Brain metastases (BM) occur in 25-50% of patients with cancer. Approximately 200,000 new cases of brain metastases are diagnosed in the United States each year, with median survival after diagnosis ranging from 3-27 months. Studies have identified clinically actionable mutations in BM that are distinct from those in the primary tumor samples such as *PTEN* nonsense and *PBRM1* frameshift mutation. Additional profiling and genomic analyses will provide deeper understanding of the pathogenesis of BM and suggest new therapeutic approaches. We collected a total of 166 tumor samples from 49 patients with four different cancer types: renal cell carcinoma (n=35), breast cancer (n=51), lung cancer (n=45), and melanoma (n=35). By studying 4 different tumor types, we aim to identify genomic features of brain metastasis that are not specific to tumor type. The samples included matched BM and primary tumors from 38 patients and matched BM and extracranial metastases (ECM) from 11 patients. We performed whole-exome sequencing at 200x depth and subsequent analyses to call somatic point mutations. Our initial analysis was based on functional somatic mutations. To determine whether somatic cancer-associated mutations we identified had been previously studied and functionally validated, we compared our calls with the Database of Curated Mutations, which includes highly curated lists of disease-causing mutations. We detected 32 curated cancer-gene mutations (13 unique genes) in the cohort and found that 23 of them (71%) were shared between BM and primary tumors or BM and ECM. This suggests that BM and primary tumors may have been derived from a common ancestral clone. Among the 9 non-shared mutations, 8 were from BM-primary tumor pairs, and 1 was from a BM-ECM pair, implying that BM could accumulate additional cancer gene mutations that are not present in both primary tumors and ECM. We examined the genes that were found mutated only in BM in at least 3 patients. We uncovered mutations in 4 genes that were not previously associated with metastasis: *GABRE*, *RUNX1*, *SCML2*, and *SPEG*. *RUNX1* mutations were recurrent in breast cancer patients, and mutations in *SCML2* were detected in a majority of the tumor histology. This study aims to confirm the landscape of BM-specific mutations in tumors from diverse sites. We will perform further analyses of indels and clonal relationships for better understanding of BM-specific sub-clones and their metastatic outgrowth in the brain.

## PgmNr 1048: Roles of genome-wide biased-allelic-expression (BAE) effect in tumor development from the perspective of liver hepatocellular carcinoma (LIHC).

---

The majority of germ-line or somatically derived mutations stay in heterozygous status among patients. Besides, according to genome wide association studies (GWAS), disease associated single nucleotide polymorphisms (SNPs) are mostly located in non-coding regions. Those SNPs are suspected of regulating pathogenic gene expression in quantitative trait loci (eQTL) by changing the transcription factors binding sites or by altering CTCF binding motifs. Either in cis- or trans- regulating ways, above mentioned SNPs are supposed to cause abnormal biased-allelic-expression (BAE) effect, where BAE means the transcriptional levels between two alleles of a gene are different.

Therefore, I presume that if the BAE effect is inclined to express the pathological allele higher, it may be associated with exacerbating disease status. Particularly for the unstable genomes such as cancer cells, where BAE prevails in genome-wide. And the emergence of BAE effects in some genes can play critical roles in oncogenesis.

I have integrated high-throughput sequencing data from The Cancer Genome Atlas (TCGA) and Genotype-Tissue Expression (GTEx) projects. Above two databases enable us to compare each liver hepatocellular carcinoma (LIHC) tissue to its corresponding paired normal-like tissue (from cancer patients), and also to those control-normal tissues (from non-cancer individuals).

Firstly, differential expression analysis implies that the transcriptional changes of tumor tissues might be caused from genomic disturbs, which let new dividing cells abort expressing tissue specific genes, and stochastically increase expressing other unrelated genes.

Secondly, tumors exist higher genome-wide BAE effects, and most BAE genes are not directly caused by their allelically unbalanced copy number variations (CNV) in DNA level but by the irregularity in their transcriptional level. And those BAE occurring rates locating in non-CNV regions display positive association with the total somatic CNV length of cell, which implies BAE effect associates with the instability of chromatin.

Thirdly, there are few commonly shared BAE genes inside each sample group, which implies most BAE effects initially fall on genes stochastically without specific targets through genome-wide distribution. Finally, I demonstrated that BAE genes present special distribution patterns in tumor tissues, which might be associated to the evolutionary process of pro-tumor cells inside body.

## PgmNr 1049: Analysis of whole exome sequencing data of hereditary lung cancer families identifies germline Copy Number Variations (CNVs) in multiple genes.

---

About 10% of lung cancer (LC) cases (22,000 cases per year) in the U.S. have at least one first-degree relative affected with LC, and about 1% of cases have at least three first- or second-degree affected relatives. To identify susceptibility gene(s) for hereditary lung cancer (HLC) in families ( $\geq 3$  LC/family) collected by the Genetic Epidemiology of Lung Cancer Consortium, we conducted whole exome sequencing (WES) on eight highly aggregated families ( $\geq 4$  LC cases/family). These families included samples from sixty-five individuals, twenty of whom were affected and forty-five were unaffected at the time of data collection. We used two CNV-specific algorithms as incorporated in CANOES (<http://www.columbia.edu/~ys2411/canoes/>) and XHMM (<https://atgu.mgh.harvard.edu/xhmm/>) to identify germline copy number variations (CNVs). To confirm, CNVs were then visualized independently using Integrative Genomics Viewer (IGV).

We identified CNVs in more than 25 genes that are deleted or duplicated in two or more individuals in two or more families. Furthermore, both CNV-specific algorithms identified four cancer related genes: *GSTM1* (1p13.3), *RHD* (1p36.11), *CFHR3* (1q31.3), and *CFHR1* (1q31.3) in more than five families in two or more affected individuals/family. Reports from other studies show CNVs in those genes in somatic LC samples. Previously, no germline specific CNVs have been reported in those genes in HLC families. Comparison with the available public database (Database of Genomic Variants or DGV) also demonstrate that these alterations are rare and are not common polymorphisms found within the general population. The results from the other available database on somatic mutations (The Cancer Genome Atlas (TCGA) and Catalogue of Somatic Mutations in Cancer (COSMIC)) verify that these alterations are found in a small number of lung cancer tumor samples. The CNVs identified in our study are found to be common within these high-risk families, which are overall a small portion of the population. This observation calls for more in-depth analysis to take place on the next generation sequencing data that might be useful for the development of HLC-specific biomarkers in the future.

## **PgmNr 1050: A flexible, high-throughput software pipeline for identifying candidate variants and their effects on protein structure, starting from NGS data or VCF files.**

Advances in DNA sequencing have made identifying genetic variation from any individual routine, allowing researchers to analyze variation across populations or cohorts for candidate mutations causing diseases or traits of interest. To address the significant bioinformatic, data management and computing resource challenges inherent to this analysis, we have developed an integrated software solution for each step in the pipeline.

First, variant call profiles for each sample are either determined directly from raw NGS sequencing data or extracted from existing VCF files. For NGS data processing, reads from each sample are aligned to a reference genome using a fast, non-memory bound assembler. Gapped alignments are analyzed in-stream using a Bayesian modeled probabilistic variant caller to produce annotated single nucleotide variant (SNV) and small indel calls. To leverage existing variant information in VCF format, we have also developed a VCF annotation tool which maps the variants onto a corresponding annotated reference sequence and “decorates” each variant with information such as the affected gene(s) and impact on protein encoding regions and/or splice sites.

Next, annotated variant profiles from each sample, supplemented with their allele frequencies as well as predictions about functional impact and pathogenicity, are automatically combined into a single project for analysis. Various filtering and statistical methods then enable candidate genes and/or variants of interest to be readily identified. Further, for genes with known 3D protein structures, the effect of candidate missense mutations on the structure can be automatically predicted and analyzed using our molecular structure visualization module.

As a demonstration of the pipeline, we will present results from our reanalysis of 96 targeted resequencing samples from a Chinese cohort with lung squamous cell carcinomas (LSCC, Li et al., Sci Rep. 2015. 5:14237). We will show how the software can be used to easily identify unique mutations in numerous samples across the cohort which all lead to nonsense and frameshift mutations in the *TP53* tumor suppressor gene. We will also show how filtering on the functional impact and pathogenicity predictions can be used to identify likely deleterious *TP53* missense mutations in other members of the cohort and how in one of those cases, the predicted protein structure change indicates that the DNA binding activity of the protein is likely directly affected.

## PgmNr 1051: The benign variants in the COSMIC cancer gene census confound somatic mutation interpretation.

**Background:** The presence of benign variants or passenger mutations in driver genes from public databases is one of the well-documented limitations when reporting clinical actionability of somatic mutations. However, our understanding on classification and interpretation of somatic mutations is far from being perfect. The aim of this study is to investigate the frequency of benign variants from the Catalogue of Somatic Mutations in Cancer (COSMIC) Cancer Gene Census (CGC) and the interpretation concordance of OncoKb variants in depth.

**Methods:** We used a total of 339,425 somatic mutations in CGC genes registered in the COSMIC. Multiple databases including CIViC and Gene Drug Knowledge database and *in silico* tools were used to interpretate the clinical actionability of the mutations. All mutations were reanalyzed by a four-tiered system based on the consensus recommendation of the Association for Molecular Pathology (AMP), American Society of Clinical Oncology, and College of American Pathologists, and compared to OncoKb classification.

**Results:** The frequency of benign or likely variants, which were categorized as Tier IV variants according to AMP guideline, in the COSMIC CGC was 1% (4,200/339,425) of the mutations. Although 75% (3,129/4,200) of the Tier IV variants were flagged as polymorphism, while there was no warning sign in remaining 25% of benign variants. In addition, 70% (2,952/4,200) of the Tier IV variants were recurrently observed in at least two samples. Overall concordance of actionable mutations between AMP classification (Tier I or Tier II) and OncoKb (Oncogenic or likely oncogenic) were 88% (3,118/3,565) of variants studied.

**Conclusions:** Interpretation and reporting of somatic mutations in cancer databases need to use with caution. We found that significant number of somatic mutations registered in COSMIC CGC may not be clinically-actionable mutations. In addition, we revealed that there was some disagreements in interpretation of oncogenic role and actionability of somatic variation according to the databases and classification criteria. This study highlights the importance of the reinterpretation of the reported mutations and could be a good starting point for in-depth review of somatic mutation information essential for precision oncology.

## PgmNr 1052: A denoising sparse autoencoder to decipher mutational signatures (DeepMS) in human cancers.

Most cancers are originated from somatic mutations on genome. Somatic mutations are often associated with mutational processes that generate characteristic mutational signature. However, systematic understanding of the mutational processes is still far from enough. Previous studies have applied Non-negative Matrix Factorization (NMF) or related methods to decompose mutational signatures using large-scale somatic mutation data from next-generation sequencing. In this study, we developed a deep learning approach to systematically search for mutational signatures using the most recent somatic data curated by the Pan-Cancer Analysis of Whole Genomes Project (PCAWG). We focused on a total of 52,671,908 somatic mutations from 2780 whole cancer genome of 37 most common cancer types. We proposed a deep generative model, called Denoising Sparse Auto Encoder Neural Network (DSAENN), and identified 54 single base substitution (SNV), 11 doublet base substitution (DBS) and 16 small insertion and deletion (InDel) mutational signatures. We further developed a regression model to estimate the association of each signature with previously known mutagenesis process. As a result, we found that 37/54 SNV, 5/11 DBS and 9/16 InDel signatures of our findings are newly reported. Estimation of the explained variance of each mutational signature to each cancer type revealed cancer type specific signatures (such as tobacco smoking in squamous-cell lung carcinoma and solar ultraviolet exposure in melanoma) as well as general signatures (such as DNA repair deficient related process by POLE or APOBEC). These analyses provide an important supplementary resource to the repertoire of mutational processes.

## PgmNr 1053: Associations between cancer and non-cancer-related Mendelian disease genes and specific cancer types in TCGA.

### Authors:

B. Salisbury; S.M. Bray; B.G. Parikh; M.A. Schroering; T.D. Barber; S.S. Wong

[View Session](#) [Add to Schedule](#)

**Affiliation:** LifeOmic, Indianapolis, IN

---

**Background:** We hypothesized that genes and variants established to be involved in Mendelian diseases outside of cancer might also be predisposing for certain cancer types.

