL5A1*, *TNXB*, *ZEB1* and *ZNF469*. The top hit in the single-SNP association test was obtained for a common variant in the *COL12A1* gene. Interestingly, *COL5A1*, *TNXB*, *ZNF469* and *COL12A1* are all known Ehlers-Danlos Syndrome (EDS) genes. Though the co-occurrence of KC and EDS has been reported previously, this study is the first to demonstrate a consistent role of genetic variants in EDS genes in the etiology of KC. In conclusion, our data show a shared genetic etiology between KC and EDS, and clearly confirm the currently disputed role of *ZNF469* in disease susceptibility for KC. Besides the role for EDS genes, we also confirm the reported previously involvement of genetic variation in *ZEB1* in KC

## PgmNr 2225: Whole genome sequencing study identifies novel variants associated with intrinsic circadian period in humans.

### Authors:

C. Polymeropoulos; S. Smieszek; D. Xiao; G. Birznieks; M. Polymeropoulos

[View Session](#) [Add to Schedule](#)

**Affiliation:** Vanda Pharmaceuticals, Washington DC, District of Columbia.

---

Non-24 is a circadian rhythm disorder in which the master body clock runs either slightly earlier or, more commonly in the disorder, longer than 24 hours. We conducted the first whole-genome sequencing study of a non-24 population of 174 individuals that we identified as being totally blind with Non-24 Disorder. We have directly tested the association between SNPs and circadian period length ( $\tau$ ) as calculated from the measurements of urinary 6-sulphatoxymelatonin (aMT6s) rhythms ( $n=69$ ). Linear regression corrected for PCs and covariates identified a strong signal in *HCN1*, Brain Cyclic Nucleotide-Gated Channel 1, *HCN1*. *HCN1* channel is responsible for the feedback on the rods regulating the dynamic range of light reactivity under dim or intermediate light conditions. Minor allele rs72762058 associates with longer  $\tau$ , a difference of 12 minutes, and mean  $\tau$  of 24.71. In *Drosophila* there is only one HCN channel encoding gene, *Dm1h*. Interestingly, *Dm1h* mutant flies display alterations in the rest: activity pattern, and altered circadian rhythms, specifically, arrhythmic behavior or a shorter period in constant darkness. Hyperpolarization-activated cyclic nucleotide-gated channels control neuronal excitability and their dysfunction has been previously linked to epileptogenesis.

In addition, we identify others variants that strongly associate with  $\tau$ , such as a missense variant (rs16989535), (minor allele associated with longer  $\tau$ ), within *DEPDC5*, GATOR Complex Protein; found in Familial focal and Rolandic Epilepsy). Subjects carrying the rare allele have a period  $> 25.2$ . *DEPDC5* is part of GATOR1 complex, together with NPRL2 and NPRL3 acts to inhibit the mTORC1 pathway. The mTOR signaling is part of the photic entrainment pathway in the SCN, it regulates autonomous clock properties in a variety of circadian oscillators and regulates network properties of coupled circadian oscillators, such as the SCN neurons. Light-induced mTORC1 activation appears to be important for photic entrainment of the SCN clock.

Our study illustrates the role of *HCN1* in circadian clock biology in humans as shown by an effect on  $\tau$ . We identify variants in *DEPDC5*, previously implicated in epilepsy, as exhibiting significantly longer  $\tau$ . Genetic determinants of period length are not only essential for the understanding of the basic clockwork mechanisms but could also provide insights into mechanistic links between circadian dysfunctions and human diseases such as epilepsy.

## PgmNr 2226: Expression and alternative splicing QTLs integrated with GWAS reveal novel genetic associations and causal genes for glaucoma.

---

Genome-wide association studies (GWAS) have detected 24 genomic loci associated with Primary Open Angle Glaucoma (POAG) and 112 loci associated with intraocular pressure (IOP), a major risk factor for POAG. Yet, the implicated causal genes for these associations, explaining 5-17% of the traits' heritability, are largely unknown, as most associated variants lie in noncoding regions and tag multigenic regions. We thus tested whether *cis*-acting expression quantitative trait loci (eQTLs) or splicing QTLs (sQTLs) in 49 tissues from the Genotype-Tissue Expression (GTEx) Project (release v8) could prioritize causal genes in known GWAS loci and detect new genetic associations with POAG and IOP.

We found that 70% of POAG and IOP associated-variants were in LD with  $\geq 1$  eQTL in any of the tissues. Applying colocalization analysis to the co-occurring GWAS and eQTL signals, considering allelic heterogeneity, proposed one to several high confidence causal genes per GWAS locus. One example is *ANGPT2*, whose increased expression specifically in artery is associated with decrease in IOP (eCAVIAR Posterior Prob.=1). We next tested whether genome-wide significant to subthreshold ( $p < 0.05$ ) POAG or IOP associations were enriched among eQTLs and sQTLs using *eQTLEnrich.v2* that corrects for MAF, distance to TSS, and LD. Using the NEIGHBORHOOD POAG GWAS meta-analysis and UK Biobank IOP GWAS, we found significant enrichment of POAG and IOP associations among eQTLs and sQTLs ( $P < 2.5E-04$ ) in relevant tissues: artery, a potential proxy for Schlemm's canal involved in fluid removal from the eye; brain, a potential proxy for retinal ganglion cells; and adipose, suggesting lipid-related processes. While the adjusted fold-enrichment was higher for sQTLs (1.2-1.8) than eQTLs (1.16-1.6), a larger number of eQTLs was estimated to underlie POAG and IOP associations than sQTLs (170-1300 eQTLs and 90-800 sQTL per tissue). Top POAG-ranked eQTLs and sQTLs replicated in an independent POAG GWAS (UK Biobank; adj. fold-enrich: 2-2.5). Using our gene set enrichment method *eGeneEnrich.v2* that adjusts for expression levels in a given tissue, we found that target genes of top ranked eQTLs were enriched in specific biological processes, e.g. mitochondria organization,

morphology of retinal vasculature and anterior chamber of the eye, and regulation of neuron death.

This work suggests an important role for regulatory mechanisms in POAG risk and proposes new causal genes and pathogenic processes for glaucoma.

## PgmNr 2227: Whole genome sequencing study identifies a novel region in HCN1 affecting human chronotypes, circadian period length and sleep consolidation.

Circadian rhythms affect most aspects of human physiology including a wide range of molecular and behavioral processes. Chronotype known as morningness/eveningness preference describes one's propensity for earlier/later sleep timing and is indicative of individuals' circadian rhythms. Variation thereof is coupled with the propensity for sleeping. To ascertain the genetic risk factors for morningness/eveningness (ME) phenotypes, we conducted a large whole-genome sequencing association analysis using 316 healthy sleeping participants.

We have directly tested the association between SNPs and morning-evening questionnaire (MEQ). We detect a large region on chromosome 5 (more than ~400 adjacent SNPs in LD, spanning ~2mb) centered within HCN1, Brain Cyclic Nucleotide-Gated Channel 1. Regional enrichment yields a p-value of  $< 10^{-99}$ . It is highly expressed in the brain and potentially modulates excitability in the brain (The protein is expressed in frontal cortex and the retina.) and responding to regulation by cyclic nucleotides, playing a critical role in shaping the autonomous activity of single neurons and the periodicity of network oscillations. It has been shown previously in a double mutant mouse model that lack of HNC1 mediated feedback in rod photoreceptor cells prolongs rod responses and saturates the downstream retinal network during bright light stimulation. The risk allele (rs12188518) is effectively correlated with lower MEQ score hence evening phenotype. The OR between morning and evening is 5.78. The locus has been shown to be a significant ( $1.6e^{-09}$ ) eQTL for HCN1 in GTEX.

HCN1 channel is responsible for the feedback on the rods regulating the dynamic range of light reactivity under dim or intermediate light conditions. We hypothesize that if this feedback is not functioning properly an individual may get saturated with even dim light resulting in misperception of the light conditions resulting in a circadian delay. Furthermore, we identify an association between the HCN1 variants and intrinsic circadian period length as calculated from the measurements of urinary 6- sulphatoxymelatonin (aMT6s) rhythms in 69 individuals (for which whole genome sequencing was performed). Our work delineates a novel role of HCN1 in circadian biology, specifically its effect upon human chronotypes, tau regulation and sleep consolidation.

## PgmNr 2228: Accumulation of RB1 LOF variants in a Non-24 whole genome sequencing study.

Non-24 is a circadian rhythm disorder in which the master body clock runs either slightly earlier or, more commonly in the disorder, longer than 24 hours. It is a serious rare, circadian rhythm disorder, highly prevalent in blind individuals (Lockley). We conducted the first whole-genome sequencing study of a non-24 population of 174 individuals that we identified as being totally blind with Non-24 Disorder. Intrinsic circadian period length as calculated from the measurements of urinary 6-sulphatoxymelatonin (aMT6s) rhythms. We explored the LOF landscape of the Non-24 population. We find an accumulation of rare RB1 LOF variants. Altogether we detect 11 rare LOF mutations (7 stopgains, 1 splicing, 2 frameshift, 1 non-frameshift deletion). The OR, when compared to with a control population, is 47. All of the 15 people have a confirmed history of retinoblastoma diagnosis. The average tau is 24.4. In addition we report a single case with RB1:NM\_000321:exon1:c.110delG:p.S37fs and a *CRY1* c.1657+3A>C allele. For that one subject retinoblastoma resulted in bilateral enucleation and subsequently Non-24. Furthermore, we detect the accumulation of other variants in *MYOC*, causative of juvenile-onset open angle glaucoma, *GPER*, estrogen receptors expressed in the suprachiasmatic nucleus, which regulates circadian rhythm, *CYP11B1*, a risk factor for Glaucoma 3, and *ARMS2*, pathogenic in macular degeneration. This report underscores the genetic characterization of patients with a history of retinoblastoma, and may assist in further understanding the association of RB1 mutations and comorbidities, increased risk for non-24 as seen in patients with germline RB1 loss of function variants. Furthermore, we delineate some of the underlying germline variants that may manifest with the non-24 disorder.

## PgmNr 2229: Identification of genetic markers associated with variable response in total sleep time in the first two-thirds of the night of tasimelteon-treated subjects.

---

The JET8 study was a randomized, double-blind, placebo-controlled, multicenter phase III study that randomized 318 healthy subjects. Whole-genome sequencing (WGS) was performed on a population of 158 subjects treated with tasimelteon and on 158 subjects treated with placebo. Tasimelteon is a MT1 and MT2 melatonin receptor agonist.

Subjects received 20 mg of tasimelteon or placebo orally prior to an 8 hour phase advance, relative to their habitual bedtime, and were assessed on nighttime sleep parameters including total sleep time in the first two-thirds of the night ( $TST_{2/3}$ ), as measured by polysomnography (PSG). Genetic markers associated with  $TST_{2/3}$  response in tasimelteon-treated subjects were analyzed. We computed association test results by linear regression assuming additive allelic effects. We used covariates of age, gender, and the top PCs to account for residual population structure. This study design induced the circadian challenge experienced by transmeridian travelers who experience symptoms of jet lag disorder.

A significant association was identified between rs11735877, a highly regulatory variant within *CPLX1*, and  $TST_{2/3}$  ( $p=10e-8$ ). *CPLX1* encodes complexin 1, a neuronal protein, which belongs to the highly conserved complexin protein family. Presumably, *CPLX1* regulates vesicle fusogenicity by interfering with the C-terminal stability of the SNARE complex (soluble N-ethylmaleimide-sensitive factor (NSF) attachment protein receptor), which is an essential effector of the synaptic vesicle fusion process and the neurotransmitter release cascade. The locus is a significant eQTL ( $p=2.6e-10$ ) for UV Stimulated Scaffold Protein A (UVSSA). Variation in UVSSA may cause increased cellular sensitivity to UV light and cutaneous photosensitivity. Based on enrichments and pathway analysis of the top scoring variants, we have identified two related categories, circadian clock and melatonin, with variants in *LRP6*, *WNT5B*, *SEMA3C*, and *GABARAPI3*, among other contributors.

We identified a locus highly associated with response to a melatonin agonist. This can be relevant to understanding the action of melatonin agonists involved in a wide array of responses.

## PgmNr 2230: A meta-analysis of 44,039 individuals doubles the number of genetic loci associated with central corneal thickness and provides important biological insights.

H. Choquet<sup>1</sup>; J. Yin<sup>1</sup>; T.J. Hoffmann<sup>2,3</sup>; K.K. Thai<sup>1</sup>; M.N. Kvale<sup>2</sup>; Y. Banda<sup>2</sup>; C. Schaefer<sup>1</sup>; N. Risch<sup>1,2,3</sup>; K.S. Nair<sup>4</sup>; R.B. Melles<sup>5</sup>; E. Jorgenson<sup>1</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Kaiser Permanente Northern California (KPNC), Division of Research, Oakland, CA 94612, USA; 2) Institute for Human Genetics, University of California San Francisco (UCSF), San Francisco, CA 94143, USA; 3) Department of Epidemiology and Biostatistics, UCSF, San Francisco, CA 94158, USA; 4) Departments of Ophthalmology and Anatomy, School of Medicine, UCSF, San Francisco, CA 94143, USA; 5) KPNC, Department of Ophthalmology, Redwood City, CA 94063, USA

**Purpose:** Central corneal thickness (CCT) is associated with common vision disorders and has a strong genetic component, with heritability estimates ranging between 0.68 to 0.95. To date, 45 CCT-associated loci have been reported, explaining approximately 8.5% of CCT heritability. Here, we report a combined multiethnic meta-analysis of participants from the Genetic Epidemiology Research in Adult Health and Aging (GERA) cohort and previously reported data from the International Glaucoma Genetics Consortium (IGGC).

**Methods:** The GERA cohort is an unselected cohort of adult members of the Kaiser Permanente Northern California integrated health care delivery system, with ongoing longitudinal records from vision examinations. For this study, our GERA sample consisted of 18,129 individuals from 4 ethnic groups (79.9% non-Hispanic white, 7.5% Hispanic/Latino, 8.4% East Asian, and 4.2% African American) having CCT measured. Genome-wide genotype data were generated on Affymetrix Axiom arrays and imputed to the 1000 Genomes reference panel. Genetic association analyses with CCT were performed using linear regression adjusted for age, sex, and ancestry principal components. Associations between the identified CCT-associated loci and common vision disorders (i.e., glaucoma and keratoconus) were assessed in GERA and UK Biobank.

**Results:** We identified 74 genome-wide significant loci ( $P < 5 \times 10^{-8}$ ) for CCT, including 31 novel. The effect estimates of the 31 lead variants at novel loci were consistent across the 2 studies ( $R^2 = 0.72$ ,  $P = 3.70 \times 10^{-13}$ ), and no significant heterogeneity was observed between GERA and IGGC. While conditional analyses revealed additional 11 novel independent variants within the identified loci, gene-based analysis identified a novel gene (*CIART*) associated with CCT ( $P = 2.10 \times 10^{-6}$ ). Among the lead CCT-associated variants identified, only variant rs3740685 in *RAPSN* was associated with glaucoma in GERA after multiple testing correction ( $P = 1.9 \times 10^{-4}$ ) and nominally associated in UK Biobank ( $P = 0.0017$ ). We also confirmed the negative correlation of effect estimates between CCT and keratoconus ( $R^2 = -0.26$ ,  $P = 9.53 \times 10^{-3}$ ), and the associations between keratoconus and CCT-associated loci ( $P < 0.05$ ), including *COL4A3*, *FOXO1*, *SMAD3*, and *COL5A1* as previously reported.

**Conclusions:** This largest study conducted to date on CCT not only doubles the number of CCT-associated loci reported, but also explains up to 14.2% of the CCT heritability, and provides novel biological insights.

## **PgmNr 2231: Method for predicting disease onset risk by genetic variants associated with primary open-angle glaucoma.**

### **Authors:**

---

**Purpose:** To predict the onset risk on primary open-angle glaucoma (POAG) by the additive effects of genetic variants associated with POAG.

**Methods:** Twenty genetic variants associated with POAG were genotyped for 516 Japanese patients with POAG and 246 control subjects. The total number of risk alleles of these genetic variants was calculated for each participant as a polygenic risk score (PRS), and the association between the PRS and POAG was evaluated. The ratio of POAG patients to control subjects was compared with respect to the PRS.

**Results:** The PRS ( $23.8 \pm 2.6$ , mean  $\pm$  standard deviation) in patients with POAG was significantly higher ( $P < 0.0001$ , Student t-test) than that ( $22.7 \pm 2.6$ ) in control subjects. An almost 1.2-fold increase in POAG onset risk was found for the PRS. ( $P < 0.0001$ , odds ratio: 1.17 per risk allele, 95% confidence interval: 1.10 to 1.25, logistic regression analysis adjusted for age and gender) The ratio (1 POAG patient / 7 control subjects) of POAG patients to control subjects in patients with  $PRS \leq 17$  was significantly smaller ( $P = 0.0009$ , Chi-square test) than that (516 POAG / 246 control) in all patients. In contrast, the ratio (126 POAG / 29 control) in patients with  $PRS \geq 26$  was significantly larger ( $P = 0.0008$ ) than that in all patients, and the patients with  $PRS \geq 26$  had a 2.1 times higher onset risk on POAG compared with all patients.

**Conclusion:** This evaluation method by the PRS of genetic variants associated with POAG may be clinically useful for predicting the onset risk on POAG.

## PgmNr 2232: A Scandinavian whole genome sequencing study of familial asthma.

---

Asthma risk is influenced by numerous biological factors in conjunction with environment. Although many SNPs significantly associated with asthma have been identified in genome-wide association studies, there are relatively few reports of individual loci that contribute to a high risk, and only a handful of purported Mendelian variants. To perform an unbiased search for high-risk/Mendelian variants involved in paediatric familial asthma, we present a rare variant analysis of asthma pedigrees ascertained with multiple affected members.

The Scandinavian Asthma Genetic Study (SAGA) study is an AstraZeneca study of familial, childhood asthma, where inclusion criteria required at least two children per family to be affected. We performed initial analyses on virtual exomes from 389 unrelated probands where whole genome sequence (WGS) was available and compared them to 6,624 European control exomes.

We investigated whether any genes were case-enriched for rare, protein-damaging variants. We also applied a novel method, MegaGene, to detect signals of enrichment among ~10K predefined gene-sets, including KEGG pathways and gene ontology sets. Neither gene-based collapsing analysis nor MegaGene burden analysis detected a significant enrichment of deleterious rare variants among our familial asthma cohort of 389 unrelated probands.

We selected the underlying variants in nine top ranked genes from collapsing analysis for segregation analysis. First degree affected family members were genotyped for those variants contributing to the gene-based enrichment to determine if the rate of allele sharing was significantly greater than the expected 50%. No tested gene showed significant enrichment.

With our currently limited sample size, our unbiased survey of the exome for asthma risk did not identify individual genes or gene-sets with significant enrichment of rare, deleterious variants. We now aim to: a) study structural and rare, noncoding variation in the WGS data, b) expand the study to selected cases from other available cohorts with asthma and a family history of respiratory disease, c) apply to our WGS data existing respiratory polygenic risk scores derived from large-scale Scandinavian studies such as FinnGen, and d) expand the WGS for selected pedigrees with the greatest asthma burden or where Linkage analysis will be most informative. We will present the available updates from these extended analyses.

## PgmNr 2233: Human leukocyte antigen (HLA) region class II alleles influence asthma risk through differential gene expression and differences in protein coding regions.

### Authors:

Variation in the HLA region is associated with more diseases in GWAS than any other genomic region, including strong and consistent associations with asthma. Recently, independent associations were shown for childhood-onset and adult-onset asthma with rs28407950 ( $P=1.3 \times 10^{-59}$ ) and rs17843580 ( $P=3.5 \times 10^{-50}$ ), respectively, in the UK Biobank (UKB) (Pividori, Schoettler et al. 2019; *Lancet Respir Med* 7:509). To determine the relative contributions of regulatory and coding variation in HLA genes to asthma risk, we used imputed 4-digit resolution of classical HLA alleles and asthma diagnoses from the UKB. Class II HLA alleles were tested for association in each group, revealing 15 childhood-onset and 13 adult-onset class II 4-digit alleles at the *DRB1*, *DQB1*, and *DQA1* loci associated with asthma protection or risk ( $P < 5 \times 10^{-8}$ ). We then included the genotype at the lead class II GWAS SNPs as covariates. The GWAS SNPs remained significant in all analyses ( $P \leq 2.3 \times 10^{-22}$ ). Of the HLA alleles, only *DRB1\*0401* remained significant for childhood-onset asthma and *DRB1\*0401*, *DQB1\*0302* and *DQA1\*0301*, which often occur on a single haplotype, remained significant for adult onset asthma. To assess whether haplotypes tagged by the GWAS risk/protective alleles are associated with increased or decreased expression of the HLA genes, we analyzed allele specific expression in peripheral blood leukocyte RNA-seq data from 132 Hutterites after aligning RNA-seq reads to reference sequences for each person's known HLA type and phasing the GWAS SNPs and the HLA alleles. We conducted these studies in individuals heterozygous for both the GWAS SNP and HLA alleles at each gene. The patterns of expression were similar for childhood-onset and adult-onset GWAS risk alleles, with increased expression of *DQA1* transcripts (+27%) and decreased expression of *DQB1* transcripts (-35%) on the GWAS risk haplotype compared to transcripts on the non-risk haplotype. No differences in *DRB1* expression were observed between the risk and non-risk haplotypes. Independent effects of the childhood-onset and adult-onset SNPs could not be determined due to the strong LD in the Hutterites. Taken together, these data suggest that associations of class II alleles with both childhood- and adult-onset asthma are due to HLA regulatory variation acting on the HLA-DQ genes and protein coding variation in the *DRB1* gene, with *HLA-DRB1\*0401* associated with asthma risk.

## PgmNr 2234: COPD-associated miRNA-145-5p is differentially expressed in children with asthma on low lung function trajectories.

Chan School of Public Health, Boston, Massachusetts, United States of America

**Introduction:** MicroRNAs (miRNAs) are small non-coding RNAs that regulate their target mRNAs post-transcriptionally through degradation or translational repression. We have previously characterized lung function growth of childhood asthmatics into four patterns: normal growth (NG); reduced growth (RG); early decline (ED); and reduced growth with early decline (RGED). We have shown that reduced growth patterns can lead to COPD diagnosis prior to age 30.

**Objective:** The purpose of this study was to determine if circulating miRNAs from serum taken from an early age in asthmatic children would be prognostic of reduced lung function growth patterns over the next 16 years.

**Methods:** We performed small RNA sequencing on serums from 492 children aged 5-12 from the Childhood Asthma Management Program (CAMP) clinical trial with mild-to-moderate asthma, who were subsequently followed up for 12-16 years. We had previously assigned each CAMP participant to a longitudinal lung function pattern (NG, ED, RG, or RGED) based on their FEV1 trajectory over the course of observation. Small RNA-seq libraries were prepared using the Norgen Biotek Small RNA Library Prep Kit and sequenced on the Illumina NextSeq 500 platform. The ExceRpt pipeline was employed for QC. Mapped read counts <5 were filtered and miRNAs with coverage <50% of all subjects were removed. Using DESeq2 we normalized reads by relative log expression and identified differentially expressed miRs between lung function patterns. A significance threshold of 10% FDR was used. The top microRNA was then assessed *in vitro* for effect on human airway smooth muscle cell hypertrophy.

**Results:** After quality control, filtering and normalization, we had 448 samples and 259 miRNAs for differential analysis between the four growth patterns. In the comparison of the normal vs. the most severe group, NG vs. RGED, we found one strongly dysregulated miR, hsa-miR-145-5p (NG, n = 137; RGED, n = 89; p < 8.01E-05, FDR p = 0.021). miR-145-5p was strongly associated with airway smooth muscle cell growth *in vitro*.

**Conclusion:** Our results show that miR-145-5p, previously associated with COPD, is also associated with patterns of lung function growth leading to COPD in children with asthma and additionally increases airway smooth muscle cell proliferation. This may indicate a prophylactic role for miR-145-5p in long-term lung health and may represent a potential druggable target.

---

Autism spectrum disorders (ASDs) are neurodevelopmental conditions characterized by social-communication deficits and restricted, repetitive behaviours. ASDs are highly heritable and have a complex genetic etiology, with more than 100 genes implicated to date. The Autism Speaks MSSNG resource is a database of whole-genome sequencing (WGS) and phenotypic data from families affected with ASDs, and recently achieved the milestone of 11,364 individuals sequenced. These include 5,134 ASD-affected individuals from 4,231 families, of which 2,941 include both parents. Of the families with both parental sequences available, 741 are multiplex and 2,200 are simplex. Anyone with an ASD-related research question can apply for access to MSSNG, with 69 principal investigators and 179 users from 59 institutions in 14 countries having been approved for access to date. MSSNG data can be analyzed via either a cloud-based environment or a web-based portal, and is also part of the Beacon Network. MSSNG currently includes sequence data aligned to GRCh38/hg38, single nucleotide variants (SNVs), short insertions/deletions (indels), and copy number variants (CNVs); the next iteration will include several enhancements, including improved phenotype querying, epigenetic data, and structural variants (SVs).

Given their phenotypic and genetic heterogeneity, furthering our understanding of the genetic basis of ASDs requires all categories of variants to be considered, including those of differing frequency (common and rare), size (from SNVs and indels to CNVs and SVs), and location (coding and non-coding). Unlike chromosomal microarrays and whole-exome sequencing, WGS allows almost every type of variant to be detected; thus, we are currently examining all variant categories, with a focus on those that are refractory to other technologies, such as non-coding variants and SVs. We are applying state-of-the-art machine learning methods to identify regulatory regions disrupted in individuals with ASDs. To enable functional analysis of potentially clinically-relevant variants, we have generated 63 iPS-derived neuronal cell lines from individuals with ASDs and familial controls, and another 25 lines using CRISPR modelling in an isogenic line. Overall, the Autism Speaks MSSNG project combines high-quality WGS data with extensive phenotype information to allow researchers of all backgrounds to help further our understanding of the genetic architecture of ASDs.

## PgmNr 2236: Genomic prediction of objective sleep behavior in sleep-deprived and shift-work population.

Medical internship is characterized of sleep deprivation and shift work. Maintaining enough sleep and stable sleep pattern is crucial to medical interns' wellness and performance. Recent GWAS of morningness and sleep duration and derived polygenic score have elevated the perspective to study the biological basis of sleep behavior. Meanwhile, the emerging of wearable devices have provided inexpensive tools to objectively measure sleep in a more precise and convenient way than self-report. These progress have made it possible to conduct large-scale study on the relationship of biological basis and sleep behavior in sleep-deprived and shift-work populations like medical interns.

Intern Health Study is a longitudinal cohort study that assesses multiple aspects of medical interns around US. For 2017 cohort, whose medical internship lasted from July 2017 to June 2018, we followed 316 medical interns since baseline (one to two months prior to internship) until the end of internship. We collected DNA samples from the subjects and generated polygenic scores of morningness and sleep duration based on a recent GWAS from UK Biobank (Jones et al., 2016). We also distributed *Fitbit* to the subjects, and collected daily measures of sleep duration and timing.

With linear regressions adjusted by age, gender and top 10 principal components, we found that higher morningness polygenic score predicted smaller deviations in internship sleep timing, especially wake time, from baseline routine. One SD higher in morningness polygenic score was related to 13 less minutes in the change ( $p=0.007$ ). Also, higher sleep duration polygenic score predicted longer average daily sleep time both at baseline ( $\beta=7$  mins,  $p=0.019$ ) and during internship ( $\beta=14$  mins,  $p=2.35 \times 10^{-4}$ ), and the association during internship was marginally stronger ( $\beta=6$  mins,  $p=0.055$ ).

Our results indicated that genomically predisposed morning person was more prone to maintain a similar schedule to baseline during internship. And difference in sleep duration predicted by genomic predisposition was even wider during internship than usual. Previously we discovered that longer sleep and less deviation from baseline sleep routine were associated with better mood of medical interns (Kalmbach et al., 2018). Therefore, a deeper understanding of biological basis of sleep behavior may have potential to guide personalized intervention in improving sleep and mental health within medical interns and other sleep-disturbed professionals.

## **PgmNr 2237: Genetic correlations between brain imaging traits and dietary choices reveal complex interactions between diet and brain morphology.**

---

In the developed world, the genetics of food and drink consumption plays a significant role in population health by influencing the incidence of numerous diet-related diseases such as obesity, type II diabetes, or coronary heart disease – it is estimated that in the US alone unhealthy diet contributes to 678,000 deaths each year. It has been demonstrated previously that genes significantly associated with dietary choices are differentially expressed in the brain. In this study we aim to understand the genetic overlap between food choices and several brain characteristics ranging from brain area volume to activation during rest and activity. To do this we estimated the genetic correlations between genome-wide association of several specific food consumption traits such as beef and cheese and brain imaging traits from UK Biobank. The brain phenotypes were obtained using T1-weighted structural imaging, resting-state functional MRI, task functional MRI, T2-weighted FLAIR structural imaging, diffusion imaging, and susceptibility-weighted structural imaging and include traits such as white matter lesions, total brain volume and volumes of specific structures. Preliminary results show that dietary choices that fall into the cluster of “unhealthy diet” (i.e. meat/fatty foods and alcohol) tend to be negatively correlated with brain volume traits, while foods usually considered “healthy” (i.e. fruit and vegetables) show an opposite pattern. These correlations remain significant after normalisation for head size, implying that the effects are not caused by body size. Looking at specific brain areas we find that the volume of hippocampus, which has been shown to play an important role in the regulation of human food intake, has a positive genetic correlation with the consumption of fortified wine and salt and a negative correlation with the consumption of beer and cider, decaffeinated and instant coffee as well as bread. Optic chiasm volume is positively genetically correlated with the consumption of lamb and processed meat. The findings give us a better understanding of the complex interactions between dietary choices and brain morphology that in the future might allow for a more personalised approach to nutrition and prevention of diet-related diseases.

## **PgmNr 2238: A genetic landscape of human behavioral traits: A cross-domain analysis of heritability, polygenicity, and biological pathways.**

**Authors:**

S.K. Jang; M.Z. Liu; S. Vrieze

[View Session](#) [Add to Schedule](#)

**Affiliation:** Psychology, University of Minnesota, Twin Cities, Minneapolis, Minnesota.

---

It is a fundamental observation in behavioral science that behaviors are heritable and correlated. Theories on the etiology of behaviors will benefit from knowledge on whether differential heritability exists, and whether and how the genetic correlations are systematically structured and what gives rise to this structure. The current study examines whether narrow-sense heritability specifically estimated by *ldsc* is different across behavioral, non-behavioral, and brain phenotypes as well as across different behavioral domains. It also examines the structure of genetic correlations among behavioral and related- physical traits using dimension reduction techniques and inspects whether this might correspond to the shared biological pathways of behaviors. A total of 61 GWAS summary statistics were collected, including 19 physical, 35 behavioral and 7 brain volume phenotypes. Physical phenotypes included medical disease, anthropometric traits, and biomarkers, while behavioral traits included psychiatric disorders, substance use, sleep, lifestyle, diet, and social relationship. A random-effects meta-analysis on the heritability produced a weighted mean of heritability for each phenotype domain. Behavioral phenotypes showed relatively smaller heritability ( $h^2=0.09$ , 95%CI=0.071-0.109) than that of physical ( $h^2=0.18$ , 95%CI= 0.13-0.22) and brain phenotypes ( $h^2=0.19$ , 95%CI=0.13-0.24). The analysis of within-domain genetic correlations indicated that brain volume and behavioral phenotypes tend to be more highly genetically correlated to themselves than physical phenotypes with the median absolute value of correlation 0.24, 0.13, and 0.05 for each domain, respectively. The graph analysis of genetic correlations categorized behavioral traits into two clusters with one associated with most psychiatric disorders and reduced fertility, and the other associated with externalizing behaviors and cognitive ability. We will conduct a sensitivity analysis on our differential heritability results with a recently developed summary-statistics based heritability estimates using *SbayesR* and discuss potential sources of differential heritability including measurement errors of psychological constructs. Further, results of cross-domain analyses of polygenicity and biological pathways will be reported.

## PgmNr 2239: Cathepsins play a major role in alpha-synuclein accumulation in Lewy body disorders.

---

Synucleinopathies including Parkinson disease (PD) are characterized by the presence of Lewy bodies (LBs) in neuronal cells of substantia nigra, which contain accumulations of the protein  $\alpha$ -synuclein (SNCA). The biophysical properties and proteolytic processing of SNCA are poorly understood. Recently, there has been evidence that cathepsins (Cts), endolysosomal cysteine proteases, are involved in the cleavage of SNCA. It has also been shown that truncations in the C-terminal of SNCA promote fibrillization and are enriched in LBs. To identify the origin of the truncated forms of SNCA, we used a *SNCA*<sup>A53T</sup> mouse model, where human transgenic A53T mutated SNCA is overexpressed. The mice were monitored for weight loss and neurological symptoms, including impaired axial rotation and limb paralysis. Symptomatic mice were euthanized, and lysosomes were isolated from brain samples along with samples from age matched wildtype and non-symptomatic *SNCA*<sup>A53T</sup> mice by density gradient. Using antibodies specific for different epitopes, including C- and N-terminal SNCA, we compared levels of the different SNCA species in purified brain lysosomes by immunoblotting. The data revealed enrichment of C-terminal truncated SNCA in symptomatic mice, which results from cleavage by CtsB and CtsL. HPLC and mass spectrometry were used to identify the specific amino acids sequence in the C-terminal truncated forms. No changes were observed using different substrates to measure Cts activity. The results were confirmed in rat dopaminergic N27 cells treated with exogenous SNCA fibrils, indicating that the terminal truncated forms of SNCA originated from incomplete degradation of fibrils in lysosomes. This work demonstrates the essential role of brain lysosomal function in PD. The increased levels of C-terminal truncated SNCA in LBs appears to result from the burden of aggregated SNCA inside the lysosome and not inactivation of Cts. Most likely, the C-terminal truncated forms of SNCA migrate to the cytosol, where they initiate SNCA aggregation, resulting in LBs formation.

## PgmNr 2240: Determining genetic correlation and causality of clinical biomarkers in human disease using population biobanks.

---

Genetic correlation is frequently reported between intermediate traits, such as biomarkers, and human diseases. These correlations could either represent causal associations of biomarkers in human disease, genetic subgrouping or non-causal relationships such as secondary effects of the disease/treatment biology or pleiotropy. In this study, we used summary statistic data from genome-wide association studies in two large population biobanks, FinnGen (n=~100,000) and UK Biobank (UKB, n=~500,000), to elucidate the relationship between blood count measures and human disease. Linkage disequilibrium score regression was applied to assess genetic correlation ( $r_g$ ) between disease (FinnGen) and blood counts (UK Biobank). Results indicated both well-known correlations; such as eosinophils and asthma ( $r_g = 0.35$ ,  $se = 0.033$ ,  $P = 9.2 \times 10^{-27}$ ) and reticulocytes and diabetes ( $r_g = 0.33$ ,  $se = 0.026$ ,  $P = 8.3 \times 10^{-36}$ ), as well as less well described associations such as reticulocytes and nerve and plexus disorders ( $r_g = 0.18$ ,  $se = 0.030$ ,  $P = 9.7 \times 10^{-10}$ ). To assess whether significant associations represent causal relationships, subgrouping or pleiotropy, Mendelian Randomisation and BUHMBOX were applied. This analysis highlights the utility of large biobanks in assessing the role of intermediate traits using a disease-agnostic approach that allows for unbiased assessment and the identification of novel causal associations and disease biology.

# PgmNr 2241: Characterization of CFTR mutations in chronic obstructive pulmonary disease.

**Affiliation:** Brigham and Women's Hospital

---

**Introduction**

Chronic obstructive pulmonary disease (COPD) is a complex disease caused by cigarette smoking and influenced by genetic contributors. COPD is phenotypically heterogeneous, with varying manifestations of emphysema, chronic bronchitis, and airway wall thickening and bronchiectasis despite similar degrees of lung function impairment. While mutation in the cystic fibrosis transmembrane conductance regulator (*CFTR*) is associated with cystic fibrosis (CF), data suggests that cigarette smoke results in impaired *CFTR* function in smokers with and without COPD. Here, we hypothesize that heterozygous mutations in *CFTR* are associated with COPD and related phenotypes.

**Methods:**

Whole genome sequencing was performed in 5773 non-Hispanic white subjects, including 3150 moderate COPD (GOLD stage 2-4) cases and 3629 controls, from the COPDGene study through the TOPMed program. Variants within the *CFTR* gene boundary were annotated using the WGS Annotator pipeline. We examined the occurrence of previously described clinically annotated *CFTR* variants, and performed single and grouped variant testing for COPD related phenotypes. All association analyses were adjusted for principal components of genetic ancestry, age, gender, pack-years, and current smoking status.

**Results**

Within the *CFTR* gene boundary we identified 11,567 polymorphic variants, including 10,577 SNPs and 990 indels. Of these, 10,442 have been previously described. The majority of these variants are located in intergenic (1831) or intronic (7611) regions; 199 are nonsynonymous coding variants. Out of the 400 variants in the CFTR2 database of CF mutations, 75 were polymorphic in our data; of these 29 are known to be CF-causing. We identified 177 individuals who are heterozygous for deltaF508 mutation, and 80 subjects heterozygous for the 28 additional known CF-causing mutations. This combination of 29 *CFTR* mutations was nominally associated with chronic bronchitis (0.015) but not COPD or emphysema. Furthermore, burden testing weighting with percent pancreatic insufficiency as a measure of mutation severity revealed that the CF causing mutations were additionally associated with bronchodilator response ( $p=0.018$ ).

**Conclusions**

We found that a subset of 29 *CFTR* variants may be associated with chronic bronchitis in non-Hispanic white smokers. This suggests that heterozygous *CFTR* mutations together with cigarette smoking could result in pulmonary disease through lack of functional *CFTR* activity.

# PgmNr 2242: Common and low-frequency coding variants at the *ERN1* and *XBP1* loci are associated with dental caries in the primary dentition.

## Authors:

## Introduction

Enamel secretion and maturation is a tightly regulated process that impacts the quality of enamel and its ability to resist carious attacks. The Endoplasmic Reticulum (ER) stress signaling pathway IRE1/XBP1 has been indicated in enamel secretion in an IRE1 conditional knockout mouse model and an *amelogenesis imperfecta* mouse model. Here, we hypothesize that coding variants in the *ERN1* (which encodes IRE1) and *XBP1* genes contribute to caries susceptibility in humans. We investigated the association between common and low-frequency coding variants in *ERN1* and *XBP1*, with caries in the primary dentition.

## Methods

Decayed and filled primary teeth (dft) indices were collected from Caucasian, non-Hispanic children ages 1 to 12.9 years from two cohorts: the Center for Oral Health Research in Appalachia (COHRA, N=619), and The Pittsburgh Orofacial Clefting (POFC, N=559). Exome variants were genotyped on the Illumina Exome chip for COHRA and on Exome add-on for POFC. Variance components modeling was used to individually test the association between common missense SNPs (*ERN1*:rs186305118 and *XBP1*:rs5762809) and dft. Low-frequency coding variants in *ERN1* and *XBP1* were tested in aggregate by Combined and Multivariate Collapsing (CMC) and Sequence Kernel Association Test (SKAT) using an MAF cutoff of 1% in a gene-based framework. Analyses were adjusted for ancestry and pertinent covariates.

## Results

We discovered that the common missense variant in *ERN1* rs186305118 was associated with dft (beta=1.57 (SE = 0.09), p=0.009) in the COHRA cohort, but not in the POFC cohort. This variant was predicted to be damaging by Combined Annotation-Dependent Depletion (CADD). Gene-based association tests revealed a significant association between low-frequency coding variants in the *XBP1* locus and dft in the POFC cohort ( $p^{\text{CMC}} = 0.0006$ ,  $p^{\text{SKAT}} = 0.005$ ). The association was mainly driven by a variant that causes a frameshift in exon 1 of *XBP1* (c.14\_15insGCCG), and is predicted to result in the production of a truncated nonfunctional protein via PROVEAN (Protein Variation Effect Analyzer).

## Conclusion

Protein-coding variants predicted to be damaging at the *ERN1* and *XBP1* loci are associated with dental caries in the primary dentition. These data, coupled with experimental evidence, indicate a possible regulatory role for *ERN1* and *XBP1* genes in enamel development and caries etiology in children.

## PgmNr 2243: Assessment of oxidative stress among agriculture workers exposed to pesticides in Punjab.

**Authors:**

---

Pesticides are exogenous products that are metabolised to active intermediates leading to generation of free radicals, creating oxidative stress in the biological systems and obligate changes in human defence system. Farmers are occupationally exposed to pesticides and thus are more prone to oxidative stress. The present study was aimed towards analysis of oxidative stress among agricultural workers. A total of 538 subjects were enrolled in the study which included agricultural workers (n=260) and non-exposed subjects (n=278) from Punjab. Calorimetric techniques were used to analyse the oxidative stress by estimation of malondialdehyde (MDA), reduced glutathione (GSH) levels and superoxide dismutase (SOD) activity. A significant increase in lipid peroxidation was observed among exposed group indicated by significantly increased levels of MDA as compared to non-exposed subjects. Alternatively, a decreased SOD activity was seen in exposed subjects. The GSH levels were slightly higher in agriculture workers but, the difference was not significant. The exposed and non-exposed subjects were stratified w.r.t. demographic factors, perturbation in levels of oxidative stress parameters dependent upon alcohol intake, previous medical history of co-morbid conditions, duration of exposure, use of personal protective equipment, recent exposure to pesticides, occurrence of acute health problems were seen among exposed subjects. However, in the absence of occupational exposure, all demographic factors affected the one or more oxidative stress parameters among non-exposed subjects. Thus, a positive association of pesticide exposure with oxidative stress was observed. Since oxidative stress affects reproduction, progression of cancer, and other disorders, strict regulations for use are recommended.

## PgmNr 2244: Assaying lung-specific accessible chromatin to predict the causal variants in COPD.

---

Genome-wide association studies have identified dozens of loci associated with risk of chronic obstructive pulmonary disease (COPD). However, identifying the causal variants and their functional role in the appropriate cell type remains a major challenge; the latter in particular because of the dearth of regulatory profiling in human lung cells.

We generated ATAC-seq data for four primary lung cell types implicated in disease pathology: ATII, bronchial epithelial (NHBE), small airway epithelial (SAEC), and lung fibroblast (LF) cells, as well as the 16HBE human bronchial epithelial cell line. We used these profiles as well as ENCODE data to generate cell type-specific regulatory sequence vocabularies using deltaSVM.

We predicted the effect of 1,235 COPD risk variants corresponding to 22 COPD loci in five lung cell types. We observed that in 14 of the 22 loci (63.6%) the index variant deltaSVM scored in the highest decile for positive or negative effect for at least one cell type, suggesting a functional role. Four of the index variants (near CHRNA5, RIN3, EEFSEC, and DSP) scored large deltaSVM values across the four primary lung cell types. However, at most loci the largest deltaSVM values were at non-index variants. Even in the EEFSEC locus, two nearby variants, rs2955084 (127 bp downstream) and rs2999082 (5 kb upstream), scored comparably large deltaSVM values. The top scoring variants in the COPD credible set suggest novel functional roles for several single nucleotide polymorphisms (SNPs) for nine additional loci.

We further compared the functional consequences of COPD variants in a diversity of cell types and tissues from ENCODE and observed that many variants with the largest predicted effect sizes were not cell type specific, which could be consistent with functional variants in COPD affecting multiple tissues. Correlation and clustering of the samples revealed cell-specific patterns of variant effects, suggesting distinct regulatory effects of COPD genetic factors in lung epithelium, endothelial, and immune cells. In total, this analysis identified >100 COPD risk variants with novel putative functional effects in specific lung cell types. Further experimental validation will be required to evaluate function of these candidate causal variants in vitro and in vivo.

## PgmNr 2245: Dissecting the genetic basis of variation in cocaine and methamphetamine consumption in *Drosophila melanogaster*.

Studies on *Drosophila melanogaster* can identify genetic and transcriptional networks that underlie variation in voluntary consumption of cocaine and methamphetamine to serve as a blueprint for subsequent studies on humans. Exposure to these psychostimulants in flies results in behavioral and physiological effects that resemble those observed in humans. We derived an outbred advanced intercross population (AIP) from 37 of the sequenced inbred wild-derived lines of the *Drosophila melanogaster* Genetic Reference Panel (DGRP). These lines are maximally genetically divergent, have minimal residual heterozygosity, are not segregating for common inversions, and are not infected with *Wolbachia pipientis*. We assessed voluntary consumption of sucrose, methamphetamine-supplemented sucrose and cocaine-supplemented sucrose and found significant phenotypic variation in the AIP, in both sexes, for consumption of both drugs. We performed whole genome sequencing and extreme QTL mapping on the top 10% of consumers for each replicate, sex and condition, and an equal number of randomly selected flies. We evaluated changes in allele frequencies genome-wide among high consumers and the control flies and identified 3,033 variants associated with increased consumption that reside in 1,963 genes, enriched for genes associated with nervous system and mesoderm development. We assessed the effects of ubiquitous RNA interference (RNAi) on consumption for 22 candidate genes, of which 14 showed a significant increase or decrease in consumption. Extensive recombination in the AIP generates increased statistical power compared to genome-wide association analysis of the DGRP and illustrates the polygenic genetic architecture that underlies variation in cocaine and methamphetamine consumption. Supported by NIH grant U01DA041613.

## PgmNr 2246: Distinguishing genetic and tissue regulation of gene expression in human multi-traits by network-based stratification.