**Methods:** The germline genomes of over 10,000 cancer cases in The Cancer Genome Atlas (TCGA) from whole exomes sequencing were loaded on LifeOmic's Precision Health Cloud platform and annotated using the Gnosis knowledge system. We examined the distribution of all variants in ClinVar for enrichment in the 32 cancer types. For control comparison, we conducted the same analysis for 152 cancer-predisposing genes. Enrichment was assessed in comparison with the gnomAD-exomes database of reference population frequencies.

**Results:** Consistent with expectations, ClinVar "pathogenic" and "likely pathogenic" variants in known and suspected cancer-predisposition genes were significantly more common in cancer patients than in the gnomAD-exomes population pool, whereas "benign" and "likely benign" variants were not enriched. This enrichment included striking cancer-type specific patterns in cases such as *BRAC1* and *BRCA2* with breast and ovarian cancers and *RET* with pheochromocytoma and paraganglioma. The same pattern, but less pronounced, was found for non-cancer genes: pathogenic and likely pathogenic variants were overall more common in cancer cases than in gnomAD-exomes, while benign variants were not. Some non-cancer genes showed patterns of specific cancer-type enrichment; other variants and genes showed enrichment in a pan-cancer fashion.

**Discussion:** Our results suggest that previously unrecognized relationships may exist for cancer risk and Mendelian disease genes. The etiology of cancer in these situations is unclear, perhaps involving organ system damage from the primary disease or treatment. This analysis also supports clarification of the pathogenicity of variants of uncertain significance in known cancer-predisposition genes (also enriched in cancer cases) and the extension of some genes' relevance to cancer types with which they are not traditionally associated.

## PgmNr 1054: Systematic identification of MYC-dependency in non-MYC-amplified tumors across 19 tumor types.

---

Transcription factor MYC is a well-known oncogene in many cancer types. It is estimated that 70% of all tumors exhibit MYC misregulation. Although the most common type of MYC alteration is MYC amplification, several other mechanisms can contribute to dysregulation, including: amplification of MYC family members MYCN and/or MYCL, point mutations in the MYC coding region, stabilization of MYC mRNA, reduced methylation of the MYC gene or, activation of signaling pathways that augment MYC expression. In order to establish a metric that can capture all of these MYC-related alterations, we established a tumor-specific MYC activity score. We show that our activity score captures MYC amplification status, but also additional MYC alterations, including MYCN or MYCL amplification, decreased methylation, and increased MYC expression. We identified that MYC activity scores are more clinically relevant compared MYC amplification status in several tumor types. In addition, we could risk-stratify patients without MYC amplification based on their MYC activity scores, even after adjustment for clinical variables. Lastly, we identified several oncogenic mutations and pathways that might contribute to high MYC activity in non-MYC amplified samples. In conclusion, we show that several mechanisms can activate MYC in non-MYC amplified tumor samples and that this can limit prognosis and contribute to tumor progression.

## PgmNr 1055: TOD-CUP: A gene expression rank based algorithm for tissue origin diagnosis of cancer of unknown primary across different data types.

### Authors:

---

Carcinoma of unknown primary (CUP) represents a group of heterogeneous cancers and is defined by the presence of metastatic disease without an identifiable primary tumor site on presentation. It constitutes 3-5% of all human malignancies. This type of cancer is called a cancer of unknown primary (CUP) or occult primary tumor. Some biomarkers based on gene expression profiles had been identified to aid cancer tissue origin diagnosis of cancer of unknown primary. However, because of the batch effect and differences between different data types of RNA-seq and microarray measurements and heterogeneity of cancer patients, the predictive performances of biomarkers based on gene expression profiles often decrease greatly in inter-laboratory and different data type validation. To address this problem and assist in more precise diagnosis, we developed a general gene expression rank-based algorithm for tissue origin diagnosis for cancer of unknown primary (TOD-CUP). Massive (10553) tissue-specific RNA-Seq data sets were first obtained from The Cancer Genome Atlas (TCGA) and 538 feature genes were used to train and validate the TOD-CUP algorithm. The accuracy of the model was >97% based on cross validation by the data from TCGA. To validate the TOD-CUP method can accurately predict the tissue origin of CUP in different data types, 1,029 TCGA microarray cancer samples which generated by Agilent microarray platform and 2,277 microarray data set which generated by Affymetrix and Illumina microarray platform were tested in the TOD-CUP method using TCGA RNA-seq data as the training data sets. The accuracy of the method in these two microarray data set is 91% and 94%. Furthermore, we curated a data set which included 141 metastatic cancer tumor samples RNA-seq data from five cancer types to evaluate the performance of the TOD-CUP method in tissue of origin diagnosis of the metastatic cancer. The accuracy of the TOD-CUP method in the metastatic cancer tumor samples is 94%. Based on our findings, we believe that the TOD-CUP algorithm is a powerful robust methodology to accurately identify the tissue origin of cancer of unknown primary across different data types and an important step toward more precision-based medicine in cancer diagnosis and treatment.

## **PgmNr 1056: Mutational signatures and clinicopathological relationship extracted from clinical sequence data of 201 cases with colorectal cancer.**

The concept of mutational signatures has significantly improved our understanding of relationship between mutagenesis and carcinogenesis. Although signatures of more than 30 mutational processes have been identified in cancer genomes through thousands of experiments, many of which still have unknown etiologies. Tracing of their origins may help for the development of potential ways to reduce the risk of getting cancer. Mutational signatures may also be useful predictor of a response to different treatments. Therefore, elucidating the cause of unknown mutational signatures may open new avenues for both cancer prevention and cancer treatment. In this study, signatures were depicted using substitution classification defined the substitution type and sequence context from our archived comprehensive targeted panel sequencing data of 201 Japanese patients with non-hereditary colorectal cancer. We then performed extraction of mutational signatures, estimated the contributions of each clinicopathological factor and frequently mutated gene. We found that multiple clinicopathological factors and frequently mutated genes are significantly associated with several types of mutational signatures.

## PgmNr 1057: Integrated transcriptomic-genomic tool Texomer profiles cancer tissues.

Achieving precision and individualization is the key to further advance the understanding and treatment of cancer. Molecular profiling of tumor using bulk DNA sequencing are of limited power and precision. Multi-omics profiling promises comprehensive, functional readout of a tissue sample. However, novel, systematic approaches are required to leverage the increased data dimensionality, heterogeneity and complexity.

To address the issues of intra-tissue heterogeneity and integration of multi-omics in cancer, we developed a statistical approach called Texomer that enables a joint analysis of bulk whole exome (WES) and whole transcriptome sequencing (WTS) data to perform allele-specific deconvolution and quantify tumor purity and heterogeneity. Texomer first estimates tumor DNA purity, intratumor heterogeneity (ITH) and allele-specific copy numbers (ASCNs) using germline single nucleotide polymorphisms (SNPs) and somatic single nucleotide variants (SNVs) from WES data. It then estimates tumor RNA purity and allele-specific expression levels (ASELs) through the autologous WTS data, given the estimated DNA purity and ASCNs. Texomer further probabilistically classifies each SNP and SNV as copy number concordant or discordant, which can be used to reveal functionally selected variants in copy number altered regions. Finally, Texomer estimates a differential allelic cis-regulatory effect (DACRE) score to quantify the tumorigenic potential of a variant allele relative to its wildtype. Evaluation using simulated data and multiple datasets from the cancer genome atlas indicated that Texomer achieved desirable technical accuracy and outperformed existing tools. Based on Texomer-transformed profiles, we found more accurate genotype-phenotype association and breast cancers categorization, resulting in more clusters with homogeneous profiles and distinct biological properties than do the bulk data. In addition, the improved power achieved by Texomer manifested in significantly improved accuracy for functional variant prioritization. Applying DACRE score as a filter doubled the precision in predicting the known functional variants.

Our study clearly revealed the analytical challenges involved in performing joint WES and WTS profiling of patient samples, and delivered a statistically robust solution Texomer to accomplish the benefits of multi-omics profiling towards the realization of personalized genomic medicine.

## **PgmNr 1058: Expressional single nucleotide variations (eSNV) of autophagy genes are associated with poor survival of lung adenocarcinoma patients.**

---

Expressional single nucleotide variations (eSNV) are caused by genetic variation, somatic mutations or RNA editing and play oncogenic roles in cancer development. To comprehensively characterize the eSNVs associated with human cancers, we developed a robust computational framework for identification and quantification of non-synonymous eSNV from RNA sequencing data. The framework performs sequence alignment, variant calls, and subsequent counting of the reads that cover the variant alleles and corresponding reference alleles, respectively. The read counts for the non-synonymous variants and reference alleles are normalized and correlated with clinical outcomes after adjustment for demographic characteristics. We applied this approach to RNA sequencing data from a TCGA lung adenocarcinoma cohort (LUAD, n=459) and identified 22295 non-synonymous eSNVs occurring in at least 5% of patients. Cox regression analysis with the counts of eSNV and reference alleles identified expression levels of 579 eSNVs (but not corresponding reference alleles) associated with poor overall survival. Interestingly, the most significantly enriched functions for 460 genes harboring these prognostic eSNVs are autophagy and viral process with p values less than  $1.0 \times 10^{-8}$ . These preliminary findings might shed light on the role of autophagy in LUAD progression at the transcriptional level and will be extensively validated.

## PgmNr 1059: Comparison and evaluation of pathway and gene-level methods for cancer prognosis prediction.

---

Cancer prognosis prediction has become an important research goal. A limited number of gene-level analyses have led to clinically useful methods like Oncotype DX but these remain very difficult to develop and implement. A promising direction for improving the performance and interpretation of expression-based predictive models involves aggregating gene-level data into biological pathways. Although a few studies have used pathway-level predictors, a comprehensive comparison of pathway-level and gene-level prognostic models has not been performed.

To address this gap, we characterized the performances of penalized Cox proportional hazard models built using either pathway or gene-level predictors for the cancers profiled in The Cancer Genome Atlas (TCGA) and pathways from the Molecular Signatures Database (MSigDB). When analyzing the TCGA data, we found that pathway-level models are more parsimonious and easier to interpret than the gene-level models without a loss of predictive performance. For example, both pathway and gene-level models have an average Cox concordance index of 0.85 for the TCGA glioma cohort, however, the gene-level model has twice as many predictors on average and the predictor composition is less stable across cross-validation evaluations. In simulations, when the correlation structure of the real data is broken, the pathway-level models have greater predictive performance and superior interpretative power relative to the gene-level models. For example, the average concordance index of the pathway-level model is 0.88 while the gene-level model falls to 0.56 for the TCGA glioma cohort.

## PgmNr 1060: Comprehensive analysis of structural variants in clinical cancer samples.

---

Tumors are often comprised of heterogeneous populations of cells, with certain cancer-driving mutations at low allele fractions in early stages of cancer development. Effective detection of such variants is critical for diagnosis and targeted treatment. However, typical short sequence read sequencing is expensive at coverage depths needed for detection of variants in rare clones. Short read sequencing is also limited in its ability to span across repeats in the genome and this results in high error rates in structural variant (SV) analysis. Based on specific labeling and mapping of ultra-high molecular weight DNA, we developed a single-molecule platform that is able to detect disease-relevant SVs and give a high-resolution view of tumor heterogeneity.

We have developed a pipeline that effectively detects structural variants at low allele fractions. It includes single-molecule based SV calling and fractional copy number analysis. Preliminary analyses using simulated data and well-characterized cancer samples showed high sensitivity for variants of different types at as low as 5% allele fractions with reasonable genomic coverage easily collectable on a Bionano Saphyr Chip.

The candidate variants are annotated and further prioritized based on control data and publically available annotations such as DGV and dbVar. The SQL-based infrastructure also allows new databases to be incorporated as they become available. Also, we have developed an algorithm to detect loss of heterozygosity events, which have been reported in cancer genomes.

The data are imported into a graphical user interface tool that includes new visualization features (such as dynamic variant filtering, Circos diagrams, and report generation) for interactive visualization and curation. Together, these components allow for efficient analysis of cancer genomes of interest.

## PgmNr 1061: A general probabilistic algorithm to predict *de novo* mutations in familial diseases as demonstrated in Li-Fraumeni syndrome.

### Authors:

---

Germline *de novo* mutations (DNMs) have been increasingly recognized as causal factors for rare diseases. The ability to identify heterozygous DNM carriers, scarcely distributed among all mutation carriers, will allow researchers to study the likely distinct molecular mechanisms of DNMs in these diseases. However, testing the mutation status of the parents in retrospective studies is often impractical due to lack of blood samples. Using Li-Fraumeni syndrome (LFS), caused by heterozygous germline pathogenic variants in *TP53*, as a representative of a rare inherited syndrome, we developed Famdenovo to predict the *de novo* status (*de novo*/familial) of germline mutation carriers.