---

Context-specific genetic regulation of gene expression plays significant roles in disease etiology. Transcriptome-wide association studies (TWAS) using tissue expression profile opened a new avenue to understand complex diseases in a tissue-specific way. In this study, we collected summary statistics of genome-wide association studies (GWAS) for 57 complex traits from 4 major groups: immune related, psychiatric, cardiovascular, and anthropometric traits. For each trait, we determined trait-related tissues by conducting a tissue-specific enrichment analysis using our recent method, deTS, and conducted TWAS in these tissues. As a result, we constructed a *gene*×*TWAS* matrix containing ~500 TWAS in 32 tissues for 57 traits, with each column representing a tissue TWAS result for a trait. The matrix was then overloaded to a human protein-protein interaction network, followed by network propagation and stratification. Using the uniform manifold approximation and projection (UMAP) method, we found that a majority of traits were clustered by the original trait groups (51/57) while others by tissues (6/57). With a stratified non-negative matrix factorization method, we identified 17 principal patterns (PPs) that represent the major variation in the data. Among them, 10/17 PPs were trait-driven, i.e., the significant trait-tissue pairs were enriched with a trait group, and 5/17 PPs were tissue-driven, i.e., the significant pairs were enriched with a few tissues. For example, we found the 8<sup>th</sup> PP (trait-driven) was enriched with education level and college attendance and the 13<sup>th</sup> PP (trait-driven) was enriched with height TWAS from various tissues. We also found genes contributing differently to each PP. For example, we found the gene *C4A*, which was recently identified as a causal gene in schizophrenia, was most contributive to a brain-driven PP and two trait-driven PPs (immune and blood related traits). Another gene, *SORT1*, a causal gene to lipoprotein cholesterol, was highlighted in a liver-driven PP for total cholesterol, high-density lipoproteins and low-density lipoproteins. Interestingly, the gene *STXBP5*, which was originally reported in plasma and attention-deficit/hyperactivity disorder GWAS, was found in the 8<sup>th</sup> PP (education and college attendance). In sum, our findings distinguished and quantified the contribution of genetic and tissue-specific regulation underlying complex traits, providing insights into the pleiotropic effects of genes and disease etiology.

---

Chronic obstructive pulmonary disease (COPD) is one of the leading causes of morbidity and mortality worldwide. Cigarette smoking is a major risk factor, though only a minority of smokers develops COPD; the estimated heritability is approximately 40%. We hypothesized that a polygenic risk score (PRS) developed from genome-wide association studies (GWAS) of lung function predicts moderate-to-severe COPD, quantitative computed tomography (CT) imaging phenotypes, and patterns of reduced lung growth in children and young adults.

We constructed a PRS using penalized regression accounting for linkage disequilibrium (lassosum) based on summary statistics from GWASs of two measures of lung function in UK Biobank (n=321,047) and SpiroMeta (n=79,055). We tuned model parameters using participants from the GenKOLS case-control study and calculated PRSs in 16 cohorts: COPDGene (non-Hispanic white [NHW] and African American [AA] subjects), ECLIPSE, NETT/NAS, MESA (4 ancestry groups), CHS (African-American and European), Lung Health Study, SPIROMICS NHW, Rotterdam (3 NHW cohorts), and KWU (Korean). In the 16 cohorts, we tested for association between a combined lung function PRS and: moderate-to-severe COPD and five distinct quantitative CT imaging phenotypes. Results were meta-

analyzed across cohorts of either European or non-European ancestry. We also tested the combined PRS association with patterns of reduced lung growth in the Childhood Asthma Management Program (CAMP) cohort.

The combined lung function PRS was associated with COPD in European (OR per PRS SD: 1.7-1.8,  $p=1.6e-156$ ) and non-European ancestry (OR per PRS SD: 1.3-1.5,  $p=4.7e-24$ ) cohorts. Compared to individuals in the first decile of the combined PRS, the tenth decile had an increased odds of COPD in European (OR 6.1 [95% CI: 5.1-7.4,  $p=2.4e-76$ ]) and non-European ancestry (OR 4.8 [95% CI: 3.5-6.8],  $p = 3.5e-16$ ) cohorts. The PRS was associated with four of the five tested CT imaging phenotypes, including percent emphysema ( $p=3.0e-17$ ), wall area percent ( $p=4.7e-38$ ), gas trapping ( $p=0.015$ ), and the 15<sup>th</sup> percentile of the lung density histogram ( $p=2.5e-58$ ). The combined PRS was also associated with a reduced lung growth pattern ( $p = 1.1e-5$ ) in CAMP.

A combined lung function PRS predicted COPD in European and non-European ancestry cohorts and was associated with COPD-related CT imaging features and patterns of reduced lung growth.

## PgmNr 2248: Use of whole transcriptome sequencing to detect molecular signatures from stress reduction interventions.

---

Mindfulness Based Stress Reduction (MBSR) and Music Therapy Stress Reduction (MTSR) programs have been used as clinical interventions to reduce stress and improve chronic disease outcomes in complex conditions such as depression, chronic pain, dementia, etc. However, molecular understanding of the biological underpinnings of such interventions remains limited. In this study, we investigate the feasibility of using whole transcriptome sequencing on RNA from peripheral blood to evaluate gene expression changes following either MBSR or MTSR programs in a cohort of 154 healthy individuals at three time points: baseline level, 2 and 3 months after intervention. All subjects were randomly age-and sex-matched into the two groups of either MBSR or MTSR. Each stress reduction course consisted of structured 2-hour sessions over an 8 week period. The courses were led by certified MBSR and music therapy facilitators. RNA-sequencing was carried out from peripheral blood cells of subjects and reads were aligned using HISAT2 and gene expression changes were estimated at baseline and compared between subjects after 2 and 3 months of MBSR and MTSR using Ballgown R package. MBSR and MTSR groups were also compared with each other at Baseline, 2 months and 3 months. The genes significantly upregulated or downregulated were estimated using a p-value < 0.01 and fold change > 2 (upregulated) and fold change < ½ (downregulated). The results show differential expression of genes involved in immune, neurological, signaling and stress-related pathways such as NF-kappaB Signaling, Mitogen-activated protein kinase (MAPK) pathway and IL2 signaling pathway. Both mindfulness and music interventions could elicit downregulation of pro-inflammatory genes as much as 4 folds while adaptive and innate immune genes were upregulated by 2 -14 folds from baseline. The data points to a complex network of genes and transcripts that regulate stress response and nervous system and provide evidence of molecular response to environmental stimuli through mindfulness meditation and music therapy.

## PgmNr 2249: Whole genome sequence association study of sleep duration in the TOPMed program.

### Authors:

J. Lee<sup>1</sup>; T. Sofer<sup>1,2,3</sup>; S. Redline<sup>1,2,4</sup>; D. Gottlieb<sup>1,2,5</sup>; TOPMed Sleep Working Group

---

**Background:** Sleep duration is heritable, and short and long sleep durations are each associated with numerous adverse health outcomes. Prior genetic studies did not evaluate rare variants. We performed a whole genome sequence (WGS) association study using multi-ethnic data from the Trans-Omics for Precision Medicine (TOPMed) program in Freeze 5b.

**Methods:** We harmonized self-reported usual sleep duration across eight cohorts. We performed associated analyses with sleep duration, short vs normal sleep, and long vs normal sleep, where short sleep was defined as usual sleep  $\leq 5$ hrs, normal sleep as 6-8hrs, and long sleep as  $\geq 9$ hrs. For binary traits, we removed cohort-ethnicity subgroups with fewer than two cases. Sample sizes were 22304, 20021, and 19486, for the continuous, short, and long sleep duration analyses, respectively. We applied linear (sleep duration) and logistic (short and long sleep) mixed-models, with random effects modeled via a genetic relatedness matrix to account for population structure. All models were adjusted for age, sex, and cohort-ethnicity subgroup. For sleep duration, rank-normalized residuals were used in the association analyses. We tested single variants with minor allele count using the Score test for sleep duration, and SAIGE/SPA for short and long sleep. We also tested rare variants in aggregate units of genes and functional categories, and non-overlapping 3000bp sliding windows of variants with a FATHMM-XF score  $> 0.5$  and maximum alternate allele frequency of 0.01. For aggregate tests we used both the SKAT test with weights of Beta(1, 25), and unweighted burden test. In each set, we required at least 3 variants, and at least 20 counts of alternate alleles for the burden test.

**Results:** Rs141617869 (MAF=0.08) located 27kb downstream of *BMP15* in the Xp11.22 region, was associated with sleep duration ( $p=2.7e-08$ ); and two rare variants (MAF=0.002) in the 2p22.3 region were associated with short sleep ( $p=2.6e-08$ ). The top gene associations were *TNFRSF10D* for short sleep (high confidence loss of function; SKAT  $p=3.4e-09$ ), *IL31RA* for long sleep (high confidence loss of function; SKAT  $p=1.0e-08$ ), and *XRCC1* for sleep duration (missense; burden  $p=9.9e-07$ ). There were additional significant sliding window associations ( $p<1e-8$ ).

**Conclusion:** Novel variants and genes were associated with sleep duration, short sleep, and long sleep, including an X-linked variant and genes associated with inflammation and DNA damage.

## PgmNr 2250: A GWAS identifies novel susceptibility loci for irritable bowel syndrome.

---

Irritable bowel syndrome (IBS) is the most frequently diagnosed functional gastrointestinal disorder, which is characterized with recurrent abdominal pain and discomfort. The worldwide prevalence of IBS ranges from 10% to 20% and over 60% of IBS patients are female. The pathogenesis of IBS is complex and there is no specific laboratory test or effective cure treatment. It is essential to characterize the genetic components of IBS in order to further understand its pathogenesis. We conducted a genome-wide association study including 2164 IBS cases and 2097 controls of African American ancestry. After quality control filtering and genome-wide imputation, we found a significant locus at 8q21.13 (rs113344155, OR=1.98, P-value=2.52E-08). SNP rs113344155 is located in gene *CHMP4C* which encodes a protein belonging to the chromatin-modifying protein/charged multivesicular body protein (CHMP) family. Several loci were approaching genome-wide significance, such as SNP rs116608329 at 4p13.1 (OR=0.48, P-value=2.42E-07). GWAS in 2348 IBS cases and 4481 controls of European ancestry did not yield any genome-wide significant locus. SNP rs10152423 showed suggestive level of significance (OR= 0.69, P-value=1.7E-06). Further replication and functional characterization of these loci are underway.

## PgmNr 2251: Genome-wide association study identifies genetic polymorphisms and genes possibly associated with chronic pain and postherpetic neuralgia.

---

**Purpose:** Human twin studies and other studies have indicated that chronic pain has heritability ranging from 30-70%. Various kinds of drugs were administered to patients with chronic pain for the treatment of pain, and some of these drugs may be effective for certain patients, whereas others may not. We conducted genome-wide association study (GWAS) in patients who suffer from chronic pain to identify potential genetic variants that may significantly contribute to susceptibility to chronic pain and effects of administered drugs. **Methods:** Subjects enrolled in our analyses were 191 patients with chronic pain or pain-related disorders including neuropathic pain such as postherpetic neuralgia (PHN) who visited several hospitals in Tokyo in Japan for the treatment of chronic pain. We conducted GWAS by using whole-genome genotyping arrays with more than 700,000 markers in 191 patients and 282 healthy control subjects in trend, dominant, and additive genetic models. Genome-wide associations between genetic polymorphisms and susceptibility to PHN were also investigated by comparing only patients with PHN and control subjects. Further, we applied GWAS to the effects of drugs for the treatment of pain, which included opioids, antidepressants, anticonvulsants, non-steroidal anti-inflammatory drugs (NSAIDs), and gamma-aminobutyric acid (GABA) receptor agonists, in the patient subjects. **Results:** Although none of the single-nucleotide polymorphism (SNP) markers were found to be genome-wide significantly associated with chronic pain in a GWAS in all patients ( $P \geq 1.858 \times 10^{-7}$ ), another GWAS including only PHN patients revealed that rs4773840 SNP within the *ABCC4* gene region, which mapped to 13q32.1, was identified to be significantly associated with PHN in trend model (nominal  $P = 1.638 \times 10^{-7}$ ). In additional gene-based analyses, only one gene, *PRKCQ*, was significantly associated with chronic pain in trend model (adjusted  $P = 0.03722$ ). However, none of the genes were significantly associated with PHN in any genetic models. Moreover, further GWAS on the effects of drugs for the treatment of pain in the patient subjects observed no SNPs significantly associated with the phenotypes in any genetic models. **Conclusions:** Our results suggested that the *PRKCQ* gene and the rs4773840 SNP within the *ABCC4* gene region could be related to susceptibility to chronic pain conditions and PHN, respectively.

## PgmNr 2252: Correlation between gut microbiota and 6 facets of neuroticism in Korean adults.

---

Personality affects fundamental behavior patterns and has been related with health outcomes and mental illness. Neuroticism is a heritable personality trait that is comprised of distinct sub-facets. We reported that Neuroticism showed significantly correlated with diversity and composition of gut microbiota (Han-Na Kim, BBI, 2018). In the present study, diversity of gut microbiota association studies for six facets of neuroticism which includes N1-Anxiety, N2-Hostility, N3-Depression, N4-Self-consciousness, N5-Impulsiveness and N6-Vulnerability was performed. This research was performed using the Korean version of the Revised NEO Personality Inventory and the sequencing data of the fecal 16S rRNA gene in 513 men and 311 women. Each subject provides a stool sample and bacterial DNA is extracted. The V3 and V4 hypervariable region of bacterial 16S rRNA gene are sequenced using Illumina MiSeq platform. DADA2 pipeline of R was used for identifying ASV feature table and 16S rRNA data was analyzed using QIIME2 software.

The diversity and the composition of the human gut microbiota exhibited significant difference when stratified by Neuroticism facet quartiles: For male, in groups with high N1, N3 and N6 scores, the observed diversity was increased while evenness shows significantly decreased. On the other hands, female showed less significant difference in microbiota diversity between low and high neuroticism facets.

Our findings implicated association between the gut microbiota and personality, and providing useful visions toward developing and testing of personality- and microbiota-based interventions for improving health condition. This research was supported by National Research Foundation of Korea (NRF) funded by the Ministry of Education (NRF-2018 R1D1A1B07-050067).

## PgmNr 2253: Beyond GWAS: Fine-mapping, functional, and phenotypic follow-up of 44 genome-wide significant endometriosis associations in 61K cases and 711K controls.

---

Endometriosis is an oestrogen-dependent condition seen in 5-10% of women of reproductive age, associated with infertility and chronic pelvic pain. The heritability has been estimated to be ~50% with 26% due to common genetic variants. We have undertaken the largest genome-wide association study (GWAS) meta-analysis of endometriosis to date, including 61,077 cases and 711,319 controls of European and Japanese ancestry. We identified 44 genome-wide significant (GWS,  $P < 5 \times 10^{-8}$ ) loci associated with endometriosis, 32 of which are novel with 22 showing larger effect sizes for severe (American Society of Reproductive Medicine (ASRM) stage III/IV) disease vs. mild (ASRM stage I/II). Conditional analyses revealed multiple distinct association signals for 11 GWS loci, including 7 mapping near the Estrogen Receptor 1 (*ESR1*) gene. A functional GWAS (fGWAS) analysis revealed enrichment of endometriosis association signals mapping to binding sites for 5 transcription factors (EGR1, GATA3, RELA, SUZ12, TFAP2C) and enhancers in the ovary (OVRY-EnhA). EGR1 mediates oestrogen activity to establish uterine receptivity for embryo implantation. GATA3 is induced by oestrogen in a dose/response manner promoting cytokine secretion in endometrial cells. TFAP2C is involved in epigenetic regulation of *ESR1* expression in breast cancer. RELA and SUZ12 are involved in immune and inflammatory response pathways. Fine-mapping of endometriosis loci, informed by enriched annotations from the fGWAS analysis, uncovered 15 high-confidence variants (>50% probability of being causal for the association signal): rs9789525 in *GREB1*, rs6456259 near *ID4*, rs851983 in *ESR1* and rs71575922 in *SYNE1*, rs979165 near *miR148a* and rs6970537 in *HOXA10*, rs10757279 near *CDKN2-BAS1*, rs507666 in *ABO*, rs10828247 near *MLLT10*, rs4071558 near *FSHB*, rs3803042 near *HOXC10*, rs6538618 near *VEZT*, rs3742716 in *RIN3*, rs7183386 in *SRP14-AS1*, and

rs73241342 near *PLAC1*. Furthermore, we have conducted analyses of RNAseq data from endometrium tissue collected from endometriosis cases (N=58) and controls (N=70), revealing 12 significantly differentially expressed genes mapping to GWS loci. Phenotypic stratified analyses of the GWS loci in deeply phenotyped datasets are ongoing. Taken together the results will provide better understanding of the underlying functional mechanisms of genetic risk variants on endometriosis and its subtypes.

## PgmNr 2254: Structural variants associated with GWAS SNPs provide mechanistic explanation of phenotypic associations.

---

**Background:** Genome wide association studies (GWAS) use common single nucleotide polymorphisms (SNPs) to identify genomic regions associated with phenotypic traits. The SNPs identified in GWAS are rarely the causal variants for the evaluated phenotype. Typically, these are genetically linked on a common haplotype carrying functional variants. Structural variants (SVs) have been reported to co-occur with SNPs identified by GWAS (Liu et al., 2018) and insertion variants occur disproportionately at GWAS loci (Payer et al., 2017). Optical genomic mapping (OGM) allows for improved detection of SVs not found using short-read DNA sequencing. SVs are among the most common sources of genomic variation and occur at polymorphic frequencies similar to SNPs (Levy-Sakin et al., 2019).

**Objective:** Using public datasets of SVs in well genotyped individuals, we characterized common SVs co-occurring with GWAS SNPs.

**Methods:** SVs identified using OGM on 154 individuals (Levy-Sakin et al., 2019) were merged with phased haplotypes from the 1000genomes project (The 1000 Genomes Project Consortium, 2015). SNPs associated with phenotypes were obtained from the NHGRI-EBI GWAS Catalog (Buniello et al., 2019). Genotype counts were calculated for 1,315,891 pairs of SNPs and SVs with allele frequencies greater than 5% located within 10 megabases of each other. Phased haplotypes were counted for all genotypes except the doubly heterozygous cases where phase is ambiguous. P-values for linkage were calculated using Fisher's exact test under the null hypothesis of independent assortment of the two loci and Bonferroni correction applied.

**Results:** There were 1,146 pairs of SVs and GWAS-reported SNPs with significant associations including loci associated with diverse traits including biometric measurements and disease susceptibilities. These pairs involved 1,098 distinct SNPs and 361 distinct SVs with candidate gene involvement consisting of 197 deletions, 157 insertions, and 7 inversions. The SV more frequently associated with the SNP minor allele in 612 pairs and the major allele in 534 pairs.

**Conclusions:** Common SVs provide plausible mechanistic explanations of many GWAS associated SNPs. Due to larger size, SVs likely have larger effects on gene expression, regulation, and splicing than SNPs. As the marker SNP is observed on haplotypes both with and without the SV, direct evaluation of polymorphic SVs may demonstrate stronger associations than SNP based GWAS.

## PgmNr 2255: Upper airway microbiota diversity in infancy is associated with nasal mucosa DNA methylation patterns and allergic rhinitis at 6 years of age.

---

Allergic rhinitis (AR) is a common inflammatory disease of the nasal mucosa, characterized by the presence of specific IgE (sensitization) to inhaled allergens and symptoms such as sneezing, rhinorrhea and nasal congestion. Nasal mucosa forms a physical and immune barrier to inhaled allergens and to microbes, both of which can alter immune responses and subsequent risk for disease, such as AR. We hypothesized that early life exposure to microbes in the upper airway alters the epigenetic landscape in nasal mucosa, leading to allergen sensitization (AS) and AR later in childhood. To address this hypothesis, we examined airway (hypopharyngeal) microbiota assessed by 16S rRNA gene sequencing at 1 week, 1 month and 3 months of life and DNA methylation (Illumina 850k EPIC array) profiles in cells obtained by nasal brushings at age 6 from 454 children in the Copenhagen Prospective Studies on Asthma in Childhood (COPSAC)<sub>2010</sub> birth cohort; 24 of these children were diagnosed with AR and 331 had neither AS or AR at age 6. Our study revealed that children with AR at age 6 had a significantly less diverse nasal microbiota at 1 week (richness: median 17 and 21, Wilcoxon rank sum test  $P=2.9 \times 10^{-3}$ ) and 1 month (Shannon diversity index: median 0.87 and 1.12, Wilcoxon rank sum test  $P=0.039$ ), but not at 3 months of age, compared to children with neither AS or AR. Using linear models (limma) adjusted for cell composition, we identified 720 differentially methylated probes (DMPs; FDR 5%) in nasal brush cells at age 6 (80% were less methylated in children with AR). Genes near DMPs were enriched for relevant gene ontology pathways, such as immune system process and response. Richness measures at 1 week were correlated with methylation levels at 31 DMPs (Spearman  $\rho > |0.15|$ ;  $P < 0.01$ ), which was never observed in 1000 subsamples of 720 probes that were not differentially methylated (median and maximum number of correlations with  $\rho > |0.15| = 7$  and 18; permutation  $P < 1 \times 10^{-3}$ ). These data indicate that a less diverse upper airway microbiota in infancy is associated both with subsequent development of AR and altered DNA methylation patterns in airway mucosal cells that differ between children with and without AR at age 6. Taken together our results suggest that trajectories for development of AR is modulated by microbial exposures in infancy, at least in part through epigenetic modification of nasal mucosal cells. Supported by NIH R01 HL129735.

## PgmNr 2256: Exome sequencing identify a damaging mutation in *ABI3BP* in a family with hereditary gingival fibromatosis from Nigeria.

---

Hereditary gingival fibromatosis (HGF) is a slow and progressive enlargement of the attached gingiva covering the teeth and affecting speech, mastication and aesthetics. This is a rare oral disease which may be localized or generalized, may be isolated or part of a syndrome. Several genetic factors have been associated with the syndromic type however little is known about the genetic factors associated with the isolated type. In this study, we conducted exome sequencing using DNA from a Nigerian family. The father presented with a localized form of HGF while the 4 year old child has a 2 year history of generalized form of HGF. However, the mother does not have any history of this disease. Out of the 255,692 variants called 207,026 passed the quality check. VarSeq® software was used in the annotation and analyses of the variants called. The called variants were filtered for shared dominant variants (present only in the father and son but absent in the mother). These variants are expected to affect the structure and function of the protein hence results in the phenotype based on bioinformatics predictions using Silico tools like Polyphen, SIFT, HOPE and CADD scores. These variants were also filtered for very low minor allele frequency by comparing to the publicly available control database which contains over 5000 individuals from African populations. Out of the 207,026 variants that passed the quality check, 10 variants met the filtering criteria and were validated by Sanger sequencing. Among the 10 variants, the *ABI3BP* variant (c.53G>T p.Cys18Tyr) has the highest Combined Annotation Dependent Depletion (CADD) score of 24 meaning it is among the top 1% deleterious mutation in the human genome. Sorting Intolerance From Tolerance (SIFT) and Polymorphism Phenotyping (PolyPhen) predicted this variant to be deleterious and probably damaging, respectively. *ABI3BP* variant is predicted to be pathogenic by ClinVar and has an increased size and reduced hydrophobicity according to HOPE (Help Your Protein Explained). This gene has 2 fibronectin domains and it is involved in collagen binding and organization of the extracellular matrix. Whole exome sequencing of a triad identified a gene involved in the organization of extracellular matrix, which is associated with HGF. Identification of variants in *ABI3BP* in more families with HGF and functional study in human gingival mesenchymal stem cell lines to validate these variants is ongoing.

## PgmNr 2257: Novel mutations screening by family based whole exome sequencing in premature ovarian insufficiency patients.

Premature Ovarian Insufficiency (POI) is defined as amenorrhea over 4 months before the age of 40-year and the incidence of POI is about 1~2 % of women worldwide. Autoimmune dysfunctions, metabolic disorders and genetic abnormalities such as chromosomal abnormalities or gene mutations are well-known etiologies of POI, however, most cases of POI are still idiopathic. In this study, whole exome sequencing (WES) analysis was performed in three pairs of POI patient and her mother. All patients had a normal 46, XX karyotype, and *FMR1* premutation was ruled out. To investigate causative genetic mutations, rare variants were selected with minor allele frequencies (MAF) < 0.1% based on the public population genomic data bases. After several filtering steps, one or two convincing variants were elucidated in each proband. These variants were confirmed by Sanger sequencing in the patients and 115 control women.

A heterozygous non-synonymous variant of *AKT1* (c.225C>G, p.Ile75Met) was found in proband P1, but not in her unaffected mother and control subjects. SIFT and PolyPhen-2 predicted the variant as a damaging mutation. AKT1, RAC- $\alpha$  Ser/Thr protein kinase, is involved in various of regulating processes including cell proliferation and growth via phosphorylation activity to downstream targets. In another family, a heterozygous premature stop variant of *BLM* (c.2410G>T, p.Gly804\*) was discovered in the proband P2. This novel premature stop variant was not found in her mother and controls. BLM, a bloom syndrome protein is an ATP-dependent DNA helicase that required for DNA replication and repair. A heterozygous missense variant in *NPPC* (c.131A>G, p.Gln44Arg) was identified in proband P3 and her mother with early menopause. A natriuretic peptide C (NPPC) and natriuretic peptide receptor 2 (NPR2) maintain cGMP and cAMP-mediated meiotic arrest in oocytes for ovarian reserve. The physiological roles of these newly identified genetic variants will be explored by *in-vitro* functional analysis in further studies. This work is supported by National Research Foundation of Korea (NRF) Grants from the Korean Government, No. 2019R1A6A1A03032888 and NRF-2017R1C1B5077023.

## PgmNr 2258: Polygenic effects and outlier individuals on gene expression to assess disease susceptibility.

---

It has been shown that variants that are rare in the population can have extreme effects on the expression of genes and also extreme effects on risk of disease. It has also been shown that genes can be regulated by multiple independent common variants. Similarly to how polygenic risk scores are used to predict individuals whose combinations of genotypes place them at the extreme end of the disease risk spectrum, we hypothesize that particular combinations of these common regulatory variants, representing combinations (cis haplotypes) that are rare in the general population, could also have extreme effects on expression and downstream effects on disease risk. These rare haplotypes of common variants may also show evidence of selective constraint.. Linking particular haplotypes both to extreme effects on expression and risk of disease would provide stronger evidence for mechanistic effects on disease. Our analysis focuses on individuals with extremely high or extremely low expression of a particular gene -because of the combined effect of multiple eQTLs on that gene- compared with the population. We aim to discover rare combinations of common variants with extreme effects on gene expression. We replicate the analysis in different datasets including the 49 tissues in GTEx for which eQTL data is available and UK Biobank, to link these combinations with diseases and other common traits in large GWAS studies. We further investigate if there is any evidence of selection acting on those haplotypes by implementing extended haplotype homozygosity (EHH) methodologies. By using lists of independent eQTLs from the GTEx project, we aim to find individuals whose predicted expression from genetic code is an extreme outlier. After defining haplotypes with extreme effects, we are planning to assess, using the UK Biobank dataset, if these haplotypes are associated with disease or other quantitative traits. Our preliminary results show that these effects while rare can have a profound impact on identifying individuals with increased disease risk due to cumulative effects in a few genes.

## PgmNr 2259: Polygenic risk score accuracy is dependent on local ancestry.

**Background:** Polygenic risk scores (PRS) have been developed and optimized in European populations, resulting in potentially biased and less predictive scores among non-Europeans. It is unknown whether these limitations are due to improper SNP selection or incorrect weighting, although previous studies have focused on the latter. In addition, the amount of bias may be individual-specific and dependent on the local ancestry at a given disease locus. To better understand the lack of generalizability of European PRSs across non-European populations, we will assess the relationship between bias and local ancestry at PRS variants. **Methods:** Genotypes for individuals of European (CEU) and African (YRI) ancestry were simulated. A subset of individuals were used as founders to create a new admixed population (n=4000) with RFMIX. True PRSs were computed for admixed and non-founder European individuals as described in *Martin et. al. 2017 (AJHG)* assuming 1000 causal variants and heritability of 0.67. To reflect European bias, a GWAS was conducted using 100,000 CEU individuals with 10,000 cases to identify independent GWAS significant variants and derive weights for an empirical PRS. **Results:** In our simulations we found that the Pearson's correlation between the true (m=1000) and empirical (m=820) PRSs diminished with increasing proportion of African ancestry at PRS variants. Individuals of European-only ancestry had high correlation (r=0.645) and those with low European ancestry (CEU<20%) had low correlation (r=0.432). Admixed individuals with high European ancestry at PRS variants (CEU>80%) had lower correlation (r=0.606) than European-only; however, this trend reflects that increasing noise is added into the empirical PRS with higher divergence from European ancestry at PRS variants. Utilizing this simulation framework, we will test different approaches for creating less-biased models, including effect size adjustment and SNP selection specific to local-ancestry population allele frequency and LD. **Conclusion:** Through simulations we show that the bias introduced by European GWAS when applied to non-European individuals is dependent on local ancestry and seen even when assuming identical causal SNPs across populations. This is likely a result of GWAS identifying the best European tag-SNP, which may be in lower LD with the causal variant in the non-European population. Local ancestry will be crucial to generalizing polygenic risk scores across admixed populations.

## PgmNr 2260: The genetic background of intrahepatic cholestasis of pregnancy: Findings from the FINNGEN study.

---

Intrahepatic cholestasis of pregnancy (ICP, 0.4-1.5% of pregnancies) is a reversible liver disease of the late second or third trimester of pregnancy. It is characterized with pruritus, elevated serum bile acids, and elevated liver enzymes. It is linked to increased fetal risk: stillbirth, meconium passage, respiratory distress syndrome and asphyxia as well as maternal risk for gestational diabetes and pre-eclampsia. ICP has a complex aetiology with a genetic component. A handful of candidate genes, mainly involved in metabolism and transport of bile acids, have been implicated. No genome wide association studies have been published yet. Given this we set out to investigate ICP comorbidity associations, as dissecting the genetics underpinnings of disease.

The FinnGen study aims to create a dataset of ~500,000 genotyped Finns (~10% of the population) connected to electronic health records (EHRs) by unique personal identification number. Using the EHR's we constructed disease endpoints for ICP and a range of comorbidities. The current FINNGEN data freeze contains ca. 140,000 study participants. There were 581 ICP cases, among 26,343 women (2.2%) who had delivered at least once.

Both prevalent autoimmune disorders (Fisher test  $p=0.00015$ ), and diabetic pregnancy ( $p=5.9e-6$ ) were associated with ICP, while we saw no evidence of association to malignancies, cardiovascular diseases or pre-eclampsia ( $p>0.05$ ).

Next, we explored whether ICP predisposed to later morbidity (age adjusted Cox regression). The set of morbidities was in line with those in the J Hepat article by Wikstöm Shemer et al (2015), including malignancies, autoimmune diseases, cardiovascular diseases and pregnancy-related outcomes. Among ICP patients the following outcomes were more frequent: Crohn's disease ( $p=0.012$ ), polyarthropathies ( $p=8.0e-4$ ), adverse pregnancy outcomes ( $p=0.011$ ), including preeclampsia ( $p=6.5e-10$ ).

Finally, we performed a PheWAS scan for the FINNGEN participants. ICP was associated with regions in several liver transporter genes. Some of these regions were also associated with cholelithiasis.

In conclusion, ICP has a strong genetic background, and it is associated to autoimmune disorders and adverse pregnancy outcomes. We are currently expanding our analysis with >2,000 cases from an additional cohort. The understanding of the genetic underpinnings of this disease will lend itself to a greater understanding of the mechanisms responsible for the disease susceptibility.

## **PgmNr 2261: A genome-wide association study on landmark based phenotypes identifies novel loci for facial variations in East Asian populations.**

### **Authors:**

S. Du; S. Wu; M. Zhang

[View Session](#) [Add to Schedule](#)

---

Numerous studies have shown evidence of a genetic basis for facial morphology. Previous studies based on 3D facial surface images have identified a number of genetic loci associated with facial quantitative traits. However, most studies on facial morphology were performed on Caucasian and African populations, while few studies were based on East Asian populations. In this study based on 19 anatomical landmarks automatically placed on 3D facial surface meshes of 6,132 individuals of East-Asian ancestry, we calculated 192 linear distances between each two landmarks as traits. We then carried out a genome-wide association study of linear distances and observed genome-wide significant associations ( $p < 5 \times 10^{-8}$ ) for traits related to nose and eyes with six genetic loci including previously reported signals at 1p36.32, 2q36.1, 4q31.3 and 17q24.3, as well as novel signals at 3p25.2, 6p12.1 and 15q23. By visualizing the morphological effects of the associated loci at the local and global levels, we could observe that the loci associated with linear distances in nose and eyes also influenced the global facial morphology. These results provided a more comprehensive understanding of the relation between genetic loci and human facial morphology.

## **PgmNr 2262: SNPs in *PDE3A*, *OLFM4*, and *CYP1A2* were associated with caffeine consumption in a genome-wide association study of the Coriell Personalized Medicine Collaborative.**

### **Authors:**

---

More than 90% of Americans consume caffeine daily, but the amount consumed varies widely between individuals. Previous studies have shown that genes related to caffeine metabolism and receptor binding may influence caffeine consumption. Better understanding the relationship between genotype and caffeine consumption has the potential to inform potential mechanisms of the cardioprotective effects of caffeine, as well as its role in headache including migraine.

We performed a genome-wide association study (GWAS) of 2,783 participants in the Coriell Personalized Medicine Collaborative for the phenotype of self-reported caffeine consumption in drinks per week using a generalized linear model using age, cohort, gender, and principal components to account for population structure. Participants reported the number of caffeinated drinks they consumed in a typical week at baseline.

Our analysis identified three genetic loci associated with caffeine consumption near the Bonferroni-corrected alpha significance threshold. One locus, rs12580173 ( $p\text{-value}=2.8\times10^{-7}$ ), is located in *PDE3A*, the gene for phosphodiesterase (PDE) 3A. PDE3A is one of several PDEs inhibited by caffeine that catalyze the elimination of cyclic adenosine monophosphate (cAMP) and has been linked with cardiovascular disease and migraine. The second locus, rs11620007 ( $p\text{-value}=8.2\times10^{-7}$ ), is near *OLFM4*, which is reported to play roles in metabolic function, pancreatic cell proliferation, and cell adhesion. The third locus, rs2472297 ( $p\text{-value}=2.2\times10^{-6}$ ), upstream of the gene for CYP1A2 (the enzyme primarily responsible for caffeine metabolism), has been associated with caffeine consumption in prior studies. Though these loci did not meet the threshold for genome-wide significance ( $p\text{-value}=5\times10^{-8}$ ) in this relatively small GWAS, the biological relevance of CYP1A2 and PDE3A to caffeine metabolism and pharmacodynamics lend plausibility to the associations.

These findings add to a growing body of literature characterizing the influence of genetics on caffeine consumption that has the potential to inform lifestyle choices (i.e. consumption behavior), as well as associations with health outcomes. These results suggest that further research into the role of PDEs such as PDE3A in mediating the effects of caffeine on cardiovascular health and headache may be warranted. Such work has the potential to eventually inform personalized interventions aimed at improving cardiovascular, metabolic, and quality of life outcomes.

## PgmNr 2263: Genetically mediated variation in one carbon metabolism is associated with the development of edematous severe acute malnutrition.

Severe acute malnutrition (SAM), which affects 16.9 million children globally and contributes to the death of 3 million annually, occurs as either edematous SAM (ESAM), characterized by swelling and extensive organ failure and seen most commonly in Central Africa and the Caribbean, or non-edematous SAM (NESAM), characterized by extensive wasting and seen most commonly elsewhere. The diet and environment of SAM-affected children is similar regardless of sub-type, so the reasons why some children develop ESAM while others develop NESAM remain unclear. However, we have previously shown that ESAM is associated with significant hypomethylation of DNA at metabolic and nutritional gene loci. This is consistent with a growing body of work that suggests abnormal one-carbon metabolism (OCM) is a key factor in the development of ESAM. As genetic variation is known to significantly impact OCM, we sought to determine whether variants in genes regulating OCM contribute to the development of ESAM versus NESAM.

Using samples from 711 Jamaican and Malawian children, evenly split between those with ESAM or NESAM, we assayed 1.8 million SNPs using the H3Africa SNP microarray. Logistic regression coupled with hypergeometric sampling uncovered evidence of a cumulative significance of OCM-related SNPs associated with ESAM ( $z = 3.058$ ). This was partially driven by SNPs in *GABBR2*, a gene associated with OCM homocysteine levels, that seem to confer protection from ESAM ( $P_{\text{locus}} = 2.18 \times 10^{-5}$ , odds ratio = 0.5659). Logistic regression in Jamaica and Malawi samples separately also uncovered strong evidence of association between SNPs in *PRICKLE2*, a modulator of OCM folate concentration, and ESAM in Malawi that was attenuated in Jamaica ( $P_{\text{locus}} < 5 \times 10^{-4}$ ). Admixture analyses identified differing proportions of ancestral Bantu-speaking components in Jamaica and Malawi, suggesting that differences in local ancestry may contribute to differing strengths of disease association and geographical patterns of disease prevalence.

Our findings provide the first molecular evidence for genetic variation as a mediator of clinical outcomes in severe nutritional stress, and emphasize the importance of integrating local ancestry and

population genetics with disease studies to elucidate associations and understand geographical variation in disease. Work to leverage local ancestry and haplotype analyses to further clarify these associations and to integrate previously identified methylation QTLs is ongoing.

## PgmNr 2264: First genome-wide analysis of developmental stuttering identifies genome-wide significant signal near *EFNA5*.

### Authors:

---

Developmental stuttering is an often debilitating speech disorder characterized by prolongation of sounds and interruptions in speech with childhood onset. It can negatively affect job performance and employability in adults and frequently results in decreased classroom participation and increased bullying in children. Persistent stuttering is also very common, with a prevalence of 1% of the general adult population. Moreover, despite large heritability estimates and strong familial trends, the genetic architecture and etiology of developmental stuttering remain elusive, in part due to the challenges associated with amassing a large enough cohort for well-powered population-based analyses. To date, no genome-wide association study of developmental stuttering has been published.

Here, through collaborative efforts and an innovative social media campaign, we genotyped 809 developmental stuttering cases on the Illumina multi-ethnic genotyping array (MEGA) measuring 1,842,793 variants. Approximately 3000 ancestry matched randomly selected population-based controls were drawn from Vanderbilt's identically genotyped and called DNA biobank, BioVU. Using logistic regression in an unrelated, Caucasian subset of cases (n=589) and controlling for the first three principal components we analyzed 790,192 common variants measured in both case and control data sets, and identified one variant reaching genome-wide significance, rs17159693 (p-value  $4.302e^{-08}$ , OR 1.692) and 22 variants with suggestive significance (p-values less than  $5e^{-06}$ ). For variant rs17159693, developmental stuttering cases had a minor allele frequency (MAF) of about 16%; whereas, controls had a MAF of about 10%, aligning with reported MAF in European ancestry populations (per dbSNP). Validation analyses include cross-ancestry analysis in an additional 800 developmental stuttering cases, fine mapping, and rare variant analysis in 1500 whole exomes.

Interestingly, variant rs17159693, is physically adjacent to *EFNA5*, a member of the ephrin gene family implicated in mediating developmental events, particularly in the nervous system. These intriguing preliminary results are the first to implicate genes that regulate nervous system development in the etiology of developmental stuttering.

# PgmNr 2265: Functional haplotypes in the *ADIPOQ* gene are associated with underweight, immunosuppression and viral suppression in Kenyan HIV-1 infected injection substance users.

## Authors:

---

## Background

Human immunodeficiency virus (HIV) and injection substance use have both direct and epigenetic effects on genes. These effects could be beneficial or detrimental in defining disease outcomes. *ADIPOQ* gene is key in modulating metabolic and immunoregulatory functions. Understanding the effects of HIV and injection substance use on the gene in the context of antiretroviral therapy is important for predicting disease outcomes.

## Methods

This cross-sectional genetic study determined polymorphisms in the promoter region of the *ADIPOQ* gene. Two loci were analyzed rs2241766 and rs266729. The polymorphisms were associated with clinical markers of disease outcome; underweight, immunosuppression and viral suppression. The selected variants were amplified via PCR then genotyped via random fragment length polymorphism.

## Results

GC haplotype associated with higher odds of having underweight (OR, 2.21; 95% CI, 1.83-4.60;  $P=0.008$  vs. OR, 2.30; 95% CI, 1.89-4.71;  $P=0.006$ ) in ART-naïve and experienced ISUs and immunosuppression (OR, 1.90; 95% CI 1.67-3.98,  $P=0.041$ ) in ART-naïve while TC haplotype associated with lower odds of having underweight (OR, 0.49; 95% CI, 0.31-0.74;  $P=0.019$  vs. OR, 0.43; 95% CI, 0.19-0.89;  $P=0.028$ ) in both ART-naïve and -experienced ISUs and immunosuppression (OR, 0.42; 95% CI 0.16-0.81,  $P=0.023$ ) in ART-naïve ISUs. Circulating total adiponectin levels were higher in ART-naïve (median, 19.5; IQR, 7.9 µg/ml) than -experienced (median, 12.0; IQR, 4.4 µg/ml) ISUs ( $P<0.0001$ ). Underweight and immunosuppressed ISUs presented with lower serum adiponectin levels while virally suppressed participants had higher serum adiponectin levels. GC carriers presented with low while TC carriers presented with higher adiponectin levels in both ART-naïve and -experienced ISUs.

## Conclusion

The study revealed haplotypes of the *ADIPOQ* gene at loci rs2241766 and rs266729 that could determine disease outcomes in HIV-1 ART naïve and experienced ISUs.

## PgmNr 2266: Elucidation of the causative gene of non-obstructive azoospermia by whole-exome sequencing.

---

**BACKGROUND:** About 10% of male infertility patients do not have sperms in their semen and are diagnosed with azoospermia. The condition without obstruction of the post testicular genital tracts and no sperm production is called non-obstructive azoospermia (NOA). The causes of NOA, excluding Klinefelter syndrome, includes deletion of the Y chromosome azoospermia factor (AZF) region. A diagnostic test for detection of the AZF region is useful to predict sperm recovery by microdissection testicular sperm extraction (MD-TESE). About 10% of NOA patients have a deletion of the AZF region; however, other causes remain to be elucidated. This study aimed to clarify the pathogenesis and condition of individual NOA patients by genetic analysis using next-generation sequence analysis. **METHODS:** Five men diagnosed with NOA at the International University of Health and Welfare Hospital and who had undergone MD-TESE were recruited in this study. After extracting the DNA, exome sequencing was performed, and genes that affected protein function and with an allele frequency of 1% or less were narrowed down. Subsequently, we searched relevant literature for relationship between genes and spermatogenesis.

**RESULTS and DISCUSSIONS:** The BRWD1, HFM1 and NLRP14 genes, which were narrowed down in three patients in whom sperm could not be recovered with MD-TESE, were reported to be involved in spermatogenesis. Therefore, we speculate that variants in these genes may have caused spermatogenesis failure in these three patients. On the contrary, no gene reported to be associated with spermatogenesis was found in the two subjects whose sperms could be recovered by MD-TESE; this may be due to unexplained genetic or other environmental factors. These results indicate that whole-exome sequencing would enable us to understand the causes of NOA. Furthermore, because genes that are associated with spermatogenesis were found only in patients whose sperm could not be recovered by MD-TESE, whole-exome sequencing for NOA patients undergoing MD-TESE may lead to the prediction of sperm recovery.

## PgmNr 2267: Genome wide association analysis suggests three novel genetic associations with specific language impairment in a large DNA biobank.

Specific language impairment (SLI) is a developmental language disorder in which children will often have reduced or absent language capabilities during early childhood. In addition to late onset of speaking skills, children with SLI often have difficulty mastering basic grammar patterns and utilizing proper tenses. Children with SLI are phenotypically distinguishable from patients whose speaking capabilities are directly affected by alternative correlative phenotypes including hearing loss, autism, and other developmental disorders. This diagnosis is relatively common for children in their kindergarten years, having a prevalence of approximately 7% within school aged children in the US. SLI profiles within patients can vary, and patients are often stratified into those with expressive language delays, receptive language delays, or both.

Early twin studies demonstrated moderate heritability for SLI, with estimates ranging from 0.5 to 0.75 for school aged children. Despite this strong genetic component, the genetic architecture of SLI is still largely unknown. Previous linkage analyses have demonstrated an association between abnormalities in the FOXP2 gene and SLI, providing a potential causative pathway. However, most patients with SLI have no abnormalities in FOXP2, suggesting undiscovered genetic components of SLI remain.

We utilized BioVU, a large DNA biobank at Vanderbilt University Medical Center linked to electronic health records (EHR) and deployed a novel EHR-based SLI phenotyping algorithm to identify likely cases of SLI. We matched probable cases to controls based on genetic ancestry principal components, including in our preliminary analysis 247 cases and a total sample size of 1,235. We ran an association analysis using logistic regression, controlling for three principal components, in order to identify variants associated with specific language impairment.

Our top hits following the regression include variants rs7642482 (OR=1.821;  $\beta$  = 4.694; p=2.679E-6) and rs1692421 (OR=4.646;  $\beta$  = 1.821; p=3.391E-6) which flank *ROBO2* (19kb 3', chr5) and *MAP1B* (83kb 5', chr5) respectively. Each of these genes are associated with neuronal extension/guidance. The analysis additionally suggests an association with the variant rs35938541 (OR=5.084;  $\beta$  = 2.141; p=3.368E-7), found within the first intron of the KIF3A gene. This analysis will be extended to an additional 1,322 SLI cases in BioVU.

## PgmNr 2268: A genome-wide association study of the gut microbiome in Africans.

---

Human genetic variation is one of several factors that influence the gut microbiome. However, genetic association studies of the gut microbiome have not yet been done in African populations. In the present study, we conduct a genome-wide association study (GWAS) of gut microbiome composition in 291 adult continental Africans (224 women, 67 men; 56.1 (SD 12.6) years; mean BMI 31.0 (SD 6.1) kg/m<sup>2</sup>) enrolled from Nigeria. Gut microbiome profiling was done using fecal 16S rRNA V4 sequencing followed by identification, filtering and classification of operational taxonomy units (OTU). Genotypes were obtained using the Illumina Multi-Ethnic Genotyping Array (MEGA) followed by imputation into the African Genome Resources Reference Panel. Gut microbiome characteristics analyzed included measures of alpha diversity (Shannon Diversity and OTU richness), beta diversity (Bray-Curtis Dissimilarity) and relative abundance (RA) of selected OTU. All analyses were adjusted for age, sex, diabetes status, antibiotic use, metformin use and principal components of the genotypes. The most abundant OTU at the phylum level were Firmicutes, Actinobacteria, and Bacteroidetes. There was a single genome-wide significant (GWS) locus for beta-diversity (lead SNP rs12341440, MAF=0.093,  $p=1.66 \times 10^{-8}$ ), near *MED27*. None of the two alpha diversity indices had a GWS variant (best SNP for OTU richness rs35347638  $p=1.30 \times 10^{-7}$ ; Shannon Diversity chr3:138998067,  $p=2.46 \times 10^{-7}$ ). Each OTU displayed a unique pattern of genetic association. Proteobacteria had two GWS associations (rs77476041 near *MTUS2*,  $p=3.28 \times 10^{-8}$ ; rs112957979 in *DNAH7*,  $p=4.24 \times 10^{-8}$ ) while Akkermansia and Bacteroidetes each had a single GWAS locus at rs59849632 (*RP11-544L8\_B.4*,  $p=1.69 \times 10^{-8}$ ) and rs116703580 (chromosome 12;  $p=2.26 \times 10^{-7}$ ), respectively. Notably, Bifidobacterium showed GWS in *AMPD3* (lead SNP rs6484218, MAF=0.409,  $p=4.66 \times 10^{-8}$ ); in previous studies, this SNP was significantly associated with depression, bipolar disorder and schizophrenia. The phyla Firmicutes and Blautia showed only suggestive association ( $5 \times 10^{-7} > p > 5 \times 10^{-8}$ ). Most of the GWS SNPs in the study are eQTL and/or have regulatory annotation (alter motifs or are in promoter or enhancer histone marks). This first gut microbiome GWAS in Africans has identified distinct patterns of association with overall composition and specified taxa. Our understanding of microbiome composition would be advanced by studies that model both genetic and non-genetic effects.

## PgmNr 2269: Genetics of gut microbiome composition: Results of MiBioGen consortium.

### Authors:

A. Zhernakova; on behalf of MiBioGen consortium

[View Session](#) [Add to Schedule](#)

**Affiliation:** Department of Genetics, University Medical Center Groningen, The Netherlands

---

Gut microbiome composition is influenced by environment and host factors, including host genetics. Several population-based genome-wide association studies (GWAS) have identified dozens of SNPs influencing microbiome composition and function, however, the overlap in findings from different cohorts is limited, suggesting that current studies are underpowered and/or subject to population-specific effects. To address both problems, we established the MiBioGen consortium to perform multi-cohort microbiome GWAS. The consortium includes >18,000 samples from 23 cohorts from the USA, Canada, Israel, South Korea and seven European countries, with both microbiome (16S rRNA gene sequencing) and genome-wide SNP data imputed using the Haplotype Reference Consortium reference panel. Processing of genetic and microbiome data were performed following standardized procedures developed within the consortium, and then meta-analysed using individuals summary statistics data.

We performed the genetic analysis in relation to three microbial traits: alpha-diversity of gut microbiome, abundance of bacteria (quantitative analysis) and presence of bacteria (binary analysis). At genome-wide significance level, we identified 40 QTLs that affect presence or abundance of specific microbial taxa (mbQTLs), 38 of them novel. The two established mbQTLs include the lactose intolerance locus (*LCT*) affecting the abundance of *Bifidobacterium* and the *FUT2* locus that affects abundance of two genera from the Lachnospiraceae family).

We explored the potential relevance of microbiome-affecting loci to host health by testing for causality between host genetics, microbiome composition, diseases and disease-related phenotypes using PheWAS and Mendelian Randomization (MR) approaches. We focused on the genetic overlap of mbQTLs with non-communicable diseases, metabolomics, nutritional preferences and immunological markers. PheWAS analysis indicated an overlap of mbQTLs with genetic variants that influence metabolic, nutritional and immune phenotypes. Using MR we were able to causally link serum metabolites (68 associations passed 5% FDR), nutrition phenotypes (18 signals passed 5% FDR) and systemic non-infectious diseases to microbial taxa abundance. In turn, microbial taxa act as mediators of genetic predisposition to ulcerative colitis.

Overall, our results provide broader insight into the effect of host genetics on the microbiome, and consequently on human health and disease.

---

Racial disparities may arise in part due to phenomena that increase the frequency of trait-increasing alleles in one geographic parental subpopulation relative to another. In admixed offspring populations, those differences manifest as association between proportions of genetically inferred ancestry and traits. We therefore estimated six geographic genetic ancestry proportions based on 1000 Genomes reference populations in 60,267 non-Hispanic white (NHW) and 10,168 non-Hispanic black (NHB) participants from the electronic MEdical Records and GENomics (eMERGE) Network and performed a phenome-wide association study (PheWAS) searching for ancestry-dependent phenotypes. Associations of ancestry proportion, ancestry-body mass index (BMI) interactions, and ancestry-ancestry interactions with PheWAS outcomes were adjusted for age, sex, and BMI. We identified 509 phenotypes significantly associated ( $p < 2.75 \times 10^{-5}$ ) with at least one ancestry. Among NHW participants, Northern European (NEUR) and Southern European (SEUR) ancestries were associated with eye disease (e.g. presbyopia;  $p_{\text{NEUR}} = 9.67 \times 10^{-276}$ ,  $p_{\text{SEUR}} = 2.20 \times 10^{-207}$ ) and immune system disorders ( $p_{\text{NEUR}} = 2.80 \times 10^{-172}$ ,  $p_{\text{SEUR}} = 3.29 \times 10^{-153}$ ). Among NHB participants, East African (EAfr) and West African (WAfr) ancestries were associated with rosacea ( $p_{\text{EAfr}} = 6.73 \times 10^{-6}$ ), stage III chronic kidney

disease (CKD;  $p_{\text{WAFR}}=2.51 \times 10^{-6}$ ), diabetic kidney disease ( $p_{\text{WAFR}}=1.27 \times 10^{-5}$ ), and hypertensive kidney disease ( $p_{\text{WAFR}}=4.29 \times 10^{-6}$ ). Protective effects for WAFR ancestry were observed for pregnancy complications among NHB women (e.g. malposition and malpresentation of fetus or obstruction;  $p_{\text{WAFR}}=9.37 \times 10^{-8}$ ), which is consistent with a model of increasing admixture promoting reproductive success. Significant ancestry-BMI interactions were observed for psychiatric (e.g. suicide;  $p_{\text{NEUR\_BMI}}=5.03 \times 10^{-11}$ ;  $p_{\text{SEUR\_BMI}}=1.08 \times 10^{-8}$ ), respiratory (e.g. pulmonary congestion;  $p_{\text{NEUR\_BMI}}=1.07 \times 10^{-6}$ ;  $p_{\text{SEUR\_BMI}}=4.67 \times 10^{-6}$ ), and infectious (e.g. tuberculosis;  $p_{\text{WAFR\_BMI}}=7.82 \times 10^{-6}$ ) diseases. Significant ancestry-ancestry interactions were observed for infectious (e.g. arthropod-borne disease;  $p_{\text{WAFR\_NEUR}}=3.08 \times 10^{-7}$ ), metabolic (e.g. mixed hyperlipidemia;  $p_{\text{WAFR\_NEUR}}=1.16 \times 10^{-6}$ ;  $p_{\text{EAFR\_NEUR}}=2.97 \times 10^{-5}$ ), hematopoietic (e.g. hereditary hemolytic anemias;  $p_{\text{WAFR\_NEUR}}=1.64 \times 10^{-5}$ ), and renal diseases (e.g. stage IV CKD;  $p_{\text{WAFR\_SEUR}}=1.24 \times 10^{-5}$ ). These results demonstrate the ability of geographic genetic origin to predict many types of disease risk.

# PgmNr 2271: Using phenome-wide association study results to predict Mendelian phenotypes.

**Authors:**

L. Tang; Q. Chen; J. Denny; L. Bastarache

[View Session](#) [Add to Schedule](#)

**Affiliation:** Vanderbilt University Medical Center, Nashville, TN.

---

**Background:**

Mendelian and complex diseases have traditionally occupied separate spaces. However, common variants with minor allele frequencies (MAFs)  $>1\%$  in and around Mendelian genes, or Mendelian-matched variants (MMVs), have been linked to complex diseases that can share similar clinical phenotypes to their linked Mendelian disease. We tested the efficacy of using the phenome-wide association studies (PheWAS) to elucidate the phenotype patterns of Mendelian disease. We hypothesized that MMVs were more likely to be associated with corresponding Mendelian disease features than non-Mendelian-matched variants (nMMVs).

**Methods:**

We obtained clinical features and their linked genes of Mendelian diseases from Online Mendelian Inheritance in Man (OMIM). We performed PheWAS on 72,000 individuals of European ancestry, adjusted for age, sex, and principal components for MMV and nMMVs. We analyzed associations between 978,030 MMV-phecode pairs (86,271 SNPs from 3,409 genes and 853 phecodes). We randomly sampled nMMVs from 10,000 randomly-selected non-Mendelian genes to obtain a 1:1 MMV-to-nMMV ratio for each Mendelian phecode. We used logistic regression to measure the enrichment of significant PheWAS results (i.e. PheWAS results with  $p < 1e-5$ , the same cutoff for significance that is used in the GWAS Catalog) for MMVs vs. nMMVs. Among MMVs, we also evaluated the significance of disease inheritance pattern (autosomal dominant vs. recessive), SNP function (e.g. intronic, exonic), and affected biological systems as predictors for significant PheWAS results. We adjusted for the number of SNPs tested in each gene.

**Results:**

Globally, the odds of a significant SNP-Mendelian phecode result were 56 times greater for MMVs vs. nMMVs ( $p = 2.97e-46$ ). Among MMVs, inheritance pattern was not a significant predictor ( $p = 0.49$ ). The odds of a significant result were 15 times greater for intronic vs. intergenic SNPs ( $p = 8.47e-3$ ). Compared to connective tissue phecodes, the odds of a significant result were 5 times greater for the endocrine system ( $p = 9.95e-5$ ).

**Conclusion:**

We explored the utility of using PheWAS data on common variants to predict the effect of rare, potentially deleterious variants. Such data can be useful for interpreting genetic testing results that can reveal deleterious variants in genes not linked to Mendelian diseases. Our findings support the use of association data from common variants to predict the Mendelian phenotype.

## PgmNr 2272: The status of vitamin D and its receptor *Fok I* gene polymorphism among adult TB patients of Mulago Hospital, Kampala, Uganda.

---

*Tuberculosis* (TB) is an infectious disease causing severe problems throughout the world. However this disease is prevalent in Africa. The antimicrobial activity of vitamin D may plays a significant role in prevention of TB. The vitamin D receptor gene is associated with susceptibility. The functional Single Nucleotide Polymorphism rs2228570, *Fok I* gene has been found to be inconsistent among the TB patients. Additionally, patients with active TB have significantly lower vitamin D serum concentration than their contacts from the same ethnicity. This study investigated the relationship between vitamin D status and Vitamin D receptor *Fok I* gene polymorphism, in TB patients. A pilot case-control study was conducted in 41 newly diagnosed Tuberculosis patients and 41 non-TB healthy workers enrolled between April and June, 2013 at Mulago National Referral Hospital. Levels of Vitamin D and PTH were analyzed by Electrochemiluminescence using Cobas 6000. Genotyping of *Fok I* gene was done by Polymerase Chain Reaction and direct sequencing method using the ABI Sequencer. The Prevalence of hypovitaminosis in the TB patients was 24.4% and 26.8% in the healthy subjects. Vitamin D deficiency in TB patients was 9.7% and 4.9 in healthy subjects respectively. Severe vitamin D deficiency was only found in the TB patients. Subjects with vitamin D deficiency were only found in the FF genotype. There was no significant difference between vitamin D levels among the *Fok I* gene variants ( $p = 0.78$ ). Although there was no significant difference between vitamin D status in the different genotypes of Vitamin D receptor *Fok I* gene polymorphism among TB patients and controls in this Ugandan cohort, the hypovitaminosis D noted dominantly in the FF genotype should not be under estimated. On the other hand optimal levels of vitamin D were predominantly found in both groups.

## PgmNr 2273: Using genome-wide SNPs to estimate components of heritability for 24 quantitative and dichotomous psychological characteristics in 14,675 Han Chinese.

### Authors:

Perceived stress characteristics, resilience, future orientation and healthy behaviors have been major research topics over the last decades. However, genetic and environmental factors and their interrelationships remain unclear and have not been well conducted among Han Chinese populations. In the present study, we made use of psychological phenotype data fulfilled by 14,675 Han Chinese participants, who had been genotyped by ~700,000 SNPs on microarrays as part of the WeGene Personal Genome Services. Ten psychological scales and demographic questions were used to define 24 quantitative and dichotomous psychological traits. We firstly validated 71 SNPs reported being associated with perceived stress, future orientation and healthy behaviors discovered by candidate-gene approaches, only 4 SNPs can be verified ( $P$ -value  $< 0.05$ ). We further conducted genome-wide association studies (GWAS) using these traits and only 21 loci can reach genome-wide statistical significance ( $P$ -value  $< 5e-8$ ) in 7 phenotypes defined by Childhood Trauma Questionnaire, Future-oriented Coping Inventory, Connor-Davidson Resilience Scale, Work Stress Scale and Maslach Burnout Inventory. We also obtained heritability estimates using array and imputed data in unrelated individuals. The estimated heritability are around 5~12% and 12~18% of the variance in quantitative and dichotomous traits respectively. These scales of heritability and sample size should obtain a sufficient GWAS power to detect genotype-phenotype associations. We propose that the majority of heritability is attributable to genome-wide variants of small effect and variance explained by individual effects are too small to pass stringent significance tests. We verified our hypothesis by further partitioning additive variance onto chromosomes. We found that the variance explained by each chromosome is proportional to its length (17 of 24 traits with  $P$ -value  $< 0.05$ , Pearson's product-moment correlation; the most significant phenotypes is defined by Maslach Burnout Inventory-achievement). As far as we are aware of, this is the first study estimating the shared and unique heritability of psychological characteristics in Han Chinese, which provide insights for future experimental designs to map additional trait loci and to understand the association between gene and environments. According to our findings, larger GWASs will be needed to further detect casual SNPs for these psychological traits.

## PgmNr 2274: Exome-wide low-frequency genetic variants contribute to human craniofacial morphology.

---

The genetic basis of normal-range variation in human craniofacial traits is still poorly understood. Most studies to date have approached facial morphology via univariate measurements with genetic hypotheses centered on common genetic variants. In recent years, studies of other complex traits have identified fruitful associations with rare and low-frequency variants involved. To better understand the genomic architecture of normal-range facial traits, we studied the influence of low-frequency coding variants on multi-dimensional facial shape phenotypes. We genotyped a cohort of 2329 healthy individuals of European ancestry for approximately 245,000 coding variants on the Illumina Exome v1.2 array. Using three-dimensional facial images, we partitioned the full face into 31 hierarchically arranged segments, which we call modules, to model global-to-local features, and generated multi-dimensional phenotypes representing the shape variation within each module. We used multivariate kernel regression (implemented in the MultiSKAT R package) to test the association between the multivariate facial phenotypes and exome-wide variants with frequencies <1% in a gene-based manner. After accounting for multiple tests, eight genes (*AR*, *CARS2*, *FTSJ1*, *HFE*, *LOC108783645*, *LTB4R*, *TELO2*, *NECTIN1*) showed significant association with morphology of the cheek, chin, nose and philtrum. These genes displayed a wide range of phenotypic effects, with some impacting the full face and others affecting only localized regions. Certain cellular processes and functions were enriched in the group of nominated genes, including metal ion transport, steroid-hormone signaling, tRNA metabolism, DNA repair and cell-cell adhesion. Notably, *NECTIN1* is a well-established craniofacial gene that underlies the etiology of a syndromic form of cleft lip and palate (CLPED1; MIM#225060). We identified the significant missense variant rs142863092 in *NECTIN1*, predicted bioinformatically to be deleterious to the encoded protein. Little is known about the roles of the other implicated genes in craniofacial development, and future investigation holds the promise of yielding new insights. These results have expanded our understanding of the genetic basis of normal-range human facial morphology by implicating rare and low frequency coding variants in novel candidate genes.

## **PgmNr 2275: Creating a reporting framework for polygenic risk scores to improve transparency and standardization: Results from a ClinGen complex disease working group literature review.**

---

Over the past few years, the polygenic risk score (PRS) has become a more common tool for bridging the gap between the hypothesis-generating genome-wide association study (GWAS) and clinical application for disease risk estimation. In contrast with other clinical risk tools, there are no accepted standards for the development, reporting, and application of PRS. To address this gap, the Complex Disease Working Group (CDWG) of the Clinical Genome Resource (ClinGen, [clinicalgenome.org](http://clinicalgenome.org)) is working to specify and standardize reporting criteria for PRS with a two-fold approach: (1) assess the comprehensivity and clarity of a pilot reporting framework and (2) conduct a literature review of current PRS reporting practices including major gaps and trends. ClinGen's CDWG is uniquely positioned with membership of 30+ experts in the fields of epidemiology, statistics, disease-domain expertise, implementation, actionability, and ELSI with interests in the application of PRS.

To create a preliminary PRS reporting framework, we iteratively built upon previously established expert consensus guidelines, starting with the GRIPS statement (2011). This statement recommends a checklist of 25 items when reporting out genetic risk estimation studies. The ClinGen CDWG expanded on the original checklist to include 44 unique items, of which 33 should be reported for both training and validation sets, by incorporating expert feedback on anticipated reporting gaps and inconsistencies. Here we present the pilot results evaluating the utility of this expanded reporting framework through a literature review of 36 articles selected by NHGRI's Genomic Medicine XII (Genomics and Risk Prediction) planning committee as a comprehensive sample of PRS across a variety of disease domains. Each article was assessed by two independent reviewers according to our expanded reporting framework for completeness and clarity. Here we will present trends captured in this review with respect to our reporting framework, highlighting areas that lack reporting such as model fit and calibration, as well as inconsistent interpretations of common terms. We will also discuss the CDWG's revised reporting framework, which will enable the standardized dissemination of PRS while weighing barriers to participation in these reporting standards and ultimately facilitating translation into clinical care by allowing for the establishment of management guidelines based on PRS risk estimation.

## PgmNr 2276: Whole-blood RNA-Seq analysis detects differences in exon expression and alternatively spliced genes in smokers with emphysema.

---

**Introduction:** Emphysema, irreversible destruction of lung parenchyma, is commonly observed in smokers. GWAS have revealed multiple genetic loci associated with emphysema. An integrative analysis of GWAS with blood and lung tissue gene expression has identified associations of *LILRA3* and *DCBLD1* genes with emphysema. However, no investigation to-date has evaluated the possible associations of emphysema with complex regulatory phenomena such as alternative splicing and differential isoform usage.

**Methods:** Short reads were generated from whole-blood RNA-Seq data from 1,984 subjects in the COPDGene study. Read alignment was performed using the STAR aligner. We quantified exon level counts using Rsubread and inferred isoform counts using Salmon. We tested gene expression, exon usage, and isoform usage associations with emphysema percentage (CT densitometry low-attenuation area less than -950 Hounsfield units (%LAA-950)) using the voom/limma method and adjusting for age, sex, race, current smoking, pack-years of smoking, FEV1, cell counts, and library batch. We also conducted gene set enrichment analyses using Gene Ontology (GO) categories and findings from prior COPD studies to provide biological and disease relevance.

**Results:** At FDR 10%, 1113 genes were associated with emphysema with 647 up-regulated and 466 down-regulated genes. Exon level usage analysis identified 26 exons from 25 genes with significant %LAA-950-related differential usage. 23 of the 26 differentially used exons are either in the first or last exon of the isoforms (OR=3.70,  $P=0.01$ ). At the isoform level, 586 isoforms in 524 genes were differentially used with 299 up-used and 287 down-used isoforms. These genes were enriched in GO pathways related to cell morphogenesis, positive regulation of T-helper 17 cell differentiation, peptidyl-tyrosine auto-phosphorylation, negative regulation of I-kappaB kinase/NF-kappaB signaling, ubiquitin-dependent protein degradation, negative regulation of protein kinase B signaling, sulfur oxidation, microtubule sliding, and TORC2 signaling (*adjusted*  $P<0.005$ ). Only 9 genes with differential exon usage and 75 genes with differential isoform usage also showed gene level differential expression.

**Conclusion:** Complex transcriptomic changes at the exon and isoform levels from whole blood

highlighted candidate genes and pathways that complement the findings from conventional gene level analyses and may provide further insight into the pathophysiology of emphysema.

### Background

Common genetic variations in *COL4A1* and *COL4A2* at 13q34 have been previously associated with cerebral small vessel disease, including intracerebral hemorrhage (ICH) and small vessel ischemic stroke, as well as coronary artery disease. We hypothesized that rare coding variants in *COL4A1* and *COL4A2* may be responsible for ICH-associated common variant signals at 13q34.

### Methods

We performed targeted sequencing across 559Kbp at 13q34 including *COL4A1* and *COL4A2* among 2,133 individuals (1,055 ICH cases and 1,078 controls) and selected rare coding variants with predicted functional impact and appearance in at least two ICH cases and no controls. Sequence annotation for functional impact was conducted using gnomAD and the Ensembl Variant Effect Predictor (VEP). Phenomic impact in carriers of identified variants was examined using the Geno2MP database. We extended our findings to UK Biobank (UKB) exome sequence data (339 strokes and 42,610 controls) using BinomiRare. We further assessed structural effects of selected variants on protein structures of *COL4A1* and *COL4A2* using molecular dynamic simulation (MDS).

### Results

We identified two highly conserved missense variants at 13q34 appearing in six ICH cases but not in controls: 1) rs138269346 (p.I110T, *COL4A1*) in four cases; 2) rs201716258 (p.H203L, *COL4A2*) in two cases. Both variants were classified as pathogenic in gnomAD and VEP based on low frequency (MAF < 0.00035 in EUR) and predicted functional impact (*probably* or *possibly damaging*). Carriers of these two variants in Geno2MP expressed phenotypic abnormalities consistent with rare collagen mutation syndromes. In UKB, neither variant was associated with stroke (rs201716258 P=0.25; rs138269346 P=0.09) by ICD10 diagnosis but we confirmed the rarity of the variants (MAF < 0.001 for each) in the UKB EUR population. Using MDS, both variants caused a substantial decrease in physical length of the two protein structures compared with wildtype (> 8% shortening).

### Conclusion

We have identified two rare coding variants in *COL4A1* and *COL4A2* that appear only in ICH cases but not in controls. Our annotation and simulation studies imply that these variants are highly functional, disrupting the structure complexed by *COL4A1* and *COL4A2*. Associations with stroke in UKB were

limited by power. Further experiments will examine the contribution of these variants *in vitro* and test for associations with additional refined vascular phenotypes in UKB.

## PgmNr 2278: Whole blood gene expression analysis reveals active tuberculosis transcriptional signature in HIV co-infected children in Uganda and Botswana.

---

**SIGNIFICANCE:** Diagnosis of tuberculosis (TB) is problematic in individuals co-infected with HIV because of the atypical presentation of the disease, low infective dose of the organisms among other reasons. The difficulty is further compounded in children who have an added difficulty in the collection of sputum of optimum quantity and quality. There is, therefore, need for alternative diagnostic approaches and markers of disease. In this study, we use RNA sequence data from HIV infected children with different clinical TB phenotypes i.e. possible, probable and confirmed TB as well as non-TB infected children to determine the transcriptional signature for Active TB and/or different clinical phenotypes.

**METHODS:** IRB approval was obtained from the two study sites in Botswana and Uganda and RNA collected as a case-control study. RNA samples from a discovery data set of 24 Active TB cases and 24 non-TB infected age and gender-matched controls were sequenced on the Illumina HiSeq platform. FastQC was used for Quality Control of the sequences. The sequences were then aligned against the Human Reference Genome using Bowtie2/Cufflinks2. Transcriptome assembly was done using Cufflinks2 while differential gene expression was determined using CuffDiff2. CuffDiff2 determined the fold change in gene expression (normalized to log base 2). Geneset enrichment analysis was done using the GSEA desktop platform (Broad Institute) on the over 20,000 genes identified and ranked by fold change in expression. Multidimensional scaling (MDS) was done using the Orange Data Mining software.

**RESULTS:** Over 20,000 genes were identified in the cases and controls with 1500 and 300 genes upregulated and downregulated respectively in the cases. The gene set enrichment analysis showed enrichment of genes in gene sets involved in innate immunity and cytokine pathways.

**CONCLUSION:** Active TB disease upregulates gene expression of genes involved in innate immunity. We also show that whole blood gene expression profiles may be able to delineate clinical TB phenotypes.

## PgmNr 2279: Genome-wide linkage study of childhood gender nonconformity in males.

---

Male sexual orientation is a scientifically and socially important trait shown by family and twin studies to be influenced by environmental and complex genetic factors. Childhood gender nonconformity (CGN) is one of the strongest correlates of homosexuality, especially in males, and also has substantial familiarity. We have utilized a collection of families each with two or more homosexual brothers (409 concordant sibling pairs in 384 families), with a 23-item CGN questionnaire administered to all brothers and then converted to a quantitative scale. To map loci for CGN, we have conducted a genome-wide linkage scan (GWLS) using genotypes from the Affymetrix 5.0 SNP array analyzed with MERLIN after rigorous quality control steps. The strongest linkage peaks, each with multipoint LOD scores over 2.0, were on chromosomes 5q (maximum LOD = 2.11) and 8q (maximum LOD = 2.25), with the latter not overlapping with previously reported strongest linkage region for male sexual orientation on pericentromeric chromosome 8. Family-based association analyses were used to identify associated variants in the linkage regions. The current GWLS results may help prioritize findings from future large-scale sexuality GWAS on samples with CGN data available now being collected. Further increasing genetic knowledge about CGN and its relationships to male sexual orientation, especially via large GWAS, should help advance our understanding of the biology of these important traits. This work was supported NIH grants R01HD041563 and R21HD080410.

---

Spontaneous dizygotic (DZ) twinning results from the release and fertilization of two or more oocytes during a single pregnancy. Considered a common complex trait, DZ twinning events affect approximately 1-4% of women worldwide with large regional differences known to exist. Genome-wide association studies of DZ twinning have implicated common genetic variants in *FSHB* and *SMAD3*. Some rare genetic variants, including a loss of function mutation in *GDF9*, have been thought to influence DZ twinning, but with conflicting results. To optimize rare genetic variant detection, we analyzed whole genome sequences of four distantly related mothers of DZ twins from a large Dutch pedigree with a rich history of DZ twinning. The pedigree spans seven generations and includes 18 mothers of DZ twins and 21 sets of DZ twins. Samples were sequenced on an Illumina Hi-Seq 2500 instrument (101bp paired-end reads). Sequence data were aligned to human reference genome build 37 with Burrows-Wheeler Aligner. Variant discovery was performed with GATKv3.8. To define haplotypes that segregate with being a mother of DZ twins, we identified regions in common between the four sequenced mothers. Elucidation of high-priority regions was done by comparing genotypic data, obtained from an Illumina GSA array, of an additional nine affected mothers from the same pedigree using a minor allele frequency filter (MAF 0.001) to remove monomorphic variants. Overlapping regions were determined to be located on chromosomes 11, 14, and X. Based on these overlapping regions between all affected mothers, we will construct haplotype blocks for further investigation and test for deleterious mutations. In a next step, we will make use of the Genome of the Netherlands (GoNL) resource, in which 250 trios were sequenced on an Illumina Hi-Seq 2000 (see Genome of the Netherlands, 2014). Of the trios, 110 were derived from the Netherlands Twin Register and included 46 mothers of dizygotic twins. We plan to evaluate if either the identified mutation is only present in the pedigree or whether the haplotype is shared between DZ twinning affected mothers.

---

Arsenic is a carcinogen affecting ~56 million people in Bangladesh and 13 million in the U.S. via drinking water. Once consumed, inorganic arsenic is converted to mono- and di-methylated (DMA) forms. DMA, expressed as a percentage of urinary arsenic, is a measure of arsenic metabolism efficiency (AME). Inherited genetic variation in the 10q24.32 region, containing the *AS3MT* (arsenic methyltransferase) gene, impacts AME, with 2 independent association signals identified in our prior studies. The causal variants and mechanisms underlying these associations are unknown. To comprehensively study variation in the 10q24.32 region, we performed targeted sequencing in 3 populations. This includes 2436 Bangladeshi individuals from the Health Effects of Arsenic Longitudinal Study (HEALS), 874 American Indians from the Strong Heart Study (SHS), and 706 European Americans from the New Hampshire (NH) Skin Cancer Study of squamous cell carcinoma. Conditional, forward stepwise regressions in each population identified variants independently associated with DMA%. We identified potential causal sets in each population and the estimated likelihood of a shared causal variant, using a Bayesian method implemented in the Sum of Single Effects Regression (SuSiE) R package. We used tissue-specific eQTL results from GTEx and Bayesian co-localization analysis to determine if SNPs affecting DMA% also impact expression of *AS3MT* or nearby genes. We identified 3 independent association signals in the 10q24.32 region in HEALS (p-values  $10^{-17}$  to  $10^{-11}$ ), 4 in SHS (p-values  $10^{-20}$  to  $10^{-5}$ ), and 1 in NH (p-value  $7 \times 10^{-5}$ ). HEALS and SHS share a lead SNP, rs4919687, and moderate LD was observed between this SNP and the lead SNP in NH. All identified SNPs are in a 360kb region containing *AS3MT*, *BORCS7*, *CNNM2*, and *NT5C2*. There were cis-eQTLs for *AS3MT* in 13 GTEx tissue types for which the lead SNP was in LD ( $r^2 > 0.7$ ) with one of the 3 lead SNPs in HEALS. Our primary association signal co-localized with cis-eQTLs for *AS3MT* in 11 tissue types (posterior probability >80%). We also found evidence of co-localization between 5 additional genes in the 10q24.32 region and cis-eQTLs in 39 tissue types. Our results suggest 1) the presence of shared associations, allowing us to leverage population LD differences to identify

candidate causal variants and 2) at least one variant likely acts via regulation of local gene expression. This increases our understanding of the 10q24.32 region and its role in AME.

## PgmNr 2282: Dissecting out the bones of height.

---

Despite years of study, and hundreds of identified associated genetic variants, not all of the genetic variation in morphological traits, such as height, is currently explained. Dividing height into its constituent parts, such as the long bones in the leg, may help to identify novel height-associated variants, and to better understand bone morphology, as well as the components of growth. The major long bones of leg are the largest contributors to height in humans, and, while their length correlates with height, significant variation exists independent of variation in height. Genetic variants acting on the length aspect of morphology may have larger relative effect sizes on long bone length than they do on height, so focusing on these more immediate phenotypes should result in greater power to uncover single nucleotide polymorphism (SNP)-trait associations. Bone lengths have previously seen limited study in humans due to the difficulty of measuring them accurately for living participants, and the lack of cohorts with both long bone lengths and genetic data available.

The major long bone lengths in both the arms (humerus, radius, ulna) and legs (femur, tibia, fibula) were obtained from dual x-ray absorptiometry (DXA) whole-body scans in the ORCADES cohort ( $N=1,150$ ). Genotyping was performed using the Illumina<sup>®</sup> HumanHap300 and OmniExpress arrays (278,618 and 599,638 markers), and data were imputed to the Haplotype Reference Consortium panel (12.3 million SNPs after imputation and QC). Bone length SNP heritability estimates for these traits range from 34% for ulna length, to 59% for fibula length, after accounting for height, age, and sex. We carried out a genome-wide association study (GWAS) using a mixed-linear model framework to look for genetic variants associated with the length of the major long bones in both the arms and legs. GWAS uncovered genome-wide significant associations with SNPs not identified in height GWAS, or known to be in linkage disequilibrium with height-associated variants. Many of the identified variants are found in intergenic regions near genes whose function provides plausible biological explanations for the associations, however replication is still required. Based on these preliminary findings, further work is underway using the UK Biobank DXA whole-body scans ( $N=15,000$ ) and image-analysis software that has been developed in-house to automatically extract long bone lengths from the scans.

## PgmNr 2283: Cross-population fine-mapping of 50 complex traits and diseases in ~675,000 individuals across three global biobanks.

Identifying causal variants for complex traits is one of the major challenges in human genetics. The causal variants in most GWAS associated loci remain unknown due to insufficient power and to high linkage disequilibrium (LD) among variants in a locus. Cross-population fine-mapping studies may improve fine-mapping resolution by leveraging sample size and differences in LD and minor allele frequency (MAF) across populations. However, lack of availability of non-European GWAS and proper statistical methods have limited the success of previous studies.

Here, we fine-mapped 50 complex traits and diseases from three large-scale biobanks, UK Biobank (UKB;  $n = 361,194$ ), FinnGen ( $n = 135,638$ ) and Biobank Japan (BBJ;  $n = 179,066$ ). We first conducted single-population fine-mapping using two state-of-the-art methods, FINEMAP (Benner *et al*, 2016) and SuSiE (Wang *et al*, 2018). In total, 51,302 putative causal variants were identified (posterior inclusion probability [PIP] > 0.1), with a median number of 21 variants in 95% credible sets. Our results suggested that single-population fine-mapped variants are rarely shared across populations (915 variants; 1.8%), whereas their posterior effect sizes in allelic scale are largely consistent if shared (Pearson's  $r = 0.83$ , 95% CI: 0.81–0.84). This inconsistency of PIP is partly due to difference in MAF, imputation quality, and various quality control criteria, which all resulted in missing putative causal variants in one population or incorrect imputation of haplotypes. For example, among 42,345 non-shared fine-mapped variants in UKB, we observed lower MAF in BBJ than in UKB (mean MAF = 0.19 and 0.24, respectively). In addition, 16.7% of them are monomorphic (MAF = 0 or non-existent in

imputation reference) and 15.6% are missing (available in reference but removed after QC) in BBJ. Our results highlight the importance of these factors for robust fine-mapping, even in a single population.

To tackle this issue and maximize our power, we investigate a novel cross-population fine-mapping method that leverages single-population fine-mapping results from a harmonized pipeline and applies an empirical Bayes approach that leverages genome-wide data to learn patterns of shared causality across populations (see McCaw *et al*, ASHG19). We apply our method to a set of biobank-scale simulated datasets and the 50 complex traits and diseases. Our preliminary results suggest that our method successfully improves fine-mapping power and resolution.

## PgmNr 2284: 203 SNPs with combinatorial effects contribute to the genetic architecture of facial morphology.

In this study, we highlight groups of SNPs with potential large to fine scale combinatorial interactions affecting the human face. The initial pool of SNPs comes from a meta-analysis GWAS of 3D facial shape in two large cohorts ( $N_{US} = 4,680$ ;  $N_{UK} = 3,566$ ) in which each face was densely registered with 7,160 quasi-landmarks, which were then hierarchically grouped into segments representing global-to-local facial variation. For each SNP, we first identify the linear combination of principal components that are maximally correlated with the SNP in the identification cohort. We then project the verification cohort onto this learned phenotype, creating univariate facial shape variables to be tested for association. This process is repeated, switching the dataset used for identification and verification, and the p-values are meta-analyzed. Genome-wide significant SNPs were grouped by genomic location and similarity of effect in the two cohorts, refining our follow-up analyses to 203 lead SNPs at 138 genomic positions that, in total, explain ~5% of the phenotypic variation in our cohorts and are enriched for H3K27ac activity in cranial neural crest cells and craniofacial tissues. We additionally used Structural Equation Modeling (SEM) to better understand the large-scale groupings of SNPs that together best explain the variance observed in each facial segment. For the 25 segments passing all recommended model fit parameters, the correlation between H3K27ac activity across 100 different cell-types and tissues of the SEM-refined SNPs was high, indicating that the refined SNPs potentially have coordinated actions in the same cell-types or tissues. By performing a linear regression between the facial traits identified alongside each lead SNP and the genotypes at all other lead SNPs, we additionally identified 110 traits as having associations with multiple SNPs, giving rise to a smaller set of SNPs that might work in concert to create these facial traits. Lastly, the latent univariate phenotype produced for each SEM model was used to assess whether interactions between genotypes mask or

boost the genotypic effect on a phenotype, resulting in four SNP combinations with evidence of interacting effects, three of which have been previously reported in the literature. In sum, our analyses provide new insights into the genetic architecture of human facial shape, both in terms of SNPs with single effects as well as SNPs showing combinatorial interactions.

## **PgmNr 2285: Developing a data resource for pediatric research: The Gabriella Miller Kids First Pediatric Research Program (Kids First).**

Epidemiological studies have reported that children with congenital anomalies are at a higher risk of developing certain childhood cancers. Little is known about the genetic cause-and -effect relationship between these disorders. Furthermore, a large dataset is needed to examine the role of genetics in childhood cancer and birth defects. The National Institutes of Health Common Fund's Gabriella Miller Kids First Pediatric Research Program (Kids First) is developing a large-scale data resource of clinical and genetic data from patients with childhood cancers and structural birth defects and their families. These data are now available through the Gabriella Miller Kids First Data Resource Portal which was launched by the program's Data Resource Center in 2018. To date, Kids First has selected 27 patient cohorts for whole genome sequencing through a peer-review process. Clinical and genetic sequence data from over 5,000 patient samples are accessible through the portal, including data from patients with Ewing Sarcoma and Congenital Diaphragmatic Hernia. Data from more than 30,000 DNA and RNA samples are expected to be added to the Kids First Data Resource Portal over the next few years. The Kids First program is focused on data sharing to develop tools and resources to foster collaborative analyses. The program aims to help researchers uncover new insights into the biology of childhood cancer and structural birth defects and identify shared genetic pathways among these various pediatric conditions. A complete list of conditions represented in the Kids First data resource and additional information about the Kids First program will be described in this presentation.

## PgmNr 2286: LabWAS: Investigating relationships between biomarkers and genetic risk for complex diseases.

Clinical laboratory testing provides physicians with targeted biochemical measurements (i.e., biomarkers) to aid in diagnosing and treating patients for a variety of diseases. Combining genetics of complex traits to biomarker and diagnostic data from electronic health records could point towards mechanisms of disease, provide information on the relationship between biomarkers and diagnosis, and facilitate the development of diagnostic panels. We describe a method that pairs polygenic scores with lab data derived from EHRs to screen for associations. Results from 3,800 labs were extracted for 70,184 individuals in Vanderbilt University Medical Center's biobank, BioVU. Usable labs were required to have a minimum of 1,000 observations over at least 100 individuals, and 70% of measurements to be recorded in one set of units. The remaining 475 labs were filtered to exclude observations outside 4 standard deviations from the mean. The median value of each lab for each individual was calculated, inverse normalized, and adjusted for cubic splines of age at measurement. Labs exhibiting no calculable heritability using GCTA were excluded leaving 272 labs for analysis. To screen for associations between PRS and lab measurements, we created a lab-wide association study (LabWAS) pipeline. This pipeline fits a linear regression model to each lab and determines the association between the PRS after further adjusting for sex, top 10 principal components of ancestry, and genotyping batch. We compared polygenic scores calculated using PRS-CS, PRSice, and LDpred, and selected the PRS with the highest predictive performance with CAD, PRS-CS. In a proof-of-principle analysis, PRS for coronary artery disease reproduced known associations with canonical heart disease risk factors. The strongest association was nucleated red blood cells (OR = 0.97, p-value = 1.43e-8), followed by HDL cholesterol (OR = 0.96, p-value = 9.51e-7), and blood glucose levels (OR = 1.03, p-value = 1.12e-4). Results from LabWAS provide a starting point for further sensitivity analyses to determine shared genetic architecture, relevant points in life, and effects of medication. We are currently working on ways to integrate effects of age and medication in our analysis. We will share the development of the pipeline, available software, and the results of ongoing replication efforts.

## PgmNr 2287: Estimation of heritability mediated by assayed gene expression levels elucidates gene architecture of complex traits.

Chan School of Public Health, Boston, MA; 5) Dana-Farber Cancer Institute, Harvard Medical School, Boston, MA

---

Disease variants identified by genome-wide association studies (GWAS) tend to overlap with expression quantitative trait loci (eQTLs), suggesting that genetic effects on disease could be mediated by gene expression levels. However, existing methods that aim to quantify overlap between GWAS loci and eQTLs cannot distinguish mediation (where genetic variants causally influence disease through expression levels) from pleiotropy (where genetic variants independently influence disease and expression levels), even though the latter is not informative of disease etiology. Here we introduce a new method, Mediated Expression SCore regression (MESc), to estimate heritability mediated by the cis-genetic component of assayed gene expression levels using summary association statistics from GWAS and eQTL studies. MESc distinguishes mediated from pleiotropic effects in a set of genes by relying on the idea that the magnitude of effects of a SNP on the expression of genes in that gene set should be proportional to the magnitude of effects of the SNP on the disease if any mediation is occurring, whereas these quantities will not be proportional if effects of the SNP on the trait are not mediated by expression. We show that MESc produces robust estimates of expression-mediated heritability across a wide range of simulations.

We applied MESc to GWAS summary statistics for 42 complex traits (average N = 323K) and cis-eQTL data across 49 tissues from the GTEx consortium. **We determined that a statistically significant but modest proportion of disease heritability (mean estimate 0.11 with S.E. 0.02) is mediated by the cis-genetic component of assayed gene expression levels across traits, though estimates varied substantially among individual traits (point estimates from 0 to 0.38).** We further estimated the heritability mediated by expression of different subsets of genes. **Across all tested genes, we observed a strong inverse relationship between cis-heritability of expression and proportion of heritability mediated by expression, suggesting that genes with weaker eQTLs have larger causal effects on disease.** Moreover, across a large number of functional gene sets, we observed broad patterns of mediated heritability enrichment that recapitulate known biology and implicate specific gene sets in disease. Our results provide concrete evidence for the hypothesis that SNPs impact disease via regulation of gene expression levels, and give insight into the *gene* architecture of disease.

## PgmNr 2288: Implicating effector genes at GWAS loci associated with age at menarche through genome-wide promoter-focused Capture C in human ESC-derived hypothalamic neurons.

---

Puberty marks the onset of reproductive maturity and impacts adult health outcomes including diabetes and cancer. At pubertal onset, genetic, nutritional and environmental signals are integrated to reawaken the pulsatile release of gonadotropin-releasing hormone (GnRH) from the hypothalamus to the pituitary. Despite the discovery of hundreds of GWAS signals for age at menarche (AAM) in girls and age at voice break in boys, the molecular mechanisms underlying pubertal initiation are not fully understood. Determining the effector genes and causal variants at these established GWAS loci should provide insight into molecular mechanisms for functional maturation of the hypothalamic pubertal trigger. We performed molecular fine-mapping in human embryonic stem cell (hESC)-derived hypothalamic arcuate neurons using high-resolution promoter-focused capture C coupled with ATAC-seq. We identified 32,614 proxy SNPs in LD ( $r^2 > 0.5$ ) with 379 AAM-associated sentinel SNPs, which were then further reduced using ATAC-seq to 714 proxies residing in open chromatin. Some of these open proxies were located in gene promoters, such as for *CENPW*. We used the genome interactome map established by Capture C to investigate direct contacts between open non-promoter SNPs and promoters of their putative target genes. We detected such contacts for 152 target genes at 62 loci. At the '*CADPS2*' locus, we identified an open proxy-to-promoter interaction for *FEZF1*, a gene ~150kb upstream whose product disrupts migration of GnRH neurons, resulting in hypogonadotropic hypogonadism. At the '*RNLS*' locus, we observed a contact with the promoter region ~600kb upstream of *PTEN*, a tumor suppressor gene in which mutations have been implicated in cases of precocious puberty. RNAseq further confirmed that these three target genes were highly expressed in hypothalamic neurons. Ingenuity pathway analysis across all target genes revealed significant enrichment for processes related to the central nervous system and brain development, but also to 'growth of genital organ.' Our results help clarify the possible hypothalamic effector genes among known plausible candidates, and also implicate novel target genes. Functional verification with CRISPR-Cas9 manipulation of promoter-interactors followed by target gene expression assays and assessment of key readouts, such as GnRH, should aid in confirming novel target effector genes associated with the timing of puberty.

## PgmNr 2289: Cross-population fine-mapping to identify shared and population-specific causal effects.

Fine-mapping methods aim to isolate the causal genetic variants within a genomic region previously associated with a complex trait or disease. Such loci are of interest for understanding biological mechanisms and as potential therapeutic targets. Jointly analyzing multiple populations can improve power for detecting shared causal variants. We propose a cross-population fine-mapping model that allows for shared and population-specific causal effects. Our model accommodates multiple causal variants within a single locus, and allows for cross-population correlations in effect sizes. Working within the Bayesian paradigm, we implement a variational algorithm to estimate the posterior distribution of target parameters. From this, we can construct credible sets that contain the causal variant(s) with high probability.