We collected a total 324 LFS family pedigrees with confirmed *TP53* germline mutations from four medical centers in the US. 186 pedigrees with available *TP53* genetic testing results in at least one pedigree trio served as a validation set and the remaining 138 families that did not have testing for a full trio served as a discovery set to identify potential germline *TP53 de novo* mutation carriers. In the validation set, the area under the ROC curve (AUC) of Famdenovo was 0.95 (95% confidence interval [CI] 0.92-0.98) and the ratio of the observed to expected (OE) was 1.32 suggesting excellent ability for discrimination and good concordance. In the discovery set, we predicted an additional 40 individuals (95% CI 30-50) were DNM carriers, which increased the total number of DNM carriers to 82 across the four medical institutions.

We observed similar distributions of ages-of-onset at specific cancer sites (breast, brain, leukemia, osteosarcoma, soft tissue sarcoma, lung, and adrenal cortical carcinoma) across the validation and discovery sets. Interestingly, lung cancer only occurred in female DNM carriers (n=4). Among *TP53* hotspot mutations, R248Q was more likely to be a DNM. Our new statistical method, Famdenovo, provides the probability of a person carrying a *de novo* germline mutation in rare inherited syndromes when the mutation status of both parents is not available.

Famdenovo, a freely available R package downloaded from <http://bioinformatics.mdanderson.org/main/Famdenovo>, is a general tool and can be applied to other

cancer genes where there is a good understanding of the penetrance of the associated disease phenotype. The computer-based identification of DNM carriers in *TP53* may enable future epidemiological studies of the unique cancer diagnoses in DNM carriers.

## PgmNr 1062: Systematic identification of mutational hotspots in hereditary cancer susceptibility genes.

The classification of DNA-sequence variants into pathogenic, uncertain, or benign considers a broad spectrum of criteria, from over-representation in affected individuals to the specificity of gene-disease association. Classification of missense variants remains a challenge as in the majority of cases, experimental functional evidence is either not available or clinically indeterminate. Here we propose and evaluate a method used to detect areas of potential functional and clinical importance in the absence of such experimental evidence. This method aims to directly address one of the classification criteria established by the guidelines for clinical interpretation of sequence variants by the American College of Medical Genetics (ACMG): “variant is located within a mutational hotspot or functionally critical domain (PM1)”. To date, systematic approaches to predict PM1 have not been sufficiently rigorous to implement in a clinical setting. Here we demonstrate a new, binomial likelihood-based method for the detection of fragments exhibiting clinically relevant mutational clustering. The algorithm was tested using a set of published mutations in 127 genes associated with various forms of hereditary cancer predisposition. Results demonstrated the capability of detecting both potential pathogenic hotspots enriched for pathogenic variants and benign “coldspots” depleted of them. Previously established mutational hotspots were confirmed with high confidence, while other, apparently clustered regions were demonstrated to be likely a result of a randomized pattern. The simple input structure and universal calculation enables detection of mutational hotspots for a variety of purposes, including classification of disease causing variants. This method may also be a valuable tool for the recognition of patterns in the distribution of functionally relevant protein structures. It could foster a deeper understanding of the molecular basis of disease development and protein function, potentially enabling the refinement of variant classification during clinical DNA analysis and assist laboratories to improve variant classification and reduce the number of variants of uncertain significance (VUS).

## PgmNr 1063: 20x faster and more accurate UMI-aware consensus molecule creation with the Sentieon Genomics Tools.

Next-generation sequencing (NGS) is increasingly used in sensitive clinical applications including liquid biopsy for monitoring of residual disease in cancer and detection of subclonal tumor populations. Due to the high accuracy required in these assays, elimination of false-positive signals due to errors introduced during library preparation and sequencing is critical. Towards this end, specialized library preparation methods have been developed where unique molecular identifiers (UMIs) are added to fragments molecules prior to amplification and sequencing. Using this UMI information, the sequence of the original molecule can be inferred computationally, significantly reducing the impact of library preparation and sequencing artifacts.

Here we present an improved pipeline for determination of molecular consensus molecules from UMI tagged NGS reads that is 20x faster than currently available pipelines. Compared to existing pipelines, our pipeline uses improved logic to identify reads derived from the same source molecule while accounting for sequence changes from library or sequencing artifacts. We also introduce a new model for SNP and INDEL errors that is calibrated directly from the read data allowing for more accurate removal of PCR artifacts and sequencing errors. Using publicly available benchmark datasets, we test our pipeline with popular variant callers and demonstrate improved variant calling accuracy.

## PgmNr 1064: Inference of tumor cell phylogenies using single cell sequencing.

---

Although large consortia have sequenced thousands of cancer patients' blood and tumor samples, tumor evolution remains a poorly understood process at the single cell level. Single cell whole genome sequencing lends itself well to population genetics approaches, but current methods are insufficient for application in cancer studies due to common core simplifying assumptions (such as random mating, consistent ploidy, and constant mutation rate). We present a method to better illuminate tumor evolution, by creating an inference framework to accurately call copy number changes from paired tumor/normal single cell sequencing data.

In order to account for technical noise from low coverage single cell whole genome sequencing data and to account for clonal cell growth in tumor development, we developed a Hidden Markov Model to jointly analyze read depth data from a collection of tumor cells, with matched normal cells as negative controls. By performing joint pairwise copy number calls, we are able to identify shared and singleton copy number changes in tumor cells. Furthermore, by creating a novel similarity metric based on the shared branch length in these pairwise copy number calls, we adapt existing population genetics methods to estimate cell development phylogenies. Using a combination of public datasets and simulations, we show we can accurately decode copy number profiles and reconstruct trees of tumor development. These trees can be used to obtain estimates of tumor growth rates, evidence of selection, and for inferring age of mutations and copy number changes, as well as estimates of tumor purity, tumor heterogeneity, and prevalence of tumor subpopulations.

## PgmNr 1065: Identification of a novel group of endometrial cancer patients with loss of thyroid hormone receptor expression and improved survival.

---

Endometrial cancer (EC) is the most common gynecologic cancer in women, and the incidence of EC is increasing. Though most EC has a good prognosis, the loss of nuclear hormone receptor (NHR) expression defines subtypes of EC that are often associated with poor clinical outcomes. For example, estrogen receptor (ER)-negative EC typically harbors a worse prognosis compared to ER-positive EC. In addition, resistance to hormonal therapies such as progestin and aromatase inhibitors, which block the conversion of testosterone to estrogen, is a major clinical issue and may be mediated in part through the loss of NHR expression. Though several studies have identified associations between clinical outcomes, such as survival and tumor grade, and NHR expression loss, the molecular basis for and consequences of the loss of NHR expression in endometrial tumors is largely unknown. Furthermore, there is no statistical framework designed to identify tumors that lose NHR mRNA expression relative to normal tissue. The development of such an approach could aid in the classification of patients into subgroups that are associated with survival or treatment outcomes. Here, a new method, termed receptLoss, is developed for identifying hormone receptor expression loss in endometrial cancer relative to adjacent normal tissue. Using a score-based approach, we identify 6 out of the 49 NHRs that are highly expressed in normal tissue and that exhibit expression loss in a subset of endometrial tumors. Several of the NHRs previously known to lose expression in certain endometrial cancers, such as estrogen, progesterone, and androgen receptors, were among the 6 NHRs identified. A novel association was found between thyroid hormone receptor beta (*THRB*) expression loss and increased rates of 5-year survival. *THRB* expression loss occurs independently of estrogen and progesterone expression loss, suggesting that this subgroup of patients is indeed different from previously reported subgroups. Developing a quantitative approach to identify NHR expression loss in endometrial tumors could lead to the development of biomarkers of disease progression and personalized hormonal treatment strategies for patients with endometrial cancer.

## PgmNr 1066: Recovery of genetic and epigenetic heterogeneity using single-cell DNA and methylome sequencing.

Genetic and epigenetic heterogeneity within tumor samples reflect the molecular mechanisms underlying tumor evolutionary dynamics. Intratumor heterogeneity is commonly studied at the clonal level where a “clone” is usually defined by DNA mutations such as single nucleotide variations (SNVs) and copy number variations (CNVs). Recently developed single-cell DNA-sequencing (scDNA-seq) enables mutation detection at the single cell level. In addition to DNA mutations, epigenetic heterogeneity is also prevalent in tumor samples. Single-cell methylome sequencing enable methylation detection in individual cells. These two types of sequencing data are low-coverage and plagued by dropout events, and computational methods are required to address these issues. Currently, mutation detection methods for scDNA-seq and methylation profiling methods for single-cell methylome sequencing data are lacking in accuracy and scalability. Although the two types of data reflect different genomic features, they can be treated under the same statistical and computational framework.

In this study, we develop a statistical framework to denoise scDNA-seq and single-cell methylome sequencing data using an unsupervised neural network called autoencoder. For scDNA-seq imputation, we borrow the raw allele frequency of alternative alleles/CNV states across all detected SNV/CNV sites in all cells to impute the missing genotypes and denoise all positions. Results show that the autoencoder outperforms two existing methods in terms of SNV signal estimation. We found that the autoencoder was able to impute missing SNV genotypes under different simulated scenarios. The SNV signals estimated by the proposed method allows the recovery of underlying clonal structures. A similar strategy is employed to impute the methylation states for single-cell methylome data. Our results reveal the potential of low dimensional latent space methods in the recovery of genetic and epigenetic signals for scDNA-seq and single-cell methylome sequencing data, facilitating the characterization of intratumor genetic and epigenetic heterogeneity.

## PgmNr 1067: HiC-Hiker: A probabilistic model to determine contig orientation in chromosome-length scaffolds by Hi-C.

### Authors:

R. Nakabayashi; S. Morishita

[View Session](#) [Add to Schedule](#)

---

Detection of structural variants (SVs) such as inversions, duplications and translocations in cancer genomes has been crucial to understand the mechanisms and consequences of cancer genome instability, demanding an accurate and inexpensive way to detect missing SVs. Recent studies demonstrated that Hi-C could be a powerful and cost-effective means to output chromosome-length scaffolds for non-model species with no genome marker resources, because the Hi-C contact frequency between a pair of two loci can be a good estimator of their genomic distance even if there is a large gap between them.

We attempted to extend this novel *de novo* assembly technique to be applicable to accurate cancer genome SV detection. However, we found it challenging to reduce errors in contig orientation because shorter contigs have less contacts with their neighboring contigs. There is a pressing need to overcome this problem because these orientation errors can cause a number of false-positive SVs and disturb the analysis.

To correct these contig orientation errors in draft genome assembly from Hi-C data, we here propose a new algorithm and its implementation named HiC-Hiker, which has a firm grounding in probabilistic theory, models Hi-C contacts across contigs rigorously, and effectively infers most probable orientations by Viterbi algorithm. We compared HiC-Hiker and 3D-DNA using a human genome contigs generated from short reads, evaluated their performance, and observed a remarkable reduction in contig orientation error rate from 3.0% (3D-DNA) to 1.0% (HiC-Hiker). Of note, HiC-Hiker outperformed 3D-DNA in repairing orientation of both short and long contigs simultaneously.

Our method achieved a higher accuracy in estimating contig orientation because it can consider long-range information between distal contigs, and estimates Hi-C read contact probabilities among contigs precisely. Our probabilistic approach to Hi-C scaffolding could be also promising for generating most probable ordering of contigs.

## PgmNr 1068: Comprehensive structural and copy-number variant detection with long reads.

**Authors:**

To comprehensively detect large variants in human genomes, we have extended pbsv – a structural variant caller for long reads – to call copy-number variants (CNVs) from read-clipping and read-depth signatures. In human germline benchmark samples, we detect more than 300 CNVs spanning around 10 Mb, and we call hundreds of additional events in re-arranged cancer samples.

Long-read sequencing of diverse humans has revealed more than 20,000 insertion, deletion, and inversion structural variants spanning more than 12 Mb in a typical human genome. Most of these variants are too large to detect with short reads and too small for array comparative genome hybridization (aCGH). While the standard approaches to calling structural variants with long reads thrive in the 50 bp to 10 kb size range, they tend to miss exactly the large (>50 kb) copy-number variants that are called more readily with aCGH and short reads. Standard algorithms rely on reference-based mapping of reads that fully span a variant or on *de novo* assembly; and copy-number variants are often too large to be spanned by a single read and frequently involve segmentally duplicated sequence that is not yet included in most *de novo* assemblies.