We present realistic, bio-bank scale simulation studies validating our estimation and inference procedures. Individual-level genotypes for  $N = 500K$  subjects from each of African, European, and East Asian ancestry were simulated using *msprime* (Kelleher, et al., 2016). The coalescent simulation incorporated a demographic model (Gravel, et al., 2011), estimated from 1000 Genomes data, to ensure the simulated genotypes reflect modern human population histories. The simulated genomes were partitioned into loci, and within each locus, causal variants were assigned to populations based on two parameters: the probability of a locus harboring at least one causal variant, and the probability of a causal variant being shared across populations. These parameters have been estimated empirically using data from multiple biobanks (see Kanai, et al., ASHG19). Effect sizes at the causal variants were drawn from a multivariate normal distribution, with the covariance structure depending on the SNP heritability, MAF, and the cross-population genetic correlation. Using these data, we characterize the sensitivity and specificity of the proposed fine-mapping model for identifying shared and population-specific causal effects.

---

Using multivariate phenotypes derived from 3D facial images, we recently identified 203 genetic signals influencing human facial shape in a meta-GWAS of 8242 European individuals. These facial GWAS signals showed significant enrichment for genes implicated in dysmorphic facial traits, most notably orofacial clefts (OFCs), suggesting some overlap between genes responsible for normal and abnormal facial variation. While a number of genetic loci have been recognized as risk factors for OFCs, a large portion of the heritable variation remains unexplained. Loci that contribute to normal-range facial traits may help to identify new candidate genes and pathways involved in the etiology of OFC and prioritize possible biologically meaningful associations that fail to achieve standard thresholds for genome-wide significance. To evaluate this hypothesis, we selected a subset of 155 of the 203 GWAS signals implicated in normal-range facial morphology. We then tested these signals in two independent nonsyndromic OFC cohorts (n=7053 and n=5417) for which GWAS results were available. We observed a significant ( $p < 0.0001$ ) association between OFC and 55 loci influencing facial morphology. Fourteen loci pointed to known candidate genes for OFC and showed strong evidence of association in one or both of our OFC cohorts. The remaining 41 loci were novel for OFC. Of these 41 novel loci, seven showed independent evidence of association across the two OFC cohorts, including *THRB/RARB*, *CACNA2D3*, *PRDM5/TNIP3*, *4q28*, *FREM1*, *ALX4*, and *DAAM/DACT1*. Variants at these loci may modify risk for OFC, possibly by altering embryonic facial shape in ways that could alter lip and palate fusion. Future work will evaluate whether these variants have an effect on phenotypic severity through interactions with other well-established OFC risk variants. This research is supported by NIH grants U01-DE020078, R01-DE016148, and R01-DE027023.

## PgmNr 2291: Using wearable devices and genetics to estimate and validate mechanisms of sleep.

---

The widespread availability of wearable devices, such as wrist worn accelerometers, offers the potential to objectively measure sleep, and thus better understand the role of sleep in disease development. While polysomnography (PSG) is regarded as the gold standard method of measuring sleep, it is impractical to perform in large cohorts. To better understand the mechanisms of sleep, we aimed to derive accelerometer estimates of sleep duration, timing and quality and perform subsequent genetic analyses on these phenotypes to identify novel genetic associations.

Using accelerometer data in up to 85,670 participants from the UK Biobank study, we derived measures of sleep duration (duration and variability), quality (sleep efficiency and number of nocturnal sleep episodes), and timing (including nocturnal sleep and the least active 5-hours) using an algorithm previously validated against PSG data. Genetic data available from the UK Biobank was used for genome-wide association analyses and validation of phenotypes.

The phenotypic correlation between accelerometer-estimates of sleep timing and measures of sleep duration and quality were low ( $-0.10 \leq R \leq 0.12$ ), consistent with data from self-reported chronotype ("morningness") and sleep duration in the UK Biobank ( $R = -0.01$ ). We observed a stronger correlation between sleep duration and sleep efficiency ( $R=0.57$ ). Heritability estimates ranged from 2.8% (95% CI 2.0%, 3.6%) for sleep duration variability, to 22.3% (95% CI 21.5%, 23.1%) for the number of nocturnal sleep episodes. We identified 47 genetic associations at  $P < 5 \times 10^{-8}$ . These include 26 novel associations with measures of sleep quality and 10 with nocturnal sleep duration. We replicate a previously reported gene locus (*PAX8*) associated with sleep duration based on self-report data. We observe variants previously associated with restless legs syndrome associate with multiple sleep traits. As a group, sleep quality loci are enriched for serotonin processing genes.

Using accelerometer data in the UK Biobank, we have derived eight measures of sleep characteristics. Genetic associations between these measures and known restless legs syndrome associations provides validation of our methods.

## PgmNr 2292: A large-scale genome-wide association scan in East Asians revealed genetic mechanisms underlying variations of human facial morphology.

---

The facial surface is visible and recognizable based on the facial shape variation which represents a set of highly polygenic and correlated complex traits. Understanding the genetic basis underlying facial shape traits has important implications in population genetics, developmental biology, and forensic science. However, relatively little is known about which and how genes influence human facial variation in East Asians. Here, we conduct a genome-wide association scan for facial features in ~9,500 East Asians from high resolution 3dMD facial images. We identified 54 loci that significantly associated with facial shape at multiple levels of organization, showing distinctive patterns of global-to-local genetic effects on facial shape. Among the 54 loci, 33 were supported in the literature, while 21 were newly identified. Functional enrichment analysis showed that most of genes were linked to regionalization, appendage morphogenesis and embryonic organ development, suggesting that the facial morphology variation be shaped during the pattern specification process. Finally, we found that the associated loci were enriched for signals of positive selection, indicating that facial morphology had undergone strong local adaptation during the recent evolutionary history. These results substantially advanced our understanding of the genetic mechanisms underlying human facial variations.

*GDF15* is a stress response cytokine known to be upregulated in cardiovascular diseases and diabetes. Animal model studies have reported knock-out of *GDF15* to result in increased body weight, whereas overexpression leads to reduced body weight and food intake and improved metabolic profiles. *GDF15* has been identified as a potential target for treatment of obesity and related diseases. However, data supporting its causal role in human disease is sparse (O’Rahilly 2017). Here, we undertake an unbiased assessment of phenotypic and genetic associations of *GDF15* by utilizing a well characterized, Finnish population-based cohort with baseline plasma *GDF15* concentrations (n=6610).

Associations between *GDF15* levels and 677 disease endpoints and 96 quantitative biomarkers were examined. *GDF15* was significantly associated with 37 diseases and 33 biomarkers ( $p < 6.5 \times 10^{-5}$  multiple test correction threshold). The most significant association was found for all-cause mortality (OR=1.8,  $p=9.8 \times 10^{-27}$ ) and mortality due cardiac causes (OR=1.8,  $p=7.7 \times 10^{-14}$ ). A strong association was found for type 2 diabetes (OR=1.5,  $p=2.2 \times 10^{-9}$ ) with both incident and prevalent cases showing increased *GDF15* levels. Elevated *GDF15* levels were detected in cardiovascular diseases (OR=1.2,  $p=5.6 \times 10^{-6}$ ; major coronary heart disease and stroke OR=1.3,  $p=1.6 \times 10^{-9}$ ; atherosclerosis OR=1.7,  $p=1.3 \times 10^{-10}$ ; hypertension OR=1.2,  $p=3.1 \times 10^{-5}$ ) and key components of metabolic syndrome (triglycerides  $b=0.1$ ,  $p=2.4 \times 10^{-22}$ ; fasting insulin  $b=0.1$ ,  $p=1.2 \times 10^{-13}$ ; waist-to-hip ratio  $b=0.1$ ,  $p=7.0 \times 10^{-10}$ ). Associations were also observed for chronic kidney disease (OR=2.5,  $p=6.8 \times 10^{-8}$ ), pneumonia (OR=1.3,  $p=2.7 \times 10^{-8}$ ), schizophrenia (OR=1.8,  $p=9.8 \times 10^{-6}$ ) as well as biomarkers of sepsis and inflammation (Mid regional pro-adrenomedullin  $b=0.2$ ,  $p=1.2 \times 10^{-91}$ ; C-reactive protein  $b=0.2$ ,  $p=4.6 \times 10^{-64}$ ; hepatocyte growth factor  $b=0.2$ ,  $p=4.2 \times 10^{-43}$ ) supporting role for *GDF15* in stress adaptive responses. Contrary to the proposed role of *GDF15* in cancer we found no associations with cancer phenotypes.

To understand the genetic factors regulating plasma *GDF15* levels, we performed GWAS of *GDF15* (n=5817). We identified 100kb locus on chromosome 19, around the *GDF15* gene, strongly associated with *GDF15* levels (top  $p=4.6 \times 10^{-83}$ ) and fine-mapping revealed 4 putative causal variants (rs16982345, rs1054221, rs1059369, rs189593084). Our results suggest that *GDF15* has a role in stress adaptive

responses in several diseases and genetic factors play a significant role in regulation of *GDF15* levels in blood.

## PgmNr 2294: Accurate estimation of SNP-heritability from biobank-scale data irrespective of genetic architecture.

The proportion of phenotypic variance attributable to the additive effects of a given set of SNPs (i.e. SNP-heritability) is a fundamental quantity in the study of complex traits. Recent works have shown that existing methods to estimate genome-wide SNP-heritability often yield biases when their assumptions are violated. While various approaches have been proposed to account for frequency- and LD-dependent genetic architectures, methods based on REML are highly computationally intensive when applied to datasets such as the UK Biobank ( $N > 400K$ ), and it is currently unknown whether methods based on summary statistics produce accurate estimates of total SNP-heritability. Thus, it remains unclear which estimates of SNP-heritability computed from biobank-scale GWAS are reliable.

Here, we describe an approach to estimate genome-wide SNP-heritability accurately from biobank-scale data irrespective of the underlying genetic architecture of the trait, without specifying a heritability model or stratifying SNPs by minor allele frequency (MAF) and/or LD. We use theoretical justifications coupled with extensive simulations starting from real genotypes from the UK Biobank ( $N = 337K$  unrelated white British individuals) to show that, unlike existing methods, the accuracy of our closed-form estimator is invariant to the strength of coupling between effect size and genomic features such as MAF/LD. Across 126 simulated genetic architectures with different parametric forms of the per-SNP effect sizes, the maximum bias we observe with our estimator is 2% of the simulated SNP-heritability whereas existing methods yield biases between -64% and 28%.

We apply our approach to estimate SNP-heritability for 22 complex traits and diseases in the UK Biobank and show that, consistent with our results in simulations, existing biobank-scale methods yield estimates up to 30% different from our theoretically-justified approach. Across 18 of the traits with SNP-heritability estimates greater than 0.05, estimates from stratified LD score regression (Finucane et al. 2015, Gazal et al. 2017) and SumHer (Speed & Balding 2019) differ from our estimates by a median of -9% and 11%, respectively. Overall, our results show that while existing methods can yield biases, for the purpose of estimating total SNP-heritability, most methods are relatively robust to different genetic architectures.

## **PgmNr 2295: Overfitting in polygenic risk score analyses: Exploring the impact of sample overlap and first degree relatives.**

**Authors:**

S. Medland

[View Session](#) [Add to Schedule](#)**Affiliation:** Psychiatric Genetics, QIMR Berghofer, Brisbane, Queensland, Australia

---

Independence of the discovery and target samples is essential to avoid estimation bias due to overfitting within polygenic risk score analyses. Although this is a well-known methodological issue, in recent years perceptions have arisen that this may not matter with biobank type discovery samples when the overlap is very small and few authors have considered the impact of relatedness across the discovery and target samples. To empirically examine these issues a discovery sample of ~340,000 individuals were extracted from the UK Biobank (app. 25331) and GWAS were conducted for a continuous (height) and a binary trait (day-time sleepiness) and for random continuous and binary traits. Polygenic risk scores were calculated and polygenic risk score analyses were conducted using target samples comprising randomly selected baseline samples of 2,000, 5,000 and 10,000 individuals who were not in the discovery sample. To examine overfitting due to non-independence, the target samples were spiked with 5, 10, 50, 100 and 200 individuals who had been part of the discovery sample or their first degree relatives. Sample size was maintained between baseline and spiked samples and 1,000 replicates were performed. As expected degree of overfitting increased with degree of overlap, decreased with total target size and also arose due to non-independence due to relatives. Overfitting was present with as few as 5 overlapping individuals (0.001% of the initial discovery sample) confirming the importance of independence for accurate estimates of variance explained. The impact of non-independent controls (in the absence of overlapping cases) will also be presented.

## PgmNr 2296: PheWAS with a comprehensive health check-up database across 10,349 Korean population.

### Authors:

---

The rapid growth of resource of genomics linked to the electronic health records (EHRs) database has increasingly leveraged by phenome-wide association study (PheWAS) to elucidate not only the phenotype – gene associations but also the genetic pleiotropy. Most PheWASs introduce International Classification of Diseases, Ninth Revision (ICD-9) billing codes, to define phenotypes, which was not primarily set up for research purpose. Thus, there are limitations by specificity and accuracy of billing information-based phenotypes. In this study, we analyzed the results from comprehensive medical check-ups and screening in a single healthcare center in the Korean population, as a confirmative phenotype to perform PheWAS. Phenotypic data on 10,239 samples who went through check-ups including physical examination, laboratory test, imaging test (ultrasonography, CT, fundoscopy or MRI), and functional studies (electrocardiography, pulmonary function test or endoscopy) were obtained. The genotyping was done using Affymetrix Axiom KORV1.1-96 Array, customized for the Korean population. After standard quality controls, 9,742 samples were used for PheWAS. In our dataset, total 166 EHR-derived phenotypes (94 binary, 72 continuous) were extracted. We calculated the associations between these health check-up phenotypes and 548,762 common frequency SNPs with minor allele frequency > 0.01. We found many SNPs that replicate the previous reports from GWAS as well as novel SNPs associated with depression, tumor markers, skeletal muscle mass, or vitamin D. Among the significant associations, there were novel PheWAS associations potentially driven by pleiotropy. One of the most meaningful findings as potential pleiotropy was the cross-phenotype associations with a variant near SLC19A1 gene for depression, vitamin D3, obesity, liver function, diabetes, and hematologic trait. SNPs associated with tumor markers such as carcinoembryonic antigen had a cross-phenotype associations with other clinical laboratory measures. Using the phenotypes defined by the results during the comprehensive check-up, we were able to identify significant links between several diseases. This is the first large-scale single-cohort PheWAS study using the comprehensive health check-up database in the Asian population. By using this database, it may enable us to overcome some of the limitations of Phecode and to discover novel disease-disease associations.

## PgmNr 2297: Genetic architecture of phenome-wide latent factors in the UK Biobank.

H. Chan School of Public Health, Boston, MA

---

Large-scale biobanks and electronic health records can offer unprecedented insight into the genetic architecture of a wide range of traits in the general population. However, the high dimensionality of phenotypic data, with thousands of traits measured per individual, can make it difficult to interpret genetic results. Here we derive and genetically characterize latent phenotypic factors representative of the spectrum of traits measured in UK Biobank (UKB).

Beginning with 4203 traits, we identified individuals and traits with low missingness (i.e., ~10%) in order to limit association with survey structure. We performed exploratory factor analysis in this core dataset of 33,860 individuals and 730 items and confirmed the fit of the initial model in an additional low-missingness group (N=8,465). The final model includes 36 stable, interpretable factors accounting for ~30% of total phenotypic variance and spanning a wide range of physical (e.g., body size, general pain), behavioral (e.g., neuroticism, smoking), and lifestyle (e.g., education, urbanicity) dimensions.

To investigate the genetic architecture of these latent factors, we performed a genome-wide association study (GWAS) of each factor, weighted by factor-specific missingness per individual, in the full European ancestry subset (N=361,144). Using LD score regression, we observe a roughly twofold increase in median common variant heritability for the derived factors compared to that of the individual items. We also evaluate whether each latent factor is associated with an increased burden of rare coding variants, especially in loss-of-function intolerant genes, in exome sequencing of UKB.

We contextualize these factors by estimating genetic correlation to psychiatric and somatic disorders studied outside of UKB. In preliminary results, genetic correlations confirm expected associations (e.g.,  $r_g=0.58$  for coronary artery disease and the heart attack factor,  $r_g=-0.61$  for ADHD and the education factor) and also reveal a surprisingly broad, diffuse pattern of genetic correlation between common psychiatric disorders (i.e., ADHD and major depressive disorder) and phenotypic factors.

Overall, these results suggest that phenotypic factor analysis enhances interpretability, boosts power for heritability analyses, and can yield meaningful reduction in dimensionality to drive the next generation of genetic studies.

## PgmNr 2298: Population-specific non-synonymous variants in *PRSS53* influence morphology of human scalp hair.

Fine-Mapping of Adaptive Variation (*FineMAV*) of 1000 Genomes Project continental populations has previously identified two population-specific high-frequency non-synonymous transitional mutations, rs201075024 (g.31087679C>T; p.Gly34Ser) and rs11150606 (g.31087690T>C; p.Gln30Arg), in the South and East Asian continental populations, respectively. These mutations are 10 bp apart and lie in the third exon of serine protease 53 (*PRSS53*) on human chromosome 16. The gene has been associated with curly hair in knock-out animal models and with hair shape in genome-wide association analysis of admixed Latin Americans. We tabulated *FineMAV* scores for these variants in published high-coverage whole-genome sequenced population samples from Singapore and from the Han Chinese and observed high frequencies for rs201075024 in the Indian and rs11150606 in the Malay populations from Singapore. We also examined the genotype and allele frequencies of these variants in 98 additional individuals from Malaysia using PCR amplification and Sanger sequencing. Subsequently, we used scanning electron microscopy to examine phenotypic differences in the shape, thickness and cross section of scalp hair in a subset of the Malaysian samples (n= 25). In Malaysians, the derived allele frequency was 0.75 for rs201075024 and 0.15 for rs11150606. Several Malaysian individuals (n = 15) were heterozygous for both variants and this has not been reported previously. A Multivariate ANOVA (MANOVA) model was used to compare the two *PRSS53* variants and ethnicity to the measures obtained with electron microscopy. The results show that the number of derived alleles for both SNPs significantly affected the shorter cross-sectional diameter of scalp hair (p = 0.005) when individuals with 0, 1 or 2 copies of the derived alleles were compared. However, the effects of the two SNPs were in opposite directions. The most extreme variation in the average shorter diameter was observed between the homozygous derived rs201075024 (South Asian) genotype (Mean  $\pm$  SD = 39.42  $\pm$  5.49  $\mu$ m) and homozygous derived rs11150606 (East Asian) genotype (81.01  $\pm$  4.58  $\mu$ m). These results suggest an opposing role for these two variants in shaping the cross-sectional diameter of scalp hair and further studies will be required to elucidate the mechanism of action of these derived alleles and their interaction with other loci such as the ectodysplasin A receptor, *EDAR*, that has also been associated with hair thickness in East Asians.

## PgmNr 2299: Genome-wide association studies for metabolic traits in the Ryukyu populations.

---

Genome-wide association studies (GWAS) have identified more than several hundreds of variants for individual common diseases or quantitative traits in various ethnic groups, including Japanese. Previous researches have shown that Japanese populations are genetically divided into two clusters, one is the Hondo cluster, which is a major Japanese cluster. The other is the Ryukyu cluster including individuals originally from the Ryukyu Archipelago, which is a chain of Japanese islands that stretch southwest from Kyushu to Taiwan, and is composed of dozens of islands. Because previous GWAS have focused on people belong to the Hondo cluster, there are few genetic information for individuals belong to the Ryukyu cluster. To obtain the genetic information for people living in the Ryukyu Archipelago, we have been attempting to establish a bio-resource, Okinawa Bio-information Bank, consisting of genomic DNA and clinical information from ~13,000 participants living in the Ryukyu Archipelago. To understand the regional population structure, we first obtained genome-wide single nucleotide variations (SNVs) data using Asian Screening Array (ASA, Illumina, CA, U.S.A.) for ~4,000 individuals, living in Ryukyu islands, including Miyako, Kumejima and Okinawa islands. Interestingly, results of principal component and admixture analyses indicated distinct clusters of each island group in the Ryukyu Archipelago. Subsequently, GWAS for metabolic traits, including serum uric acid (sUA), low density lipoprotein cholesterol (LDL-C), triacylglyceride (TG) and high density lipoprotein cholesterol (HDL-C), were conducted, and we identified several loci significantly associated with these metabolic traits ( $p < 5 \times 10^{-8}$ ); sUA ( $n = 2,945$ ); rs57633992 (Chromosome (Ch) 11, *NRXN2-SLC22A12*,  $p = 3.3 \times 10^{-18}$ ), rs6822046 (Ch 4, *SPP1*,  $p = 7.5 \times 10^{-9}$ ), TG ( $n = 2,863$ ); rs662799 (Ch 11, *ZPR1-APOA5*,  $p = 6.7 \times 10^{-23}$ ), rs78358410 (Ch 8, *LPL*,  $p = 6.8 \times 10^{-10}$ ), HDL-C ( $n = 2,879$ ) rs183130 (Ch 16, *CETP*,  $p = 3.1 \times 10^{-19}$ ), rs113932726 (Ch 11, *ZPR1-APOA5*,  $p = 2.2 \times 10^{-16}$ ). In summary, we observed the genetic differentiations among the island groups of the Ryukyu Archipelago. These genetic differences may reflect ancient migrations and admixtures of the people living in the Ryukyu Archipelago. We also identified several loci significantly associated with several metabolic traits in the Ryukyu population.

## PgmNr 2300: Analysis of runs of homozygosity segments in the Kuwaiti population.

### Authors:

S. John; P. Hebbar; A. Channanath; F. Al-Mulla; T. Thanaraj

[View Session](#) [Add to Schedule](#)

**Affiliation:** Genetics & Bioinformatics, Dasman Diabetes Institute, 15462, Dasman, Kuwait, Kuwait

---

**Background:** Runs of Homozygosity (ROH) are contiguous, homozygous segments of the genome having identical haplotypes inherited from the parents. The number and length of ROH provide useful information on the demographic history of populations and individuals, while the homozygosity burden could be a powerful tool to unravel the genetic architecture of complex diseases. Admixed populations carry the fewest ROH regions whereas consanguineous communities harbor very long ROH. Kuwait and the other Middle Eastern countries adorn a strategic place in the human migration route out of Africa. The Middle Eastern populations, characterized by a high proportion of consanguinity, becomes a preferential target for the study of nature and distribution of ROH. The aim of this study is to evaluate the patterns of Long ROH in the Kuwaiti population and characterizing regions marked by a high (hotspots) or low (coldspots) degree of homozygosity.

**Methods:** We carried out this analysis on a cohort of 291 healthy Kuwaiti individuals, whose exomes were sequenced. Computational detection and classification of ROH was done. We compared the number and length of ROH in Kuwait exomes with that of other global populations. Furthermore, we characterized the hotspot and coldspot regions in the shared ROH regions between individuals and annotated these regions for potentially deleterious variations.

**Results:** By comparing ROH in Kuwaiti exomes with global populations, in terms of numbers, we found that they lie somewhere in the middle between groups that are highly inbred and diverse. Lengthwise, they outdo most of other populations highlighting their consanguineous nature. Analysis of variants in the hotspot regions led to the identification of genes associated with metabolic disorders such as obesity, type 2 diabetes and triglycerides, and autosomal recessive disorders which are highly prevalent in this region.

**Conclusion:** Our study shows that exome sequencing, even on limited number of individuals, combined with ROH mapping can be a powerful tool to identify some of the potentially deleterious disease variants in Middle Eastern populations, which are otherwise poorly represented in the world genetic map.

## PgmNr 2301: GATTC1 haplotype in *CD36* gene may predict the risk of developing T2DM associated BMI and hypertension.

---

Type II diabetes mellitus (T2DM) is now considered to be a serious disease that is always associated with long-term and life-threatening complications, attributed deaths and economic burden to nations. Several Single nucleotide polymorphisms (SNPs) in *CD36* gene have been found to be associated with metabolic syndrome and HDL metabolism, both predictors of the risk of heart disease and T2DM. We studied eleven SNPs in entire *CD36* gene and their association with 100 each of control subjects and T2DM. The haplotypic analysis of few significant SNPs was carried out in individuals from families with diabetic history in order to evaluate its utility in disease prediction. Polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) was used for genotyping. Ten families with a family history of diabetes were identified and blood samples were collected from as many family members as possible. Genotyping of three SNPs viz. rs1761667 (G>A) in exon 1 A, rs3211938 (T>G) in exon 10 and rs3212018 (16 bp del) in exon 14 was performed in all samples. In our study on North Indian population SNP G>A (rs1761667) genotypes showed a highly significant association ( $P<0.001$ ) and 1264T>G (rs3211938) showed mild significant for T2DM ( $P=0.045$ ). Moreover, individuals having a 'GATTC1' haplotype might be at risk of developing T2DM ( $P<0.001$ ). In addition of it, 'A' 'G' and 'G' alleles of SNPs rs1761667 (G>A), rs3211938 (T>G) and rs1984112 (T>G) respectively tend to have increased BMI in families. Though their lipid profile were found to be normal in both patients as well as innondiabetic individuals of families but BMI and slightly enhanced blood pressure of Nondiabetic individuals were found to be high which is suggested that they may develop diabetes in near future. Such studies may be helpful for disease prediction in individuals at risk of T2DM and could be used as a genetic marker.

## PgmNr 2302: Comparison of genotypic divergence with phenotypic divergence for type 2 diabetes and related traits among continental ancestry groups.

Prevalence of type 2 diabetes (T2D) differs among ancestry groups, and many hypotheses invoke differential natural selection to account for these differences. To assess the potential role of differential natural selection across major continental ancestry groups for T2D and related traits, we analyzed genetic and phenotypic differences among 734 individuals from urban Phoenix (none of whom was more closely related to another than 3<sup>rd</sup> degree relatives), including 83 African Americans (AA), 523 American Indians (AI) and 128 European Americans (EA). Participants were not recruited based on T2D status or other traits. Body mass index (BMI) was calculated, and diabetes was diagnosed by a 75g oral glucose tolerance test. In those with normal glucose tolerance (n=434), fasting insulin (FI) and 30-minute post-load insulin ( $I_{30}$ ), adjusted for 30-minute glucose, were taken as measures of insulin resistance and secretion, respectively. Whole exome sequencing was performed using HI-SEQ (Illumina, San Diego, CA) resulting in 97,125 common (average minor allele frequency >5%) variants;  $F_{ST}$  was calculated across all markers as a measure of genetic divergence among populations. The phenotypic divergence index,  $P_{ST}$ , was also calculated from the phenotypic differences and heritability (which was estimated from genetic relatedness calculated empirically across all markers in 766 AI participants prior to the exclusion of close relatives). Under evolutionary neutrality, the expectation is  $P_{ST}=F_{ST}$ , while for traits under differential selection  $P_{ST}$  is expected to be much greater than  $F_{ST}$ . A bootstrap procedure was used to test the hypothesis  $P_{ST}=F_{ST}$ . With adjustment for age and sex, prevalence of T2D was 34.1% in AI, 12.4% in AA and 10.4% in EA ( $P=2.9 \times 10^{-10}$  for difference among groups). Mean BMI was 35.5, 32.4 and 31.8 kg/m<sup>2</sup> respectively ( $P=1.9 \times 10^{-7}$ ). Mean FI was 64.7, 47.3 and 44.0 pmol/l ( $P=9.2 \times 10^{-5}$ ), while mean  $I_{30}$  was 567.8, 539.0 and 349.6 pmol/l ( $P=5.7 \times 10^{-8}$ ).  $F_{ST}$  across all markers was 0.146, while  $P_{ST}$  for liability to T2D, adjusted for age and sex, was 0.147 ( $P=0.99$  for difference with  $F_{ST}$ ).  $P_{ST}$  was 0.094 for BMI ( $P=0.31$ ), 0.092 for FI ( $P=0.37$ ) and 0.219 ( $P=0.40$ ) for  $I_{30}$ . These analyses suggest that while T2D and related traits differ significantly among continental ancestry groups, the differences are consistent with expectations based on heritability and genetic distances; thus, differential natural selection may not be necessary to explain these differences.

---

Samoa is part of the Polynesian Islands which were settled 3,000 years ago. Challenges faced by the settlers of Samoa may have led to positive adaptive selection when food was limited, especially for energy efficient alleles. Selection may also have occurred as a result of exposure to infectious diseases during migration or contact with outside populations. Genetic signatures of adaptation have been identified in other population isolates so, given Samoa's genetic isolation, they are likely to be identified in Samoa as well. We performed a SNP-based population branch statistic analysis (PBS) to simultaneously compare the genetic population differentiation between Samoa and a closely-related in-group and a distantly-related out-group. 419 unrelated Samoans were compared to 1,432 unrelated Taiwan Chinese and 1,083 unrelated Europeans. All individuals were sequenced as part of the TOPMed Program. We also tested for evidence of selective sweeps in 419 unrelated Samoans using  $n_S$ , a single-population haplotype-based analysis. Since  $n_S$  values are dependent on allele frequency,  $n_S$  was calculated once with  $MAF > 0.01$  and once with  $MAF > 0.05$ . The top 25 variants from the PBS,

$nS_{L(0.01)}$ , and  $nS_{L(0.05)}$  analyses were explored further. We performed gene ontology (GO) enrichment analysis on the PBS results. The top 25 variants from the PBS,  $nS_{L(0.01)}$ , and  $nS_{L(0.05)}$  analyses included 29 variants in/near genes (*ADH5P2*, *ARHGEF28*, *CLN3*, *GRIN2A*, *KIAA1217*, *LOC101929563*, *LRFN5*, *OFCC1*, *PDZD8*, *RNU5F-1*, *SCN3A*, *SEMAB*, and *TIGAR*) that have been associated with BMI and 17 variants in/near genes (*ARL17B*, *B4GALNT4*, *C22orf34*, *LOC101929563*, *MIR4289*, *MROH1*, *PFKFB3*, *PLXNC1*, and *PPP2R2D*) that have been associated with the immune system or respiratory disease. Genes (*ABC11*, *ARL17B*, *MCU*, and *TMEM132C*) which have been identified in other genome-wide scans of selection were also identified. Of the 10 gene sets that were significantly enriched in the GO enrichment analysis, 4 were associated with immune system-related biological processes. This suggests that variants associated with an energy efficient metabolism and the immune system may have been selected for in Samoans. Selection for BMI related alleles may have occurred during times of food scarcity. Selection for immune related alleles may have occurred in response to exposure to an infectious disease at some point in Samoan population history.

## PgmNr 2304: Exploring health, disease, and diet in Ancient Rome through paleogenomics.

Daily life in the Roman Empire has been studied in extensive depth across the humanities, social and natural sciences. Here we draw on this rich body of evidence to contextualize whole-genome sequence data from three well-documented Roman sites - Portus Romae, the port of Rome on the Tyrrhenian Sea, Crypta Balbi within the city of Rome, and Villa Magna, in the countryside south of Rome. This approach allows us to explore genetic changes in the context of changing mobility patterns, cultural practices and environmental conditions. We integrate existing isotopic data, dental calculus studies, and paleopathological evidence to better understand and interpret frequency changes we observe in functional alleles related to health and diet, such as malarial resistance and lactase persistence.

---

Recurrent 600 kbp copy number variations with breakpoints BP4 and BP5 at human chromosome 16p11.2 are among the most frequent genetic causes of neurodevelopmental and psychiatric disorders. These pathogenic rearrangements are mediated by human-specific duplications through non-allelic homologous recombination. These duplications appeared at the beginning of the modern human lineage, rapidly increased in frequency, and are now nearly fixed in humans, suggesting that their expansion has a possible evolutionary advantage that outweighs the accompanying chromosomal instability. They are copy number polymorphic and include 3 to 8 copies of *BOLA2*, a gene involved in the maturation of cytosolic iron-sulfur proteins. To investigate the potential advantage provided by the rapid increase in the number of copies of *BOLA2*, we assessed hematological traits and anemia prevalence in 379,385 controls and individuals who have lost or gained copies of *BOLA2*: 89 chromosome 16p11.2 BP4-BP5 deletion and 56 reciprocal duplication carriers in the UK Biobank. We found that the 16p11.2 deletion is strongly associated with anemia (18/89 carriers, 20%,  $P=4e-7$ , OR=5), particularly iron-deficiency anemia. We observed similar enrichments in two clinical 16p11.2 deletion cohorts, with 6/63 (10%) and 5/19 (26%) unrelated individuals with diagnosis of anemia, low serum iron, or low blood hemoglobin. Upon stratification by *BOLA2* copy number, we found an association between low *BOLA2* dosage and anemia ( $P=2e-3$ ). In particular, 6/14 (43%) individuals with three copies were anemic. In parallel, we analyzed hematological traits in mice carrying the 16p11.2 orthologous deletion or duplication that include *Bola2*, as well as *Bola2*<sup>+/-</sup> and *Bola2*<sup>-/-</sup> animals. Consistent with human data, the 16p11.2 deletion mouse model and *Bola2*-deficient mice showed early evidence of iron deficiency, including a mild decrease in hemoglobin, lower plasma iron, smaller red blood cells, and an increased red blood cell zinc protoporphyrin to heme ratio. Our results indicate that *BOLA2* participates in iron homeostasis in

*vivo*. Its rapid expansion through segmental duplication might have evolved to protect humans against iron deficiency as our species successfully expanded its ecological range at the cost of increased predisposition to rearrangements associated with autism.

## PgmNr 2306: *HLA-G* gene associated with vitiligo in a Brazilian population sample.

---

Vitiligo is an autoimmune disease characterized by skin depigmentation due to failure of melanocytes function. It is the most frequent cause of depigmentation worldwide, affecting people from various ethnic backgrounds, notwithstanding, with no satisfactory treatment available. Genetic association studies have described 50 loci associated with vitiligo, many of them related to other autoimmune diseases. Classic *HLA* loci have already been associated with this condition, but no study investigated the association of *HLA-G* with vitiligo considering its whole genic region (exonic, intronic and regulatory regions – 5'URR and 3'UTR). We have identified the genetic diversity of *HLA-G* by next-generation sequencing in a population sample composed of 50 vitiligo cases and 393 healthy control individuals from São Paulo State, Brazil. Individual ancestry was determined by the SNPforID 34-plex ancestry informative marker (AIM) SNP panel included in this same assay. DNA libraries were prepared using the Haloplex Target Enrichment System (Agilent Technologies) and sequenced at the MiSeq platform (Illumina). CutAdapt, hla-mapper, and GATK software packages were used for trimming adaptor sequences, alignment and genotype calling, respectively. Missing alleles and haplotypes were inferred by using the PHASE method. Ancestry was estimated by STRUCTURE, considering EUR, AFR, and EAS groups from 1000 Genomes Project as reference. Case-control associations, adjusted by ancestry, were performed using logistic regression at PLINK v.1.9. We detected 105 variation sites distributed along the *HLA-G* locus fitting Hardy-Weinberg expectations ( $p \geq 0.01$ ). Comparing patients with controls, we detected associations with rs1625907\*G ( $p=0.026$ ; OR=1.639; 95%CI 1.061-2.529), and rs9380142\*G ( $p=0.040$ ; OR=1.590; 95%CI 1.020-2.479). The first one, rs1625907\*G, is associated with the G\*01:01:01 and G\*01:03 allele groups. The second one (rs9380142) is located at the 3'UTR, at position +3187, with allele Guanine composing the 3'UTR haplotype previously described as UTR-1. The rs9380142 has already been associated with different pathological conditions, as well as to mRNA stability. This is the first report that highlights the association of rs9380142 with vitiligo, suggesting a possible mechanism in the development of the disease. Financial Support: CAPES - Finance Code 001. CNPq (448242/2014-1), FAPESP (2013/15447-0), USP/COFECUB (2017.1.1337.1.5). M.L.G.O (141908/2016-5); C.T.M.J. (312802/2018-8).

## PgmNr 2307: Higher Native American ancestry proportion is associated with TB progression risk in the Peruvian population.

A potential link between Native American ancestry (NAT) and tuberculosis (TB) risk has been extensively studied over the past two centuries (Jones, 2003), but the conclusions studies have been unsatisfactory and controversial due to the lack of adequate control for confounding factors. Here, we investigated the relationship between NAT and TB progression risk in a cohort of 3,980 genotyped admixed Peruvians from Lima. Upon admission of index cases, their household contacts (HHCs) were tested for TB at 2, 6, and 12 months and were recruited as cases if they developed active TB and as controls with latent TB if they were tuberculin skin test positive but did not develop active TB. We also collected extensive socio-demographic information for all participants. We merged our data with the data from Native American (Reich, 2012) and 1000 Genomes project populations to infer ancestry proportions using ADMIXTURE (K=4). NAT was associated with TB progression risk after correction for age, gender, household as a proxy for unmeasured environmental variables, and a genetic relatedness matrix to correct for relatedness and population structure (2,160 cases, 1,820 HHCs,  $p=1.82 \times 10^{-15}$ , OR for 10% increase in NAT ( $OR_{NAT0.1}$ )=1.24 (1.18-1.31)). Correction for 7 additional covariates including African and Asian ancestry, smoking, drinking, malnutrition, BCG vaccination, and socioeconomic status had no effect on this result ( $p=1.09 \times 10^{-6}$ , 1.26 (1.15-1.38)). To better control for factors related to transmission, we restricted our analysis to secondary cases (e.g. HHCs who developed TB during the follow-up, N=203) and their HHCs (N=253). This analysis resulted in an odds ratio similar to the one observed for the whole cohort ( $p=7.78 \times 10^{-4}$ ,  $OR_{NAT0.1}=1.30$  (1.12-1.52)). We next used admixture mapping to search for specific genomic regions that might explain some of this association. No genomic region reached the genome-wide significance threshold ( $< 5.68 \times 10^{-5}$ , lowest observe  $p=1.1 \times 10^{-3}$ ). Our results show that, relative to European ancestry, NAT is associated with TB progression risk. This association is unlikely to be due to confounding factors and is driven, at least in part, by genetics. This effect is most likely to follow a polygenic architecture. It is possible that the long, shared history of Europeans and TB has led to selective pressures that have mitigated TB risk, and that such pressures have not been present in the Americas.

## PgmNr 2308: Paternal age is significantly associated with higher *de novo* mutation rate in rhesus macaques, but not associated with sociality in male offspring.

---

The nature and rate of *de novo* mutation is fundamental to our understanding of genome content, genome evolution and biomedical genetics. Studies in humans show that paternal age is a major factor determining the number of *de novo* mutations. Furthermore, evidence suggests advanced paternal age increases the risk of autism, possibly due to the elevated mutational burden from older fathers. To quantify *de novo* mutation in nonhuman primates and test for paternal age effects on behavioral variation, we generated whole genome sequences for three-generation families of rhesus macaques (*Macaca mulatta*) and used behavioral assessments of 203 male rhesus to ask whether offspring of older fathers differ in sociality compared to those with younger fathers. We sequenced the genomes (Illumina Nova-Seq) of 32 individuals, including 14 probands. We estimate the average mutation rate to be  $0.37 \times 10^{-8}$  per site per generation, with a strong association between paternal age and number of *de novo* mutations per offspring. For each additional year of paternal age offspring exhibit 1.3 additional *de novo* mutations ( $r^2 = 0.75$ ,  $p < 5 \times 10^{-5}$ ). The pedigree structure allowed phasing of new mutations, and 66% were derived from fathers. We found a weak relationship between maternal age and mutation rate, consistent with environmental effects. To investigate the effect of paternal age on social behavior, 8 behaviors involved in general social functioning were quantified across 203 male macaques. Principal component analysis yielded general scores summarizing social function. The first principal component (PC1) captures individual tendencies to interact with females versus males. PC2 captures overall contact with and proximity to both sexes and is correlated with observer ratings of sociability as a broad personality trait. We find no evidence of an effect of paternal age on social functioning. We conclude that, as in humans, *de novo* mutation in macaques is driven primarily by male mutation and that this rate increases with paternal age. The absolute frequency of macaque mutations fits the model of Thomas et al. (*Curr. Biol.* 28: 3193, 2018) which relates per generation mutation with reproductive longevity rather than simple generation length. We find no evidence for an effect of increased paternal age on social behavior among male rhesus macaques, consistent with hypotheses that the increased risk of neurodevelopmental disorder from parental age is not primarily due to *de novo* mutation.

## PgmNr 2309: Environmental and genetic drivers of telomere length variation in ethnically diverse Africans.

---

Telomeres are repetitive non-coding sequences at the ends of chromosomes that maintain genomic stability. Telomeres progressively shorten at each cell division until a critical length is reached and cell division stops. Thus, telomere length is closely associated with aging and lifespan. In addition, longer telomeres are associated with increased risk of many cancers, while shorter telomeres are associated with elevated cardiovascular disease risk. Finally, telomeres can shorten as a result of many intrinsic and extrinsic factors, including chronic stress and infection status. However, relatively little is known about the genetic architecture underlying telomere length, or the environmental factors that influence telomere loss. Additionally, the evolutionary history of telomere length in humans, and whether selection has influenced telomere dynamics, remain to be explored. Here, we investigate the relationship between telomere length, genetics, and environmental factors in a set of ethnically diverse African people (n=1820) originating from populations in Botswana, Tanzania, Ethiopia, and Cameroon. We find significant variation in telomere length among populations after adjusting for age and sex, with the San hunter-gatherers from Botswana having the longest telomeres, and pastoralists from Cameroon having the shortest telomeres. After accounting for genome-wide ancestry and relatedness among individuals, we find that a large proportion of inter-individual variation in telomere length (>40%) is explained by genetic factors. Finally, telomere length varies significantly with environmental factors across Africa, as we find that altitude, UV-B radiation, and temperature explain small but significant amounts of variation in telomere length after adjustment for age, sex, and genome-wide ancestry. Ongoing work examines whether patterns of polygenic adaptation at genetic loci underlying telomere length vary with environmental factors globally and within Africa. This research will help elucidate the evolutionary forces driving telomere length variation in humans, which will provide insight into the basis of telomere-related disease risk.

## PgmNr 2310: Complete mitogenome sequencing of 605 CEPH family pedigree samples reveals spurious substitutions attributed to cell culture.

---

The present study evaluated mitochondrial genome sequence variability in the CEPH family pedigree cell lines with the intentions of developing interpretation guidelines for forensic casework. This involved an assessment of the inter-generational substitution rate, which can also inform clinical genetics and human evolutionary research. A total of 605 mitogenomes from 87 maternal lineages were produced using a long-range dual PCR amplification, KAPA HyperPlus library preparation, and Illumina sequencing workflow. Sequence data were analyzed with a minor variant detection threshold of 2% and a minimum read depth of 350. Then the number of point substitutions from mother to child was calculated for each of 516 generational events. A substitution was defined as a complete base change with no indications of heteroplasmy in either the mother or the child, which is unexpected given the multicopy inheritance of mitochondrial DNA in which several dozen are carried through oogenesis. The CEPH data showed 29 substitutions from mother to child, two of which were observed in a single sample, for an inter-generational substitution rate of 5.4%. This is in contrast to the 0% substitution rate reported in a similar study of non-cell line samples from mother-child pairs comprising 39 generational events. Of the 29 substitutions in the CEPH family pedigrees, 13 (45%) appeared to be spurious substitutions, defined as variants that were not observed in any other samples in the lineage and are also rare for the haplogroup. Raising the minor variant detection threshold to 10% increased the inter-generational substitution rate to 23.4%, and raised the number of spurious substitutions to 97, impacting 30 (5%) of the 605 CEPH family pedigree samples. If the same rate of spurious substitutions could be expected from the HGDP cell lines used for human evolutionary studies, this would erroneously speed up the molecular clock. Furthermore, the present results indicate an inflated heteroplasmy occurrence in the CEPH cell lines at an average of 1.85 point heteroplasmies per individual, in contrast to other serum, blood and buccal sample data at ~0.50 point heteroplasmies per individual. Overall, this study highlights the necessity for low-level heteroplasmy detection for accurate mitogenome reporting of cell line sequence profiles, and quantifies the expected rate of spurious substitutions and heteroplasmic sequence artifacts that may be reported from immortalized cell lines.

## PgmNr 2311: Multi-copy nuclear elements of mitochondrial DNA mimic paternal inheritance in humans.

Mammalian mitochondrial DNA (mtDNA) is generally believed to be inherited through the maternal lineage. A few studies claim paternal mtDNA inheritance mostly in patients suffering mitochondrial myopathies. We report the similar observation of a mixture of two phylogenetically distinct full mitogenomes in healthy individuals. Different tissues from a total of eight maternally related individuals spanning three generations gave to varying degrees mixtures of two mitotypes assigned to haplogroups V and U4c1a. While suggestive of paternal inheritance, the U4c1a contribution could instead be ascribed to a multi-copy mtDNA insert (NUMT) in chromosome 14, by fluorescence in situ hybridization and sequencing of DNA from cultured fibroblasts that were depleted of their mtDNA (p<sup>0</sup> cells). Droplet digital PCR and multiplex qPCR suggested 45–56 copies of the NUMT insert per p<sup>0</sup> cell. Our study casts doubt on earlier claims of paternal inheritance that lack explicit testing for the presence of NUMT sequences.