We extended pbsv to utilize signatures of read clipping and read depth to detect CNVs missed with the spanning read and *de novo* assembly approaches. PacBio long-read sequencing has very consistent coverage across the genome, which combined with clipped reads at CNV boundaries, provides power to detect CNVs. We apply the extended pbsv to characterize CNVs in Genome in a Bottle germline benchmark samples and a highly-rearranged breast cancer lines. Together with insertion, deletion, inversion, duplication, and translocation calling from spanning reads, this allows pbsv to comprehensively detect large variants from a single data type.

## PgmNr 1069: Mela-Immu portal: An open platform for exploring immunotherapy-related multidimensional genomic profiles in Melanoma.

### Authors:

**Aims:** Although immune checkpoint blockade (ICB) antibodies therapies provide significant clinical benefits for advanced melanoma, predictors of response to these therapies remain incompletely characterized. There are increasing studies to identify genetic and nongenetic factors that may influence sensitivity or resistance to immunotherapy. In order to make these data available, we developed Mela-Immu, (<http://bioinfo.vanderbilt.edu:3838/Mela-Immu/>), which is an open-access resource for interactive exploration of a variety of known and novel signatures predictive of immunotherapy response across multiple datasets in melanoma.

**Methods:** We collected all public available datasets which have both genomic profiling and ICB therapy outcome. All the datasets are stored at different genetic profiling, including genomics, transcriptomics and cell subpopulations and correlated with three types of clinical outcome, immunotherapy response, overall survival and progression free survival.

**Results:** The current version of Mela-Immu contains 889 samples derived from both bulk sequencing and single cell RNA sequencing. The association between each genetic profiling and clinical outcome can be queried, visualized, and downloaded across multiple datasets to explore the consistency of signatures. Each genetic profiling provides multiple types of features, including the known or novel signatures predictive of immunotherapy response. Genomic profiling provides gene mutation, tumor mutational burden, and mutational signatures. Transcriptomic profiling includes gene/gene sets expression, gene expression relations, and immune cell components. The single cell RNA-seq contains gene expression signals of cells and cell population components. In addition, integrative analysis of multi-features is also implemented in Mela-Immu to identify potential predictors. To be noted, Mela-Immu allows users to upload their own datasets, therefore they can be analysed independently or co-analyzed with Mela-Immu's existing datasets to validate the reliability and generality of identified signatures.

**Conclusions:** With the ability of easily exploring the relationship between multidimensional genetics data and ICB therapy response across multiple datasets, Mela-Immu will facilitate discoveries in immune-mediated therapy of melanoma.

## PgmNr 1070: Aggregating multiple rare variant association tests to enhance gene discovery in rare variant association studies.

### Authors:

Y. Yu; J. Chen; R. Bohlender; C. Huff

[View Session](#) [Add to Schedule](#)

**Affiliation:** Department of Epidemiology, The University of Texas MD Anderson Cancer Center, Houston, TX

---

Gene-based association tests have been widely used in rare variant association studies to evaluate statistical evidence of disease association, yielding numerous novel discoveries of susceptibility loci. Various statistical tests have been proposed in recent years, such as burden tests, variance-component tests, and combined omnibus tests. Typically, a rare variant association study applies between one and three of these tests to evaluate all coding variants in each gene. This approach has three potential disadvantages: First, selecting the optimal test is difficult as the power of each test varies according to genetic architecture, which differs by gene and is generally unknown. Second, using more than one test increases the multiple testing burden, which may reduce overall statistical power. Third, testing all coding variants in a gene, irrespective of transcript isoform, is often approximately equivalent to a test of the largest isoform, which is not always optimal. To address these questions, we introduce the X-Method Association Test (XMAT), which is a permutation approach to conduct gene-based tests, incorporating multiple statistics and all isoforms in a given gene. XMAT summarizes the contribution of each test and each transcript to calculate a single gene-level p-value, without the need to explicitly model correlation between tests or transcripts. XMAT can be applied in conjunction with any gene-based association test and can include tests that restrict variants to particular function categories (e.g. truncation, missense, and splice-altering variants). To demonstrate the utility of XMAT, we conducted case-control studies involving 783 TCGA breast cancer cases, 272 TCGA ovarian cancer cases, and 3,607 population controls of European ancestry. We evaluated 24 rare variant association tests with different combinations to compare the power of XMAT relative to each individual test. In general, we observed that the p-values in XMAT were comparable to the most powerful individual test, with equivalent power in most scenarios (e.g. *BRCA2* in breast cancer, *BRCA1* and *RAD51C* in ovarian cancer) and a modest attenuation of association signal in some scenarios (e.g. *BRCA2* in ovarian cancer). In all examples, XMAT outperformed any combination of individual tests after correcting for multiple testing. Our results demonstrate that XMAT is a statistically robust approach for incorporating multiple gene-based tests in rare variant association studies.

## PgmNr 1071: Computational strength of evidence for clinical sequence variant classification without circular reasoning.

### Authors:

S.V. Tavtigian <sup>1</sup>; C.C. Young <sup>1</sup>; B.J. Feng <sup>2</sup>; E. Ziv <sup>3</sup>; S.L. Neuhausen <sup>4</sup>

---

The American College of Medical Genetics (ACMG) sequence variant classification guidelines include two criteria based on computational evidence, 'PP3' and 'BP4'. These equate to supporting evidence in favor of and against pathogenicity, respectively and further equate to odds in favor of pathogenicity of 2.1-4.3 (or the reciprocal range, for BP4). While some investigators in the field believe that computational evidence should be able to provide more than 'supporting' evidence, rigorous tests of strength of evidence have been difficult to perform due to hidden multiple testing, circularities between sets of sequence variants used for creation and testing of computational tools, and because tools may opaquely leverage more than one ACMG evidence code.

As a proof case that avoids these obstacles, we evaluate *CHEK2* case-control mutation screening data with the computational tool Align-GVGD. A relatively simple tool created more than a decade ago, Align-GVGD was calibrated using *BRCA1/2* data and has no circular connections to *CHEK2*. As an initial step, we performed a pooled analysis of two *CHEK2* mutation screening studies: the first a multi-ethnic study with approximately 1,300 early onset breast cancer cases and ~1,100 ethnically matched controls first reported on in 2011, and the second a series of ~1,100 Latina early onset and/or familial cases and ~1,200 matched controls described this year.

Analyzing these case-control data, which include 56 distinct rare missense substitutions, we estimate odds in favor of pathogenicity without reference to existing *CHEK2* variant classifications, further avoiding logical circularities. Using the same ordered categorical groupings that are applied to *BRCA1/2* sequence variants (thereby reducing multiple testing), we found that: the expected benign Align-GVGD grade, C0, exceeds odds of benign effect required for BP4; the C15, C25 grade yields an indeterminate result; and the logically more pathogenic C35-C55 and C65 grades both exceed odds of pathogenicity required for PP3. There was no evidence of heterogeneity between the two studies.

We will report results from identical analyses applied to order of magnitude larger series of breast cancer cases and controls, allowing us to draw firm conclusions regarding the strength of evidence that can be achieved without concern about hidden circular reasoning and, in particular, whether ACMG 'moderate' evidence of pathogenicity is within reach of simple computational tools.

## PgmNr 1072: Prioritization of variants and genes in an exome study of familial lymphoid cancers.

### Authors:

S. Ralli <sup>1,2</sup>; S.J. Jones <sup>1,3</sup>; S. Leach <sup>1</sup>; A. Williams <sup>1</sup>; J.M. Connors <sup>4</sup>; A. Brooks-Wilson <sup>1,2</sup>

---

In lymphoid cancer affected families, members often develop different types or subtypes of lymphoid malignancies rather than developing the same disease. This implies presence of shared genetic factors that affect susceptibility to more than one type or subtype of lymphoid cancer. In large multicase families, genetic factors can be identified using methods such as linkage analysis. It remains a challenge, however, to detect susceptibility factors in small families with fewer cases. We propose a method to prioritize variants and genes in collections of lymphoid cancer families for where genetic heterogeneity is likely but biological commonalities are plausible.

We are applying the method to a collection of 185 multigenerational families, with 2-10 members with Hodgkin lymphoma, non-Hodgkin lymphoma, chronic lymphocytic leukemia or myeloma. Exome data from 89 affected individuals within 40 families will be used to discover and prioritize putative genetic variants. The remaining families will be used for further study of prioritized genes and variants.

The approach involves filtering step to retain genotypes that are shared among lymphoid affected individuals in each family. Shared genotypes are prioritized by weighting them for five criteria's: 1) the number of affected individuals in a family (family weight), 2) the percentage of the genome that is shared amongst affected individuals in a family (sharing weight), 3) the minor allele frequency of the variant (population allele frequency weight), 4) *in silico* prediction of variant function (prediction weight) and 5) a Surveillance, Epidemiology, and End Results (SEER) incidence rate that combines sex, age of lymphoid cancer onset, subtype of lymphoma and ethnicity (individual weight). These weights are normalized to the range of 0 to 1 and multiplied together to produce an overall weight for each variant in each family. The overall weights are combined to generate a multifamily weight for each variant. Genes with variants that have multifamily weights above a user-defined threshold are analyzed for enrichment at the level of the gene, biological process and pathway. Identifying genetic factors that contribute to susceptibility to lymphoid cancers will allow a better understanding of the biological processes underlying these malignancies. The weighting system proposed here for searching for biological commonalities can be used in other familial diseases with small families.

## PgmNr 1073: Whole genome bisulfite sequencing of paired primary and recurrent high grade serous ovarian cancer identifies epigenomic reprogramming and modes of clonal expansion that confer chemoresistance.

---

High grade serous ovarian carcinoma (HGSOC), the most aggressive and prevalent type of epithelial ovarian cancer, continues to be the leading cause of gynecological cancer-related deaths. Several factors such as late stage diagnosis and increased metastatic potential contribute to poor prognosis. Despite many patients responding positively to debulking surgery followed by platinum-chemotherapy, over 70% of patients will experience disease relapse and chemotherapy resistance will progress to fatal disease. Recent studies of methylation in primary HGSOC tumors using microarrays demonstrated widespread differences between chemo-resistant and chemo-responsive patients at the molecular level; for instance, BRCA1 promoter hypermethylation was linked to reduced patient survival. To identify genomic landscape changes in chemotherapy resistant HGSOC tumors, we used whole genome bisulfite sequencing (WGBS) and RNA-seq to profile paired primary and recurrent HGSOC tumors (n=73) from patients who have either BRCA1/2 mutations (n=12) or are BRCA wild type (n=24). Stark differences in global DNA methylation and transcriptome signatures were observed that could potentially explain the relapsing course of the disease. We identified 11,844 (q<0.05) differentially methylated regions (DMRs) between primary and recurrent patient samples; 3,873 of these DMRs overlapped between two or more patients. Using our novel computational method ELMER (Enhancer Linking by Methylation Expression Relationships) constrained by the DMRs, we identified genes known to be perturbed in ovarian cancer such as *RADX*, *AGR2*, and *CLDN2*, as well as other novel genes. Additionally, we identified 118 transcription factors hypomethylated in primary samples and 83 hypomethylated in recurrent samples (q<0.05, OR>1.1). Interestingly, we also observed changes in epigenetic domain structure, specifically deep PMD (partially methylated domain) hypomethylation in multiple recurrent samples indicating a tumor purity as well as a high level of proliferation. These results provide strong evidence for alterations in methylation that promote chemotherapy resistance and provide a better understanding of development and a basis for therapeutic decisions and interventions. Our WGBS data represent the first whole methylome analysis of HGSOC patients to date and the combinatorial approach has provided a genome-wide cis-

regulatory epigenetic landscape in ovarian cancer as it acquires and maintains chemoresistance.

## PgmNr 1074: Targeting noncoding RNAs can improve the effectiveness of radiation therapy for cancer patients.

**Authors:**

H.S. Chiu; S. Somvanshi; E. Patel; P. Sumazin

[View Session](#) [Add to Schedule](#)

**Affiliation:** Texas Children's Cancer Center, Baylor College of Medicine, Houston, TX 77030, USA

---

Profiling of many tumor types revealed dramatic upregulation of long-noncoding RNAs (lncRNAs). These lncRNAs are promising therapeutic targets because inhibitors that specifically target them may be able to target cancer cells while having minimal toxicity in non-tumor cells. We developed software—including longhorn (Chiu *et al.*, 2018) and bighorn (Chiu *et al.*, 2019)—to infer disease-relevant functions for lncRNAs. Using these tools, in conjunction with data from hundreds of cell lines and thousands of patients, we identified lncRNAs that target DNA-repair pathways and are predicted to improve the effectiveness of x-ray and proton therapies. Expression and genomic alterations at the loci of these lncRNAs predict cell and patient response to radiation therapies. Focusing on pan-cancer lncRNAs, which have high expression in many cancer types, we showed that silencing these lncRNAs *in vitro* increases the susceptibility of cell lines to radiation and reduces radiation dosages required for killing cancer cells. We argue that tumor-suppressor lncRNAs that regulate the DNA repair pathway can indicate candidates for lower-dosage radiation therapy and that pan-cancer and cancer-specific lncRNAs that are upregulated in tumor cells and are predicted to disrupt DNA repair pathways are excellent candidate therapeutic biomarkers.

## PgmNr 1075: DiNeR: A nonparametric *Differential* graphical model of *Network Rewiring* to infer transcription factor co-binding alterations.

---

During transcription, numerous transcription factors (TFs) are recruited in a highly coordinated manner to control the temporal and spatial expression pattern of genes. TF-target edge gain or loss in the regulatory network, also known as network rewiring, can change the co-regulation of TFs, which in turn can potentially introduce expression changes and phenotypic variations. However, quantification of changes in TF co-binding relationships between normal and disease states has not been comprehensively studied. To address this problem, we propose a computational method DiNeR to directly construct the differential TF-TF regulatory network from paired disease-to-normal ChIP-seq data. Specifically, we assembled genome-wide binding profiles of 104 common factors in K562 and GM12878 human cell lines. We then applied a non-parametric differential graphical model to estimate the TF-TF co-binding changes between chronic myeloid leukemia (CML) and normal samples. We further applied network stability analysis by sub-sampling the network to control the sparsity in the differential network. As a result, we identified 351 significantly altered edges during oncogenesis. Specifically, we found that in leukemia the co-binding of the tumor suppressor BRCA1 and RNA polymerase II, a well-known transcriptional pair in healthy cells, was disrupted in tumor cells. Further extraction of hub regulators and the discovery of well-known CML risk genes demonstrates the effectiveness of our DiNeR method in highlighting key regulators of gene expression in disease.

## PgmNr 1076: Internal normalization of RNA sequencing data using genes with stable expression.

Cancers are heterogeneous and can be difficult to characterize from any single perspective. Multi-dimensional characterization of tumors has the potential to improve our ability to classify tumors, identify germline genetic risk, and associate with clinical outcomes. Our goal is to identify biologically relevant quantitative tumor traits using transcriptome data.

Previously we used principal components analysis of the expression of PAM50 genes to identify breast tumor dimensions. We illustrated utility of these for gene mapping, prediction of prognosis, and response to paclitaxel (Madsen et al. 2018, Camp et al. 2019). The potential impact of applying this approach more broadly is high. The PAM50 panel, however, is a small set of highly curated genes. To expand the same concept to whole transcriptome RNA sequencing data will require normalization for gene size, library size, and RNA composition; the latter particularly challenging. Many normalization procedures for RNA composition exist, however, most are targeted to differential gene expression applications and implement a reference to remain robust. Our goal is a reference-free method, which is important to allow tumor traits to be calculated in a single sample and compared across different studies. To achieve this, we have developed a procedure for 'internal normalization' that uses STABLE (STeady And reliABLy Expressed) genes.

We identified STABLE genes using all samples in the TCGA and GTEx datasets. In each resource, we eliminated genes that had zero expression in any sample. The remaining genes were naively corrected for library size, and ranked by coefficient of variation within each dataset (least to most variation). Rank aggregation across TCGA and GTEx was used to identify 101 genes with expression stability across both resources; the STABLE genes. In an independent dataset, we calculate a sample-based size factor based on the median expression level of the 101 STABLE genes from within each sample. Gene counts for each sample were adjusted by gene size, library size, and STABLE size factor.

To test the effectiveness of our method, we constructed several datasets engineered to contain issues of library size and RNA composition, and normalized using established methods and our novel procedure. Internal normalization using STABLE genes performed as well or better than other methods. This is a significant step toward the development of universal tumor traits using transcriptome data.

## PgmNr 1077: Inference and characterization of copy number variants from bulk and single cell RNA-sequencing datasets.

---

RNA sequencing has become the de facto standard for measuring the expression levels of genes. Each RNA sequencing experiment generates large amounts and spectrum of information about expression levels of genes including expression levels of splice variants, gene fusions, and novel non-coding and intergenic transcripts. With the recent advancement in the single cell technologies, single cell RNA-sequencing is now utilized to deconvolve complex tissues and organs with respect to changing expression patterns in development and disease. Although they are mainly used for quantifying expression levels, they contain much more biologically relevant information about the genetic variants. For example, well-known variant detection tools such as the genome analysis toolkit (GATK) has semi-standardized pipelines for detecting single nucleotide variants and small insertions and deletions from the RNA-seq datasets with decent accuracy. Among these variants, detectability of structural variants and copy number variants (CNVs) from RNA-sequencing data is not well-studied. We present CaSpER, a signal processing approach for identification, visualization, and integrative analysis of focal and large-scale CNV events in multiscale resolution using either bulk or single-cell RNA sequencing data. CaSpER utilizes a novel smoothing of the genomewide RNA sequencing signal profiles in different multiscale resolutions, identifying CNV events at different length scales. CaSpER next employs a novel methodology for generation of genomewide allelic shift signal profile from the reads and utilizes it in multiscale fashion for correction of CNVs calls. The allelic shift signal is used to quantify the loss-of-heterozygosity, LOH, that is valuable for CNV identification. The multiscale nature of CaSpER enables comprehensive analysis of focal and large-scale CNVs and LOH segments. CaSpER performs well in accuracy compared to gold standard SNP genotyping arrays. In particular, analysis of single cell GBM RNA sequencing data with CaSpER reveals novel mutually exclusive and co-occurring CNV sub-clones at different length scales. CaSpER increases the utility of RNA-sequencing datasets and complements other tools for complete characterization and visualization of the genomic and transcriptomic landscape of single cell and bulk RNA sequencing data, especially in cancer research.

## PgmNr 1078: Single cell cancer heterogeneity: Clonotype detection in renal cell carcinoma.

### Authors:

---

Among urological malignancies, one of the most lethal and responsible for around 80 percent of all primary renal neoplasms is the renal cell carcinoma (RCC). The single cell sequencing have the potential to provide a new insight about RCC cancer heterogeneity since clonotype and variant detection at the highest resolution. In order to study the extensive cancer heterogeneity of RCC, we used single cell sequencing copy-number analysis and clonotype detection in four RCC tumors. Single cell 10x Chromium<sup>TM</sup> Technology was used to reach detection of 100 Kb CNV events and calling clonotypes down to 10 of 1000 cell inputs. By processing four samples, one resulted in around 500 total with tumor cells more than 50% of the total cells, other samples had lower percentage. Variable media ploidies were calculated through genome-wide ploidy analysis of the tumor cells. We used 20 Kb cases of reads to estimate regional copy number. Different sub-clones were identified among samples. In sample number one four clusters of sub-clones characterized cancer heterogeneity. Genome-wide ploidy analysis of the tumor cells showed variable median ploidies. The regional copy number was estimated by processing our data in 20 Kb cases of reads. By applying Fast maximum-likelihood (ML) genetic clustering and Bayesian Information Criterion (BIC) it was detected different sub-clones in each sample; in sample number one, there where four clusters of sub-clones characterized cancer heterogeneity which also showed copy number changes on entire chromosome arms and mutations at variant detection level, other samples resulted with different number of clusters. Among cells from sample one, it was detected *VHL* gene mutations that have been reported in RCC samples as signatures of clinical prognosis. Genomic features were detected since the highest resolution applied using this single cell technology. This highest resolution allow the identification and stratification of sub-clones as a new alternative to understand the extensive heterogeneity that characterize RCC.

## PgmNr 1079: SCOPE: A normalization and copy number estimation method for single-cell DNA sequencing.

---

**INTRODUCTION:** Whole-genome single-cell DNA sequencing (scDNA-seq) enables characterization of copy number profiles at the cellular level. This increases resolution and decreases ambiguity in assessing tumor heterogeneity and tracking cancer evolutionary history. ScDNA-seq data is, however, sparse, noisy, and highly variable even within a homogeneous cell population due to the biases and artifacts that are introduced during library preparation and sequencing procedure. Existing methods either build an optimized normal/reference set for normalization or adopt a cell-specific normalization procedure for removing biases, followed by a post hoc procedure for ploidy estimation and adjustment. They cannot adequately remove such artifacts and, furthermore, they do not address the challenges and complexities caused by aberrant copy number changes or the complicating factor of tumor ploidy.

**METHODS:** SCOPE integrates both null and non-null genomic regions for unbiased estimation of both GC content bias and latent factors for cell- and region-specific background correction. The distinguishing features of SCOPE include: (i) utilization of cell specific Gini coefficients for quality control and for identification of normal cells, which are then used as negative control samples in a Poisson latent factor model for read depth normalization; (ii) modeling of GC content bias using an expectation-maximization algorithm embedded in the Poisson regression models to account for the different copy number states along the genome; and (iii) a cross-sample iterative segmentation procedure to identify breakpoints that are shared across cells with the same genetic background.

**RESULTS:** SCOPE is shown to more accurately estimate subclonal copy number aberrations and to have higher correlation with array-based copy number profiles of purified bulk samples from the same breast cancer patient. Ploidy estimates by SCOPE are highly concordant with those from previous reports based on single-cell flow sorting. We further show that the copy number profiles returned by SCOPE can also be recapitulated by whole-exome sequencing and single-cell RNA-sequencing. We finally demonstrate SCOPE on scDNA-seq data that was produced using the 10X Genomics single-cell CNV pipeline, showing that it can reliably recover proportions of the cancer cell spike-ins from a background of normal cells and that it can successfully reconstruct cancer subclonal structure across 10,000 breast cancer cells.

## PgmNr 1080: Sparse conditional generate adversarial networks (CGAN) for individualized biomarker selection and treatment effect estimation.

---

Next generation genomic, epigenomic, sensing and image technologies produce ever deeper multiple omics, physiological, imaging and phenotypic data with millions of features. Integrating omics, physiological and imaging data provides invaluable information for identification of individualized biomarkers that will be used for estimation of individualized treatment effects and optimal selection of individualized therapy. The classical methods for biomarker identification use average treatment effect information. However, treatment response is heterogeneous. Only using average treatment effect information presents a problem in selecting the optimal treatment for each individual to ensure that the right therapy is offered to “The right patient at the right time.” Unfortunately, estimating individualized treatment effects and design of individualized therapy is beyond the state-of-the-art of the current biomarker selection paradigm. A key issue for individualized treatment estimation is to estimate counterfactuals of treatment. However, counterfactuals are unobserved and are therefore a missing value problem. The classical treatment effect estimation methods cannot accurately estimate the counterfactuals due to lack of methods for missing value estimation. The recently developed conditional generative adversarial nets (CGAN) are accurate tools for estimating the counterfactuals. Imaging, omics and physiological data involve millions of features. Since neural networks (NN) are complicated nonlinear functions, identifying biomarkers from omics and imaging data in CGAN is a challenging task. To identify individualized biomarkers and estimate individualized treatment effects, we combined a novel instance-wise feature selection method that consists of three neural networks: a selection network, a prediction network and baseline network, and CGAN. The algorithms are applied to the TCGA Uterine Corpus Endometrial Carcinoma (UCEC) dataset with histological imaging, gene expression (mRNA and miRNA), methylation data and 145 chemotherapy response records from 67 unique individuals. Real data analysis results show that the proposed algorithms substantially outperform the state-of-the-art methods. We find our prediction model has strong predictive performance on mislabeled drug response (N=134) compared with overall survival (OS).