With very few exceptions, mitochondrial DNA (mtDNA) in humans is transmitted exclusively from mothers to their offspring, suggesting the presence of a strong evolutionary pressure favoring the exclusion of paternal mtDNA. We have recently shown strong evidence of paternal mtDNA transmission. In these rare situations, males exhibiting biparental mtDNA appear to be limited to transmitting just one of their mtDNA species to their offspring, while females possessing biparental mtDNA populations consistently transmit both populations to their offspring at very similar heteroplasmy levels. The precise biological factors underlying these unusual transmission events remain unclear. Here, we have examined heteroplasmy levels in various tissues among individuals with biparental inheritance. Our results indicate that individuals with biparental mtDNA have remarkable inter-tissue variability in heteroplasmy level. At the single-cell level, paternal mtDNA heteroplasmy in sperm varies dramatically, and many sperm possess only one of the two mtDNA populations originally in question. Taken together, these results show a fundamental, parent-of-origin difference in how mtDNA molecules transmit and propagate. This helps explain how a single population of mtDNAs are transmitted from a father possessing two populations of mtDNA molecules, suggesting that some mtDNA populations may be favored over others when transmitted from the father.

Mitochondrial variants are causative for rare mitochondrial diseases (1 in 5,000 clinically affected adults), and are also linked to common health conditions such as obesity and Alzheimer's disease. For those with deleterious variants, differences in heteroplasmic levels can lead to varying phenotypic presentations of the same disease in a population. Understanding the genetic contribution of mitochondrial variation to human health is challenging due to the unique nature of mitochondrial biology and its coexistent, complementary, yet distinct inheritance from that of the nuclear genome.

Smaller mitochondrial-specific databases are biased due to their composition; our current understanding of human mitochondrial variation is largely informed by studies that recruit for patients with inherited mitochondrial disease, and by studies of human evolution and migration patterns. In both cases, there is often bias in recruitment, and baseline rates of variation may be skewed. Information on the frequency of a homoplasmic or heteroplasmic variant in the population would help develop, test, and refine or disprove hypotheses for causality.

Here we characterize the mitochondrial genomes of more than 250,000 individuals sequenced in the Helix clinical laboratory. This collection is unbiased towards individuals with a mitochondrial disorder. We also provide the community with a research resource of all mtDNA variants identified and their frequencies. Our database includes more than 10,000 mtDNA variants, with ~20% present as singletons, and ~54% mtDNA bases invariant in the population. While our variant count is similar to MitoMAP, our singleton rate is lower and invariant base fraction higher as is expected in an unbiased cohort with improved mtDNA variant frequency estimates. We find that heteroplasmic-only variants are enriched at sites of high conservation, supporting the presence of heteroplasmy as an indicator of pathogenicity. We show that this large population-based approach improves our ability to interpret disease-associated variants by analyzing those reported to be pathogenic for Leber's Hereditary Optic Neuropathy (LHON). We find that many reportedly pathogenic variants have a frequency far above the maximum plausible allele frequency for a LHON-causing variant, including the primary variant m.14484T>C. We further confirm these findings with matched medical records for participants in the UK Biobank and Healthy Nevada Project.

The Garifuna is a Caribbean population that originated in the mid 17th century, with origins tales of shipwrecks off the coast of the island of St. Vincent. In addition to admixture with local Caribs, the Garifuna experienced a number of bottlenecks, periods of migration and exponential growth. In this study, we aimed to better understand the history of the Garifuna by leveraging genotype data available through Consortium on Asthma among African-ancestry Populations in the Americas (CAAPA).

Samples were genotyped on Illumina's MEGA chip. After quality control, 520 samples were available for analysis from 8 communities (Alfonzo Lacayo n=43; Bajamar n=64; Corozal n=105; Sambo Creek n=122; San Juan n=28; Tornabe n=43; Travesia n= 95 and Triunfo de la Cruz n=20). We estimated frequencies of mitochondrial haplogroups (using Haplogrep2), Y- chromosome haplogroups (SNAPPY) and HLA genotypes (HIBAG), and compared frequencies among different communities. We phased genotype data and estimated segments of genetic material shared identical-by-descent (iLASH), to infer patterns of effective population size in current and past generations (IBDNe).

The most common mitochondrial haplogroups observed are L (83%; continental African), C1 and B2 (4.7% and 0.6%; continental American). The C1 American haplogroup was observed more frequently in Travesia (17.8%) and Bajamar (7.9%); was rare in Sambo Creek (2.5%); and absent in other communities. The most common Y haplogroups observed in the Garifuna are E1b1a1 (64.5%; continental African), Q1a2a1a1 (29.5%; continental American) and R1b1a2a1a (2.2%). Contrary to the mitochondrial data, the American origin Q1a2a1a1 haplogroup was common in all communities. The most common HLA alleles are A\*23:01 (21.3%), C\*04:01 (19.2%), DQA1\*01:02 (19.2%) and DPB1\*01:01 (32%) with corresponding African American frequencies of 10%, 20.5%, 30.7% and 27% respectively (obtained from allele frequencies.net). Consistent with previous analysis based on whole genome sequence data of n=41 subjects, our estimates of effective population size points to a

bottleneck event 10-15 generations ago, corresponding to the period when slaves of African ancestry first settled in this region.

For future work, we plan to genotype additional samples from coastal communities to expand our analysis. We will also generate ~100 whole genome sequences of indigenous Caribbean populations from Honduras, which will enable us to characterize admixture events in the Garifuna.

## **PgmNr 2315: *Deciphering the genetic mechanism of epilepsies using a founder population structure.***

### **Authors:**

---

### **Introduction**

Epilepsy is defined as a group of neurological disorders characterized by epileptic seizures defined as brief episodes of symptoms that are caused by abnormal or excessive neuronal activity in the brain. Although monogenic forms of the disease have been reported, they represent less than 2% of epilepsy cases. Until recently, most studies on epilepsies did not focus on a specific type of epilepsy, probably due to small sample sizes and lack of appropriated methods.

### **Methodology**

For the present study, we used 522 French-Canadians suffering from various types of epilepsies in addition to 954 French-Canadian control individuals. The French-Canadian population is well-known for its founder effect and its elevated frequency of some population-specific genetic disorders. All patients and controls underwent whole-genome genotyping and 212 epilepsy patients had their whole-genome sequenced. Additionally, all patients and controls had their genealogies reconstructed to identify a common pool of ancestors dating back to the 17<sup>th</sup> century (arrival of French colons in America). We imputed whole-genome sequences using genotypes to perform a GWAS and to calculate polygenic risk scores (PRS) and heritability on more specific types of epilepsy as described in other studies. We also used the genotypes to infer identity-by-descent (IBD) shared segments to try to identify shared haplotypes that could be related to the disease. Following this, we conducted a haplotype-based genome-wide association study in addition to enrichment analyses.

### **Results**

We were able to replicate several associations identified by the ILAE GWAS study. The same study was used to establish heritability profiles as well as significant PRS regression analysis (using the pairwise IBD matrix as covariates) for several types of epilepsy. These results show different profiles for cases and controls. We found several IBD segments with significantly higher frequency for specific types of epilepsy when compared to the control individuals.

### **Perspective**

Our comprehensive study on the genetics of epilepsy in the French-Canadian population shows the multifactorial nature of the disease as well as the need to use complimentary strategies in order to unravel the genetic mechanisms of the disease. It also shows the importance of refining the individual diagnosis of each patient and that having a good knowledge of the population structure will help to decipher the genetic mechanisms of epilepsies.

## PgmNr 2316: Fishing for function in the evolutionary gene pool: A zebrafish model of human duplicated gene *SRGAP2*.

---

Gene duplication is a rich source of species innovation contributing to novel phenotypic features. Comparison of great ape genomes has identified millions of base-pairs uniquely duplicated affecting >30 gene families that may contribute to neurological features in humans. *SRGAP2*, one notable example, has duplicated uniquely in the *Homo* lineage to produce three partial paralogs present in modern humans. Previous studies show that expression of truncated human paralog *SRGAP2C* in mice impacts cortical neuronal migration and synaptogenesis by antagonizing the function of the full-length ancestral ortholog. Considering most human duplicated genes are uncharacterized, we propose using zebrafish (*Danio rerio*) to quickly test gene function. Zebrafish are advantageous over other vertebrate model systems based on their rapid development, small size, fecundity, transparent bodies, and high efficiencies of gene editing.

As proof of principle, we used CRISPR to generate a stable knockout of zebrafish ortholog *srgap2*. RNA-seq and *in situ* hybridizations show that *srgap2* expression peaks at ten hours post fertilization when postmitotic neurons begin forming in the developing zebrafish embryo. Consistent with previous findings that link *SRGAP2A* dysfunction with epilepsy (human) and synaptic connectivity (mouse), zebrafish *srgap2* mutants exhibit seizure-like behavior when exposed to GABA antagonist pentylenetetrazol (median distance moved in 18 hours, homozygous=42.3 m, wildtype=22.4 m, P=0.037). Experiments are ongoing to assay additional neurodevelopmental defects. Preliminary data show that *srgap2* mutants exhibit deviations in head size at two days post fertilization, suggesting its conserved function in neuronal migration. Based on the high conservation of *srgap2* between zebrafish and human (74% amino acid identity) and previous results in mouse models, we hypothesize that expression of human truncated paralog *SRGAP2C* in zebrafish will impede the function of endogenous *srgap2* and, thus, phenocopy defects identified in our knockout mutants. While a work in progress, promisingly, we observe significant levels of *SRGAP2C* transcripts retained in zebrafish two days post injection of *in vitro* transcribed RNA. Ultimately, if successful, these experiments will provide a roadmap to quickly assay the function of additional duplicated genes to understand if/how they contribute to the evolution of novel neurological traits and diseases unique to humans.

## PgmNr 2317: Diversity and directionality of a large human-specific repeat expansion.

So far, over 30 tandem repeat expansions in the human genome are known to cause neurological disease. However, the mechanism by which these repeats expand remains uncertain, largely because most disease-causing repeats are composed of an uninterrupted sequence tract, making it difficult to identify where the repeat arises within the expansion. We have identified a variable number tandem repeat (VNTR) in the last intron of the gene *WDR7*, which is predicted to fold into a stable hairpin structure and exhibits striking nucleotide variability in humans. This VNTR is 69 nucleotides long, with six variable nucleotide positions within each repeat unit. It expands from 1 copy in phased non-human primate genomes to 6 copies in the reference human genome, without adjacent repetitive elements that could facilitate this expansion. By performing multiplexed long-read sequencing in 144 individuals, we found that the *WDR7* repeat ranges anywhere from 1-86 repeat copies, with a mean of 16 copies. The internal sequence is even more complex, a feature we are leveraging to understand the origin and mechanism of its expansion. Alignment of the complete repeat sequence for each allele reveals that the 3' region is fixed, while variability increases towards the 5' end, opposite the direction of transcription. Evaluating the repeat in 1000 Genomes Project samples reveals that while super-populations share a similar distribution of length and internal repeat unit composition, certain repeat units are highly enriched in specific groups. Notably, these rare repeat units are biased to the 5' edge of the repeat. Analysis of repeat matches from short-read sequences provides evidence of two repeat copies in the Neanderthal genome, while the Denisovan genome has a mean of 27 repeat copies and a composition similar to modern-day humans. We also note several instances of large duplications within the repeat in several individuals, and that the majority of new sequence occurs in combinations of repeat units divisible by two. Two repeat units roughly match the length of an Okazaki fragment, which could account for this curious periodicity. Finally, we have confirmed that the unique hairpin structure of the repeat can generate microRNAs, suggesting a functional role for this repeat. Overall, our analysis of this complex intronic repeat expansion allows us to evaluate the roles of VNTRs in human evolution and disease, and uncover their mechanism of expansion.

## PgmNr 2318: Evolutionary patterns of conservation at schizophrenia GWAS loci reveal varying histories of natural selection.

Schizophrenia (SCZ) is a common, complex, severely debilitating psychiatric disorder likely due to many genomic loci of small effect. Sequencing-based rare variant discovery efforts often focus on coding regions or assume a highly deleterious nature to the variants. While Mendelian disease mutations usually occur at coding nucleotide sites with high evolutionary conservation, this may not be true for alleles underlying common complex traits with persistent prevalence across time and populations. Disorders such as SCZ with reduced reproductive fitness in modern societies may instead fit a model where recent evolutionary constraint is detectable but constraint over deep phylogenetic time is not. Here, we used a GWAS meta-analysis of 65,205 SCZ cases and 87,919 controls that identified 248 independent loci as a dataset to determine the relationship between evolutionary site conservation and potential etiology. We applied the phylogenetic measure of evolutionary conservation PhyloP, which represents the likelihood of the observed conservation site score across phylogenetic time, for each of the different periods spanning vertebrate (n=100), mammalian (n=30), and primate (n=17) evolution. We also employed an analysis using a composite of tests of natural selection across the 248 loci within populations from the 1000 Human Genome Dataset. The PhyloP site distribution for the 248 GWAS variants showed no significant differences across the three time periods. However, there are significant outliers within each period with ~50% of the SCZ associated variants showing little conservation. To identify deviations across depths, we standardized the PhyloP scores within each locus at each depth and found significant heterogeneity. Several sites underlying GWAS signals show low conservation at deep vertebrate evolutionary time, but significantly higher evolutionary conservation within the primate lineage. We also identified loci with high vertebrate evolutionary conservation but with human population-specific positive natural selection. The observation that a majority of SCZ GWAS variants show little site conservation in deep time, and that this pattern changes over evolutionary time, is consistent with the prediction of a spectrum of functional variation expected for disorders with mild impact on reproductive fitness. These results demonstrate that GWA studies should consider evolutionary histories associated with complex traits to identify underlying disease variants.

## PgmNr 2319: Genome-wide detection and characterization of *de novo* repeat expansions in the general population.

---

Tandem repeats (TRs) consist of 1-20bp sequence motifs repeated consecutively. TRs have mutation rates that are orders of magnitude higher than SNPs, indels, or CNVs, and thus represent one of the largest sources of human genomic variability. Dozens of TRs have been associated with a range of phenotypes, including Huntington's Disease, Fragile X Syndrome, cancer risk, and schizophrenia. So far, population-scale analyses of TR mutations have been limited to several hundred loci due to technical challenges. Here, we use deep WGS of families and our recently developed TR genotyper, GangSTR, to conduct the first genome-wide (GW) population analysis of *de novo* TR mutations. GangSTR is capable of genotyping nearly 2 million TRs GW, ranging from short homopolymer repeats to large pathogenic repeat expansions.

We applied GangSTR to profile TRs from WGS of 1,916 quad families from the Simons Simplex Collection collected for autism research. We then developed a novel method, CookieMonSTR, to identify germline *de novo* TR mutations in WGS data of parent-offspring trios. CookieMonSTR combines genotype likelihood scores and estimated TR mutation rates to determine the posterior probability of a mutation at each locus. We identified an average of 300 *de novo* TR mutations per child and validated a subset of mutations using Sanger sequencing and capillary electrophoresis. Per-locus mutation rates were highly concordant with previous studies. Similar to other class of *de novo* variants, TR mutation rates were strongly correlated with the age of the father and had on average a 3x increase in mutational burden from fathers vs. mothers. Our results confirm a known mutational bias in direction dependent on the repeat length of the parental allele: alleles longer than the population mean are far more likely to contract, whereas shorter alleles are more likely to expand. We characterized the effects of replication timing, recombination, local SNP mutation rate, repeat unit base composition, recombination rate, local GC content, and modifier mutations on GW TR mutational processes.

Lastly, we develop a novel metric for prioritizing putative pathogenic TR mutations by combining per-locus constraint scores and population allele frequencies for each mutation. We apply our metric to identify a candidate set of TRs potentially involved in autism. Overall, GW identification and prioritization of TR mutations is an important tool for enabling the discovery of novel pathogenic loci.

## PgmNr 2320: Grave goods, mortuary practices, and ancient DNA at the Yukisma Mound in Central California.

### Authors:

K.G. Beaty<sup>1,2</sup>; E. Lenci Jr.<sup>3</sup>; A. Leventhal<sup>4</sup>; M.V. Arellano<sup>3</sup>; C. Nijmeh<sup>3</sup>; R. Cambra<sup>3</sup>; C. Monroe<sup>1,2</sup>

---

The archaeological record indicates that the end of the Late Period (900 BP-250 BP) in Central California was marked with shifts in settlement and mortuary patterns which was influenced by environmental and social change. Mortuary treatment and distribution of grave goods suggest either a reduction in social inequality with wealth concentrated in a distinct few, or a shift toward a corporate group identity that was associated with kinship. These interpretations were tested using data collected from 200 individuals from Yukisma Mound (CA-SCL-38), including a combination of mitochondrial DNA (mtDNA) sequences and restriction length polymorphisms, demographic information including sex and age, the distribution and type of burial site, and the number and type of grave goods associated with each burial. Thirty-six haplotype lineages belonging to Native American haplogroups A (5.5%), B (22%), C (29.5%), and D (43%) were identified at Yukisma Mound. Seventy-eight percent of these burials were associated with grave goods, with the number and type of good varying widely between burials. Spatial autocorrelation showed that the distribution of these haplotypes throughout the site were not correlated ( $r \approx 0$ ) between maternal relatedness and burial type, or between maternal lineage and the quantity or diversity of grave goods, indicating that group identity was not associated with maternal kinship. The distribution and diversity of mtDNA lineages throughout the site may instead show its use as a cemetery for wealthy elites that lived throughout the Bay area.

## PgmNr 2321: Identification of introgression events between archaic hominins and modern human populations.

**Authors:**

Z. Jin; H. Watanabe

[View Session](#) [Add to Schedule](#)

**Affiliation:** Genome Information Science Laboratory, Graduate School of Information Science and Technology, Hokkaido University , Sapporo, Japan

---

With the discovery of fossils and the accelerated accumulation of genome sequence data, increasing evidence supports the hybridization and introgression between the modern human lineage and archaic human lineages, e.g., Neanderthals and Denisovans, and between those archaic lineages. So far, a number of introgressed fragments have been suggested via different introgression identification methods.

In this study, we searched for genomic regions containing population-specific SNPs shared with archaic hominins and identified different introgression events, including unreported ones. The number of the genomic regions supporting a specific introgression event varies significantly among events, probably due to the timing of the event and natural selection. We will discuss the unreported events.

## PgmNr 2322: *DCDC2* READ1 regulatory element: How perception shapes language.

### Authors:

---

We previously showed an association between the READ1 regulatory element in *DCDC2* and the number of consonants in the languages of 43 populations distributed across five continents. We hypothesized that this association was due to the high precision required by the auditory cortex to discriminate between consonants and the role of *DCDC2* in modulating temporal precision of neuron firing. READ1 is associated with normal variation in phonological processing necessary for receptive language. This current study was designed to provide a link between the population frequency of the RU1-1 group of READ1 alleles with the neurophysiology of consonant perception. In particular, we focus on five consonant classes that differ in terms of their manner of articulation called stops, affricates, fricatives, nasals and approximants. We show that only stops and nasals associate with RU1-1. The nature of these consonant classes and the direction of their relationships with RU1-1 supports an account of how the sound system evolved to maintain phonemes that are easy to perceive.

## PgmNr 2323: Human adaptation to rice cultivation: Genetic evidence from contemporary China.

---

It is widely accepted that agriculture, one of the most important transitions in human history, has strongly changed the way people lived and eventually made us who we are today. Following the initial domestication in the lower Yangtze River valley 9,400 years ago, rice farming became widespread throughout China, changing patterns of food consumption, labor supply, and reproduction among Neolithic populations. Here we show that, the advent of rice domestication and cultivation has shaped the humans not only culturally but also genetically.

Using a dataset of 4,538 individuals recently collected from mainland China, we test whether genetic variants associated with various phenotypes have been under selection of the rice cultivation history. We leverage recent findings from molecular genetics to construct a number of polygenic scores that use individual genetic information to predict their height, body mass index (BMI), age at first birth, time discounting, risk tolerance, educational attainment, depression, and alcohol tolerance. We then examine associations between these polygenic scores and proportion of cultivated paddy rice field of the individual's birthplace at the county level.

Our results imply that rice cultivation may have exerted selective pressures in favor of earlier reproduction and higher levels of alcohol intolerance. Under such selection, the beneficial genes became more common among populations in rice farming areas as their carriers have more descendants. These results are robust after we control for individual ethnic makeup, regional differences (i.e. average temperature, historical population density, herding history, regional economic development, adjusted river length, historical pathogen epidemics), and potential endogeneity of rice farming. Our results provide evidence that human evolution occurred over the past generations due to culture and lifestyle inherited from a rice-cultivating society, shedding light on the potential role of rice domestication/cultivation in the history of human evolution for the first time.

## PgmNr 2324: The first intron of genes is functionally relevant: Analysis of epigenetic chromatin marks in the first intron.

**Authors:**

S.S. Choi; S.S. Jo; H. Choi

[View Session](#) [Add to Schedule](#)

**Affiliation:** Kangwon National University, Chuncheon, Gangwon-do, Korea, Republic of

---

The first intron of genes exhibits several interesting characteristics not seen in other introns: 1) it is the longest intron on average in almost all eukaryotes, 2) it presents the highest number of conserved sites, and 3) it exhibits the highest density of regulatory chromatin marks. Here, we expand on the aspects by integrating various multiomics data, leading to further evidence supporting the functionality of sites in the first intron. First, we show that trait-associated single-nucleotide polymorphisms (TASs) are significantly enriched in the first intron. We also show that, in the first intron, epigenetic chromatin signals are densely located near TASs. Furthermore, we reveal that the distribution of epigenetic chromatin signals is not independent of the width or level of gene expression. Moreover, genes carrying multiple first intron TASs are shown to interact with each other within a large protein-protein interaction network connected to the *UBC* protein. We believe that our results will shed light on the functionality of first introns as the genomic entity performing gene expression regulation.

## PgmNr 2325: Whole genome sequence data reveal global demographic dynamics respond to the last ice age.

**Authors:**

Liu

[View Session](#) [Add to Schedule](#)**Affiliation:** USF Genomics, College of Public Health, University of South Florida, Tampa, Florida.

---

It has long been hypothesized that human populations experienced a shrinkage during the last ice age and then recovered and boomed following the deglaciation. However, previous population genetics studies only provide scattered evidence and most of those are from certain European populations. In this study, we analyzed 27 whole genome sequence data sets from 23 populations worldwide (5 African, 5 South Asian, 6 European and 7 East or Southeast Asian) using the Stairway Plot method and inferred their demographic histories. Our results show that many European, East Asian and Southeast Asian populations experienced population size decrease during the last glacial maximum between 30,000 to 10,000 years ago, while most of the African and South Asian population growth stagnated between 30,000 to 20,000 years ago. Beginning from 20,000 years ago, we observed population growth of some South Asian and African populations possibly responding to the deglaciation. Another wave of population growth of some European and East Asian populations began around 10,000 years ago, which is likely influenced by both the deglaciation and agriculture development. Finally, most of the populations experienced dramatic population growth between 6,000 to 3,000 years ago, which are likely the results of agriculture development.

## PgmNr 2326: Dimensionality reduction in population genetics: New methods for understanding population structure.

Dimensionality reduction methods, such as PCA and MDS, have long been relied upon as both filtering and visualization tools to interpret the genetic structure present in extremely large dimensional genomic datasets. Recently, new dimensionality reduction methods, including tSNE and UMAP, have been released, but their application to genetic structure interpretation is not common. Meanwhile, algorithms for ancestry-specific PCA and MDS have also been developed, but these are not widely used or understood, and currently suffer from a few serious flaws, which we will discuss.

We will present a novel multi-array MDS algorithm, dimensionality reduction methods particularly applicable to large datasets of ancient DNA, where each sample is missing many different sites, dimensionality reduction methods for accounting for disparate noise across samples or for uneven sampling, and novel, highly accurate, methods for ancestry-specific application of a variety of dimensionality reduction techniques. We will present procedures for determining which of these novel, or existing, algorithms are appropriate for a given application, discuss widespread misunderstandings and pitfalls (including inadvertent supervised learning and unbalanced sampling), and discuss proper methods, seldom applied, for determining dimensionality of a genomic dataset. We will present guidelines and best practices, as well as theoretical interpretations for each of these different modalities of dimensionality reduction in terms of traditional statistics for population substructure and genetic drift.

## PgmNr 2327: Taiwan View: A Taiwanese genomic variation, HLA genotyping and methylation status database.

**Authors:**

M.W. Su; C.W. Lin; H.W. Chu; T.C. Lee

---

Taiwan Biobank intends to conduct a large-scale prospective cohort studies and case-control studies on local diseases. The cohort study will call for 200,000 volunteers, while the case-control study will invite 100,000 patients with the 10 to 15 most common diseases. There are currently over 114,533 participants are recruited in the cohort study and 27,751 participants have TWB1 genotyping array data. Taiwan View (<https://taiwanview.twbiobank.org.tw>) consists of the relational database and the web interface. The database includes single nucleotide variations (SNVs) frequency, mean methylation  $\beta$  value, and HLA genotyping frequency. The web interface consists of functions to search SNVs and explore the chromosome region surrounding an SNV. In the third release, this database contained frequency data of SNVs among 1,517 whole genome sequence samples and 24,625 Affymetrix Axiom TWB1 genotyping array samples from the Taiwan Biobank cohort study. There also 2,091 blood samples have DNA methylation status at > 850,000 CpGs sites. The DNA methylation status was examined using the Illumina Infinium MethylationEPIC BeadChip. At each targeted site, the ratio of the fluorescence signal was measured using a methylated probe relative to the sum of the methylated and unmethylated probes, the so-called  $\beta$  value, which ranges from 0.00 to 1.00, reflecting the methylation level of an individual targeted site. HLA genotyping data of 1,103 Taiwan biobank cohort study samples were generated with NXType™ Ion S5 NGS for Class I (HLA-A, -B, and -C) and Class II (HLA-DR, HLA-DQ, and HLA-DP).

## PgmNr 2328: Changes in ancestry-related assortative mating in the United States across multiple generations.

### Authors:

R. Sebro; S. Murray

[View Session](#) [Add to Schedule](#)

**Affiliation:** Department of Genetics & Radiology, Univ Pennsylvania, Philadelphia, Pennsylvania.

---

### Abstract

**Introduction:** The United States of America (USA) is a cosmopolitan, multiracial, multiethnic country with over 800 different ancestries. Ancestry-related assortative mating is required for population substructure to persist. The aim of this abstract is to evaluate the rate of the change of endogamy across several generations in the United States and to evaluate how this affects genetic studies.

**Materials and Methods:** The data were extracted from the 2000 and 2010 decennial USA Censuses and the 2011 to 2016 American Community Survey (ACS) Census. Data collected included individual age, sex, race, ancestry, and marital status. Spouse-pairs were considered to be from the Silent Generation (1928-1945); Baby Boomer Generation (1946-1964); Generation X (1965-1981); or Millennials (1982-2000). Estimates of endogamy in the 50 most common ancestries were calculated using phi-coefficient. McNemar's odds ratio was used to evaluate asymmetry in assortative mating. Statistics were all two-sided and P-values<0.05 were considered statistically significant.

**Results:** Over 3 million spouse-pairs were available for analysis (1.5 million spouse-pairs from Census 2000, and over 1.5 million spouse-pairs from Census 2010). The data show strong ancestry-related assortative mating based on self-reported ancestry, which decreased across each generation. The ancestry-related assortative mating was weakest among European-derived populations ranging from 0.24 (P<0.05) (between Danish and Germans) to 0.989 (P<0.05) (between Danish and Eastern Europeans). Ancestry-related assortative mating within Hispanics ranged from 0.816 (P<0.05) (between Mexicans and Central Americans) and 0.989 (P<0.05) (between Mexicans and Dominicans); within Asians ranged from 0.925 (P<0.05) to 0.995 (P<0.05) (between Japanese and Vietnamese); within Native Hawaiian and/or Pacific Islanders (NHPI) ranged from 0.888 (P<0.05) (between Samoans and Hawaiians) and 1.00 (between Samoans and Guamanians). Asymmetry was largest within Europeans between the Italian and Spanish (OR=1.35); largest within Hispanics between the Cubans and Dominicans (OR=2.19); largest within Asians between Asian-Indians and Koreans (OR=7.75); and largest within NHPI between Samoans and Hawaiians (OR=4.00).

**Conclusion:** Ancestry-related assortative mating decreased across each generation consistent with decreased endogamy. Significant asymmetric mating was noted, which will have implications for diseases affected by genetic imprinting.

## PgmNr 2329: Gene loss and functional decline of chitinases and chitinase-like proteins in dog.

Chitin is a linear  $\beta$ -1, 4-linked polymer of *N*-acetyl-D-glucosamine (GlcNAc) and it is a major component of fungal cell walls and exoskeletons of invertebrates. Although humans and mice do not synthesize endogenous chitin, they express two active chitinases, chitotriosidase (Chit1) and acidic chitinase (Chia). In addition, they also produce chitinase-like proteins, chitinase 3-like-1 (Chi3L1) and chitinase 3-like-2 (Chi3L2), which are structurally homologous to chitinases but lack the ability to degrade chitin. Chia has attracted considerable attention due to its increased expression under specific pathological conditions including asthma and allergic inflammation. We have reported that chitinolytic activity of human Chia is significantly lower than that of the mouse counterpart and that human Chia became an inactive pseudogene during the course of evolution. Recently, we also showed that Chia is highly expressed in mouse, chicken, and pig stomach tissues and it can digest chitin in the respective gastrointestinal tracts. In this study, we focus on dog, a major domestic and carivorous animal. Chia mRNA level was significantly lower in the dog stomach than those in mouse. In addition, the chitinolytic activity of dog Chia enzyme was lower compared with that of the mouse Chia enzymes. Furthermore, dogs do not possess both Chit1 and Chi3L2 genes in the genome, although it possess Chi3L1 gene. These results suggest that dog lost their Chit1 and Chi3L2 genes and that Chia is likely to be a gene undergoing loss of function during the course of evolution.

## PgmNr 2330: Functional recovery of dog acidic chitinase.

Chitin, a polymer of *N*-acetyl-D-glucosamine (GlcNAc), functions as a major structural component in crustaceans, insects and fungi and is the second most abundant polysaccharide in the nature. Chitin-containing organisms such as insects and fungi have been suggested as novel animal feed resources. The drawback of using these organisms as livestock diets has been considered the high content of chitin which has long been thought to be indigestible fibers. We showed that Chia functions as a protease-resistant digestive enzyme in mouse, chicken and pig (omnivores), whereas the chitinolytic activity were lower in the bovine (herbivores) and dog (carnivores). Here, we show that dog Chia is activated by introducing specific regions of mouse Chia. To identify regions responsible for the reduced chitinolytic activity in dog Chia, we expressed chimeric dog-mouse Chia proteins in *E. coli* and measured the chitinolytic activity. Chimera with the region encoded by dog exon 6 and 7 regions exhibited weak chitinolytic activity toward the fluorogenic substrate and similar to that of the dog enzyme. In contrast, chimera with region encoded by mouse exon 6 and 7 showed strong chitinolytic activity. Thus, the region encoded by exon 6-7 in dog Chia significantly reduced chitinolytic activity. These results suggest that dog Chia integrated some amino acids in the region leading to the reduced chitinolytic activity during evolution.

## PgmNr 2331: A functional genomics investigation reveals the molecular basis for adaptation to diving in Sea Nomads.

We present molecular mechanisms underlying the recently discovered genetic adaptation to diving in a group of Sea Nomads. The Bajau people were shown to have evolved enlarged spleens to enhance their diving capabilities. In all mammals, including humans, the spleen contracts during diving to infuse a bolus of oxygenated red blood cells into systemic circulation. Therefore, a larger spleen has been proposed to prolong dive time in this population. The large spleen phenotype observed in the Bajau is associated with a genetic variant in the gene *PDE10A*, hypothesized to affect spleen size by stimulating thyroid hormone production. However, the precise molecular mechanisms underlying the relationship between thyroid hormones and spleen size are yet unknown. We used a functional genomics approach to demonstrate a significant increase in spleen size ( $p = 0.049$ ) in mice that pharmacologically simulate the Sea Nomad *PDE10A* genetic variant. Using flow cytometry, immunocytology, and hematological measurements, we have identified hematopoietic variation potentially underlying changes in spleen size. Further, we link these hematological phenotypes to Genome Wide Association Study (GWAS) data from human populations. Our results indicate that the large spleen phenotype observed in the Bajau is inducible in mice via manipulation of *PDE10A* and that the underlying mechanism involves red blood cell production and turnover, which could have important implications for hematological disorders.

## PgmNr 2332: Uncovering the evolutionary history of the Turkana, a desert pastoralist tribe.

### Authors:

---

In a blink of evolutionary time, humans have explored every corner of this planet and have shown an amazing capacity to adapt to extreme conditions. However, few well-understood examples of selection pressures, adaptive genetic variation, and phenotypic outcomes exist for a single population, limiting our knowledge of how genetic variation arises and gives rise to complex traits in our species. This gap is largely due to difficulties in sampling populations of interest, generating large genome-wide datasets, and connecting loci identified by selection scans with their phenotypic effects.

We are addressing this problem by studying the Turkana of northern Kenya, a semi-nomadic pastoralist tribe that inhabits one of the most arid regions in East Africa. In addition to living in an extreme desert climate, the Turkana subsist on a very high protein diet (>70-80% of the diet is animal-derived). In fact, daily protein intake exceeds the FAO/WHO requirements by >300%, despite general caloric intake being limited (1,300–1,600 kcal/day for adults).

To uncover loci associated with desert living and a pastoralist lifestyle, we collected DNA samples and extensive biomarker data from several hundred Turkana, as well as individuals from 10 nearby tribes. We compiled a large dataset comprised of 31 high (>20x) and 270 low (~6-7x) coverage genomes, as well as genome-wide array data for a subset of individuals for validation (n=188). Using this dataset, we imputed missing genotypes in the low coverage samples from the high coverage reference set with ~98% accuracy. Admixture analysis identified many regions of shared ancestry between the Turkana and other nearby groups, confirming the complex demographic history of this tribe. Finally, we identified dozens of genes that exhibit signatures of positive selection, and may contribute to the Turkana's ability to tolerate extreme desert conditions and a high protein diet. In particular, we identified an enrichment of genes involved in fatty acid metabolism, amino acid metabolism, and vasoconstriction/vasodilation, which we are currently linking to our phenotypic data. Together, this work provides a comprehensive picture of how natural selection shapes genetic and phenotypic variation in a unique population, providing insight into evolutionary processes and present day human diversity.

## PgmNr 2333: HLA allele frequency distribution and evolutionary relationships of ethnically diverse African populations.

---

Genes of the immunologically important human leukocyte antigen (HLA) are key candidates for both adaptive divergence and introgression among human populations, depending on lifestyle and environment. This project investigated whether population evolutionary relationships inferred from highly polymorphic HLA genes in chromosome 6p21.1-21.3 differed from those inferred from genome-wide neutral loci. Volunteers (N=231) were sampled from 12 ethnically diverse sub-Saharan populations (≥13 participants per population) from Eastern (Ethiopia, Tanzania), Central (Cameroon) and Southern (Botswana) Africa. These populations practice traditional subsistence lifestyles including agro-pastoralism (4 populations), pastoralism (3 populations) and hunting-gathering (5 populations). All individuals were fully characterized at 11 HLA loci (*HLA-A*, *-B*, *-C*, *-DPA1*, *-DPB1*, *-DQA1*, *-DQB1*, *-DRB1*, *-DRB3/4/5*) by targeted next generation sequencing (Holotype HLA, OMIXON). Overall, 291 alleles, including 260 known and 31 previously unknown alleles (representing 6 synonymous and 25 non-synonymous point mutations), were identified. Clustering analysis using population allele frequencies per population was performed separately for 8 classical HLA loci. The first axis of Principal

Component analysis (PCA1) was able to explain between 16% and 25% of inter-population variation per locus. Heat maps based on allele frequencies confirmed the pattern of clustering at each locus. Neighbor joining phylogenetic trees were constructed using genetic distance matrices. In accordance with PCA, there was great variation in population clustering between loci; for some HLA loci, phylogenies reflected population distances based on neutral data whereas they did not for others. These observations are consistent with contrasting evolutionary trajectories of HLA loci (non-neutral) versus neutral loci used in genome-wide analysis. In addition, they suggest that some HLA alleles may be more driven by selection than others, and that in some cases the similarities between divergent populations could reflect similar selection pressure. Computational modeling and examination of shared selective forces (e.g. infectious disease exposure) could be useful for distinguishing the role of demography and natural selection influencing patterns of variation at the HLA region in ethnically diverse African populations.

## PgmNr 2334: Evolutionary dynamics of sex-biased gene expression in mammalian tissues.

### Authors:

S. Naqvi <sup>1,2</sup>; A.K. Godfrey <sup>1,2</sup>; J.F. Hughes <sup>1</sup>; M.L. Goodheart <sup>1,3</sup>; R.N. Mitchell <sup>4</sup>; D.C. Page <sup>1,2,3</sup>

---

**Introduction:** Sex differences are widespread in both humans and other mammals. As one example, the distribution of height or body size is shifted upwards in males relative to females. However, little is known about how gene expression differs between the sexes in a broad range of mammalian tissues and species. A catalogue of such sex-biased gene expression could serve to better understand phenotypic sex differences. Assessing the extent to which sex-biased gene expression is conserved across the body could also have important implications for the use of non-human models of sex differences.

**Rationale:** To identify both conserved and lineage- or species-specific sex differences in gene expression, we sequenced RNA from male and female samples in twelve tissues in each of four non-human mammals (macaque, mouse, rat, dog), and analyzed these data jointly with publicly available data from post-mortem male and female human tissues. To assess the impact of sex-biased gene expression on the sex difference in mean human height, we applied methods that integrate the effects of genetic variation on both gene expression and phenotype (height in this case). We sought to understand which transcription factors (TFs) contribute to evolutionary changes in sex bias by analyzing motifs gained or lost concurrently with lineage- or species-specific changes in sex bias.

**Results:** We identified ~3,000 genes with conserved (species-shared) sex bias in gene expression, most of which was tissue-specific. The cumulative effects of conserved sex bias explain ~12% of the sex difference in mean human height. However, most sex-biased gene expression (~77%) was specific to single species or subsets of species, implying that it arose more recently during evolution. We estimate that gains and losses of motifs for sex-biased TFs can account for ~27% of lineage-specific changes in sex bias.

**Conclusion:** By conducting a 12-tissue, five-species survey of sex differences in gene expression, we found that while conserved sex bias in gene expression exists across the body, most sex bias has been more recently acquired during mammalian evolution. Height is likely subject to opposing selective pressures in males and females; our study thus documents how such selective forces can result in sex-biased expression which can lead to trait distributions shifted between the sexes. Our findings also suggest that, in many cases, non-human mammals may not recreate molecular sex differences observed in humans.

## PgmNr 2335: Paternal diversity in different ethnic groups of Jammu and Kashmir.

### Authors:

E. Rai <sup>1</sup>; I. Sharma <sup>1</sup>; V. Sharma <sup>1</sup>; G. Singh <sup>2</sup>; P. Kumar <sup>3</sup>; M. Vilar <sup>4</sup>; S. Sharma <sup>1</sup>

### Affiliations:

1) School of Biotechnology, Shri Mata Vaishno Devi University, Katra, 182320, India; 2) Department of human Genetics, Guru Nank Dev University, Amritsar; 3) Institute of Human Genetics, University of Jammu, Jammu and Kashmir, 180006, India.; 4) Human Genographic Project, National Geographic Society, USA.

**Background:** Jammu and Kashmir is located on the crossroads of Eurasia, it has been believed that this region might have acted as corridor to various migrations and immigrations to and from mainland India, Eurasia or northeast Asia. These migrations and immigrations have impacted the cultural and social structure of society. Ethnically and linguistically this region is diverse.

**Objective:** To find out the paternal diversity among different ethnic groups of Jammu and Kashmir.

**Methodology:** 133 markers of non-recombining (NRY) region of Y chromosome belonging to major haplogroups from A to R, were genotyped for 291 samples. Genotyping was done by using Agena Massarray Platform.

**Results:** A total of twenty one different haplogroups: C, G2, H1, H1a, H1b, J, J2, J2b, K, L, P, Q, R, R1a1a, R1a1a1, R2, E1, F, G and H1a3 were found after genotyping. The frequent haplogroup found was R1a1a1, H1b was the second frequent and R2 was the third frequent haplogroup found in the present study. Huge paternal diversity is indicated in the population studied by the presence of diverse paternal haplogroups.

**Conclusion:** Multiple lines of paternal ancestry and geographic origins is highlighted by the presence of more than one haplogroup in each of the ethnic groups in the present study. Even these ethnic groups are presently endogamous, yet their genetic architecture suggests their genetic relations. This unifies populations of the region genetically as the presence of haplogroups was not observed as caste specific.

## PgmNr 2336: Genetic and environmental contributions to variations in intellectual development: A twin study.

**Authors:**

A. Panghal; B. Dhanda

[View Session](#) [Add to Schedule](#)

**Affiliation:** HDFS, CCS HAU, Hisar-125004, Hisar, India

---

We analyzed how the effects of genetic and environmental factors on intellectual development of twins from 6-8 years. The data were collected by assessment, interview, observation and questionnaire method from the Hisar twins (N=110) and Bhiwani twins (N=90) at 6-8 years of age and from their parents for environmental circumstances by using the WISC-R (Wechsler, 1974) and HOME Inventory by Bradley *et al.* (1988). The data analyzed by using heritability estimates, mean, standard deviation, z-test, correlation coefficient and chi square test. The correlation coefficient of monozygotic twins was  $r=0.93$ ,  $r=0.95$  at the age group 6-7 years and 7-8 years respectively and the correlation coefficient was dizygotic twins was  $r=0.64$  (6-7 years) and  $r=0.69$  (7-8 years). The heritability estimate explained the variation in intellectual development of twins was attributed to genetic factors ( $h^2=58\%$ ) at 6-7 years and ( $h^2=51\%$ ) at 7-8 years. Simultaneously, the remaining variations in intellectual development of twin were due to environmental factors (42%, 49% at 6-7 years and 7-8 years respectively). These findings suggest that the correlation coefficient of monozygotic twins was more than the dizygotic twins i.e. monozygotic twins share 100% genetic material whereas the dizygotic twins share 50% genetic material. On the conclusion of the heritability estimates showed that reverse trend with regard to the genetic influence on intellectual development of twins as decreasing of scores on heritability estimates with increasing age of the twins. It clearly reveals that the influence of genetic material decrease as the age of twins increase and the contribution of environmental circumstances increase the age of twins increase.

## PgmNr 2337: A catalogue of human ancestry components from population studies.

The latest studies of ancient and modern DNA are revealing a high-resolution picture of human history and migration, by improving the sample geographic coverage and the methodological power. New open questions are concerning the appropriate framing of the results, and the impact of those for the society at large.

With genomic datasets routinely analyzed, the field of population genetics is shifting from using discrete units of variations (such single genetic markers, or uniparental haplogroups) to other complex forms of ancestry, often identified with ethnolinguistic references, cultural attributes, or geographic descriptors. This level of information is sometimes difficult to translate to non-experts. Cultural studies, forensic applications, and commercially available ancestry tests brought examples of how combining genetics with human history can generate a problematic narrative bordering genetic determinism and identity marking. How much do such ancestry components define the history of actual people, or distinct populations?

Here we examine the state-of-the-art in the studies of admixture components retrieved by ancient and modern DNA. We perform Admixture analysis on a global dataset of more than 3000 individuals and evaluate clustering and frequencies of components in different macro regions. This analysis returns a catalogue of discrete ancestries which we assemble in a hierarchical fashion, and confront against the structure of known haplogroup phylogenies. We then discuss the frequency and distribution of these components as shaped by human migration and admixture. By reconsidering the history of our genetic structure, this work ultimately aims at deconstructing the strict association between ancestry components and human populations.

## PgmNr 2338: Exploring the demographic history of tribal and caste groups from West Maharashtra (India) using dense genome-wide data.

---

The South Asian subcontinent has a complex history of human migrations and interactions, which is reflected in an extensive cultural and genetic diversity. One of the defining characteristics of the Indian human landscape is the presence of endogamous tribal and non-tribal groups. Additionally, non-tribal groups are hierarchically arranged in social classes termed castes. Recent studies based on genomic data for ancient and modern South Asian populations have indicated that the genetic diversity in this region is derived primarily from three population sources: *i)* Ancient Ancestral South Indians (AASI), which represent an early South Asian hunter-gatherer lineage, *ii)* Iranian agriculturalists, which started to expand from West Asia to South Asia via the Iranian Plateau in the 7<sup>th</sup> and 8<sup>th</sup> millennia BCE, and *iii)* Steppe pastoralists, which arrived in the region in the 2<sup>nd</sup> millennium BCE. In this study, we characterized the population diversity and demographic history of six populations from West Maharashtra (WM), India using dense genome-wide SNP data. The dataset includes 331 individuals from four Indo-European tribal groups (Kokana, Warli, Bhil and Pawara) and 125 individuals from two castes (Deshastha Brahmins and Kunbi Marathas). Comparisons of the six WM samples with other available ancient and modern DNA samples indicate that the WM tribal groups are characterized by some of the highest proportions of AASI ancestry reported in South Asia. The relative contributions of Steppe pastoralists and in particular Iranian agriculturalists have been very small in the tribal groups. In contrast, in the two caste samples both the Steppe and agriculturalist contributions are substantially higher, in line with what has been described in other Indian caste groups. The Deshastha Brahmin sample has a higher Steppe contribution than the Kunbi Maratha sample, also in agreement with previous reports indicating relatively high Steppe proportions in Brahmins. Overall, this study highlights the complex demographic histories of tribal and caste groups from India.