## PgmNr 1081: Allele-specific QTL fine-mapping with PLASMA.

Although quantitative trait locus (QTL) associations have been identified for many molecular traits such as gene expression, it remains challenging to distinguish the causal nucleotide from nearby variants. In addition to traditional QTLs by association, allele-specific (AS) QTLs are a powerful measure of cis-regulation that are largely concordant with traditional QTLs, and can be less susceptible to technical/environmental noise. However, existing asQTL analysis methods do not produce probabilities of causality for each marker, and do not take into account correlations among markers at a locus in linkage disequilibrium (LD). We introduce PLASMA (PopuLation Allele-Specific Mapping), a novel, LD-aware method that integrates QTL and asQTL information to fine-map causal regulatory variants while drawing power from both the number of individuals and the number of allelic reads per individual. We demonstrate through simulations that PLASMA successfully detects causal variants over a wide range of genetic architectures, with upwards of a 10-fold reduction in credible set size over conventional QTL-based fine-mapping on the same data. We apply PLASMA to RNA-Seq data from 524 kidney tumor samples and show that over 13 percent of loci can be fine-mapped to within 5 causal variants, compared less than 2 percent of loci using existing QTL-based fine-mapping.

**PLASMA furthermore achieves a greater power at 50 samples than conventional QTL fine-mapping does at over 500 samples.** Overall, PLASMA achieves a 6.4-fold reduction in median 95% credible set size compared to existing QTL-based fine-mapping. We additionally apply PLASMA to H3K27AC ChIP-Seq from 28 prostate tumor/normal samples and demonstrate that PLASMA is able to prioritize markers even at small samples, with PLASMA achieving a 1.4-fold reduction in median 95% credible set sizes over existing QTL-based fine-mapping. Variants in the PLASMA credible sets for RNA-Seq and ChIP-Seq were enriched for open chromatin and chromatin looping (respectively) at a comparable or greater degree than credible variants from existing methods, while containing far fewer markers. **Our results demonstrate how integrating AS activity can substantially improve the detection of causal variants from existing molecular data and at low sample size.** More generally, PLASMA's approach in combining QTL and AS signals can potentially improve QTL-GWAS colocalization and gene expression prediction in transcriptome-wide association studies (TWAS).

## PgmNr 1082: Measures of transcript isoform diversity and alternative splicing.

The advent of high-throughput sequencing of messenger RNA, coupled with the development of software that allows the high-throughput processing of thousands of samples, makes possible a global description of alternative splicing at the level of a sample, a tissue or a species. We review global measures of diversity and define heteroformity. This measure of transcript diversity reflects the fraction of transcript pairs drawn at random from a single gene that differ. This metric is inspired by the utility of mean heterozygosity in population genetics. The heteroformity of a gene thus varies between 0 (if there is only one isoform) and 1 (the limit, when so many isoforms are present that each transcript is different). The abundance-weighted gene heteroformity of a sample can be visualized as a cumulative distribution, allowing immediate inference of some phenomena.

Application to 11,688 human samples from 30 tissues the Genotype-Tissue Expression (GTEx) project reveals some general patterns. In all samples, about 25% of transcripts are in genes with very low heteroformity. In contrast, the top quartile of transcripts are in genes with over 0.5 heteroformity. Tissues differ significantly; much greater levels of alternative splicing are consistently observed in reproductive and nervous tissue. There is also great individual variation, with specific heart samples varying over threefold in total gene-level heteroformity. We note that sample heteroformity need not correlate with differences in alternative splicing between samples, and that partitioning genes with respect to their overall heteroformity vs. their differential alternative splicing can reveal patterns of developmental regulation.

We are currently applying heteroformity to diverse biological samples and exploring its properties as a robust and useful metric, with a focus on the heteroformity of cancer RNA-seq samples, oncogenic isoforms and tumor-specific antigens generated by alternative splicing.

## PgmNr 1083: Clinical, biochemical, and pathological investigation of a patient with musculocontractural Ehlers-Danlos syndrome caused by a novel pathogenic variant in *DSE*.

---

Musculocontractural Ehlers-Danlos Syndrome (mcEDS) is a recently identified connective tissue disorder, caused by loss-of-function variants in *CHST14* encoding dermatan 4-*O*-sulfotransferase-1 (mcEDS-*CHST14*) or in *DSE* encoding dermatan sulfate epimerase (mcEDS-*DSE*), both resulting in defective biosynthesis of dermatan sulfate (DS) replaced by chondroitin sulfate (CS). Whereas 42 patients with mcEDS-*CHST14* from 28 families have been reported to date, only three patients from two families with mcEDS-*DSE* have been published. Here, we report clinical, biochemical, and pathological features in the fourth case with mcEDS-*DSE* caused by a novel biallelic pathogenic variant of *DSE*. The patient is a 36-year-old Japanese man born to consanguineous parents who were second cousin. He had recurrent large subcutaneous hematomas from childhood, sometimes requiring intravenous administration of DDAVP. He also showed adducted thumbs, delayed anterior fontanelle closure, slender and cylindrical fingers, scoliosis, bilateral cryptorchidism, bilateral high intraocular pressure and thin retina, mitral valve regurgitation, and a massive diverticular hemorrhage. He had no developmental delay and had three healthy daughters. Next-generation-based custom panel sequencing for hereditary connective tissue disorders identified a novel homozygous variant "c.2601C>A; p.Y867\*" in *DSE*. Epimerase assays, measured using COS-7 cells transfected with a *DSE* sequence including the detected variant, showed a significantly lower, an almost negligible level of epimerase activity, compared with the cells with a wild-type *DSE* sequence. A disaccharide composition analysis of DS and CS showed a negligible amount of DS in the patient's urine, and showed a small but detectable amount of DS, significantly lower than healthy controls though somewhat higher than those with mcEDS-*CHST14*. Transmission electron micrographs (TEM) including cupromeronic blue staining to visualize GAG chains on the skin specimens showed unassembled collagen fibrils with GAG chains linearly stretching from the attached collagen fibrils in some areas, similar to the findings in patients with mcEDS-*CHST14*, but in other areas, tightly packed collagen fibrils curved in close contact along the contour of attached collagen fibrils, similar to the findings in healthy controls. Milder clinical phenotypes and partial biochemical and pathological abnormalities suggest an alternate pathway producing DS in the absent activity of DSE.

## PgmNr 1084: “You can't always get what you want”: Pseudoscleroderma unraveling Hutchinson-Gilford progeria.

### Authors:

A. Pessoni <sup>1</sup>; F. Borges <sup>1</sup>; Z. Carneiro <sup>1</sup>; L. Vagnini <sup>2</sup>; C. Lourenco <sup>1</sup>

[View Session](#) [Add to Schedule](#)

---

**BACKGROUND:** Hutchinson–Gilford progeria syndrome (HGPS) was first reported in 1886 as a case of “congenital absence of hair and its appendages,” and, later, Gilford introduced the term progeria in 1904. Although signs and symptoms vary in terms of the age of onset and severity, they are remarkably consistent overall, involving skin, bones, heart, and blood vessels.

**CASE REPORT:** Female patient, born to non-consanguineous parents, was referred for failure to thrive and suspicion of infantile scleroderma with 4 months of age. On clinical examination, there was a markedly thickened, tight skin, especially on the trunk, buttocks and proximal thighs. The skin felt indurated, was shiny and had a ridged appearance on the thighs and a ‘cobblestone’ aspect on the buttocks. There were no other dysmorphic features observed. Her skin biopsy was suggestive of an “atypical scleroderma”, and her investigation was guided to evaluate genetic metabolic disorders with cutaneous manifestations like congenital disorders of glycosylation. Comprehensive diagnostic testing was performed (with brain MRI, echocardiogram, abdominal ultrasound, screening for inborn errors of metabolism) and turned out to be normal. Since there were reports of scleroderma-like lesions in HGPS, molecular genetic testing was realized and patient showed a de novo heterozygous c.1824C>T (G608G) mutation in exon 11 of the LMNA gene on chromosome 1q22.

**DISCUSSION:** HGPS is a rare, uniformly fatal premature aging disease with distinct dermatologic features. Some studies show that skin and hair abnormalities are present within the first 24 months of life in such patients. Usually, sclerodermoid changes are the most frequently reported skin feature, which commonly involved the abdomen and bilateral lower extremities. Progressively, patients present with other typical HGPS findings: prominent superficial veins, dyspigmentation, and alopecia.

**CONCLUSION:** HGPS should be considered a differential diagnosis in children with early onset findings of scleroderma/scleroderma-like lesions. Since those skin findings are very distinct cutaneous manifestations appearing during the first 2 years of life in this disease, awareness of these findings allow earlier diagnosis of HGPS and adequate patient clinical management.

## PgmNr 1085: Congenital contractural arachnodactyly and short stature in a boy with a *de novo* **FBN2** missense variant.

### Authors:

N. Urraca <sup>1</sup>; S. Holtrop <sup>2</sup>; C.W. Brown <sup>1</sup>; H. Lydigsen <sup>1</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Pediatric Genetics Division, University of Tennessee Health Science Center; 2) Le Bonheur Children's Hospital, Memphis, TN

---

Congenital Contractural Arachnodactyly (CCA), also known as Beals syndrome, is a rare connective tissue disorder. Patients with CCA have a Marfanoid habitus, as patients are tall, thin, and have arachnodactyly as well as scoliosis, congenital contractures, muscle hypoplasia and abnormalities of the external ears. Here we present a 20-month-old male referred to genetics because of short stature. Parents are healthy, of normal height, and non-consanguineous. He was born at 39 weeks by a planned C-section. His birth weight was 3.7 kg (75%ile) and length, 49 cm (30%ile). During his initial genetics evaluation at age 8-months, parents reported that he has never been able to extend his legs completely. His physical examination revealed a height <1%ile, relative macrocephaly (75%ile), frontal bossing, ears with normal position and appearance, micrognathia, camptodactyly, extra creases on the forearms, and limitation to full extension of elbows and knees bilaterally. A skeletal survey showed slight anterior, inferior beaking of L1-L2 vertebrae and urine oligosaccharides and mucopolysaccharides excluded mucopolipidoses and mucopolysaccharidoses. A chromosomal microarray and *ADAMTSL2* and *FBN1* sequencing were recommended to assess for possible chromosomal anomalies and geleophysic dysplasia, respectively but were denied by insurance. At age 15-months, he had progression of his joint restriction and underwent trio whole genome sequencing. A heterozygous, *de novo* missense variant (c.44863C>G;p.Cys1621Trp) was identified in *FBN2*. This was classified as a variant of uncertain significance, as there is phenotypic overlap between this patient's features and CCA; however, short stature has not been described in CCA and the variant has never been reported. We suggest that our patient's frontal bossing, micrognathia, camptodactyly, and joint contractures are clinically consistent with the diagnosis of CCA, and that the short stature could be a new feature of the phenotype. CCA is a rare disorder and the description of additional patients will be required to determine if short stature is within the spectrum of the disorder.

## PgmNr 1086: Probing a novel familial lipomatosis syndrome with whole genome sequencing.

---

**Introduction:** Lipomas are slow-growing adipose tumors that occur more frequently in mature adults aged 40 to 60 years old. Most lipomas are small and weigh only several grams. A giant lipoma is defined as at least 10 cm in one dimension and weighs at least 100 grams. Cases of giant lipomas have been reported, but a clinical syndrome of a solitary giant encapsulated lipoma with a strong familial component has not yet been described. **Goals and hypothesis:** We studied a large cohort of 22 individuals from a St. Croix family including a 42-year-old man born in St. Croix with macrocephaly, intellectual disability and a giant lipoma. This same condition has been traced through three generations of the patient's family including his grandmother, two aunts, uncle and cousin. We hypothesized that this condition is caused by an unknown hereditary factor. **Methods:** We employed chromosomal microarray, karyotype, and whole exome sequencing of the proband. We then captured genomes on four of the family members (3 affected and one unaffected) and performed sequencing analysis by a next generation sequencing platform with a mean coverage of 40 and sufficient depth to call variants at 99% of each targeted genome. **Results:** A disease causing factor was identified as being related to the phenotype of this family. **Conclusion:** Our results demonstrate a successful application of whole genome sequencing to identify a gene for an undescribed autosomal dominant disorder.

## **PgmNr 1087: Autonomic symptoms and autoimmune dysautonomia evaluation in patients with hypermobile Ehlers Danlos syndrome (hEDS) and generalized hypermobility on the EDS spectrum (G-HSD).**

### **Authors:**

J. Huynh <sup>1</sup>; R. Jesudas <sup>2</sup>; K. Saboda <sup>3</sup>; K. Diehl Martinez <sup>4</sup>; A. Sanoja <sup>1</sup>; C. Mauss <sup>3,5</sup>; P. Byers <sup>6</sup>; C. Laukaitis <sup>2,5</sup>

---

Hypermobile Ehlers Danlos Syndrome (hEDS) is one of 13 EDS types that is characterized by joint hypermobility. However, its physical symptoms can be similar to patients who have generalized hypermobility on the EDS hypermobility spectrum (G-HSD). The hEDS GENE study was developed to better understand the genetic causes of hEDS and to gather data on disease-related symptomatology in order to develop better hEDS diagnostic methods.

To quantify disease-related symptomatology, each participant in the study completed eight questionnaires, including the COMPASS31. This survey is an abbreviated version of the Autonomic Symptom Profile and prompts participants to answer questions on autonomic symptoms that are grouped into the following subgroups: orthostatic intolerance, vasomotor, secretomotor, gastrointestinal, bladder and pupillomotor symptoms. Totalled scores range between 0-100 with higher scores indicating greater autonomic symptoms. Total weighted scores for participants with hEDS and G-HSD (42.5) are significantly different from unaffected participants (9.4) ( $p < 0.001$ ). However, participants with hEDS and G-HSD did not significantly differ in their subgroup scores except for the GI ( $p < 0.001$ ) and Vasomotor ( $p < 0.002$ ) categories.

Additionally, serum from 40 participants was sent to Mayo Clinical labs and tested with the Autoimmune Dysautonomia Evaluation (DYS1) which tests for the presence of nine antibodies. 17.5% (7/40) of participants had measurable auto-antibodies sometimes associated with dysautonomia. Four had GAD65 levels from 0.03 to 0.06 nmol/L (normal  $\leq 0.02$ ), two had Neuronal (V-G) K<sup>+</sup> Channel antibody levels from 0.09 to 0.1 nmol/L (normal  $\leq 0.02$ ), and one had a positive striated muscle antibody titer at 1:960 (normal  $< 1:120$ ). However, none of the participants tested had measurable levels of the ganglionic acetylcholine receptor (alpha3) autoantibody which is the only antibody on the panel known to cause autoimmune dysautonomia.

Our studies suggest that though patients with hEDS or G-HSD experience greater autonomic symptoms compared to unaffected patients, patients with either hEDS or G-HSD experience similarities in their autonomic symptoms. Though 7/40 patients were found to be positive upon autoimmune dysautonomia antibody evaluation, there is not a high prevalence of antibodies or a clear correlation between antibody presence and symptoms.

## PgmNr 1088: A new mutational hotspot in the *SKI* gene in the context of MFS/TAA molecular diagnosis.

### Background

*SKI* pathogenic variations are associated with Shprintzen-Goldberg Syndrome (SGS), which is a rare systemic connective tissue disorder characterized by craniofacial, skeletal and cardiovascular features. Intellectual disability and craniosynostosis are almost consistent in the carriers of pathogenic variants in this gene. So far, the clinical description was quite homogeneous within patients, and the known pathogenic variations were located in two different hotspots of the *SKI* gene.

### Methods and Results

In the course of diagnosis of Marfan syndrome (MFS) and related disorders, we identified 6 probands (2 females and 4 males) carrying 3 different pathogenic variants in the *SKI* gene affecting the same amino acid Thr180 located in the Dachshund-homology domain (DHD). They were all sporadic cases, diagnosed at an age ranging from 2 to 14 y.o. For 5 of the probands, the family screening revealed that the molecular events occurred *de novo*. A specific clinical examination was done for all these patients by a multidisciplinary team. They all displayed a milder morphological phenotype that did not initially lead to the clinical diagnosis of SGS. They presented a marfanoid habitus with a systemic score according to the revised Ghent nosology ranging from 4 to 12. Only 3 of them had learning disorders or mild intellectual disability. Four out of 6 presented a moderate cardiovascular involvement with Thoracic Aortic Aneurysm (TAA) or Mitral Valve Prolapse (MVP).

### Conclusion

This report extends the phenotypic spectrum of variants identified in the *SKI* gene. We describe a new mutational hotspot in the *SKI* gene associated with a marfanoid syndrome with no or a mild form of

intellectual disability. A cardiovascular involvement was seen in a significant number of cases, illustrating the need to adapt the medical treatment and follow-up for these patients.

**Keywords:** *SKI* gene, Shprintzen-Goldberg syndrome, Marfan syndrome, Phenotypic spectrum

## PgmNr 1089: Detection of a novel large deletion in *FBN1* gene by MLPA.

**Objectives:** Marfan syndrome (MFS) is an autosomal dominant multisystem disorder of the connective tissue. It has varying clinical features, most frequently the skeletal, ocular, and cardiovascular systems are involved. The disorder caused by mutations in the fibrillin-1 gene (*FBN1*), mapped to chromosome 15q21.1. Majority of classic MFS patients bear small alterations (i.e. point mutations, indels), however, a smaller number of patients have larger genomic rearrangements in *FBN1* gene.

**Methods:** The study included 20 patients. All of the patients fulfilled the revised Ghent criteria. After negative results of systematic sequencing of *FBN1*, *TGFBR1* and *TGFBR2* genes MLPA (P065-P066 MRC-Holland) analyses were performed in our patient cohort.

**Results:** In contrast to the generally detected large deletions, we identified a novel two-exon deletion (exon 46-47) in two patients, who are close relatives. This deletion results in the loss of 31-32<sup>nd</sup> calcium binding EGF-like domain which is responsible for the development of classic Marfan phenotype.

**Conclusions:** Less than 10% of the disease causing mutations in *FBN1* gene are copy number alterations, in which single or multiple exon deletions can be detected by MLPA in a cost-effective manner even in the NGS era. Our findings emphasize the importance of screening for large *FBN1* deletions in clinical genetic testing, especially for those with classic Marfan phenotype.

## PgmNr 1090: Otological features in patients with musculocontractural Ehlers-Danlos syndrome caused by mutations in *CHST14* (mcEDS-*CHST14*).

### Authors:

T. Kosho <sup>1,2,3</sup>; M. Kawakita <sup>4</sup>; S. Iwasaki <sup>5,6</sup>; H. Moteki <sup>5</sup>; S. Usami <sup>5</sup>

### Affiliations:

1) Department of Medical Genetics, Shinshu University School of Medicine, Matsumoto, Japan; 2) Center for Medical Genetics, Shinshu University Hospital, Matsumoto, Japan; 3) Research Center for Supports to Advanced Science, Matsumoto, Japan; 4) Shinshu University School of Medicine; 5) Department of Otolaryngology, Shinshu University School of Medicine, Matsumoto, Japan; 6) Department of Otolaryngology, International University of Health and Welfare, Mita Hospital, Tokyo, Japan

**Background:** Musculocontractural Ehlers-Danlos Syndrome (mcEDS) is a recently identified connective tissue disorder, caused by loss-of-function mutations in *CHST14* encoding dermatan 4-O-sulfotransferase-1 (mcEDS-*CHST14*) or in *DSE* encoding dermatan sulfate epimerase (mcEDS-*DSE*), both resulting in defective biosynthesis of dermatan sulfate (DS) replaced by chondroitin sulfate (CS). To date, 42 patients with mcEDS-*CHST14* from 28 families and three patients with mcEDS-*DSE* from two families have been published. Mild hearing impairment was reported in some patients, but has not been systematically investigated. The aim of this study is to delineate otological features in patients with mcEDS-*CHST14*.

**Materials and methods:** Our cohort includes nine patients (eight ears from four male patients; 10 ears from five female patients) with mcEDS-*CHST14*, who had systemic otological investigation in Shinshu University Hospital. The mean age is 18 years old (range, 10–28 years old). Otological investigation comprised subjective symptoms, audiogram, distortion product otoacoustic emissions (DPOAE), and tympanogram.

**Results:** Only one patient felt hearing impairment. Audiogram showed hearing impairment of high-frequency sound in 12 ears (67%), low-frequency sound in six ears (33%), and specifically middle-frequency sound in two ears (11%). Normal hearing was detected in one ear (6%). DPOAE, available in 13 ears, showed hearing impairment of high-frequency sound in 10 ears (77%) and all-frequency sound in two ears (15%). Normal hearing was detected in one ear (8%). Tympanogram, available in 16 ears, showed Ad types in 12 ears (75%). No abnormalities were detected in four ears (25%).

**Discussion:** Hearing impairment is frequent in patients with mcEDS-*CHST14*, detected in 94% of ears and predominantly for high-frequency sound but with a variability including low-frequency type or middle-frequency type. In eight ears (62%), results in DPOAE were compatible to those in audiogram. Ad type in tympanogram did not seem relevant to specific types of hearing impairment. Interestingly, they tended to have conductive hearing impairment for <1kHz sound and sensorineural hearing impairment for >2kHz sound. Regular surveillance using multiple measures is recommended in patients with mcEDS-*CHST14*, and complex pathology was suggested for hearing impairment in these patients.

## PgmNr 1091: Keratin 13 mutations in two Chinese families and the mechanism of white sponge nevus.

### Authors:

W. Cai<sup>1,2</sup>

---

White sponge nevus (WSN) is an autosomal dominant hereditary disease. Keratin 4 (*KRT4*) and Keratin 13 (*KRT13*) gene mutations were involved in the WSN. We recruited two WSN Chinese families, and oral lesions biopsy with hematoxylin and eosin staining showed that patients had significantly pathological characteristics. The mutations of *KRT4* and *KRT13* gene were detected by PCR and direct sequencing. The multiple alignments of *KRT13* from 28 diverse species homology analysis were performed by the ClustalW program. The *KRT13* expression was measured by Real-Time RT-PCR and Western blot analysis. We revealed the pathological pathway of the WSN expression profile by RNA sequencing (RNA-seq). Sequencing analysis revealed two mutations of *KRT13* gene: one mutation was 332T>C, and amino acid change was Leu111Pro. Another mutation was 340C>T, and amino acid change was Arg114Cys. The sequence of *KRT13* was highly conserved. Real-Time RT-PCR and Western blot analysis results show that *KRT13* expression level is lower in patient but keep almost no change in mRNA level. When treat cells with MG132, *KRT13* protein level was increased and kept almost the same in normal and patient cell. We identified two heritable mutations in the *KRT13* gene, which were associated with the development of WSN. The abnormal degradation of *KRT13* protein of WSN may probably associate with abnormal ubiquitination process. Further RNA-seq analysis suggests that the abnormal degradation of *KRT13* protein of WSN may probably associate with Keratin 7 (*KRT7*) and abnormal ubiquitination process. All the efforts may contribute to the molecular therapy for WSN. Gene-based diagnosis and gene therapy for WSN may become available in the near future while provide reference and instruction for treating other keratin associated diseases.

**Key Words:** gene mutation; keratin 13(*KRT13*); oral disease; ubiquitination; white sponge nevus (WSN); RNA sequencing (RNA-seq)

**Funding:** This work was supported by the National Natural Science Foundation of China (No. 81600881).

Mendelian genes are generally regarded as inherently different from non-Mendelian genes. To interrogate differences between Mendelian genes and non-Mendelian genes, we focused on a small subset of genes which would likely have physical manifestations in zebrafish – zebrafish matrisome genes. 1015 zebrafish matrisome genes were identified, with corresponding 719 unique human orthologs. Of 3924 human genes known to be Mendelian, 269 are human orthologs of zebrafish matrisome genes. Of these genes, 72 are genes associated with described disorders in OMIM. These most frequent phenotypes associated with these disorders include vision and eye problems, movement abnormalities, and neurological disorders. The majority of the phenotypes fall under the neurologic category. Matrisome genes can be broken down into different categories: collagens, ECM glycoproteins, ECM regulators, ECM-affiliated proteins, proteoglycans, and secreted factors. Non-Mendelian matrisome genes are more than twice as likely to be ECM-affiliated proteins compared to Mendelian matrisome genes, and more than three times less likely to be collagens. Compared to Mendelian genes without a described disorder in OMIM, those with a described disorder in OMIM are 1.5 times more likely to be collagens. Using PredixVU developed by the Cox lab, phenotypes associated with predicted altered expression of each of the matrisome genes was identified. Cutoffs of 0.001 for both p-values and  $R^2$ -values were used. For tissue-specific associations, phenotypes associated with non-Mendelian genes were 1.4 times more likely to be rheumatologic and phenotypes associated with Mendelian genes were 1.3 times more likely to be endocrine and metabolic and 1.3 times more likely to be gastrointestinal. As more stringent p-value cutoffs are used, there are more extreme differences between category frequencies between Mendelian and non-Mendelian. When using cross-tissue results, the differences seen between non-Mendelian genes and Mendelian genes generally shrinks, only becoming more pronounced in the injuries category. While these results show some evidence of differences between Mendelian and non-Mendelian matrisome genes, further investigation will explore additional differences between Mendelian and non-Mendelian genes.