## PgmNr 2339: A population-based approach for genes prioritization in the diagnosis of Mendelian and complex diseases.

### Authors:

Gene prioritization is the process of determining which variants or genes identified in any genetic analysis are likely to cause a disease or phenotype. The advent of high throughput technologies followed by increased data production and GWAS studies results lead to the necessity of rapid prioritization of different genes. We should note that for many of them neither in vitro nor in vivo testing are available, thus assessing their pathogenic role could be difficult, leading to possible false positive or false negative results. Although several approaches have been developed to prioritize genes, most of them do not consider the role of natural selection and the genomic characteristic of the reference population of the patients. Here we propose an innovative score of gene prioritization based on the population of interest. Firstly, we introduce the concept of singleton-cohort variants (SC variant), which is a variant that has allele count equal to one in the cohort under study. Our hypothesis assumes that if a gene harbours any level of constraints (in a specific cohort), due to its function or from the presence of natural selection, the amount of SC variants in the coding region should be lower than the amount of SC variant in the non-coding regions. Then the difference between the normalized count of SC variants in the coding region respect the normalized count of SC variant in the non-coding region should give us a hint of the level of constraints for that gene in a specific population. This scoring system (from now DSC score) is negative when there are constraints that allow the presence of SC variants only in the non-coding region, on the contrary, is positive when there are no constraints. We calculated the DSC score for all genes in the different subpopulation of 1000 Genome. The DSC score is significant different (t.test p-value<0.00001) between genes deemed essential (median=-0.87) and non-essential (median=0.27) in multiple cultured cell lines based on CRISPR/Cas data. Our methodology showed a high level of constraining for genes such as *USP34*, *PRPF8*, *FBXO11* in all subpopulations; whereas some genes showed high negative score only in specific populations, for examples *HHAT* in Europeans, *BCKDHB* in East Asians, *PARD3B* in South Asian, and *NUP210* in Africans. Our aim is the definition of a gene ranking score that should be based on a population closely related to the patients under study.

## PgmNr 2340: Towards greater equity in genetics research.

Genetics research has been far from equitable in terms of engaging representative numbers of non-European participants. 23andMe, with one of the largest research cohorts in the world, aims to increase the diversity of its genetic data and improve its analysis methods so that new discoveries and products benefit people of all racial and ethnic backgrounds. Through internal projects and collaboration with the scientific community, we aim to improve our ancestry and health reports for all customers; facilitate novel discovery in underrepresented populations; and better understand barriers to participation in online genetics research.

Through our newest program, the Populations Collaborations Program, 23andMe partners with researchers engaging underrepresented populations in genetics research globally, providing genotyping and funding for project costs. The goals of this Program are to improve our Reference Data Panel, better understand the extent and patterns of human genetic diversity, and infer human migration and population history. In a complementary initiative, the Global Genetics Program, 23andMe invites individuals from regions underrepresented in our database to participate in research. Together, the data from these efforts has resulted in more granular ancestry reports for non-European customers.

Several internal projects focus on improving GWAS in non-European populations. Through the African American Sequencing Project, 23andMe has sequenced ~2300 consented customers and utilized the data to construct an imputation panel designed to improve imputation for individuals with African ancestry. We evaluated imputation performance within African American research participants and have demonstrated improved imputation accuracy over publicly available reference panels such as Haplotype Reference Consortium and 1000 Genomes. The reference panel is being made publicly available via dbGaP. We have used the panel to perform large-scale GWAS on ~100,000 African American research participants and over 300 phenotypes, yielding novel GWAS hits not previously identified via European GWAS.

Finally, to understand research participation by members of minority populations, we have conducted preliminary qualitative interviews with African Americans on perceptions of genetics and health. Future efforts will build off of these initial investigations with further qualitative and quantitative studies to understand barriers to research participation across populations.

Ethnicity estimation involves creating reference panels often based on single-origin individuals with roots tracing back to a particular geographic location. However, many modern populations in the Americas are characterized by historic admixture between American, European, and African ancestors. Using research-consented individuals with deep roots in geographic regions, we found substantial genetic substructure across the Americas. We then developed a novel method for creating reference panels using only the inferred indigenous genomic segments from admixed individuals and demonstrate improved resolution and accuracy of ethnicity inference for geographic populations across the Americas.

## PgmNr 2342: Draft assembly of an Armenian genome.

---

Commercialization of short-read sequencing (SRS) in the past decade has allowed characterization of millions of small genetic variations across thousands of human genomes for genetic diagnosis and disease susceptibility associations. However, due to innate methodological limitations of SRS, identification of large structural variants (SVs), such as deletions, insertions, inversions, translocations and copy number variants has proven to be challenging. Like smaller DNA variations, SVs are an important class of human-to-human genetic variability and have been shown to be implicated in disease. New technological advancements in genomics (such as optical genome mapping (OM) or long-read sequencing (LRS)) allow for better assessment of SVs and variants found in highly repetitive regions. However, most variant identification tools utilize a single human genome reference for different types of variant calling ranging from SNVs to SVs. The validity of identified variants in different populations is therefore not accurate due to underrepresentation of other populations in the reference genome. Hence, there is a need for a hybrid-based approach for *de novo* population-specific human genome assembly (reference quality) for variant calling. It is now possible for researchers to survey the diploid architecture of the human genome using multiple genomic technologies for a fraction of the cost of the original Human Genome Project. Here, we present a draft assembly of Armenian genome. The assembly was generated by integrating OM (Bionano Genomics) and LRS (Oxford Nanopore) data sets. OM and LRS molecule N50 values were >200kbp and >50kbp respectively. Coupling of both technologies allowed for an assembly of highly contiguous scaffolds, which in many cases covered entire chromosome arm lengths. Direct comparison of the assembly with the human genome reference GRCh38 identified thousands of previously unseen SVs. Epigenetic modifications were also detected from LRS analysis and mapped across the scaffolds, generating the epigenetic profile of the assembly. This work builds upon other published population-specific genome references necessary for accurate variant characterization in diverse populations. As such, this assembly of the previously unmapped Armenian genome provides a baseline for genomic studies serving the Armenian population and research of population-specific diseases such as Familial Mediterranean Fever, which has a higher frequency in the Armenian population.

## **PgmNr 2343: Understanding the biological meaning of the human genome sequence by studying diverse indigenous populations in East Asia and Southeast Asia.**

**Authors:**

S. Xu

[View Session](#) [Add to Schedule](#)

---

Our current biological understanding of the human genome sequence is still very much in its infancy. The functions and phenotypic effects of the majority of our genome remain unknown. There are three typical approaches to understand the biological meaning of our genome sequence. The medical approach relies on measured phenotypes and can not access many lower level genomic functions, while the experimental approach can only be done in non-human organisms or cell lines. Evolutionary analysis of diverse populations can access subtle consequences of individual mutations in humans, thus providing an economic and efficient way to sensitively probe the function of our genome sequence. Here we build a reference genomic resource of 977 diverse populations, including 1,009 newly sequenced genomes representing 16 indigenous populations living in unusual environments (e.g., tropical forests and highlands) in East Asia and Southeast Asia. This effort is expected to i) enable studies of variants that are rare or not existing in well-studied populations; ii) improve the interpretations of putative causal loci associated with Mendelian diseases and adaptations to local environments in global populations; and iii) help advance our understanding of the biological meaning of the human genome sequence.

## PgmNr 2344: Genome-wide association study identifies new regions associated with iris surface features in individuals of European ancestry.

### Authors:

F. Lona Durazo; M. Edwards; D. Cha; E.J. Parra

[View Session](#) [Add to Schedule](#)

---

The human iris is one of the most complex structures on the outside of the human body, in which several patterns influence the physical appearance and color of the eye. The two top cell layers of the iris, which arise during embryological development from the neural crest, give rise to the iris surface features, due to their composition and arrangement. These features are highly heritable, and they ultimately cause differences in eye appearance among individuals. However, research on the genetic basis of iris surface features is limited to a handful of studies, which have highlighted the association of a few genes involved in neurodevelopment. Here, we conducted a genome-wide association study to investigate the genetic basis of three iris surface features: Fuchs' crypts, Wolfflin nodules, and pigment spots, in a sample of individuals of European ancestry ( $N = 541$ ), using high-resolution photographs processed in a web-based application for phenotype characterization. We identified a region in chromosome 2 that is significantly associated with Wolfflin nodules (non-synonymous polymorphism: rs3739070,  $p$ -value =  $4.55 \times 10^{-8}$ ), overlapping *TRAF3IP1*, a gene which has been previously associated with the frequency of contraction furrows. Additionally, we identified two suggestive signals associated with Wolfflin nodules: a region in chromosome 12 overlapping the 3'UTR of *SRGAP1*, which is a gene involved in 3D collagen migration (top marker: rs1067638,  $p$ -value =  $5.43 \times 10^{-7}$ ), and a region in chromosome 2 overlapping *ERBB4*, which is a gene involved in neuronal migration and axon guidance (top marker: rs839500,  $p$ -value =  $3.12 \times 10^{-6}$ ). We also identified suggestive signals of association for pigment spots and Fuchs' crypts, which overlap genes involved in neurodevelopment, such as *DTNB* (top marker: rs9789762,  $p$ -value =  $6.49 \times 10^{-6}$ ) and *LSAMP* (top marker: rs4487267,  $p$ -value =  $3.67 \times 10^{-6}$ ), respectively. We are currently working on a meta-analysis in order to increase the power of our analyses and to possibly reinforce our current results.

## PgmNr 2345: Patterns of ROH across species: From a dog to a human.

### Authors:

A. Anderson; J. Miglo; S. Hoque; S. Smieszek; C. Polymeropoulos; M. Polymeropoulos

[View Session](#) [Add to Schedule](#)

**Affiliation:** Vanda Pharmaceuticals, WASHINGTON, D.C..

---

Animals are used as preclinical models for human diseases in drug development. Dogs, especially, are used in preclinical research to support the clinical safety evaluations during drug development, however, comparison of regions of homozygosity (ROH) patterns and phenotypes between dog and human are not well known. A ROH is defined as a continuous stretch of DNA sequence without heterozygosity in the diploid state (min ROH  $\geq 1.5$  Mb). We conducted a genome-wide homozygosity analysis (GWHA) in human and dog genomes.

We calculated ROH patterns across distinct human cohorts: the Amish, IGSR 1000 genomes, Welllderly, Vanda 1k genomes, and ADNI Alzheimer's data. The Amish provided a large cohort of extended kinships allowing for in depth family oriented analyses whereas Welllderly and IGSR 1000 genomes represented healthy aging populations. The remaining human cohorts served as statistical references. We then calculated ROH across different dog breeds (EMBARC project) with emphasis on the beagle, dog that is the preferred breed in drug development.

Vanda 1k and the Welllderly ROH analysis was conducted on whole genome sequencing data. Out of 5 human cohorts we reported the highest mean ROH in the Amish population. When we considered both the location and the allelic form of the ROHs, we were able to separate the populations by PCA, demonstrating that ROHs contain information on the demographic history and structure of a population. We next calculated the extent of the genome covered by ROH ( $F_{ROH}$ ) (human 3.2Gb, dog 2.5Gb). In our dataset,  $F_{ROH}$  differed significantly between the Amish and the 1000 genomes, and between the human and the beagle genomes. The mean  $F_{ROH}$  per 1Mb was  $\sim 16$ kb for Amish,  $\sim 0.6$ kb for Vanda 1k, and  $\sim 128$ kb for beagles. This result demonstrated the highest degree of inbreeding in beagles, far above that of the Amish, one of the most inbred human populations.

ROH can contribute to inbreeding depression if they contain deleterious variants that are fully or partially recessive. The differences in ROH characteristics between human and dog genomes question the applicability of dog models in preclinical research, especially when the goal is to gauge the subtle effects on the organism's physiology produced by candidate therapeutic agents. We should hesitate to generalize from dog to human, even if human and beagle are relatively close species phylogenetically.

## PgmNr 2346: Patterns of cross ancestry constraint in regulatory regions.

---

Evolutionary conservation is often used to identify functional elements in genomes. It relies on isolating regions with fewer differences than would be expected given divergence times between species. This makes elements that are of functional consequence in only one species difficult to detect. Recent studies have shown that estimates of human specific constraint using standing population variation improves the detection of pathogenic variants over cross species conservation. When applied to noncoding sequence where functional annotations are often unavailable, these constraint estimation approaches require a theoretical or empirical neutral model to identify regions where variation is depleted relative to neutral expectation. These neutral models are distorted by demography, we find substantial differences in the neutral site frequency spectrum (SFS) across populations. For example, SFSs generated from sampling a million intergenic bases from the genome aggregation database (gnomAD) 4,368 African/African-American and 7,509 Non-Finish European samples, demonstrate significant differences in their SFSs (permutation based logrank test:  $p < 1e-8$ ). This suggests that looking for shifts in the SFS without taking into account ancestry may produce population specific artifacts and a potential loss of power. Here we improve constraint estimates by explicitly considering demographic differences due to ancestry. Specifically, we developed a non-parametric statistical framework to test for shifts in the SFS across the genome relative to neutral intergenic variation, which is stochastically sampled within ancestry groups fitting on 15,496 whole genome samples from gnomAD. we show that by explicitly accounting for ancestry we substantially improve classification of pathogenic variation, even in non-coding sequence. For example, in classifying non-coding ClinVar pathogenic variants versus a million randomly sampled common variants taken from 62,784 whole genome Trans-Omics for Precision Medicine (TOPMed projects) samples, AUCs are significantly improved when ancestry is adjusted for (AUC=90%) relative to a similar unadjusted approach (AUC=80%). It also substantially outperforms a previously proposed approach for classifying noncoding sequence (CDTS: AUC=76%). Our results demonstrate the importance's of explicitly considering demographic factors in constraint estimation and the value of diverse large population samples of standing variation across world populations.

## **PgmNr 2347: A reference free method to identify introgressed hominin sequences reveals insights into Neanderthal ancestry in African and non-African populations.**

Admixture has played a prominent role in shaping patterns of human genomic variation, including gene flow with now extinct hominins like Neanderthals and Denisovans. We describe a novel probabilistic method called IBDmix to identify introgressed hominin sequences, which unlike existing approaches, does not use a modern reference population. We applied IBDmix to 2,504 geographically diverse populations to identify and analyze Neanderthal sequences segregating in modern humans. Strikingly, we find African individuals have substantially more Neanderthal ancestry (0.3%) than previously thought and show this can be explained by migrations back to Africa, predominately from ancestral Europeans. Moreover, IBDmix recovers comparable amounts of Neanderthal sequence among non-African populations, in contrast to notable differences observed using reference-based methods. Our results refine our understanding of Neanderthal ancestry in African and non-African populations, simplify models of archaic hominin admixture, and demonstrate that remnants of Neanderthal genomes survive in every modern human population studied to date.

## PgmNr 2348: Natural selection shapes codon usage in the human genome.

Synonymous mutations change the sequence of a gene without altering the encoded protein sequence. Though these mutations are typically considered neutral, changes in codon usage can impact multiple molecular processes. In particular, optimal codons, which correspond to tRNAs that are highly abundant in the cytoplasmic pool, increase translational efficiency, resulting in increased mRNA half-life and protein output. In this study, we leveraged the unprecedented amount of sequencing data available in two population reference cohorts—gnomAD and TopMED—to demonstrate that natural selection optimizes codon content in protein-coding regions in the human genome. We devised two scores to rank genes by their intolerance to synonymous mutations. The first metric, synRVIS, measures human-specific constraint against changes in codon optimality. The second metric, synGERP, reflects phylogenetic conservation at fourfold degenerate sites across the mammalian lineage. Consistent with the known role of codon optimality in regulating gene expression and translation efficiency, we find that both of these scores are predictive of dosage sensitivity. tRNA levels are dynamically regulated in stress conditions and during the cell cycle. Accordingly, we find that genes in the DNA damage response pathway and periodically expressed cell cycle genes display intolerance patterns that reflect these dynamic expression patterns. Finally, we demonstrate that both synRVIS can predict oncogenes and tumor suppressor genes. Importantly, we find that single synonymous variants that reduce codon optimality in *BRCA1* may result in significantly reduced protein function. Overall, our work provides some of the first direct evidence that natural selection influences human codon usage and has strong implications for the interpretation of synonymous variants in the human genome.

## PgmNr 2349: The genetic consequences in the Americas of the transatlantic slave trade.

### Authors:

---

The transatlantic slave trade marks the largest forced migration event in history, involving the deportation of an estimated 12.5 million Africans. Occurring between the 15th and 19th centuries, the slave trade involved nearly every country with an Atlantic coastline and has continued to impact the world more than a century after its abolition. Even though shipping records document the number of enslaved people disembarking across the Americas, there have been very few broad-scale genetic studies of populations across all of the Americas with ancestral ties to the transatlantic slave trade. In this study, we utilized high-density genotype data from over 25,000 23andMe research participants with western African ancestry to determine how the transatlantic slave trade has shaped populations across twenty-eight regions within the United States, Latin America, and the Caribbean. Using 23andMe's Ancestry Composition algorithm, which detects ancestry from multiple subregions of western Africa, we show that individuals with African ancestry in the Americas tend to have connections with multiple historical slave trading regions in western Africa. However, the most frequently inferred western African ancestries differ across the Americas. For instance, individuals in the United States and Caribbean tend to have connections with all historical slave trading regions in western Africa, while individuals from Latin America tend to have ancestry primarily from either west central Africa or Senegambia. To estimate the temporal connection between populations in the Americas and West Africa, we identified DNA identical by descent (IBD) between all twenty-eight disembarkment regions and seven historical embarkment regions in western and southwestern Africa. We used the distribution of IBD segment lengths to determine the probability that shared IBD between regions were inherited from a common ancestor who embarked from western Africa during the 400-year period of the transatlantic slave trade. Results suggest that genetic estimates of time to most recent common ancestor are generally concordant with documented embarkment dates from western Africa. Overall, this study provides an unprecedented investigation of the transatlantic slave trade, establishing genetic links between populations in the Americas to populations in western Africa, which has implications for individuals' understanding of their African roots.

## PgmNr 2350: Multi-omics analysis of Qatar Biobank reveals causal functional consequences of Middle Eastern genetic variation and their impact on human traits and disease.

A major goal of human population genetics studies is to unveil genetic polymorphisms and understand their influence on phenotype in health and disease. Sequencing projects e.g. HapMap, 1KG and recent national efforts have documented extensive genetic variation and LD in various populations. Yet, our understanding of its origins, global distribution, and functional consequences is far from complete. In particular, regulatory impact on gene expression has mostly been studied in small population sizes, and breadth of transcriptome is yet to be revealed on large scales mirroring the sequencing efforts. Also, studies so far lack enough diversity for regions such as Middle East & North Africa.

Qatar Genome Project aims to obtain population-level insight into genetic variation in Qatar and the wider Arabian Peninsula. So far, it has sequenced whole genomes of >10k subjects using Illumina HiSeq X ten at 30x coverage, identifying ~ 30m novel variants. These predominately-healthy subjects were enrolled at Qatar Biobank and were deeply phenotyped with diverse data on demographics, health, lifestyle, physical measurements and >66 biochemical tests. With this in hand, we present analysis of the pilot phase RNAseq (mRNA & small RNA) from whole blood of 3k subjects from this cohort and combine with genetic and phenotypic data to characterize the polymorphism discovered and its interplay with molecular and clinical phenotypes at a population scale.

Hamilton-extracted total RNA had RNA Quality Number >7.5 and yield > 1 µg for >70% of samples. 1,076 globin-depleted libraries were sequenced at 20-100m 150 pair-end reads on Illumina HiSeq 4000. High quality reads (average phred score > 30) were mapped using STAR (Dobin et al, 2013) showing >90% mapping rate followed by TMM-based normalisation (Robinson et al, 2010) of the feature counts (Liao et al, 2014). ~70 % of genes are expressed with ≥0.1 TPM in ≥20% samples. We run hidden factor analysis to identify confounding factors and correlated with available co-variables. We are running eQTL/sQTL/aseQTL analysis for various genetic variation classes, identifying novel regulatory rare variants e.g. for KCNJ2 associated with lipid levels. Also, we are applying colocalization approaches integrating genetic associations using previously applied approaches (Liu et al, 2019). Together, our study provides a comprehensive view on how regulatory and splicing variation impacts traits and diseases in a Middle Eastern population sample.

Typical approaches for showing population structure (e.g. PCA, Structure/Admixture, and EEMS) are limited in that they do not reveal how allele frequencies vary across populations. Most methods show how individuals are related to one another and help reveal the existence of sub-structure – However, they do a poor job of showing how typical alleles are distributed. This is problematic because it is easy for viewers to observe, for example, clusters in a PCA plot and falsely assume there is 'deep' differentiation, when in fact the average allele frequency varies little between populations. This has impacts in research settings as it affects how investigators understand their study populations, and in pedagogical settings for how students or the lay public understand human genetic diversity. Here, we present a simple way of showing the dominant allele frequency patterns among a set of SNPs and have applied it to the 1000 Genomes data and a few other datasets. The visualizations give a different perspective on human genetic structure, that helps viewers answer more immediately important empirical questions such as: How often should a common GWAS variant found in one population be expected to be found in a second population? How typical is it to see an allele that is highly differentiated among human groups? Overall, we argue that we have a useful tool to provide a variant-centric view of population structure, that we expect will be of broad utility to the population genetic community.

---

South Asia was one of the first geographic regions to be peopled by modern humans after their African exodus. Today, the diverse ethnic groups of South Asia comprise an array of tribes, castes, and religious groups, who are largely endogamous and have hence developed complex, multi-layered genetic differentiation. From such a complex structure, several questions have stood out from the research of our group and others that are only beginning to be resolved using modern sequencing techniques and targeted sampling of populations and archaeological specimens. In this forum, I will discuss the complex population structure of the Indian subcontinent and future research directions to understand the deep ancestry components of South Asians and Eurasians in the global context, patterns of admixture, and migrations, as revealed by the study of ancient and modern genomes.

## PgmNr 2353: Admixture mapping of TB susceptibility in a five-way admixed southern African population.

**Authors:**

---

Tuberculosis (TB), caused by the human pathogen *Mycobacterium tuberculosis* (*M.tb*), is ubiquitous in almost all populations residing in southern Africa. A number of studies indicated a disparity in the rates that different ethnic groups are infected with the TB bacterium and progress to active TB disease. The difference is not merely a reflection of socio-economic circumstances. Centuries of exposure to TB in Europe may have resulted in adaptive selection for TB resistance, in comparison to groups in sub-Saharan Africa that were only relatively recently exposed to the virulent European *M.tb* strains. Previous investigations of a highly admixed southern African population not only revealed indigenous KhoeSan ancestry in the region, but also indicated that African ancestry are associated with an increased risk to progress to active pulmonary TB rather than remaining latently infected. However, these studies relied on a limited number of controls, inadequate sample size for reference populations and low SNP density. This study focuses on localizing and investigating ancestry-specific genetic regions associated with TB susceptibility in a unique complex five-way admixed South African Coloured population. Admixture mapping of 820 individuals (413 cases and 407 controls) was done using data generated from the Illumina Multi Ethnic Genotyping Array, a more appropriate tool for our diverse and highly admixed population. Our local ancestry results identify the ancestral origins of distinct chromosomal segments with a high degree of accuracy and allow for the identification of genetic regions associated with TB susceptibility. The adjusted allelic association results point to several candidate regions.

## PgmNr 2354: Identification of potentially protective genomic variants in the Lithuanian population group.

### Authors:

[View Session](#) [Add to Schedule](#)

**Affiliation:** Department of Human and Medical Genetics, Institute of Biomedical Sciences, Vilnius University, Vilnius, Lithuania

There is a growing number of reported genomic variants shown to be protective, lowering the risk of certain diseases and conditions. The identification of such variants may serve as new potential drug targets and provide new therapeutic opportunities as well as deepen our understanding of the mechanisms of microevolution. The aim of this study was to determine protective genomic variants (PGVs) in the general Lithuanian (LT) population. This study is the first of its kind to analyze PGVs in the LT population.

Exome sequencing (*AB SOLiD*) was performed for 98 self-reported healthy individuals of the LT descent. A catalog of 123 known PGVs was constructed using *ClinVar*, *OMIM* databases as well as scientific publications. The catalog was used to sort out the PGVs that are common in the LT population from the exome sequencing data – 54 PGVs were identified. Frequencies of genotypes of these variants were determined and compared to the frequencies of the general European population from 1000 Genomes Project. Statistical analysis ( $\chi^2$  or F-test,  $\alpha=0.05$ ) was performed using *Rstudio* software. Four variants were significantly more frequent in the study group and may have protection against **alcohol dependence** (*ADH1C*, rs698,  $p=0.05$ ), **type 2 diabetes** (*PPARG*, rs1801282,  $p=0.005$ ), **obesity** (*SH2B1*, rs7498665,  $p=0.03$ ), **esophageal cancer** (*PLCE1*, rs2274223,  $p=0.034$ ). *ADH1C* encodes the class I alcohol dehydrogenase. Our results show that 50% of the LT study group carry a genomic variant (NM\_000669.4:c.1048A>G), which is denoted as protective against alcohol dependence in different databases. However, studies suggest that this variant is associated with slower ethanol metabolism and therefore people carrying it have a higher risk of heavy and excessive drinking (Tolstrup J S, 2008). These conclusions support the statistics of World Health Organization, which reports that Lithuania was the second country in Europe by consumption of alcohol in 2018. Significantly higher frequencies in our study group might partly explain such behavior of alcohol consumption. Therefore, we hypothesize that this variant may be more causal than protective and an understanding of the molecular mechanisms involved in excessive alcohol consumption is still unresolved. Other three identified variants are considered as potentially protective according to bioinformatic methods applied (Butler J M, 2017). However, functional impact of all these variants should be confirmed and additional analysis is needed.

## PgmNr 2355: Parameter reduction of sequence-context mutation models.

---

Statistical models that predict where, what type, and how frequently polymorphisms occur across the human genome have become essential to addressing basic questions in population genetics, including identifying regions under selective constraint, discovering functional genomic elements, and estimating divergence times. Basic knowledge of the mutational process is also of critical importance for phenotypic studies; for example, characterizing the parts of the genome that harbor a burden of rare variation contributing to complex disease, or nucleotide sequences that are selectively constrained and most likely to create phenotypic consequences if mutated (i.e., pLI scores).

A fundamental challenge to advancing these models is simply that the number of parameters grows exponentially as the window size of sequence context considered and number of genomic features increase. This property limits statistical power and increases error for biological inference in existing models. To address this challenge, we present an algorithm to cluster mutational parameters within models of nucleotide sequence context. We demonstrate for the first time that nonanucleotide ('9-mer') sequence-context windows explain patterns of variation better than the previously reported heptanucleotide ('7-mer') context model ( $P < 1 \times 10^{-100}$ ). We further demonstrate that a collapsed form of the 9-mer sequence context model recovers 99.99% of the likelihood using <1% of the parameters, facilitating novel hypotheses to be tested by "freeing" these parameters. Application of our approach enables systematic tests of novel hypotheses, including: (i) asymmetric sequence context models where different sizes of flanking nucleotides around the polymorphic site are considered, (ii) models with genomic features, like replication timing, nested within a condensed model, and (iii) genome-wide tabulation of scores to quantify local reduction of polymorphism levels – consistent with the action of background selection – that can be utilized in phenotypic studies.

## PgmNr 2356: Familial language history links with population structure and admixture patterns.

Language and population structure are intricately connected in human history. Past genetic studies have found that language can roughly mirror population genetics, though the two are not exactly identical. We pilot an approach using linguistic change to approximate recent fine-scale population structure. In a large cohort with rich pedigree information, we examine the relationship between genetics and recent immigration patterns, which we study using reported grandparent and reported individual language. We identify subtle differences in genetic ancestry composition, likely determined by both subpopulation structure and admixture patterns. We leverage maternal/paternal language information to further probe these differences in ancestry, identifying likely recent sex-biased admixture through linguistic differences. Using simulations, we estimate the impact of sex-biased admixture on sex chromosome local ancestry, and downstream effects of this impact on association statistics through population structure confounding. This suggests linguistic patterns may be a reasonable proxy for substantially more complex population structure, and that this population structure can have a quantitative impact on measures of genetic architecture admixed populations.

## PgmNr 2357: Ancient retroviruses drove the rapid evolution of mammalian APOBEC3 family genes.

---

The AICDA/APOBEC family genes (AIDCA and APOBEC1-4) encode cellular cytidine deaminases that target nucleic acids and catalyze cytosine-to-uracil (C-to-U) mutations. In the case of retroviral replication, APOBEC3 proteins induce C-to-U mutations in minus-stranded viral DNA, which results in guanine-to-adenine (G-to-A) mutations in the viral genome. Previous studies have implied that the expansion and rapid evolution of mammalian APOBEC3 genes has been driven to by an arms race with retroviral parasites. However, this possibility has not been thoroughly investigated. Endogenous retroviruses (ERVs) are the ancient relics of retroviral infections. These sequences sometimes bear the hallmarks of APOBEC3-mediated mutations, and therefore serve as a record of the ancient conflict between retroviruses and A3 genes. Here we systematically investigated the sequences of ERVs and APOBEC3 genes in mammals to reconstruct details of the evolutionary conflict between them. We identified 1,561 AICDA/APOBEC family genes in a comprehensive screen of mammalian genome. Of the AICDA/APOBEC family genes, APOBEC3 genes have been selectively amplified in mammalian genomes, and disclose evidence of strong positive selection – whereas the catalytic domain was highly conserved across species, the structure “loop 7”, which recognizes viral DNA/RNA substrates, was shown to be evolving under strong positive selection. Comparative analysis of mammalian ERV sequences revealed that G-to-A mutations were accumulated in ERVs, and that the sequence signature of the G-to-A mutation sites on ERVs was concordant with the target preferences of APOBEC3 proteins. Importantly, the number of APOBEC3 genes was significantly correlated with the frequency of G-to-A mutations in ERVs, suggesting that the amplification of APOBEC3 genes led to enhance the attacks on ERVs by APOBEC3 proteins. Furthermore, the numbers of APOBEC3 genes and ERVs in mammalian genomes were positively correlated, and the timings of APOBEC3 gene amplification and ERV invasions in primates were highly concordant. Our findings suggest that conflict with ancient retroviruses and ERVs was a major selective pressure driving the rapid evolution of APOBEC3 genes in mammals.

## PgmNr 2358: Rome as a genetic melting pot: Population dynamics over 12,000 years.

---

Nearly 2000 years ago, Rome was the largest urban center of the ancient world and the capital of an empire with over 60 million inhabitants. Although Rome has long been a subject of archaeological and historical study, little is known about the genetic history of the Roman population. To fill this gap, we performed whole genome sequencing on 127 individuals from 29 sites in and around Rome, spanning the past 12,000 years. Using allele frequency and haplotype-based genetic analyses, we show that Italy underwent two major prehistoric ancestry shifts corresponding to the Neolithic transition to farming and the Bronze Age Steppe migration, both prior to the founding of the Roman Republic. As Rome expanded from a small city-state to an empire controlling the entire Mediterranean, the city became a melting pot of inhabitants from across the empire, harboring diverse ancestries from the Near East, Europe and North Africa. Furthermore, we find that gene flow between Rome and surrounding regions closely mirrors Rome's geopolitical interactions. Interestingly, Rome's population remains heterogeneous despite these major ancestry shifts through time. Our study provides a first look into the dynamic genetic history of Rome from before its founding, into the modern era.

## PgmNr 2359: Genomic game of thrones: Ancient DNA analysis of European and Asian royal dynasties.

In most societies, aristocracy has a marriage pattern different from that of the general population. Dynasties of rulers often had foreign origin and thus might be genetically distant. Moreover, they tend to marry their relatives (which genetically would result in elevated inbreeding) and partners from other countries (genetically counteractive). A genomic analysis of royal families is therefore interesting not only for the sake of accurate historical identification, but also for addressing population genetic questions on an “aristocratic subpopulation”.

We analyzed genomic data representing three dynasties: the medieval North European Rurikid dynasty, the 19<sup>th</sup> century Russian Romanov dynasty, and Genghis Khan’s descendants.

The chronicles indicate that Rurikid princes, which ruled Russia over seven centuries, descent from the Viking Rurik. The genetic-genealogical analysis of the present-day princes identified the core genetic lineage rooted in Scandinavia. We analyzed the ancient DNA of medieval princes including Vladimir (11th century) who is placed in traditional genealogy just five generations apart from the Rurik, and compared the ancient and modern members of the Rurikid dynasty.

The second study was performed in parallel by the two ancient DNA labs which were approached by the Russian Church requesting kinship analyses of the anonymous bone samples. The analysis was made as a blind test, the investigation was paralleled, and the results matched. The mtDNA profiles coincided with the published data on the last Russian emperor and empress (Rogaev et al., 2009), but the new results included also the preceding generations of the dynasty. The genomic results corroborate previous PCR-based findings and will settle the remaining doubts around the authenticity of Royal family remains. Genetically, these individuals are consistent with being Central Europeans, in agreement with the genealogical records, as they were close relatives of the Danish king, Queen Victoria of the United Kingdom, and other Central European dynasties.

Finally, we analyzed Y-chromosomes of several clans claiming their origin from Genghis Khan.

Surprisingly, the genetic variation in this sample was even higher than in general population. While the Nyru’un tribe (Genghis Khan belonged to) in general carried high frequency of the “star-cluster” (C-F3796), most studied aristocratic clans from Kazakhstan, Mongolia, and China carried two other lineages (C-F1756 and C-M407).

## PgmNr 2360: Linkage disequilibrium and haplotype patterns in ancient DNA: Theory and applications.

The rise of ancient DNA studies in population genetics has been revolutionary – revealing insights into demographic history and recent positive selection. However, most studies to date have ignored the covariance between variants on haplotypes (i.e. linkage disequilibrium, LD). Basic properties of LD in samples of mixed ages are still not well understood, in part because much of population genetic theory was developed without an expectation of time-serial sampling. Here, we derive several results for summary statistics of haplotypic variation. We derive results for the: 1) The expected number of pairwise differences between time-staggered samples ( $\pi_{\{\Delta t\}}$ ) and the correlation of this statistic between two loci, in models with and without strict population continuity; 2) The time-staggered analog of the LD-metric  $\sigma_D^2$ , which can be interpreted as a measure of haplotypic similarity between a modern and ancient sample; 3) The backward-in-time evolution of a set of LD-based moments defined by Hill and Robertson (1968) – these results can be used to predict aspects of LD in the past, based on observations in the present; and 4) The expected switch rate in a haplotype copying model, which suggests how to improve and use haplotype copying models with ancient samples and modern reference panels. Overall, these results provide a characterization of how several haplotypic patterns are affected by the time-gap between sampling, recombination rates, and population size. We expect these results will help guide thinking and methodological development for the analysis

## PgmNr 2361: Imputing gene regulation in ancient humans.

---

As anatomically modern humans (AMHs) migrated out of Africa and spread throughout the world, they were exposed to many different environments, including changes in climate, diet, and lifestyle. Given that closely related species are often very similar in their protein-coding sequences (e.g., human and chimpanzee are ~99% identical), and that most variants associated with disease in modern humans are non-coding, we expect most of the functional genetic changes that have occurred in recent evolutionary history to influence gene regulation. Recent technological advances in genotyping ancient DNA provide a novel avenue for studying when genetic changes occurred, and in what populations they arose, as well as the ability to correlate those changes with environmental and demographic shifts.

Because of the age of the samples involved, it is not possible to directly assay gene expression levels in ancient human samples or the effects of regulatory variants in ancient genomes. Here, we explore the feasibility of using PrediXcan, a method for imputing gene regulation based on genotypes, to study ancient human gene regulation. We have previously shown the utility of PrediXcan in studying gene regulatory patterns in archaic hominins with high-coverage sequenced genomes. However, most ancient human genotype data is very low-coverage, rendering existing gene regulatory models unstable due to high rates of missingness. To address this and assess the feasibility of using PrediXcan on data of this type, we trained new models in 48 tissues, optimized for use with an ancient human dataset. We will report the results of applying these models in 429 ancient humans from Eurasia ranging from 318 to 45000 years ago. We also compare the patterns of gene regulation by lifestyle and time period, as well as the potential phenotypic effects of the genes showing divergence in regulation. Altogether, our results assess the feasibility of applying gene expression imputation models in low-coverage data and demonstrate the potential of these methods for understanding patterns of gene regulation in ancient humans.

## PgmNr 2362: Comparing archaic to modern human-derived sites in the genome reveals the evolution of human facial morphology.

### Authors:

Facial morphology is characterized by high heritability and rapid recent evolution in modern humans. The fossil record shows that modern humans are characterized by changes in facial size and shape compared to archaic humans. The availability of Neanderthal and Denisovan genomes, along with recent genome-wide association studies (GWAS) of modern human facial variation, provides data to investigate the genetics underlying recent evolution in facial morphology. We examined two sets of evolutionary markers: (1) Modern human-derived (MD) sites, defined as SNPs for which the derived allele is present at high frequency (>90%) in modern humans, and the ancestral allele was shared by chimpanzee and archaic humans; and (2) Archaic human-derived (AD) sites, defined as SNPs for which the ancestral allele is present at high frequency (>90%) in modern humans and is shared with chimpanzee, with the derived allele present in archaic humans. We contrasted the effects of 48,589 MD and 28,929 AD sites in a recent GWAS of 24 quantitative facial soft-tissue measures derived from the 3D surface images of 3118 individuals of European ancestry. All facial traits were adjusted for age, sex, height, weight, principal components of ancestry, and facial size (calculated as the geometric mean of the linear distance measures). Differences in the effects of AD and MD sites were most pronounced for Lower Vermilion height. Among AD and MD sites showing nominal association with facial traits (i.e.,  $p < 0.05$  in GWAS), the median effect sizes were in the opposite directions, with 63% of AD alleles having an elongating effect on lower vermilion height, and 63% of MD alleles having a shortening effect (Wilcoxon test  $p$  value =  $3E-144$ ). When a stricter significance threshold was applied (i.e.,  $p < 5E-05$  in GWAS), the corresponding percentages were 100% and 97%, respectively. Similar results were observed for lower lip height, upper vermilion height and nasal width. In contrast, features related to facial height showed AD vs. MD effects in the opposite directions, with the majority of MD alleles having an elongating effect, especially for nasal height and upper facial height. Our results suggest that the features around oral region decreased in the modern human lineage, whereas the vertical height of the midface increased. These findings are based on soft tissue measurements in modern humans, and have yielded important new insights into the genetic evolution of facial morphology.

## PgmNr 2363: Multiple waves of peopling northeast Europe: An ancient DNA study through Mesolithic to the Middle Ages.

---

aDNA studies have resketched the peopling story of Europe highlighting the major role of three distinct mass immigrations in the Mesolithic, Neolithic and Early Bronze Age periods. Here we look at these processes in Estonia representing northeast Europe. One key difference of this region from the rest of Europe is high (30-40%) frequency of chr Y haplogroup N3a, which is otherwise spread in Siberia. Genome wide the Siberian component makes up only a few percent of the genepool of Northeast Europeans. We sample each major cultural transition in the region and follow the accompanying demographic changes. The earliest Mesolithic samples cluster together with the Western hunter-gatherers of Europe (WHG). The arrival of Comb Ceramics Culture (CCC) is coupled with Eastern hunter-gatherer (EHG) genetic ancestry. The arrival of Corded Ware Culture (CWC) in Late Neolithic/Early Bronze Age, is part of the massive immigration to Europe from the Steppes of contemporary Russia, and installs a new genepool.

We then turned to study the genetic ancestry of individuals (N=56) from more recent but as yet genetically unstudied cultural traditions in Estonia: i) the Late Bronze Age (EstBA) (1200-400 BC), ii) the Pre-Roman Iron Age (EstIA) (800/500 BC-50 AD), and iii) Middle Ages samples from Estonia (EstMA) (1200-1600 AD). Compared to the preceding CWC people the genetic ancestry of the EstBA samples shifts back toward that of WHG. While it is the EstIA where we see minute fraction of the Siberian ancestry component for the first time. Moreover, the respective chr Y variant - N3a - is also detected in EstIA samples and not in bearers of the older cultures. This eastern/Siberian ancestry reached the coasts of the Baltic Sea no later than the mid-first millennium BC; i.e. in the same time window as the diversification of west Uralic/Finnic languages. Furthermore, phenotypic characteristics often associated with modern Northern Europeans like light eyes, hair and skin as well as lactose tolerance can be traced back to the Bronze Age in the Eastern Baltic.

During the Middle Ages the Estonian population is socially structured into subpopulations of landlords of likely mostly German origin and the common people. In the pilot phase of the study we have confirmed, that burials from high class cemetery resemble genetically contemporary Germans, while rural and urban cemeteries of common people yield aDNA samples genetically reminiscent of the current Estonian population.

## PgmNr 2364: Evolutionary modeling of the differential contribution of Neanderthal ancestry to complex traits provides insights into selective forces that shape trait variation.

We recently developed a methodology to assess whether Neanderthal ancestry is over- or under-represented in the genetic component of complex phenotypes compared to random genetic variation. Based on 500,000 individuals from the UK Biobank, we found the estimated contribution of Neanderthal alleles to phenotypic variation (NIM heritability) is significantly depleted in the great majority of the phenotypes. This is consistent with the observation that in general, natural selection has acted to remove Neanderthal alleles since introgression. On the other hand, we have found that Neanderthal alleles were significantly over-represented in their contribution to a handful of traits.

To understand the evolutionary models that could explain these observations, we performed forward-in-time population genetic simulations to model the evolution of Neanderthal and non-Neanderthal alleles according to a demographic model relating modern humans and Neanderthals. We chose parameters used in a previous study (Petr PNAS 2019) analyzing the fitness cost of Neanderthal introgression. Specifically, an ancestral population of size 10,000 diploid individuals splits into a human population and a Neanderthal population, each one evolves separately before a single pulse of Neanderthal admixture followed by subsequent random mating. Under this demography, we modeled evolution of phenotypes subject to different forces including directional, stabilizing, and disruptive selection. We estimated a *NIM heritability Z-score*, a measure of whether NIM heritability deviates significantly from the background alleles. We found under most models of selection, the NIM heritability Z-score is near zero or negative, indicating NIM heritability is neutral or depleted. Interestingly, we were able to recreate a positive NIM heritability Z-score, indicating an elevated Neanderthal contribution to heritability in two separate models of stabilizing and directional selection. In the stabilizing selection model, the optimal value of the trait is decreased in the human branch during the split between humans and Neanderthals leading to a positive NIM heritability Z-score. We also observe a positive NIM heritability Z-score in a directional selection model in which the parameter that couples SNP effect size and fitness is reduced after introgression. This observation highlights possible mechanisms for how complex traits evolved in human history by examining the genetic contribution of Neanderthal ancestry.

## PgmNr 2365: Lactase persistence prevalence from genetic risk allele frequency.

Under simple architecture (i.e. additivity), a Genetic Risk Score (GRS) using frequencies of phenotype associating variants, should predict relative trait prevalence among populations. This should be true for monogenetic traits, of which our understanding is relatively comprehensive with respect to risk loci/alleles. As a proof of principle, we used lactase persistence (LP), the continued production of the lactase enzyme into adulthood, to test whether a GRS predicted population prevalence. LP is a monogenic trait caused by mutations affecting the expression of *LCT*, the gene encoding lactase, and is reasonably well understood in some populations. The Lactase enzyme is produced by our bodies to breakdown lactose, the sugar found in milk. Lactase production usually decreases after weaning, in some cases leading to an intolerance of lactose. To determine the relationship, if any, between population prevalence of LP and the GRS of its associated alleles, we used a polygenic weighted additive risk score based on the allele frequency distributions of trait associated alleles. The GRS was based on 11 variants with known population allele frequencies. In Europe, two alleles upstream of the *LCT* gene, -13910\*T (rs4988235) and -22018\*G (rs182549), confer LP. In non-Europe populations, other alleles may be responsible for LP, where it exists. We accessed risk allele frequency from the 1000 Genomes project and genomAD through the Ensembl browser. The estimated prevalences of LP were taken from literature. We found a strong relationship between the GRS and the population prevalence of LP world-wide ( $r^2 > 0.6$ ), and especially among European populations ( $r^2 > 0.9$ ). This trend held for both South Asian and Amerindian populations, though to a lesser extent ( $r^2 \sim 0.5$  and  $0.2$ , respectively). However, in East Asian and African populations, the GRS failed to predict the relationship between the known LP alleles and the population prevalence. This indicates that, while we have identified most variants that confer LP in European populations, and to a lesser extent Amerindian and South Asian populations, explained heritability for both African and East Asian populations of Lactase Persistence is effectively missing. Therefore, the variants responsible for LP in African and East Asian populations have yet to be discovered or there is an unknown environmental factor. Using this GRS comparative approach can inform us of the completeness of the genetic bases for human traits.

## PgmNr 2366: Differential complex trait architecture across humans: Epistasis identified in non-European populations at multiple genomic scales.

---

Genome-wide association (GWA) studies have identified thousands of significant genetic associations in humans across a number of complex traits. However, the vast majority of these studies use datasets of predominantly European ancestry (Popejoy & Fullerton 2016). It has generally been thought that complex trait genetic architecture should be transferable across populations of different ancestries, but recent work has shown a number of differences in trait architecture across human ancestries, including heterogeneity in both the identified causal variants and estimated effect sizes (Martin et al. 2017, Wojcik et al. 2017). Here, we report further evidence that complex trait genetic architecture is fundamentally different among human ancestries by jointly leveraging pathway and epistasis analysis.

Under the assumption that a given complex trait may have differential polygenic architectures across human ancestries, we hypothesize that human populations may also be enriched for differences in epistatic effects. However, since polygenic traits tend to have smaller GWA effect sizes, combining variants via pathway analysis may allow us to better reveal these signals. To accomplish this, we extend the concept of identifying marginal epistasis, moving from testing single variants (Crawford et al. 2017) to testing groups of variants for nonlinear association with a trait of interest.

We apply our new method to multiple ancestries present in the UK Biobank (Sudlow et al. 2015) and explore multiple pathway-related interaction models. Using morphometric traits we find evidence for genome-wide epistasis in African and other non-European populations. We also find evidence that these trends exist on the SNP and gene levels as well. Results also indicate this may be due to increased heterozygosity in non-European populations. This suggests that non-European populations may be well-suited for identifying non-additive effects in human complex trait architecture; this also suggests further evidence that European populations -- predominantly used for epistasis studies -- may indeed be limited and inaccurate proxies for all human ancestries in complex trait research.

## PgmNr 2367: Putting RFMix and ADMIXTURE to the test in a complex admixed population.

Global and local ancestry inference in admixed human populations can be performed using computational tools implementing distinct algorithms, such as RFMix and ADMIXTURE. The accuracy of these tools has been tested on populations with relatively straightforward admixture histories (e.g. African Americans) but little is known about how well they perform in more complex admixture scenarios. Using simulations, we show that RFMix outperforms ADMIXTURE in determining global ancestry proportions in a complex 5-way admixed population. In addition, RFMix correctly assigns local ancestry with an accuracy of 89%. The increase in reported local ancestry inference accuracy in this population (as compared to previous studies) can largely be attributed to the recent availability of large-scale genotyping data for more representative reference populations. The ability of RFMix to determine global and local ancestry to a high degree of accuracy, allows for more reliable population structure analysis, scans for natural selection, admixture mapping and case-control association studies. This study highlights the utility of the extension of computational tools to become more relevant to genetically structured populations, as seen with RFMix. This is particularly noteworthy as modern-day societies are becoming increasingly genetically complex and some genetic tools are therefore less appropriate. We therefore suggest that RFMix be used for both global and local ancestry estimation in complex admixture scenarios.

## PgmNr 2368: An overview of genetic diversity and signatures of natural selection observed in HLA-G and its ligands KIR2DL4, LILRB1/ILT2, and LILRB2/ILT4, in an admixed Brazilian sample.

*LILRB1/ILT2* and *LILRB2/ILT4* encode important Natural Killer (NK) and T cell inhibitory receptors, while *KIR2DL4* encodes an activator NK receptor. These receptors are targeted by HLA-G, an immunomodulatory molecule expressed mainly on the trophoblast. Polymorphisms at both ligand and receptor might influence their binding and expression. We assessed *HLA-G*, *ILT2*, and *ILT4* exonic diversity in 410 Brazilian samples, and *KIR2DL4* in a subset of 126 samples. Ancestry composition of the sample comprehended 71% European, 21% African, and 8% Amerindian/Asian. We used Haloplex (Agilent) for *HLA-G*, *ILT2*, and *ILT4*, and Nextera XT (Illumina) for *KIR2DL4*. Libraries were sequenced using the Miseq system in 2x300 runs. The alignment was performed with an adapted version of hla-mapper that considers known HLA, KIR, and LILR sequences. Genotyping and haplotyping were performed combining GATK HaplotypeCaller, ReadBackedPhasing, and Beagle 4. Linkage Disequilibrium (LD) was evaluated by means of Haploview and Genepop. The dn/ds ratio and Tajima's D were calculated using Mega7. DNA sequences were translated into proteins using emboss. HLA-G presented 5 frequent proteins, and the most frequent one was G\*01:01 (65%). We have found 5 frequent KIR2DL4 proteins. KIR2DL4\*001 and \*008 presented a summed frequency of 60%, and they differ by two amino acid exchanges and the latter is truncated due to a premature stop codon. ILT2 presented 12 frequent proteins, but one of them was very common (43%). ILT4 presented 10 frequent proteins, three of them with a summed frequency of 75%. According to the human genome draft hg38, there are 350 Kb between *LILRB2* and *LILRB1*, and 165Kb between *LILRB1* and *KIR2DL4*. Despite that, we detected no LD among these genes, with different combinations of *ILT2*, *ILT4*, and *KIR2DL4* receptors encoded per chromosome. In fact, there are many recombination hotspots between these genes (HapMap project). It is not clear whether receptor polymorphisms influence HLA-G binding. Nevertheless, our results indicate that *HLA-G* and *ILT2* are under purifying selection. Moreover, the number of individuals presenting some combinations, such as G\*01:03 and *ILT2* (with Lys at position 625), is higher than expected. Whether this is due to chance or not needs to be further investigated. In conclusion, here we present the genetic diversity of *HLA-G* and its ligands. *HLA-G* and

*ILT2* might be under purifying selection, and some HLA-G/*ILT2* combinations are more frequent than expected.

## **PgmNr 2369: Wavelet analysis of recombination rates: Population derived linkage maps have limited value when applied to different human populations.**

---

Recombination is the process in which pairs of homologous chromosomes cross-over during meiosis. These cross-over events are beneficial as they stop negative mutations building up along one haplotype by breaking down linkage between alleles. Recombination rates are known to be variable across the genome, with events clustering in hotspots. In the study of evolution and natural selection, it is important to understand the underlying recombination map for the population being analysed. The aim of this work is to calculate recombination rates in African and European populations and use wavelet analysis to investigate the differences on multiple scales.

Recombination rates were estimated using the widely implemented LDhat software for four human genomic datasets: two European and two African. The resulting recombination maps were then analysed using wavelets. Wavelet analysis allowed the recombination maps to be analysed at multiple scales simultaneously, rather than using a fixed window size, from the fine scale (2 Kb) through to the wide scale (16 Mb). This meant it could be ascertained whether the variance in the original scale was contained in short-term trends, or in longer ranging changes. Wavelet coherence analysis also allowed the comparison of the correlations of recombination rate changes between pairs of datasets, both globally and locally along the region.

The highest proportion of variance in the recombination rates was found at around the 16-64 Kb range across all the datasets, accounting for around a third of the total variance. The correlations between the recombination rate changes increased with scale over all pairs of datasets. The differences between African and European recombination rate changes were greatest at the fine scale. The recombination rate changes were found to be non-uniform across the region analysed, regardless of scale.

This work provides evidence that a recombination map built from one human population will not be representative of all other populations, especially at the fine scale. This has implications for methods designed to find evidence of natural selection in the genome that rely on linkage disequilibrium calculations.

## PgmNr 2370: Measuring recessive selection using summary statistics of the site frequency spectrum.

With the growth of large population sequencing datasets, measures of population constraint are becoming increasingly popular tools to predict gene essentiality or morbidity. These measures include, most notably, the constraint or loss of function intolerance score (pLI) from the Exome Aggregation Consortium (ExAC) and Genome Aggregation Database (gnomAD) datasets. A recent perspective by Fuller et al. noted that many of these measures perform poorly as estimators of the strength of selection, and that they are particularly insensitive to the difference between strong recessive selection and dominant or additive selection at a much weaker strength, in some cases even approaching neutrality. We have developed a population genetic method that is able to distinguish between recessive and additive selection in both simulated and observed genes. While previous likelihood-based methods that consider the entire site frequency spectrum (SFS) have had success in simulated models, they have been difficult to apply to actual large-scale human population sequencing data because they are highly sensitive to noise and demographic history. In contrast, our method uses summary statistics of the SFS that are chosen to be relatively robust to these factors: a measure of heterozygous burden and a logarithmic transformation of the SFS. Within the two-dimensional space defined by these summary statistics, we compare the density of known recessive genes or simulations to the density of non-recessive genes or simulations to identify regions that are typical of genes experiencing recessive selection. In addition to performing well on simulations, when this method is applied to a dataset of over 30,000 non-Finnish European human exomes derived from ExAC, we are able to identify genes implicated in autosomal recessive disease and genes suspected of being under recessive selection based on studies of consanguineous populations. Applying this method broadly to the entire exome produces potentially important insights into the biology of recessive selection. This method also has potential applications for the discovery of new recessive disease genes and clinical genetic diagnostic pipelines.

## PgmNr 2371: Gene expression in the testis shapes germline mutation signatures and modulates gene evolution rates.

---

The testis expresses the largest number of genes of any mammalian organ, a finding that has long puzzled molecular biologists. Analyzing our single-cell transcriptomic maps of human and mouse spermatogenesis, we provide evidence that this widespread transcription serves to maintain DNA sequence integrity in the male germline by correcting DNA damage through “transcriptional scanning”. Supporting this model, we find that genes expressed during spermatogenesis display lower mutation rates on the transcribed strand and have low diversity in the population. Moreover, this effect is fine-tuned by the level of gene expression during spermatogenesis. Analyzing the germline mutation datasets, we further identified novel rules governing the transcription-coupled repair of germline DNA damage. The unexpressed genes, which in our model do not benefit from transcriptional scanning, diverge faster over evolutionary time-scales and are enriched for sensory and immune-defense functions. Collectively, we propose that transcriptional scanning modulates germline mutation rates in a gene-specific manner, maintaining DNA sequence integrity for the bulk of genes but allowing for fast evolution in a specific subset.

## PgmNr 2372: Great ape-specific ATF4 retrocopies may act to regulate wild type ATF4 activity and viral infections.

### Authors:

H.M. Dalton; N.C. Elde; C.Y. Chow

[View Session](#) [Add to Schedule](#)

**Affiliation:** Department of Human Genetics, University of Utah School of Medicine, Salt Lake City, UT, United States of America

---

Multiple stress signals trigger the integrated stress response (ISR) such as endoplasmic reticulum stress and viral infection. Dysregulation of the ISR is implicated in diseases such as cancer and diabetes. The ISR activates kinases that phosphorylate eIF2alpha, causing strong inhibition of protein synthesis machinery while repair occurs. Despite this, certain genes contain specialized upstream Open Reading Frame (uORF) regulatory sequences in their 5'UTR region that allow, or even upregulate, translation during the ISR. One of the most upregulated uORF-containing transcripts is ATF4, a highly conserved transcription factor that activates pro-survival or apoptotic genes.

We have found conservation of multiple ATF4 retrocopies – labeled in humans as pseudogenes *ATF4P1-P4*. *hATF4P1* and *P2* are short, truncated retrocopies that date to the common ancestor between apes and old world monkeys, while *hATF4P3* and *P4* are ape-specific. *hATF4P3* is a full length copy that maintains all domains and uORF regulatory regions with 95% amino acid (AA) identity with the parent *ATF4* gene. The 5% AA that are diverged from the parent gene are primarily in the N-terminal side, with no differences in the C-terminal DNA binding domain. Perhaps the most interesting is *hATF4P4* which has a truncation event removing its DNA binding domain, yet maintains 90% AA identity with the parent gene in the truncated half. *hATF4P4* is well conserved in humans, chimps, bonobos, and gorillas (Homininae) and ancestral to their most common ancestor. Strikingly, independent retrocopies with similar truncation events have occurred in orangutan, gibbon, and gorilla genomes (an extra gorilla copy). In addition, all Homininae have lost their uORF regulatory sequences, while the independent truncation retrocopies maintain them.

Strong conservation and independent events in different lineages suggests that each of these retrocopies has the potential to be functional. For example, all truncated *hATF4P4*-like retrocopies maintain the transcription-enhancing P300 protein binding domain. We hypothesize that *hATF4P4*-like retrocopies may regulate the parent gene by sequestering proteins like P300 away from ATF4. In addition, viruses, like HIV, can hijack important machinery during the ISR, suggesting an alternative hypothesis where *hATF4P4* may buffer ATF4 to inhibit viral infection while not affecting ATF4-driven transcription. We will present functional analyses that will distinguish between these possibilities.

## PgmNr 2373: Prioritizing natural selection signals from the deep-sequencing genomic data suggests multi-variant adaptation in Tibetan highlanders.

Human genetic adaptation to high altitudes (>2500 m) has been extensively studied over the last few years, but few functional adaptive genetic variants have been identified, largely owing to the lack of deep-genome sequencing data available to previous studies. Here, we build a list of putative adaptive variants, including 63 missense, 7 loss-of-function, 1,298 evolutionarily conserved variants, and 509 expression quantitative traits loci. Notably, the top signal of selection is located in *TMEM247*, which is a transmembrane protein coding gene and harbors one high-frequency (76.3%) missense variant, rs116983452 (c.248C>T; p.Ala83Val), in Tibetan highlanders. The rs116983452-T is derived from archaic ancestry and carried by >94% of Tibetans but is absent or in low frequencies (< 3%) in non-Tibetan populations. This Tibetan-enriched allele is strongly and positively correlated with altitude, and is significantly associated with reduced hemoglobin concentration ( $p = 5.78 \times 10^{-5}$ ), red blood cell count ( $p = 5.72 \times 10^{-7}$ ), and hematocrit ( $p = 2.57 \times 10^{-6}$ ). These results were further validated in 1,160 replicate Tibetan samples collected from four different altitudes. In particular, *TMEM247*-rs116983452 showed greater effect size and better predicts the phenotypic outcome than any *EPAS1* variants in the association with several adaptive traits in Tibetans. In addition, modeling the interaction between *TMEM247*-rs116983452 and *EPAS1* variants showed weak but statistically significant epistatic effect. We argue that more than one variant may jointly deliver the fitness on the Plateau, and that the

adaptive evolution of the Tibetan people involves a large number of variants, of which interactions or epistatic effects might be existing.

## PgmNr 2374: Association of common genetic variants in human accelerated regions with craniofacial and subcortical morphology.

---

Human accelerated regions (HARs) are small genomic regions (100-200 base pairs) that, although highly conserved through primates, exhibit an unusually high number of mutations from the ancestral state in humans. This suggests that they may impact traits that are both functionally necessary and differentiate humans from other primates. For example, HARs have been associated with enhancers that regulate neural development. Additionally, gene ontology enrichment analyses suggest that HARs are connected to key developmental processes impacting craniofacial structure such as the regulation chondrocyte differentiation and cartilage development. We therefore determined whether common variants in HARs were associated with measures of craniofacial morphology and subcortical brain volumes. A list of 2,737 HARs compiled from previous publications by the authors of a 2016 study was used to obtain the genomic locations of HARs. Then we extracted results for 2,314 SNPs located in these HARs from recent genome-wide association studies of craniofacial morphology (N=2,329, 3D facial norms consortium) and 1809 SNPS from a recent genome-wide association study of subcortical brain volumes (N=8,064, ENIGMA consortium). We used the Bonferroni p-value threshold, adjusting for 2,314 tests for the craniofacial analysis and 1,809 tests for subcortical volumes, to declare statistical significance. We identified two SNPs within HARs that were significantly associated with craniofacial morphology, with effects concentrated in the nasal area. One of these was located within an intergenic region adjacent to *PAX3*, a gene which controls the embryonic development of bones comprising the face and has been associated with nasal morphology in several prior GWAS of human facial morphology. We observed no evidence that SNPs within HARs were associated with subcortical brain volumes. Finally, we found no evidence that HARs were enriched for SNPs associated with craniofacial morphology or any measure of subcortical volume. Future work should further explore the relationship between human accelerated regions and cortical brain structures, which are more directly relevant to human evolution.

## PgmNr 2375: Using a combination of GWAS methods and haplotype-based selection statistics to infer patterns of positive selection in Oceania.

---

The history of the settlement of the Pacific was a complex demographic event involving multiple migrations and exposure to a wide variety of environmental pressures on new islands, including the unique disease dynamics present in isolated, high-density populations with intermittent contact. These challenges resulted in opportunities for local adaptation to new conditions. However, Oceania remains largely underrepresented in studies of genetic selection. Using data from the Oceanian Genome Variation Project (OGVP), involving 980 individuals from 88 populations measured on the MEGA platform at over 1.7M sites along the genome, we searched for evidence of positive selection using the machine learning model SWIFr. Our inputs into the model were three haplotype-based statistics (iHS, nSL, and xp-EHH) and the p-values from a mixed effects model GWAS analysis using population membership as the phenotype to quantitatively assess overall differentiation. Together, these account for local population structure and suggest genome-wide significant levels of potential selection in multiple regions, including in HLA-DRB1 and -DQA1 in West Polynesia. We also find significant enrichment in East Polynesia in top scoring genes involved in monosaccharide metabolism and response to xenobiotic stimulus. The results suggest local adaptation to infectious disease and diet.

Taiwan is an island and home of multiple ethnic groups including Taiwanese Han and sixteen officially recognized aboriginal tribes. However, little is known about the levels of genetic structure/admixture and patterns of evolutionary adaption among these populations. Here, we analyzed the whole-genome SNP genotyping data from 14,496 individuals of Taiwanese people. The PCA first showed a clear discrepancy between the Taitung (dwelling in the Eastern Taiwan) and Taiwanese Han people. The ADMIXTURE analysis further revealed that the genomes of Taiwanese Han contain three major components with distinct geographic distributions while the Taitung people contain one major genetic component that contributes to many of the Austronesian populations in a great proportion. To scan for the genomic signatures of recent positive selection, we calculated integrated haplotype score (*iHS*) and subsequently identified 26 and 12 candidate loci in the Taiwanese Han and Taitung populations, respectively. Surprisingly, none of these candidate loci was shared between them except for the *HLA* genes. We further constructed a fine-scale LD map and calculated the iSAFE (Integrated Selection of Allele Favored by Evolution) and CADD scores (Combined Annotation Dependent Depletion) to pinpoint the causal variants by analyzing a subset of individuals (772) whose whole-genome sequencing data are available. As a result, we discovered some selection-targeted variants with high deleterious scores (e.g., *NFKBIA*, *WNT7A* and *NEO1* genes that play a role in either inflammatory or tumor suppressor signalling pathway). Together, our findings reveal important insights into the evolutionary history of Taiwanese people and provide an alternative approach to identify genetic basis that underlie disease susceptibility.

## PgmNr 2377: Ongoing purifying and overdominant selection in the human genome.

The release of 500,000 genomes from the UK Biobank (UKB) provides unprecedented opportunities for studying ongoing selection using deviations from Hardy-Weinberg Equilibrium (HWE). Compared to the HWE expectation, we observe increased heterozygosity in British ancestry individuals in the UKB cohort genome-wide. This observation could potentially be caused by genotyping errors. However, we find that nonsynonymous SNPs with low Minor Allele Frequency (MAF  $< 5\%$ ) are enriched for excess heterozygosity compared to other SNPs of the same MAF. This observation cannot be explained by genotyping errors, but is likely due to purifying selection against recessive deleterious alleles. Perhaps surprisingly, low MAF archaic SNPs from Neanderthal admixture show depletion of excess heterozygosity, a pattern that can be replicated in simulations incorporating selection and addition, by mutation, of new deleterious alleles, for many generations after the time of admixture. We also find that high MAF (30-50%) nonsynonymous SNPs are enriched for excess heterozygosity compared to other SNPs of the same MAF. These SNPs are enriched for genes previously identified to be under balancing selection. They also show evidence of overdominance from decreased all-cause mortality in heterozygous individuals. Population genetic simulations under realistic parameter settings can recapitulate these observations. Our study demonstrates that analyzing patterns of deviations from HWE can be a powerful way to detect selection in large cohorts and that ongoing selection in humans is common.

## PgmNr 2378: Selection of 28 AIMs analysed *in silico* and tested in Native and Mestizo Mexican samples to infer the Mexican regional ancestry.

Mexican population emerged from the admixture among Native Americans, Europeans and Africans 500 years ago. Their youth, joint to the demographic events experienced by their founder populations, and the skewed genetic mixture between Native women, and European, and African men, have yielded an intricate background ancestral. Ancestry Informative Markers (AIMs) are single-nucleotide polymorphisms used to infer populations' geographic origins. These markers have been broadly studied in worldwide populations. Nonetheless, their use in Latino populations lacks the systematic basis for its selection, validation, and minimal number to infer the ancestry of populations with complex genetic architecture. The multi-ethnicity of the Mexican population provides a unique opportunity to explore the utility of these markers, both in Mestizo as in Native populations, which data are poorly represented in HapMap. In the present study, we selected and tested the effectiveness of a reduced panel of 28 AIMs to be used in the Mexican population. These markers were selected after an exhaustive *in silico* data analyses from 200 AIMs previously reported. Different genetic parameters (i.e, genetic distance,  $F_{ST}$  among others) were used to evaluate its effectiveness. Genetic parameters such as genetic distance ( $F_{ST}$ ) was used. *In silico* effectiveness were explored using 2,504 genotypes from the 1000 genomes project with Genetix 4.05, Arlequin 3.5, and BAPS 6.0. These 28 markers were also tested in 150 samples from 90 Native Americans (Uto-Aztecan, Oto-Manguean, and Mayan linguistic families), and 60 Mexican Mestizos from Central Valley of Mexico. Our study provides additional evidence to unravelling, efficiently, the complex ancestral background of the Mexican population to low cost.

## PgmNr 2379: Ancestral origins and natural selection of Highland Tajik people in Xinjiang.

---

Recent studies revealed that Tibetan, Andeans and Ethiopian populations used different strategies and different genes to adapt high-altitude environments, although little is known about functional variants and genetic mechanisms. Studying those under-investigated highland groups might provide new insights into the genetic basis of high altitude adaptation. Here, we conducted a whole-genome deep-sequencing study of the Xinjiang Tajik (XJT) people who are residing on the Pamir Plateau with an average altitude > 3,000 meters. The majority of the ancestry of XJT was derived from west Eurasian (30.0% - 49.9%) and South Asian (42.6% - 57.3%) populations, with some minor (3.62% - 17.5%) ancestry derived from East Asian and Siberian populations. We identified a genomic region encompassing *CAPN3* and *GANC* showing signature of natural selection in XJT. The selected haplotypes[S.X.1] are enriched in XJT (carried by 26% of Tajik people) and likely originated from an unknown archaic group. Our data indicated that genetic admixture facilitated high-altitude adaption of XJK. A few candidate genes associated with XJT's adaptation were also reported previously in Ethiopian and Andeans, suggesting that some common genetic basis of high-altitude adaptation might be partly shared by indigenous groups from different highlands.

## PgmNr 2380: A comparative analysis of DNA replication timing in humans and chimpanzees.

DNA replication is accomplished by firing of replication origins across the genome at different times during S phase, resulting in a spatial and temporal pattern known as DNA replication timing. Replication timing shapes mutation rates across the genome, thus impacting sequence evolution and genetic variation. Replication timing variation between humans and other great apes can thus affect human evolution and underlie human-specific traits. To test this, we sequenced the genomes of 90 chimpanzee lymphoblastoid cell lines (LCLs) and seven induced pluripotent cell lines (iPSCs) along with similar numbers of human samples, and inferred replication timing by analyzing DNA copy number fluctuations along chromosomes. While replication timing was largely conserved between species and the greatest replication timing variation was related to cell type, we also identified numerous species-specific differences within the same cell type. Overall, human and chimpanzee replication timing varied at 311 genomic regions covering on average 523 Kb and cumulatively spanning 163 Mb (5.4% of the genome). The majority (52%) of this variation impacted replication origins, manifesting as gain (n=49) or loss (n=45) of origins in humans relative to chimpanzees, or changes in origin firing time (n=68). Of the latter, 29 regions showed advanced replication in humans compared to chimpanzees, while the remaining 39 were delayed in humans. Human-chimpanzee replication timing variants spanned 1,060 genes, including some with prior indications of human-specific evolution. For example, *CASP12*, one of the first identified cases of adaptive gene loss in humans, replicated earlier in humans compared to chimpanzees and was associated with an earlier firing human replication origin. Taken together, replication timing has been subject to dynamic evolution since the divergence of humans and chimpanzees, resulting in extensive variation between the species with potentially important implications to human evolution and phenotypes.

---

Most human mutations lead to independent single nucleotide variants (SNV). A minority, however, result in complex events such as clustered mutations. Mutation clusters provide an insight into underlying biochemical mechanisms, because a cluster contains more statistical information than a SNV.

Previously, clusters have been characterized by distances between individual mutations within clusters and by spectra of these mutations. Here, we have developed a statistical model of clustered mutations formulated as a mixture of Hidden Markov Models (HMM). Our model assumes existence of several mechanisms producing clusters, each represented by a separate HMM. We designed and implemented an algorithm to fit parameters of the HMM mixture.

We applied this method to more than 1,500,000 mutation clusters inferred from rare variants in the TOPMed dataset. This analysis identified three mutation processes generating clusters. The first process is characterized by a single A>T, A>G or G>T mutation at the 3' end of the cluster and any number of subsequent C>G mutations at the 5' end of the cluster. The second process displays nearly the same spectrum at the 3' end and any number of C>T mutations at the 5' end. The third process is dominated by A>G mutations in all positions.

The complex structure of the first and second processes lends itself to a mechanistic hypothesis. The directionality of these clusters suggests a two-step mechanism. We hypothesize that the first (3') mutation is likely caused by the nucleotide mis-incorporation opposing a DNA lesion. The following (5') mutation(s) are introduced by translesion polymerases recruited due to the replication obstacle at the original lesion. This model is supported by the analysis of clusters crossing the boundaries of transcribed regions.

Using trio sequencing data, we show that the first process is much more common among clusters of maternal origin, while the second process is more prevalent among paternal clusters. Separately, we demonstrate that the localized bursts of C>G mutations in oocytes are driven by the first mutational process.

## PgmNr 2382: A theoretical framework for interpreting the effect of geographic structure on GWAS.

Genome-wide association studies (GWAS) have shown that much of the variation in disease risk is due to rare deleterious alleles. This is likely due to the action of natural selection eliminating disease-risk alleles from the population. We expect these alleles to be geographically localized because natural selection removes them before they can spread far beyond their original location. However, the geographic distributions of these alleles have not been characterized in detail. We aim to understand how natural selection, geographic population structure, and geographic sampling bias interact to determine the inferred local and global genetic architecture of a trait.

It is inevitable that association studies will feature significant geographic bias. For example, the UK BioBank contains samples of people who have migrated to the United Kingdom from around the world, but still represents a small fraction of global diversity that is highly biased toward a relatively small geographic region. How can we use GWAS results from geographically localized studies like those from the UK BioBank to better predict disease risk in other geographic regions?

Here we develop theoretical models for the geographic spread of rare deleterious alleles. We focus on calculating the ascertained genetic architecture of a trait. The essential output of our population genetics analysis is the expected allele frequency spectrum as a function of: the geographic sampling scheme, the selection coefficient for an allele, and the population's geographic structure. Our theoretical results highlight the dependence of the inferred genetic architecture of a trait on geography and the evolutionary process, with implications for the interpretation of geographically localized GWAS cohorts.

Many commonly-used statistical genetics/genetic epidemiology methods, such as LD Score Regression (LDSC), attempt to control for population structure. Recent evidence has shown that background selection in tandem with population structure can substantially bias estimates of narrow-sense heritability  $h^2$ . This bias is due in part to the effect of selection on linkage disequilibrium (LD). However, little work has been done to investigate more generally how selection has impacted LD in humans, and the consequences for statistical genetics methods. We use model-based evolutionary simulations to demonstrate the effects of a wide range of selection scenarios on heritability estimation using LDSC. We also investigate the extent to which selection drives LD between causal variants (i.e., the Bulmer Effect), and the bias this incurs in genome-wide associations (GWAS). Finally, we analyze empirical patterns of LD between expression quantitative trait loci (eQTLs). Our results suggest that both LDSC and estimated effect sizes from GWAS may have been susceptible to biases induced by selection-driven linkage patterns.

## PgmNr 2384: Standardized statistics to detect balancing selection utilizing substitution data.

---

Long-term balancing selection leads to a build-up of alleles at similar allele frequencies at a balanced locus. Recently, we developed the  $\beta$  statistic to detect balanced haplotypes using this signature without the need for genomic data from an outgroup species. Here we extend this method to incorporate between-species substitution data, enabling this approach to outperform existing summary statistics in simulations. We also present the variance of  $\beta$  with and without substitution data, allowing calculation of a standardized score. Besides providing a measure of significance, this enables a proper comparison of  $\beta$  values across varying underlying parameters - a feature lacking from some related methods. We apply the standardized  $\beta$  statistic to 1000 Genomes data, along with substitution data from chimpanzee, to identify balanced loci in humans. One of our strongest, and novel, signals is near a bitter taste receptor, a gene class previously suggested to be under balancing selection. Additional top loci are both associated with complex traits and expression levels of nearby genes, suggesting that balancing selection may be affecting complex trait architecture via gene regulation.

## PgmNr 2385: A likelihood method for estimating selection on polygenic traits while controlling for pleiotropy.

---

There has been substantial interest in identifying selection in the human genome. While there are a handful of examples of strong selection acting primarily on one locus, there is an overall paucity of strong signals of selection at individual loci. Furthermore, genome wide association studies (GWASs) have shown that most human traits of interest are highly polygenic. Thus, it is commonly speculated that polygenic adaptation may be a dominant mode of human adaptation, as it would allow traits to differentiate rapidly while only leaving subtle signals at each locus. Furthermore, compared to inferring whether selection has acted on a locus, inference of selection on traits can be confounded by genetic correlations; these can induce indirect selection on correlated traits, making it unclear which trait actually affects fitness if one tests traits marginally rather than jointly. To this end, we present a full-likelihood method to pinpoint selection among a set of correlated traits. We calculate the likelihood by aggregating estimates of both the local coalescent tree and effect sizes across loci. We show using simulation studies that even at modest sample sizes, our method is able estimate the strength and timing of selection, and accurately disentangles selection among genetically correlated traits. We apply our method to pinpoint selection among a set of genetically correlated anthropometric traits (including height), re-analyzing previous claims that waist-to-hip ratio appears has been under selection in Europeans, even after correcting for correlated response. We also analyze eQTLs from the GTEx consortium, using our method to identify tissues enriched for selection on tissue-specific eQTLs.

## PgmNr 2386: Mortality, comorbidity and fertility effects of a per-individual burden score.

---

Human genetic variation harbors a large number of deleterious variants which collectively can decrease an individual's fitness. Despite complex disease genetic studies showing that polygenic risk scores, which measure the cumulative effect of disease-associated variants typically with common or low-frequencies (>0.5%), can have profound effects on complex disease, little is known about the cumulative effect of deleterious variants are acted upon by purifying selection at the individual level and its effect on disease. In the present study, analogous to polygenic risk score analyses, we developed a per-individual burden score by summing the effect of deleterious variants after applying a weight reflecting purifying selection. Using the site frequency spectrum, we evaluated four established methods for our weight: Gerp, phyloP, CADD, and fitcons to see how well each score approximates purifying selection by qualitatively tracking with allele frequency, and observed that phyloP was the best performing score. We next calculated a per-individual burden score, weighted by phyloP, using five sets of variants: LOF sites; LOF plus polyphen damaging sites; LOF plus polyphen damaging and polyphen possibly damaging sites; synonymous site; and all variants available. These scores were calculated for both imputed data (only sites with imputed INFO score  $\geq 0.9$ ) from the global screening genotyping array in 258,491 individuals and from a whole exome data set in 29,658 individuals from the UK biobank. We tested the associations of our burden scores with *a priori* phenotypes believed to be affected by natural selection, mainly: mortality (five year mortality), comorbidity (Elixhauser comorbidity index), and fertility (number of children, survival rate). We observed consistent nominal associations of the burden score derived from LOF+polyphen damaging with number of children in both the imputed (beta: -0.004/SD units, SE: 0.002,  $P=0.007$ ) and whole exome dataset (beta: -0.01/SD units, SE: 0.005,  $P=0.04$ ). We further observed significant nominal signals of our burden score with comorbidity (beta: 0.02/SD units, SE: 0.008,  $P=0.008$ ) in the exome dataset only. These results suggest that the accumulation of deleterious variants at the individual level can have a detectable impact on mortality, comorbidity and fertility.

## PgmNr 2387: Insights on hair, skin, and eye color of ancient and contemporary Native Americans.

---

Over the past few years, tools capable of predicting pigmentation phenotypes have been developed to contribute for criminal and anthropological investigations. Recently, some studies made public sequencing data from Native Americans from Late Pleistocene/Early Holocene. In this study, we used four genetic systems (Snipper10/12/23 and HirisPlex-S) to infer eye, hair, and skin color, and one (SNPforID 34-plex) to infer genomic ancestry, of 20 ancient and 22 contemporary Native Americans. To achieve this goal, we retrieved 92 SNPs from these 42 samples available in online repositories of DNA sequences. Pigmentation phenotypes were predicted using multinomial logistic regression (HirisPlex-S) and naïve Bayes (Snipper) methods. For ancestry analysis, we used the Structure software. This workflow made possible the prediction of eye, hair and skin pigmentation for 29 samples. HirisPlex-S predicted brown eyes for all individuals, while Snipper23 predicted brown eyes for 16 individuals, green/hazel eyes for 7 and blue eyes for 1. Regarding hair color, Snipper12 predicted black hair for all individuals, while HirisPlex predicted black hair for all individuals except for a single one that was predicted as having dark-brown/black hair. It should be emphasized that the individual that presented blue eyes and lighter hair is a contemporary Amerindian that presents more than 26.5% European admixture. For skin prediction with HirisPlex-S, 21 individuals presented dark skin with dark-black influence or dark-black skin with dark influence. Three individuals presented even darker pigmentation (dark-black skin), while Mexican Mixtec-2 (dark skin with intermediate influence) and Alaskan Saqqaq (intermediate skin) presented lighter skin color. Snipper10 predicted intermediate skin for all individuals except for S\_Mixtec-2 (26.2% European ancestry), which resulted in a white skin prediction. Since these prediction tools have been developed primarily based on markers identified in Europeans, there are genetic markers relevant to Native American/East Asian populations that are certainly not included in these panels. In spite of these limitations, we provide the first prediction of pigmentation phenotypes from Paleoamerican genomes. Overall, ancient Native Americans presented intermediate/brown eyes, black hair and intermediate/darker skin pigmentation, which is highly consistent with both predictions actual phenotypes observed among contemporary Native American populations.

## PgmNr 2388: Imputation in South Asian individuals using a high-coverage South Asian reference panel.

---

Imputation involves the prediction of genotypes not directly assayed in a sample of individuals using genome-wide sequenced reference data and known genotypes at a subset of positions in individuals for whom unknown genotypes need to be imputed. Use of a population specific reference panel can lead to an improvement in imputation accuracy over a non-specific reference panel. We present here the use of high-coverage sequencing of 6610 individuals, the majority of which are from South Asia, to generate reference panels for imputation in South Asian individuals.

This newly sequenced panel of South Asian individuals consists of 1812 individuals from Pakistan, 500 from Bangladesh, 1356 from South India, and 1810 from the Birbhum district of West Bengal, as well as some outgroup individuals from Africa, Europe, and East Asia. All of these samples were obtained through various medical and sequencing projects and sequenced to high coverage.

We use the new high-coverage sequences from the public 1000 Genomes project as an alternative reference panel for comparison, since it includes both, South Asian individuals as well as individuals from other populations. Both the reference panels are phased using *eagle*, and imputation using both reference panels is performed using *impute2*. Both reference panels are filtered for genotype quality and coverage to minimize errors arising from sequencing and variant calling.

We observe an improved imputation accuracy in South Asian individuals by using the South Asian reference panel as compared to using the 1000 Genomes panel, even though both panels have been sequenced at high coverage. Our final goal is to generate a reference panel which can be used for high quality imputation in South Asian individuals.

## PgmNr 2389: The genetic architecture of complex disease at mutation-selection-drift balance.

---

While many human diseases are known to be highly polygenic, we have little in the way of formal population genetic theory to guide our intuition about they evolve. In this talk, I will present a theoretical investigation of a complex, highly polygenic disease evolving at mutation-selection-drift balance. Under this model, we show that for all but the largest effect size alleles, the genetic architecture is insensitive to factors such as the fitness cost of disease or the environmental variance in disease liability, and instead depends only on the strength of mutational bias toward the disease state, and the distribution of effect sizes of newly arising mutations. In contrast, the disease prevalence is expected to be extremely sensitive to such external factors, and can evolve in response to changes in such factors on relatively rapid timescales.

Finally, I will show that polygenic scores for disease traits evolving at equilibrium can exhibit confusing and misleading patterns of evolution across populations and over time. These patterns may lead to the erroneous conclusion that natural selection has driven divergence among populations in the mean genetic liability burden, even when all populations are evolving under the same steady state conditions. These results suggest the need for caution in interpreting the distribution of polygenic scores across populations and in ancient DNA samples.

# PgmNr 2390: Promoter CpG density is under selection in humans and predicts genic intolerance to loss-of-function variation.

## Authors:

L. Boukas<sup>1</sup>; H.T. Bjornsson<sup>1,2,3</sup>; K.D. Hansen<sup>1,4</sup>

## Affiliations:

1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland.; 2) Department of Pediatrics, Johns Hopkins University School of Medicine, Baltimore, Maryland.; 3) Faculty of Medicine, University of Iceland, 101 Reykjavík, Iceland; 4) Department of Biostatistics, Johns Hopkins Bloomberg School of Public Health, Baltimore, Maryland.

## Background:

The current dogma states that CpG islands are not under selection (Cohen, Kenigsberg, and Tanay, 2011). Here, using large-scale sequencing data, we show that CpG density in human promoters is in fact selected for, both at the individual CpG-level and the whole-promoter level. We then use this to predict constrained promoters of protein-coding genes and lncRNAs.

## Data:

We used allele counts from the whole-genome sequences of 62,784 individuals from TOPMed, estimates of genic intolerance to human loss-of-function variation (hLoF) from gnomAD, and whole-genome DNA methylation data in the human and chimp germlines (sperm).

## Results and Discussion:

We found that, conditional on germline methylation status, variants seen in TOPMed individuals in CpGs in hLoF-intolerant promoters (i.e. promoters of hLoF-intolerant genes) were more likely to be singletons compared to these in hLoF-tolerant promoters (unmeth  $p=1.3e-9$ , meth  $p=2.5e-14$ ). Comparing human/chimp ortholog promoters, a median of 5% more CpGs were retained between species at hLoF-intolerant promoters compared to hLoF-tolerant promoters ( $p=4.1e-14$ ). These results show that individual CpGs at hLoF-intolerant promoters are under purifying selection.

However, the most efficient way to preserve promoter CpG density is through an unmethylated germline state, as this reduces the mutation rate of all CpGs by ~15-fold. We found that hLoF-intolerant promoters tend to be unmethylated in the human germline (odds ratio = 38.3,  $p<2.2e-16$ ). Despite the overall similarity between the human/chimp germline methylomes, 74% of hLoF-intolerant promoters methylated in the chimp germline, are unmethylated in the human one, versus only 5% of hLoF-tolerant promoters (odds ratio = 585.3,  $p=0.0048$ ). This shows positive selection for an unmethylated germline state, only at hLoF-intolerant promoters.

Finally, we trained a model to predict hLoF-intolerant promoters using only their CpG density and conservation, achieving 85% precision in a hold-out test set. We predicted the promoters of 182 (of 3,897) short protein-coding genes (which are hard to ascertain for hLoF intolerance due to their short length), and 64 (of 6,545) lncRNAs, to be hLoF-intolerant. Supporting our predictions, these promoters

were depleted of deletions in gnomAD, compared to promoters of well-ascertained hLOF-tolerant genes (19%,  $p=0.013$ , and 16%,  $p=0.002$ ), with the same degree of depletion as well-ascertained hLoF-intolerant promoters (18%,  $p=9.2e-10$ ).

## PgmNr 2391: Re-examining the evidence for polygenic adaptation at height-associated loci in mainland Europe and Sardinia.

---

Adult height was one of the earliest putative examples of polygenic adaptation in humans. By constructing polygenic height scores using effect sizes and frequencies from hundreds of genomic loci robustly associated with height, it was demonstrated that Northern Europeans were genetically taller than Southern European beyond neutral expectation. However, this conclusion was recently challenged. Sohail et al. and Berg et al. showed the polygenic signature disappeared if GWAS summary statistics from UK Biobank (UKB) were used in the analysis, suggesting that residual uncorrected stratification from large-scale consortium studies like GIANT were responsible for the previously observed difference in genetic. While effect sizes in consortium GWAS were likely over-estimated, it remains an open question whether height loci exhibit signals of polygenic adaptation in any human population. In this study, we re-examined this question focusing on one of the shortest European populations, the Sardinians. We showed that previously reported signature of polygenic adaptation in Sardinians remained when using height loci and effect sizes ascertained from UKB (~ 0.39 s.d. shorter than CEU,  $P = 2.18e-5$ ). To further alleviate concerns of biased ascertainment of GWAS loci, we ascertained height loci from the Biobank of Japan (BBJ), and showed that the results were unchanged (~ 0.36 s.d. shorter than CEU,  $P = 8.85e-7$ ). As in Sohail et al. and Berg et al., when we focused on mainland European populations, we could not detect a polygenic selection signal using loci ascertained from BBJ data. However, we observed a nominally significant signal of allele frequency differences using precise frequency estimates from gnomAD ( $P = 0.02$ ), as well as a stronger adaptive signature using tSDS ( $P = 3e-4$ ). In summary, by examining height loci ascertained in a distant East Asian population, we further supported evidence of polygenic adaptation among the Sardinians. By contrast, an adaptive signature in mainland Europe is subtler, only becoming more evident in haplotype-based analysis.

## PgmNr 2392: The effect of consanguinity on between-individual identity by descent on the X chromosome.

Consanguineous unions increase the frequency at which identical genomic segments are inherited along separate paths of descent, producing runs of homozygosity (ROH) within individuals. Consanguinity increases the lengths of ROH, and it has also recently been shown to increase autosomal identity by descent (IBD) *between* individuals in a population. This result was obtained by demonstrating that the mean time to the most recent common ancestor ( $T_{MRCA}$ ) for a pair of lineages in separate individuals decreases with increasing consanguinity, noting that genomic sharing increases with decreasing  $T_{MRCA}$ . Here, we extend this analysis to the X chromosome. We consider X-chromosomal IBD under a coalescent model with diploid, male-female mating pairs. We examine four possible types of first-cousin mating—matrilateral parallel, matrilateral cross, patrilateral parallel, and patrilateral cross—which are equivalent in their effects on autosomes, but which have different effects on the X chromosome. We calculate mean  $T_{MRCA}$  for X-chromosomal lineages sampled both within and between individuals. Our results illustrate an effect due to consanguinity on X-chromosomal  $T_{MRCA}$  that differs from the autosomal pattern under matrilateral first-cousin mating but not under patrilateral first-cousin mating. For matrilateral first cousins, the effect of consanguinity in reducing  $T_{MRCA}$  is stronger on the X chromosome than on the autosomes, with an increased effect of parallel-cousin mating versus cross-cousin mating. The differences produced by the various types of first-cousin mating potentially make it possible to distinguish between mating regimes using knowledge about the extent of within- and between-individual IBD on X chromosomes and autosomes in a population.

## PgmNr 2393: Mitochondrial DNA and Y chromosome variation among the South American Macushi in relation to geography and language.

### Authors:

K.L. DeRosa; C.A. Koch; D.A. Merriwether

[View Session](#) [Add to Schedule](#)

**Affiliation:** Anthropology, BINGHAMTON UNIVERSITY, BINGHAMTON, NY.

---

The Macushi are a Carib-speaking population indigenous to the Roraima state of northern Brazil that occupy the sparsely populated grasslands of the region. Their kinship system follows a bifurcate-merging pattern with preferential cross-cousin marriage. The Macushi share territories with the Wapishana and have established trade routes with the Yeukana. They also have had regular contact with non-indigenous cattle ranchers since the 19th century. Mitochondrial DNA (mtDNA) analysis of 94 maternally unrelated individuals was performed using the d-loop region (15,938-429) to assess the genetic diversity of the population. Y-chromosome analysis was performed on 50 paternally unrelated individuals using *DYS199*, *DYS390*, *DYS391*, *DYS392*, *DYS393*, and the *YAP* indel. The Macushi population is comprised of haplogroups A (n=2), B (n=47), C (n=18), and D (n=27), as expected for indigenous South American (SA) groups, suggesting the absence of admixture despite contact with non-indigenous groups. These data were compared with previously published mtDNA data from SA, indicating female migration is greatest with Amazon and Andean populations. AMOVA was used to determine the relationship between geography, language (using the Loukotka, Greenberg, and Campbell classifications), and genetic distance, with both geography and language significantly positively correlated with genetic distance. The *YAP* insertion on the Y-chromosome is present in low frequencies in SA and was not identified in the Macushi. *DYS199T* was present in 79% of males, agreeing with the average ratio of this SNP observed in indigenous SA populations. Contrary to these findings, Y-STR analysis suggests there is significant admixture as approximately 30% and 26% of the population consists of haplogroups L and T respectively (which are primarily in SE Asia, Africa, and the Mediterranean). Additional Y-loci are being screened to better assess the extent of admixture observed. Y-chromosome data was further compared to previously published data, indicating widespread male migration throughout SA. Similar to our mtDNA analyses, AMOVA of the Y-chromosome data found a significant positive correlation between genetic distance, geography, and language.

The analyses for both mtDNA and Y-chromosome data indicate differing migration patterns for males and females of the Macushi population. However, further Y-chromosome markers are needed in order to confirm these findings and the presence of admixture within the Macushi.

## PgmNr 2394: Leveraging chromosomal linkage to infer natural selection from full-genome sequencing data.

**Authors:**

E. Friedlander; M. Steinrücken

[View Session](#) [Add to Schedule](#)

**Affiliation:** Ecology & Evolution, University of Chicago, Chicago, IL.

---

We present a method for inferring natural selection from full-genome sequencing data. Natural selection for (or against) a certain allele tends to increase (or decrease) its frequency within a population. As a result, selection leaves signatures in sequencing data that can be used to infer the mode and strength of selection. Due to chromosomal linkage, selection also impacts the variation at nearby neutral sites. Leveraging this signature, one can substantially increase the power of inference methods. However, changes in population size can yield patterns in the data that mimic the effects of selection. Therefore, the demographic history of the population has to be explicitly accounted for, which is not standard practice in most inference frameworks.

Our framework is built on the two-locus Wright-Fisher diffusion that describes the haplotype frequency dynamics of two linked loci separated by a certain recombination distance. General explicit solutions are not known for the transition density of this diffusion when selection and recombination act simultaneously, as it requires solving a multidimensional system of partial differential equations. Thus, we use the so-called 'Method of Moments', in which the moments of the transition density are expressed as solutions to ordinary differential equations. These moments can subsequently be used to compute the likelihood of the observed genetic variation in a sample from the population. A key technical challenge in this method is that the moments do not 'close' in models with selection. Namely, moments of order  $n$  depend on those of order  $n+$ ,  $n+2$ , etc. We surmount this challenge by developing a novel method to estimate higher order moments from those of lower order, which can also be applied to the general problem of estimating allele frequency spectra for large samples from smaller samples.

Using these efficient approximations to the dynamics of the diffusion and two-locus likelihood computations, we develop a composite likelihood framework for estimating the strength of selection from full-genome sequencing data in a population with arbitrary population size history. We demonstrate the accuracy and efficiency of the proposed methods on simulated data and show applications to the 1000 genomes dataset.

## PgmNr 2395: Adaptive archaic introgression of copy number variants introduces novel genes in humans.

---

Copy number variants (CNVs), generated through deletions or duplications that affect large numbers of base pairs (bp) in the genome, are subject to stronger selective pressure than single-nucleotide variants (SNVs), but their roles in archaic introgression and adaptation have not been systematically investigated. In this study, we characterize Melanesian genomes and observe an enrichment of selective CNVs (n=37); of which 19 CNVs are likely introgressed from archaic hominins. We provide multiple lines of evidence for adaptive introgression of large CNVs at chromosomes 16p11.2 and 8p21.3 from Denisovan and Neanderthal, respectively, in Melanesians, and these variants are absent from most of other human populations. Using long-read sequencing data, we sequence resolve a large duplication of >383 thousand base pairs (kbp), which originated at chromosome 16p12.2, and show that the duplication was inserted at 16p11.2 and has a Denisovan ancestry. Our results show that this duplication is in high frequency (>79%) among Melanesian groups and has signatures of positive selection. At the locus 8p21.3, we identify a haplotype that carries two CNVs, a ~6 kbp deletion and a ~38 kbp duplication, with a Neanderthal origin in Melanesians and reaches to high frequency (44%) with signals of selection. We estimated the archaic haplotypes at the 16p11.2 and 8p21.3 loci introgressed into modern human gene pool 0.06-0.17 and 0.04-0.12 million years ago from Denisovan and Neanderthal, respectively. Using long-read sequencing genomic and transcriptomic data, we reconstruct the structure and complex evolutionary history for these polymorphisms and find novel protein-coding genes that have positively selected amino acid substitutions in both loci. Combined, our results suggest that large CNVs originating in archaic hominins and introgressed into modern humans have played an important role in local population adaptation and represent an under-ascertained source of large-scale genetic variation.

## PgmNr 2396: Mapping annual fine-scale genetic structure of Finland through the 20<sup>th</sup> century.

---

We illustrate the current possibilities for individual-level ancestry estimation by characterizing spatial and temporal changes in the genetic history of Finland in the 20<sup>th</sup> century.

Starting from 18,715 unrelated individuals from the National FINRISK Study, we identify a set of 1,600 reference samples who define 15 genetically homogeneous reference groups of the Finnish population. These samples are both geographically well-defined (parents born within 80 km) and strongly representative of their genetic group (ancestry component >0.5 in FineSTRUCTURE assignment). We estimate the genetic ancestry profiles of the remaining 17,115 samples with respect to the reference groups using SOURCEFINDv2.

We use the birth places (covering whole of mainland Finland) and birth years (ranging 1923-1987) of the 18,715 individuals to estimate how the contribution from each of the reference groups develops in time and across the country. As expected, more rural regions of Eastern Finland tend to be dominated by a single reference group while more urban regions of Southern Finland show diverse genetic profiles. While the individual genetic profiles on average diversify towards the present day, we observe regional differences in rate of change with the highest increase in diversity in southwestern Finland but no increase, for example, in Ostrobothnia.

We assess our estimates by monitoring how the genetic component of the ceded Karelia develops in time. Over 400,000 Karelians were relocated from the ceded areas (southeast of Finland) to other parts of Finland during and after the war 1939-1945. We detect this event as a quick change in yearly genetic profiles of other parts of Finland and can accurately assign this change to the particular component from the ceded Karelia as opposed to other reference groups from Eastern Finland. We also map the yearly patterns of further movements of the Karelian evacuees across the country. For example, we see that in Ostrobothnia the component of Karelian evacuees shrinks away already by 1950 whereas in Southwest Finland the component stabilizes to a constant level by that year.

To our knowledge, this is the first study where the annual contributions of genetic ancestry from closely related, neighboring subpopulations have been successfully separated from each other across a country. The work demonstrates the power of genetic ancestry estimation to reveal local population history and provides new avenues for individual-level ancestry estimation.

## PgmNr 2397: Fast estimation of effective migration surfaces.

---

Understanding the relationship between geography and genetic differentiation is a long-standing problem in population genetics. A widespread feature in population genetic data is 'isolation by distance,' where genetic differentiation tends to increase as populations become more geographically distant. While spatial models of 'isolation by distance' have provided powerful predictions of population structure, they do not capture heterogeneous migration that occurs when geographic features, such as a mountain range, can slow down or enhance gene-flow in localized regions. Recently, Petkova et al. 2016 developed an elegant statistical method called Estimating Effective Migration Surfaces (EEMS) for visualizing heterogeneous effective migration rates on a geographic map using a coalescent inspired model for gene-flow on a dense spatial graph. EEMS has been applied to many systems and has allowed for the discovery and interpretation of geographic features that might have restricted or enhanced gene-flow. Most importantly, EEMS is a flexible tool for users to visualize geographic structure in their data. EEMS uses Markov Chain Monte Carlo (MCMC) to obtain posterior samples of these migration rates, employing a spatial prior using a Voronoi tessellation of the focal geographic region, which favors piecewise constant structure in the migration process. Here we draw inspiration from EEMS by utilizing a similar graph-based likelihood, allowing for heterogeneous gene-flow, but take an optimization-based approach. We impose spatial structure in the migration rates, allowing for fast model exploration and iteration. We take advantage of recent developments in the generalized lasso literature to adaptively fit a piecewise polynomial function defined on a graph, without having to pre-specify change-point locations. Our method accurately recovers migration surfaces for within-model and coalescent-based simulations. Applications to Human population genetic datasets from around the globe perform comparably to EEMS but are fit orders of magnitude faster. We see our method as being a useful complementary tool alongside EEMS, expanding the ability for users to quickly visualize and interpret spatial structure in their data.

## PgmNr 2398: Implementation of personalized ancestry information in the Colorado Biobank.

**Authors:**

---

Knowledge of genetic ancestry is a critical component in modern genetic research, but is also of increasing interest among consumers and patients within health systems. With over 100,000 consented participants as of May 2019, the Colorado Biobank ([cobiobank.org](http://cobiobank.org)) is a clinical and research biorepository offering implementation and return of results to patients within the UCHHealth system. As an additional offering, we are implementing a genetic ancestry inference pipeline, with features relevant to both patients interested in ancestry testing and the broader research community. Here we present key features of the Colorado Biobank's Personalized Ancestry Information Resource (PAIR), including global ancestry, recent relatedness, archaic admixture, and Y-chromosome and mitochondrial haplogroup features, from the pilot data comprised of 3,967 participants typed on a custom Illumina MEGA array. We compare the distribution of participants' self-reported race and ethnicity in the context of well-characterized global reference panels, and highlight several key points to consider in returning ancestry results to biobank participants. Although most (77%) participants are of majority European descent, there are substantial proportions (2%-15%) of participants with Indigenous American, sub-Saharan African, East Asian, South Asian, Near Eastern and Oceanian ancestry. Our pipeline can efficiently identify closely related individuals including 16 first- and second-degree relatives. Recent shared ancestry via identity-by-descent estimation and UMAP dimensional reduction also identifies 2 clusters of cryptically-related participants sharing on average 23 cM, and comprising over 10% of our pilot dataset. Beyond analysis, PAIR will provide educational tools and walkthroughs to help educate the Colorado Biobank community. As the size of the Colorado Biobank grows, we anticipate this resource providing additional ancestry information relevant to researchers and participants alike.

## PgmNr 2399: Constructing recombination maps for populations with complex ancestry.

**Authors:**

G.E. Van Eeden; C. Uren; M. Möller

[View Session](#) [Add to Schedule](#)

**Affiliation:** DST-NRF Centre of Excellence for Biomedical Tuberculosis Research, South African Medical Research Council Centre for Tuberculosis Research, Division of Molecular Biology and Human Genetics, Faculty of Medicine and Health Sciences, Stellenbosch Univer

---

It has been shown that the majority of human genetic studies are not representative of the diversity that exists globally, since they are based on populations of European descent. The lack of inclusion of under represented ethnicities in human genetic studies also means that when these studies are translated into clinical practice, the resulting policy or protocol might be incomplete or even mistaken. Studies that investigate the genetic factors that affect disease often rely on a recombination map. There are no publicly available population specific recombination maps for southern African populations at the moment. Southern African populations have complex ancestry as a result of many migration events that have occurred over the last few centuries. Software used to develop population specific recombination maps are well-established, however, most software have either never been tested on populations with complex ancestry or have only been tested on, at most, a three-way admixed population. Any research on southern African populations with complex ancestry that require a recombination map would thus benefit from a protocol that directs the creation of population specific recombination maps using established software. However, if such a protocol cannot be established, a new approach to create high resolution population specific recombination maps for populations with complex ancestry needs to be developed. We are currently working on determining what adjustments can be made to pedigree and linkage disequilibrium based methods in order to accommodate multi-way admixed populations and comparing the results to publicly available recombination maps. The next step would be to determine whether these population specific maps yield better results than the available maps when used in an ancestry association study.

## PgmNr 2400: Study genetic ancestry and homozygosity disequilibrium in global populations.

**Authors:**

H.-C. Yang; C.-W. Chen; Y.-T. Lin; S.-K. Chu

[View Session](#) [Add to Schedule](#)

**Affiliation:** Institute of Statistical Science, Academia Sinica, Taipei, Taiwan

---

Studying genetic ancestry of global population has been long recognized as an important topic in population genetics, evolution, and pharmacogenomics. This study analyzed more than 77 million of single nucleotide variation in The 1000 Genomes Project – Final Phase, which provided the whole-genome sequencing data of 2,504 individuals in 26 global populations from four major continents (the Continent of Africa, Americas, Asia, and Europe). An ultrahigh-dimensional whole-genome principal component analysis and hierarchical clustering analysis demonstrated genetic similarity and differentiation of the 26 studied populations. In addition to an identification of ancestry informative markers and construction of prediction panels for global populations, a whole-genome homozygosity disequilibrium analysis revealed that the African-ancestry group carries a lower number and shorter regions of homozygosity disequilibrium. In contrast to the indigenous residents in Africa, the African-ancestry diaspora populations undergo a much more diverse genetic admixture. The American-ancestry group and populations exhibit the largest spread in the number and length of regions of homozygosity disequilibrium. The South Asian-ancestry group and populations exhibit a number of outlier individuals who carry much more regions of homozygosity disequilibrium. The East Asian-Ancestry group and populations carry the maximum number and widest regions of HD among the studied ancestry groups. This study developed an efficient algorithm for an ultrahigh-dimensional principal component analysis, identified ancestry informative loci/regions, constructed prediction panels for genetic ancestry, and mapped genes under homozygosity disequilibrium. The results reveal differential population structures, demographic history, and population evolution of the studied ancestry groups.

## PgmNr 2401: Genetic structure effects of ancestry-based and trait-based assortative mating.

---

The genetic structure of a population is determined by its mating patterns. This implies that the distribution of alleles and genotypes could be impacted by spouse correlations for genetic ancestry and traits. While trait-based assortative mating leads to both within-locus correlation and between-locus correlation for alleles associated with a trait, ancestry-based assortative mating leads to the same phenomena but this applies to all loci that exhibit differences in allele frequency between ancestral populations, whether they are associated with a trait or not. In this study, we evaluate spouse-pairs who are customers of AncestryDNA and have consented to participate in scientific research to assess the general impact of assortative mating on the genetic structure of a population, and also to compare the trait and genetic ancestry correlations. Phenotype data is obtained from survey responses collected from a subset of AncestryDNA customers and is used to calculate the spouse-pair trait correlations. The genetic ancestry correlations are calculated using principal components (PCs) scores obtained from the PC analysis of genome-wide data. We also explore the genetic effects of these two types of assortative matings by characterizing the genetic structure of the offspring. The results of these studies have particular impact on studies such as genome-wide association studies (GWAS), since ignoring genetic structure may lead to many false positive loci detected, and incorrect estimation of genetic relationships and heritability. These results also strongly highlight the need for careful design and interpretation of population-based genetic studies given the complex nature of structured mating.

## PgmNr 2402: The genetic structure and admixture history of Hui population.

---

With a population size of 10.5 million, Hui is the second largest of 55 minorities and the largest of the 10 official Muslim ethnic groups in China. However, the genetic study of Hui population has been underrepresented. In this study, we presented the first whole genome investigation by whole genome sequencing 234 individuals from 5 prefectures across Ningxia Hui Autonomous Region (NX), China. We comprehensively assessed the fine scale population structure and inferred the demographic history of Hui by leveraging newly developed powerful tools. Our results showed that there are four major ancestral components in Hui population derived from populations in East Asia (~82.8%), Siberia (~7.8%), West Eurasia (~7.0%), and South Asia (~2.4%). We observed a distinct South-North cline across Ningxia. From North to South, the East Asia ancestral component decreased from 87.0% to 78.5%, the West Eurasia and South Asia ancestral components increased from 5.8% to 9.6% and from 1.4% to 3.4%, respectively, while the Siberia ancestral component varied little among regional sub-populations. Hui could be modeled as an admixture of two already admixed ancestries: Eastern ancestry consisted of East Asia and Siberia ancestral components and West ancestry composed of West Eurasia, South Asia and Siberia ancestral components. Leveraging haplotype-based methods, NX Hui can be divided into two clusters: North and South. The Xinjiang (XJ) Hui showed closer relationship with South NX Hui than with North NX Hui, which could reflect recent migration into XJ. Further, we employed different methods to infer admixture history of Hui and two admixture events were detected. An ancient wave of admixture occurred about 40 generations (1,200 years) ago and a recent wave of admixture occurred nearly 20 generations (600 years) ago, which was largely consisted with historical records. This study is expected to help understand the genetic origin and admixture history of the Hui people, the spread of Islam in China and the gene flow among Eurasian populations.

## PgmNr 2403: The genetic structure of pastoralists in northern Kenya.

Genetic analyses across human populations in Africa have shed light onto the details of major population movements and migrations within Africa. However, the genetic history and how it relates to cultural practices among human populations in Africa on a more local geographic scale remain relatively unexplored. This project aims to understand the genetic relationships within and among four pastoral populations inhabiting northern Kenya - the Turkana, Borana, Samburu, and Rendille. The Turkana and Samburu speak eastern Nilotic languages that are part of the Nilo-Saharan language family, while the Rendille and Borana are Cushitic speakers, languages that are part of the Afro-Asiatic family. Today, these four populations reside among ethnic conspecifics, where ethnolinguistic territories are geographically adjacent to one another. Additionally, these populations practice patrilocal - a post marital residence system in which males stay and affiliate with their birth clan while the women move to their husband's clan after marriage. Marriages are exogamous at clan or moiety kinship levels, where individuals do not marry close relatives. Have these populations remained relatively isolated or is there evidence of migration among these groups? Also, does their genetic composition reflect their marital practices? To address these questions, we SNP genotyped 378 individuals across these four populations. For each population, we sampled individuals from at least 2 different clans. We performed principal components analysis, ADMIXTURE analysis, and  $F_{st}$  to visualize the genetic structure and differentiation among these groups and to identify any genetic relationships among these groups. Additionally, for each population, we performed sex-stratified clan based  $F_{st}$  across the autosomes and X chromosome to identify if genetic males have higher genetic differences among clans. Initial results suggest that, broadly, genetics mirrors geography, however preliminary analyses suggest shared genetic relationships among populations based on culture over geography. As Africa is the birthplace of modern humans, knowledge of the genetic composition and history of African populations can enrich our understanding of human evolution and inform studies of human health and disease.

## PgmNr 2404: Large-scale whole-genome sequencing of three diverse Asian populations in Singapore.

---

Underrepresentation of Asian genomes has hindered population and medical genetics research on Asians, leading to population disparities in precision medicine. By whole-genome sequencing of 4,810 Singaporeans with Chinese, Malay, and Indian ancestry, we found 98.3 million SNPs and small insertions/deletions, over half of which are novel. Population structure analysis demonstrated great

representation of Asian genetic diversity in Singapore and revealed a Malay-related novel ancestry component. Furthermore, demographic inference suggested that Malays split from Chinese ~24,800 years ago, and experienced significant admixture with mainland East Asians ~1,700 years ago, coinciding with the Austronesian expansion. Additionally, we identified 20 candidate loci for natural selection, among which 14 harbored robust associations with complex traits and diseases. Finally, we showed that our data can substantially improve genotype imputation in diverse Asian and Oceanian populations. These results highlight the value of our data as a resource to empower human genetics discovery across broad geographic regions.

## PgmNr 2405: Estimating the ages of rare variants using long-range identity-by-descent (IBD).

### Authors:

Large sequencing studies identify an abundance of rare variants, only a small proportion of which are functional. Identifying this functional subset enables designing powerful downstream analyses. As many functional variants are subject to selection, we aim to use the evidence for selection, namely their ages, to prioritize these variants.

To estimate a variant's age, we propose a Bayesian model to leverage the haplotype sharing pattern surrounding a variant in addition to the sample allele frequency. Intuitively, individuals sharing a recent mutation are also likely to share a large identity-by-descent (IBD) segment around that position. We model the length of this IBD segment conditional on the observed mutation as shaped by recent demographics, such as population expansion and structure. Our new method combines analytical and numerical solutions from coalescence theory to handle large sample size under any specified parameter settings of effective population size or history model used to infer the most recent demographics.

We use simulation to demonstrate that our new approach of jointly modeling IBD lengths, allele frequency and population history provides more accurate age estimates than previous methods, and that the tool we develop scales to samples with more than 100,000 individuals. Applying our method to the TOPMed data of >100,000 individuals to estimate the ages of all rare variants with sample allele counts below ten, we observe a two-fold enrichment of all protein-altering variants among the youngest 10% of doubletons, and a four-fold difference in the number of high impact (frameshift, stop/start lost/gain, etc.) variants when comparing the youngest to the oldest 10% doubletons. This indicates a clear signal that our age estimates serve as a functional annotation, provide new insights in interpreting GWAS findings and help grouping variants for association analysis.

## PgmNr 2406: Male control individuals show higher burden of rare coding SNVs across diverse ancestries.

### Authors:

M. Traglia; L. Weiss

**Affiliation:** Department of Psychiatry and Institute for Human Genetics, University of California, San Francisco, 401 Parnassus Ave, LangPorter, San Francisco, CA 94143, USA

A liability threshold model has been utilized to explain an excess of *rare* copy number variants (CNVs) and *de novo* single nucleotide variants (SNVs) in affected females compared to males observed for male-biased autism (ASD) [Jacquemont et al., 2014]. However, we surprisingly identified a significant excess of *rare* CNV mutational burden in female controls compared to male controls, particularly for deleterious CNVs [Desachy et al., 2015], later replicated independently across studies [Männik, et al., 2015; Han et al., 2016; Ruderfer et al., 2016]. We therefore hypothesized that the mutational burden of *rare* autosomal SNVs predicted to be damaging in humans, such as loss-of-function (LoF) , or missense mutations, may differ across male and female healthy carriers from diverse populations.

Assuming a random distribution of silent SNVs ( $MAF < 0.001$ ), we used 770 female-male pairs matched by synonymous SNV content and by subpopulation from 1000G phase3 data and we assessed the female and male autosomal burden of rare LoF and missense SNVs by population. We primarily observed excess burden of LoF (OR range 1.03-1.08) and missense SNVs (OR range 1.00-1.02) in male controls compared to female controls across populations. Meta-analysis of female and male burden of missense SNVs across populations confirmed significant male excess ( $OR_{Meta} = 1.01$ ;  $P < 0.008$ ). Although the LoF male excess is slightly greater ( $OR_{Meta} = 1.03$ ;  $P = 0.15$ ), it did not reach significance, likely due to the smaller number of variants or heterogeneity ( $I^2 = 45\%$ ;  $P_{het} = 0.12$ ). Conditioning for silent variant content allowed us to control for the possibility of subtle stratification and to assess population-specific rare mutation numbers across the genome. Indeed, we observed moderate correlation between LoF and silent SNV burden across sexes and populations ( $\rho = 0.29$ ;  $P < 0.01$ ).

This statistical approach will be applied to additional individual-data cohorts to further assess sexual dimorphism at human constrained loci and disease-associated loci, such as ASD. This project will help elucidate autosomal genetic sex differences, improve our understanding of sex as a biological variable, and enable more informed interpretation of rare SNVs in clinical testing.

## PgmNr 2407: Comparison study of lung function and high altitude adaptation of native Tibetan adults living at the different altitudes.

---

**Objective** The aim of the present study was to compare the difference of lung function between native healthy Tibetan adults living at 2,200 and 5,300 m and its possible associated factors, as well as its role in altitude adaptation. **Methods** Lung function tests were performed on 287 and 229 Tibetan residents living in Yigong at an altitude of 2,200 m and Pumajiangtang at an altitude of 5,300 m. Meanwhile, arterial oxygen saturation and hemoglobin concentration were also measured. Anthropometric measurements and physiological indicators were described as mean  $\pm$ SD. Independent sample t test was used for the comparison of mean between groups, the prevalence of polycythemia between groups was tested by Chi-square test, and multiple linear regression was applied to test the correlation between the outcome variable and groups. **Results** Mean value of height, weight, arterial oxygen saturation and diastolic pressure of Yigong males were higher than those of Pumajiangtang males whereas the hemoglobin concentration was lower than those of Pumajiangtang males ( $P < 0.05$ ). The mean value of height, weight, arterial oxygen saturation, heart rate and blood pressure of Yigong women were higher than those of Pumajiangtang women, whereas the mean values of chest circumference and hemoglobin concentration were lower than those of women in Pumajiangtang ( $P < 0.05$ ). The mean value of lung function indicators of Tibetans living at the lower altitude was significantly higher than that of the Tibetans living at the higher altitude ( $P < 0.05$ ). After adjusting for gender, age and height, there was no significant difference in lung function between the two groups. **Conclusion** The elevated hemoglobin concentration and decreased arterial oxygen saturation were detected among Tibetan adults living at the higher altitude although no difference of lung function was found between the two groups. This may indicate that lung function could no longer increase when altitude reaches the Tibetan's limitation of physiological regulation, although the enhancement of lung function is an important mechanism for Tibetans to adapt to high altitude. The mechanism of adaptation to high altitude among native Tibetan highlanders needs to be further studied.

## PgmNr 2408: Transcriptional response variation of monocytes to influenza virus infection: From population differences to the single-cell.

There is marked differences between individuals and populations in both the intensity of immune responses and susceptibility to infectious diseases. In characterizing the intra- and inter-population heterogeneity that exists in the transcriptional response of primary human monocytes following challenge with a live influenza A virus (IAV), we uncovered high inter-individual variability in RNA sequence reads of viral origin (1-13.5%). This suggests differences in the ability of IAV to enter and/or replicate among host cells. Interestingly, the average percent of IAV reads differs between African- (4.9%) and European-descent (6.8%) samples ( $p$ -value =  $1.9 \times 10^{-8}$ ), a finding that is replicated at the transcriptional (IAV mRNAs) and translational (IAV protein intensities) levels. Flow cytometry analysis suggests that in our experimental setting monocytes show varying degrees of susceptibility to infection after 6 hours of IAV challenge, and that the amount of viral mRNAs is driven by the percentage of cells that become infected. To explore whether the differences we observed in overall viral mRNA levels can be attributable to inter-individual differences in the proportions of specific monocytes sub-populations (i.e. do some individuals harbor more IAV-permissive cells), we have sequenced the transcriptomes of >100,000 individual monocytes following infection with IAV or no-virus (control) at five time points in 8 individuals who were previously found to present high or low viral mRNA levels following IAV challenge. Infected and non-infected cells are reliably distinguishable based on their transcriptomes. Within the infected condition, we find that resistant cells are characterized by increased expression of several antiviral genes, including those in type-1 interferon signaling and response to virus pathways (e.g., *IFITM3*, *APOBEC3*, *ISG20*, and *ISG15*). Using transcriptional regulatory networks inferred from single-cell profiles, we find that African- and European-descent individuals differ in terms of their activity of key antiviral transcription factors such as IRFs and STATs, these factors correlating negatively with viral mRNA levels. Collectively, these results highlight the extreme heterogeneity in response to infection observed at the cellular level, and suggest that inter-population variability in response to IAV infection is driven by differences in the proportion of cells that are able to rapidly trigger a protective response.

## PgmNr 2409: Analyzing the dynamics of short tandem repeats in large, multigenerational pedigrees.

### Authors:

---

Short tandem repeats (STRs) are tandemly repeated sequences of 1-6 bp motifs. These sequences compose only a small fraction of the genome, but length polymorphisms at specific loci have been linked to several human diseases including amyotrophic lateral sclerosis, Friedreich ataxia, Huntington disease, and Fragile X syndrome. The rapid mutation rate of STRs has made them valuable for several biological applications. Improving our understanding of these length changes would increase our knowledge of the mutational dynamics of the genome and uncover additional loci that may have a role in causing disease. Here, to better estimate the genome-wide patterns of length polymorphisms at STR loci, we utilize blood-derived whole-genome sequencing data from the three-generation CEPH pedigrees, consisting of 33 families and 603 individuals. These pedigrees contain both sets of grandparents (generation 1), the parents (generation 2), and an average of 9 grandchildren (generation 3) per family. We use existing STR analysis software (HipSTR) to identify STR lengths in each generation. The lengths are compared between parents and their offspring, and *de novo* STR mutations are identified. To test for accuracy, *de novo* STR mutations identified in the 2<sup>nd</sup> generation were examined in the 3<sup>rd</sup> generation to ensure their transmission. Analyzing 1.6 million STR loci in these pedigrees, we have established an average *de novo* STR mutation rate as  $1.9 \times 10^{-4}$  mutations per locus per generation. Furthermore, we have found that this mutation rate varies with motif length, ranging from about  $3.2 \times 10^{-4}$  for monomeric repeats to  $2.1 \times 10^{-5}$  mutations per locus per generation for hexameric repeats. Phasing our *de novo* insertions back to the parent of origin, where possible, has improved our understanding of the inheritance patterns of STR loci. Additionally, the three-generation structure of the CEPH pedigrees allows for the differentiation of germline inheritance from mosaicism. Finally, for each family we examined the correlation between the number of *de novo* STR length changes and parental age at the time of birth. The large CEPH pedigrees have afforded us an opportunity to better understand the dynamics of STR length changes through multiple generations.

## PgmNr 2410: Human-specific tandem repeat expansion and differential gene expression during primate evolution.

---

Short and variable number of tandem repeats (STRs and VNTRs) are an important source of natural and disease-causing variation, but they have been problematic to resolve in reference genomes and genotype with short-read technology. We created a framework to model the evolution and instability of STRs and VNTRs in the ape lineage. We phased and assembled three nonhuman primate ape genomes (chimpanzee, gorilla, and orangutan) using long-read and 10X phasing data for 21,442 human tandem repeats discovered in six long-read haplotype-resolved assemblies of Yoruban, Chinese and Puerto Rican origin. The repeats are nonrandomly distributed with VNTRs more likely (OR = 1.39, p-value < 10<sup>-5</sup>) to overlap with genes than STRs even after controlling for subtelomeric distribution differences. We define a set of 1,584 STRs/VNTRs expanded specifically in the human lineage, including large tandem repeats such as a 6 kbp 30-meric repeat in the intron of *CACNA1C*, or protein-coding tandem repeats such as a 22 kbp protein-coding VNTR in mucin gene *MUC3A* and numerous disease-associated STRs. We systematically reconstruct sequence compositional changes for the largest expansions revealing that longer tracts of uninterrupted repeat purity associate with larger and more unstable alleles. We find that SVA retrotransposition is the main mechanism for distributing GC-rich human-specific tandem repeats expansions throughout the genome but with a bias against genes (OR = 0.57[0.38-0.85], p-value = 0.006). In contrast, we observe that VNTRs not originating from retrotransposons have a propensity to cluster near genes especially located in the subtelomeric region of chromosomes. Using single-cell expression from cerebral organoids, we identify a subset of genes where isoform usage differs significantly in humans when compared to chimpanzee cerebral organoids likely caused by cryptic splicing variation located within the human-expanded intronic VNTR. We also observe a significant overrepresentation of subtelomeric STRs/VNTRs in genes upregulated in human when compared to the chimpanzee. Interestingly, the strongest effect was observed for genes associated with transcription profiles analogous to intermediate progenitor cells (OR = 2.21 [1.59 - 3.08], p-value = 2.49×10<sup>-6</sup>). In addition to providing a valuable resource for future evolutionary studies, this resource will be useful for the identification of unstable alleles associated with human genetic disease.

## **PgmNr 2411: Intratumoral t(2;13) translocation-positive heterogeneity in pediatric alveolar rhabdomyosarcoma (ARMS) tumors correlates to patient survival prognosis.**

### **Authors:**

A. Hollenbach <sup>1</sup>; K. Gleditsch <sup>1,2</sup>; J. Peñas <sup>1</sup>; D. Mercer <sup>1</sup>; A. Umrigar <sup>1</sup>; M. Stark <sup>3</sup>; F. Tsien <sup>1</sup>

---

Alveolar rhabdomyosarcoma (ARMS) is generally characterized by one of three translocation states: the presence of t(2;13)(p35;p14) leading to the production of the PAX3-FOXO1 fusion protein, the presence of t(1;13)(p35;q14) leading to the production of the PAX7-FOXO1 fusion protein, or a translocation-negative status. The presence of the t(2;13) is associated with greater disease severity and mortality than patients who are t(2;13) translocation negative or t(1;13) positive. To date, no clinical diagnostic assay can simultaneously differentiate between these three translocation states. The specific aim of this study is to investigate the disease severity and survival outcomes of tumor specimens obtained from ARMS patients with respect to translocation status using fluorescence *in situ* hybridization (FISH). We have designed and validated FISH probes in our laboratory that can simultaneously and distinctively identify t(2;13) and t(1;13) translocations. Our data indicates that heterogeneity of the (2;13) translocation is correlated to severity of the individual patients, in which samples with more than one t(2;13) per cell (aneuploidy) and greater amounts of t(2;13) positive cells correlate with a poorer prognosis with respect to failure-free survival. These results thereby provide a new clinical assay to differentiate between three translocation types and improve diagnostic and prognostic indicators for these tumors.

## PgmNr 2412: Optimized early cancer detection from whole genome sequencing of cell-free DNA.

### Authors:

C. Melton; P. Freese; S. Bagaria; E. Hubbell; D. Filippova; R. Calef; M.C. Maher; V. Nicula; S. Gross; O. Venn; A. Valouev; A. Aravanis; A. Jamshidi

Cancer can be detected through whole genome sequencing (WGS) of cell-free DNA (cfDNA). The most commonly derived set of features from WGS data, fragment counts in bins tiled across the genome, enable detection of somatic copy number alterations (CNAs); however, other features can be leveraged to classify cancer status. In the first substudy of Circulating Cell-free Genome Atlas (CCGA; NCT02889978) we evaluated three prototype assays for discriminating cancer vs non-cancer; we determined that fragment methylation-based features from whole genome bisulfite sequencing had the best sensitivity (at high specificity), followed by small variants detected from targeted sequencing and somatic CNAs from WGS read depth. An exploratory post hoc analysis of the first substudy evaluated the impact of alternative features derived from WGS data on classification performance. We assessed the utility of counting fragments originating at cancer-enriched fragment endpoint positions and explored alternative means of detecting CNAs by observing (a) allelic imbalance at heterozygous SNPs and (b) changes in fragment length distributions in tiled bins. Optimization of features and learning algorithms were performed in 10-fold cross-validation on a training set (561 controls, 863 cancer participants [pts], 20 solid tumor types) and final assessment performed on an independent test set (362 controls, 464 cancer pts, 20 solid tumor types). At 98% specificity, fragment endpoints had 18.1% (95% CI, 14.7-21.9) sensitivity vs 34.1% (29.7-38.6) sensitivity for methylation and 29.3% (25.2-33.7) for binned counts. 29.1% sensitivity (25.0-33.5) for fragment lengths and 21.8% (18.1-25.8) for allelic imbalance was also observed. All classifiers showed strong stage and tumor fraction dependence. An ensemble WGS classifier combining endpoints, allelic ratios, fragment lengths, and binned counts outperformed binned counts alone (+2.2% sensitivity,  $p=0.044$ ) but had lower sensitivity than the methylation-based classifier (-2.6% sensitivity,  $p=0.045$ ). WGS and methylation features combined failed to improve upon the methylation classifier alone (-0.6% sensitivity,  $p=0.546$ ). Overall, combining WGS features improved sensitivity at high specificity in the absence of methylation features but was inferior to methylation-based classification; these results, in part, motivated development of an improved methylation assay assessed in the second substudy of CCGA.<sup>1</sup>

---

### Background

Loss of Y chromosome (LOY) is a well known established phenomenon associated with cancers and ageing. Recently, LOY in peripheral blood cells was suggested as a possible biomarker for different cancers in males

### Aims and objectives:

On the basis of previous findings, the present case-control study was conducted to evaluate the association of LOY in peripheral blood cells in prostate (PC) and colorectal cancers (CRC) in males.

### Methodology:

30 CRC patients (mean age =  $44.03 \pm 10.8$ ), 36 PC patients (mean age =  $60.8 \pm 15.8$  yrs) and 36 healthy control male cases (mean age =  $54.6 \pm 15.1$  years) were recruited. DNA was extracted using a standard phenol-chloroform method. Multiplex quantitative fluorescent (QF) PCR was used to co-amplify the homologous sequences present on the Y chromosome and other chromosome followed by their analysis on the genetic analyzer (ABI 3500) and finally the Y/X ratio was calculated on the basis of the peak height obtained from the electropherogram.

### Results:

The mean Y/X ratio was significantly lower in the whole group of cancer patients ( $0.709 \pm 0.02$ ;  $p < 0.0001$ ) when compared to the controls ( $0.92 \pm 0.044$ ). Also, the Y/X ratio when calculated separately was found to be lower in CRC ( $0.701 \pm 0.078$ ;  $p < 0.0001$ ) and PC ( $0.717 \pm 0.044$ ;  $p < 0.0001$ ) cases, when compared to controls ( $0.92 \pm 0.044$ ). Multivariate logistic regression was performed by matching cancer and control subjects with age and the results suggest that LOY is not influenced by their age.

### Conclusion

The results support the significant association of LOY in peripheral blood cells carcinogenesis in males. LOY can also serve as a non-invasive cancer biomarker to improve the early diagnosis and management of cancer patients in males

## PgmNr 2414: Urinary *TERT* promoter mutations as non-invasive biomarkers for the comprehensive detection of urothelial cancer.

**Background:** Recurrent mutations in the promoter of the telomerase reverse transcriptase (*TERT*) gene (C228T and C250T) detected in tumours and cells shed into urine of urothelial cancer (UC) patients are putative biomarkers for UC detection and monitoring. However, the possibility of detecting these mutations in cell-free circulating DNA (cfDNA) in blood and urine, or DNA from urinary exfoliated cells (cellDNA) with a single-gene sensitive assay has never been tested in a case-control setting.

**Methods:** We developed a single-plex assay (UroMuTERT) for the detection of low-abundance *TERT* promoter mutations. We tested 93 primary and recurrent UC cases and 94 controls recruited in France (blood, urine samples and tumours for the cases), and 50 primary UC cases and 50 controls recruited in Portugal (urinary exfoliated cell samples). We compared our assay with urine cytology.

**Results:** In the French series, C228T or C250T were detected in urinary cfDNA or cellDNA in 81 cases (87.1%; 95% CI 78.6–93.2), and five controls (Specificity 94.7%; 95% CI 88.0–98.3), with 98.6% (95% CI 92.5–99.96) concordance in matched tumours. Detection rate in plasma cfDNA among cases was 7.1%. The UroMuTERT sensitivity was (i) highest for urinary cfDNA and cellDNA combined, (ii) consistent across primary and recurrent cases, tumour stages and grades, (iii) higher for low-risk non-muscle invasive UC (86.1%) than urine cytology (23.0%) ( $P < 0.0001$ ) and (iv) 93.9% when combined with cytology. In the Portuguese series – the sensitivity and specificity for detection of UC with urinary cellDNA was 68.0% (95% CI 53.3–80.5) and 98.0% (95% CI 89.3–100.0).

**Conclusion:** *TERT* promoter mutations detected by the UroMuTERT assay in urinary DNA (cfDNA or cellDNA) show excellent sensitivity and specificity for the detection of UC, significantly outperforming that of urine cytology notably for detection of low-grade early stages UC.

## PgmNr 2415: Distinctive expression of specific microRNAs in breast cancer patients and change during chemotherapy.

### Authors:

---

Breast cancer is the second most common cause of death from cancer in women. There is now increased prevalence of breast cancer among African women. In Ethiopia it is the leading cancer type constituting 33% of all cancer cases in women.

Tests and procedures for diagnosis and prognosis of breast cancer are still limited to invasive procedures and imaging techniques. Based on their differential expression in disease and with their exceptional stability in biological fluids, microRNAs are noticeable candidates to be used as non-invasive diagnostic and prognostic biomarker. The association of change in expression level of microRNAs with clinicopathological parameters may demonstrate their potential in sorting the heterogeneous disease to specific subgroups for effective treatment options.

The purpose of this study was to investigate the differential expression of specific circulatory microRNAs in breast cancer patients and study their association with clinicopathological parameters with samples from healthy volunteers serving as control. Changes in the level of microRNA after completing chemotherapy was also assessed and checked for association with serum CA 15-3 values to see the prognostic potential of specific microRNAs.

The levels of specific circulatory microRNAs in patient and control samples were analyzed using qRT-PCR. Serum CA 15-3 values from patient samples collected after completion of chemotherapy were measured using solid phase enzyme linked immunosorbent assay.

In this study miRNA 21-5p was significantly over expressed in the serum of breast cancer patients when compared with controls ( $P < 0.05$ ). Receiver operating characteristic curve analysis shows its potential in differentiating breast cancer patients from controls with AUC value of 0.6 ( $P < 0.05$ ). A significant decrease in serum miR-326 was observed after chemotherapy ( $P < 0.05$ ) as compared to serum samples collected before chemotherapy. No correlations was found between serum CA 15-3 values and levels of circulatory microRNAs. Mean serum CA 15-3 value of patients with stage IV breast cancer was found to be high when compared with patients with other stages ( $P < 0.001$ ). Since deregulated miRNAs in the circulation are shared by several cancer types and subtypes, further studies are necessary to identify a well characterized cluster of miRNAs with discriminative ability.

## PgmNr 2416: Performance of a novel GeneReader NGS System through hotspot panels: An analysis across specimen type and tumor type over 2000 patients.

Novel NGS systems for somatic mutation identification need to be evaluated by assessing ease of use, reproducibility, implementation and validation in clinical samples. To gain insight into the issues, we investigated the performance of GeneReader via the reasons for and frequency of repeats in hotspot multigene panel tests for genomic DNA derived from formalin fixed paraffin embedded (FFPE) tissue and liquid biopsy (LB) across various cancer types of more than 2000 patients.

Total of 2044 patients were next generation sequenced which was modified, optimized and validated in our center and repeat rates were analyzed. The two hotspot panels; Qiagen ATP including *ALK, KIT, BRAF, NRAS, KRAS, EGFR, ERBB2, ERBB3, PDGFRA, RAF1, PIK3CA, ESR1* genes and 19 gene panel including *AKT1, DDR2, MAP2K1, NTRK1, PTEN, ROS1, RICTOR, FGFR1, MET* genes in addition to ATP were used. Samples with low amount of extracted DNA were not triaged. Samples run for validation purposes were excluded from the analysis. The numbers of repeated specimens were compared across specimen, cancer and test types. Quality controls and data processing were performed via QCI-Analyze and QCI-Interpret by an experienced user.

Among 2044 samples, 1051 (51.5%) of them were FFPE tissue samples and 993 (48.5%) were LB. 50.6% of all samples were sequenced with ATP panel while 1009 (49.4%) samples were with 19 gene panel. Of all the samples that were analyzed, 152 were repeated (7.5%). The repeat rates were 6.1% for LB and 8.8% for FFPE. The distribution of specimen types among test panels and repeat rates were: a) 27.9% of FFPE samples were sequenced with 19 gene panel with 11.3% repeat rate, b) 72.1% of FFPE tissue were sequenced with ATP panel and 7.8% was re-sequenced, c) 72.1% of LB samples were sequenced with 19 gene panel with 6% repeat rate and d) 27.9% of LB were sequenced with ATP panel and 6.5% was re-sequenced.

The focus of this study was to assess the suitability of GeneReader NGS System for routine use. Thus, we documented an overall 7.5% test repeat rate which showed as low as 6.1% for LB while there are no significant differences in repeat rate across cancer and test panel types. As a conclusion, while the repeat rates suggest room for improvement, more than 90% sequencing success rate with an easy-to-operate system is deemed acceptable. Investigation of other variables in starting DNA quality and sequencing library preparation chemistry may facilitate further improvements of repeat rate.

## PgmNr 2417: Sole trisomy 6 in childhood acute myeloblastic leukemia, uncommon finding associated to bad prognosis.

Sole trisomy is a frequent cytogenetic aberration in malignant neoplasms, but rare in acute myeloblastic leukemia, mainly chromosome 8 trisomy, followed by chromosomes 4, 9, 11, 13 and 21. Here, we report a 14-year-old male patient, product from the third pregnancy, dizygotic, obtained by abdominal delivery, Weight: 3350gr. Stature 52cm is admitted for an 8 day evolution with cervical lymphadenopathy, along with intermittent fever, polydipsia, emesis and hyporexia. He started chemotherapy, receiving Cytarabine (100mg/m<sup>2</sup>/dose q12h), Daunorubicin (50mg/m<sup>2</sup>/dose q48h) and Etoposide (100mg/m<sup>2</sup>/dose q24h). At day 2, an increase in the leukocyte count is reported: 500,000 /  $\mu$ L with a monocytes predominance of 75%; leukophoresis is indicated and induction is initiated with Cytarabine. He died on day 3, with hyperleukocytosis of 728,000  $\mu$  / L, acute renal failure and pulmonary leukostasis. The bone marrow aspirate showed hypercellularity, red and megakaryocytic series absent, increased white series with a predominance of monocytic series and myeloblasts; Immunophenotype reported a myeloblastic population of 72% % expressing CD13 +, CD33 +, HLA-DR +, CD38 +, CD117 +, and a second monocytic population in 20% expressing CD14 +, CD33 +, CD36 +, CD64 +, CD38 and CD45 +. All of the above were compatible with myelomonocytic AML M4 by FAB. Bone marrow aspirate was: 47,XX,+6[12]/46,XX[3]; By FISH: nuc ish(D6Z1)x3[143]/(D6Z1)x2[57], and the absence of 16q22 chromosome rearrangements. qPCR: negative for inv16(p13.1q22). The FLT3/ITD mutation was positive. Nested multiplex RT-PCR (HemaVision®- HV01-28 N, DNA Technology A/S) to the search of 28 common AML and ALL fusion transcripts was negative. To search the prognosis, we performed an OS analysis of 29 previously cases reported with trisomy 6. Our statistical evaluation using all the available OS previously reported values from the literature of AML patients with sole trisomy 6 against a comparative group of patients from our hospital with different types of AML but normal karyotype, supports the hypothesis that trisomy 6 in AML could be related to bad prognosis in patients with this unusual cytogenetic finding.

## PgmNr 2419: Detection of fusion genes for minimal residual disease in acute leukemia using next-generation sequencing.

### Authors:

Acute leukemia can be caused by chromosomal rearrangements and a considerable number of different fusion genes have been identified. The type of fusion gene determines the type of leukemia and treatment choices. Measuring minimal residual disease (MRD), defined as persistence of leukemic cells after treatment, is important to monitor disease recurrence and is currently performed using flow cytometry and digital droplet PCR (ddPCR). Next generation sequencing (NGS) may have advantages, like the possibility of multiplexing different fusion genes and patients in one experiment, but has scarcely been investigated.

We developed an NGS method to detect low levels of plasmid DNA against a background of genomic DNA [1]. Here, we tested if an RNA-based version of this method has the required sensitivity (i.e. 0.001% cells [2]) to detect fusion transcripts for MRD.

We designed a multiplex assay targeting 13 fusion genes containing: a) labeled probes targeting the breakpoints of each fusion gene; b) non-labeled probes blocking wild-type transcripts and c) labeled probes fully tiling housekeeping genes for quantification.

RNA from 12 bone marrow patient samples and two cell lines were diluted in different percentages using wild-type control blood RNA. The RNA dilutions were rRNA and globin mRNA depleted and converted to cDNA. Sequence-adaptors containing unique molecular identifiers were added to the cDNA fragments. After capturing, libraries were sequenced on an Illumina MiSeq. Unique reads were directly aligned to fusion gene-specific reference transcripts.

First results show a sensitivity of at least 0.1% RNA copies. In further experiments, the sensitivity will be further improved by increasing the amount of input material resulting in more unique reads per sample. Currently, ddPCR is performed on the same samples for comparison of the sensitivity and to convert % RNA copies to % cells.