## **PgmNr 1093: An expanded cohort of patients indicates thrombospondin type laminin G domain and EAR (*TSPEAR*) is a cause of ectodermal dysplasia but may not directly cause hearing loss.**

---

Biallelic loss of function variants in the thrombospondin type laminin G domain and EAR (*TSPEAR*) have recently been associated with ectodermal dysplasia and hearing loss phenotypes. While the ectodermal association is supported by multiple studies of affected families, the evidence surrounding hearing loss is not well defined. We assembled a cohort of 10 newly reported, unrelated individuals to investigate the *TSPEAR* hearing loss association in greater depth. Individuals were sequenced using whole exome or targeted hearing loss panels. Skin, hair, and dental features characteristic of ectodermal dysplasia or related syndromes were present in a majority of the cohort patients (6/10 patients). Hearing loss was reported in 4/10 patients in the cohort. These results were confounded by the report of additional variants in other hearing loss genes beyond *TSPEAR* in 3 of these individuals. While variants for this cohort concentrated in exons 3, 7, and 8, there was no genotype/phenotype correlation that separated patients with hearing loss from those with ectodermal dysplasia. When presented alongside previous reports, this evidence supports the association of *TSPEAR* variants with ectodermal dysplasia and tooth agenesis features, but raises question as to whether *TSPEAR* alterations are a direct cause of hearing loss. Further functional evidence is needed to demonstrate this assertion.

## PgmNr 1094: Pulmonary complications and CT findings of vascular Ehlers-Danlos syndrome.

---

Vascular Ehlers-Danlos syndrome (vEDS) is a rare, autosomal dominantly inherited disorder, caused by heterozygous pathogenic variants in *COL3A1* gene, affecting the connective tissue in multiple organ systems. The patients are predisposed to general tissue fragility, characterized by arterial aneurysm, dissection and rupture, bowel rupture, rupture of the gravid uterus and early mortality. Although not usually related to issues of mortality, pulmonary complications including recurrent pneumothorax, hemoptysis, and intrapulmonary hematoma, are annoying and at times serious complications. We reviewed the medical records of 51 molecularly diagnosed vEDS patients retrospectively to evaluate the lung manifestations characteristic to vEDS in patients in our outpatient clinic for connective tissue and aortic diseases or in inpatient unit for vascular surgery. Data were obtained from study visits, medical records and radiology images.

Thirteen of 51 (25%) patients presented pulmonary complications. Twelve suffered recurrent pneumothorax, 11 had episodes of massive hemoptysis, and 9 had both. Pulmonary CT evaluation revealed multiple cavities or parenchymal hemorrhage in six, mostly in lower lobes and periphery. Mean and median ages of first pulmonary complications are 19 and 18, respectively. In 8 cases, pneumothorax or hemoptysis was the first significant event of tissue fragility. There was no apparent genotype-phenotype correlation. Also, there seemed to be no correlation with the risk of pneumothorax/ pulmonary cysts and tissue fragility in general. One patient with multiple giant bullae presented lung findings as a sole complication without any arterial or bowel problem. But all those with episodes of hemoptysis showed other tissue fragilities, especially vascular complications, meaning hemoptysis is an earlier sign for progressive vascular complications.

It is important to be aware of the possible pulmonary presentations of connective tissue disorders, avoid invasive procedures and consult to geneticists for the possibility of vEDS, when we encounter cases with unique radiologic findings, including atypical cysts with signs of infiltration or multiple large bullae, especially those with recurrent hemoptysis.

## PgmNr 1095: Biallelic *KRT5* mutations in epidermolysis bullosa simplex, including a complete human keratin 5 “knock-out”.

---

Epidermolysis bullosa simplex (EBS) is usually inherited as an autosomal dominant disease due to monoallelic gain-of-function mutations in *KRT5* and *KRT14*. Although autosomal recessive forms of EBS have been associated with mutations in at least 10 genes, recessive EBS due to homozygous biallelic *KRT5* mutations has not been reported previously; it has been hypothesized that it would result in prenatal lethality. We sought the genetic causes of EB in a cohort of 512 distinct EB patients by performing whole exome sequencing (WES) and using a disease-targeting next-generation sequencing (NGS) panel of 21 genes. The pathogenicity and consequences of the mutations were determined by expression profiling and at tissue and ultrastructural levels. Two pathogenic, homozygous missense variants of *KRT5* in two patients with generalized EBS and a homozygous null mutation in a patient who died as a neonate from complications of EB were found. The two missense mutations disrupted keratin 5 expression on immunofluorescence microscopy, and the human “knock-out” of *KRT5* showed no RNA and protein expression. Collectively, these findings identify biallelic *KRT5* mutations with a phenotypic spectrum varying from mild, localized and generalized to lethal, expanding the genotypic profile of autosomal recessive EBS.

## PgmNr 1096: Cardiac findings in a cohort of 47 patients with early onset cobalamin C (*cb/C*) deficiency.

Combined methylmalonic acidemia and hyperhomocysteinemia, *cb/C* type, is the most common disorder of intracellular cobalamin metabolism. One variant in *MMACHC*, c.271dup A, accounts for 30-50% of the alleles, and is associated with early onset disease in the homozygous state. While the primary manifestations of *cb/C* are ophthalmologic, neurologic, and hematologic, cardiac disease, including left ventricular non-compaction (LVNC) and other structural heart defects, has been variably noted, and not fully described. Therefore, we reviewed the structural cardiac manifestations in a cohort of 47 ethnically diverse, early onset *cb/C* patients (ages 2-36, 14 females) who received standardized evaluations under an NIH natural history protocol (ClinicalTrials.gov Identifier: NCT00078078) over the span of 15 years. 26/47 (55%) were homozygous for the *MMACHC* c.271dupA variant. We obtained 2D echocardiograms in 44/47 individuals, and cardiac MRI in five patients that could cooperate for imaging. On echocardiogram, 13 (30%) were noted to have hypertrabeculations in the left ventricle suggestive of LVNC. Nine of the 13 (69%) were homozygous for c.271dupA. Four of 13 (31%) ages 2, 12, 19 and 24 years had decreased left ventricular ejection fraction. Four of the five patients who had cardiac MRI had confirmation of LVNC and the other subject had global hypokinesis, reduced ejection fraction at age 9 and notable trabeculations, but did not meet criteria for LVNC. Cardiac findings that were comorbid with LVNC included: fetal hydrops, Ebstein's anomaly, tricuspid regurgitation, pulmonary artery dilation, hypoplastic right heart, persistent left SVC, interatrial septal aneurysm, dilated atria and global hypokinesis. Other findings variably included mildly dilated aorta, right ventricular dilatation, PFO, VSD and biventricular hypertrophy. Cardiac involvement, especially LVNC, was relatively common in early onset *cb/C* patients in our cohort. While the long-term natural history of cardiac function remains unknown in this disorder, patients with reduced LV systolic function may be at risk for progression. The chronic hyperhomocysteinemia and decreased activity associated with progressive vision loss may pose additional risks to cardiac health. Longitudinal assessment, including echocardiographic monitoring, and aggressive management of co-morbidities, such as hypertension and hyperlipidemia, are indicated and should be routine for these patients.

## PgmNr 1097: A novel mutation in *KCNJ11* gene in a late diagnosed hyperinsulinemic hyperglycemia patient.

### Authors:

E. Arslan Ates; A.I. Guney

[View Session](#) [Add to Schedule](#)

**Affiliation:** Department OF Medical Genetics, Marmara University Pendik Training and Research Hospital, Istanbul, MD

---

Hyperinsulinemic hypoglycemia is the most common metabolic disorder of neonates. It is important to diagnose and treat to prevent neurological damage such as intellectual disability, recurrent seizures, neuromotor delay if not noticed. Most common genetic causes of hyperinsulinemic hypoglycemia are *ABCC8* and *KCNJ11* gene mutations in infants.

A one year old boy was referred to us because of afebrile seizures starting at the age of 4-months. He was born to consanguineous parents at term with an uneventful prenatal and perinatal history. Physical examination,, biochemical tests, electroencephalogram and cranial imaging studies were normal. His blood sugar level was found to be 29 mg / dl in one of his biochemical tests and diagnosed as hyperinsulinemic hypoglycemia at the age of 12-months. *ABCC8* and *KCNJ11* genes were evaluated by next generation sequencing method. Homozygous c.392T> C (p.Ile141Thr) mutation was detected in the *KCNJ11* gene. Parents were carrying this mutation in heterozygous state, and referred to an endocrinology department with a diagnosis of MODY. His asymptomatic sister was also homozygous for the mutation and her fasting blood sugar level was detected 42mg / dl.

*KCNJ11* is an ATP-sensitive potassium channel gene that is expressed in endocrine cells, neurons and muscle cells, especially in pancreatic beta cells. Homozygous mutations cause neonatal hypoglycemia and persistent diabetes, and heterozygous mutations have been associated with MODY. *KCNJ11* c.392T> C mutation was not reported previously in databases or population studies. In silico analyses predicted this mutation to be pathogenic and mutation cosegregated with the clinical findings.

Here we present this study to emphasize the importance of molecular genetic diagnosis to prevent the complications of hypoglycemia and also hyperglycemia. This study also expands the mutation spectrum of *KCNJ11* gene and contribute to genotype-phenotype correlation of *KCNJ11* mutations.

## PgmNr 1098: A genetic retrospective study of maturity-onset diabetes of the young (MODY) in two population health studies.

### Authors:

A. Bolze <sup>1</sup>; S. White <sup>1</sup>; E.T. Cirulli <sup>1</sup>; L. Sharma <sup>1</sup>; K.A. Schlauch <sup>2,3</sup>; G. Elhanan <sup>2,3</sup>; J. Grzymalski <sup>2,3</sup>; N.L. Washington <sup>1</sup>; J. Lu <sup>1</sup>

---

### Background:

Maturity-Onset Diabetes of the Young (MODY) has been reported to account for 1-2% of all diabetes cases. Like most rare diseases, MODY is usually underdiagnosed and it is reported that up to 90% of MODY cases are misdiagnosed as Type 1 or Type 2 Diabetes. Properly diagnosing MODY has medical implications as the first line of treatment is usually different for MODY patients who may not require insulin medication. MODY is generally inherited in an autosomal dominant manner, with variants in *GCK*, *HNF1A* and *HNF4A* explaining more than 80% of reported cases.

### Aims:

The aims of this retrospective study were: (i) to provide the frequency of known pathogenic or likely pathogenic variants, as well as predicted loss-of-function variants in the population, (ii) to estimate the penetrance of these variants, and (iii) to assess the potential medical implications of screening the general population for pathogenic variants in these three genes.

### Method:

We analyzed the exome sequence data of ~70,000 individuals, with 50,000 individuals from the UK Biobank and 20,000 from the Healthy Nevada project, irrespective of their ancestry. Participation in either project was not based on a personal or family history of diabetes. We used ClinVar to select known MODY pathogenic and likely pathogenic variants and Variant Effect Predictor version e!95 annotations to identify predicted loss-of-function variants in *GCK*, *HNF1A*, and *HNF4A*. Electronic health records were available for all individuals analyzed. We looked in particular at (i) ICD10 codes related to diabetes, (ii) medication code(s) for insulin and metformin, as well as (iii) the age of diabetes diagnosis.

### Results:

The frequency of known pathogenic or likely pathogenic variants (n=14 in Healthy Nevada + 42 in UK Biobank), or predicted loss-of-function variants (n=4 in Healthy Nevada + 12 in UK Biobank) in these 3 genes was about 1 in 1,000 individuals (0.1%). Less than 25% of the individuals carrying a pathogenic or likely pathogenic variant had a diagnosis of MODY (2 in Healthy Nevada + 10 in UK Biobank). Moreover, none of the other individuals carrying a pathogenic or likely pathogenic variant had a diagnosis of diabetes. We further characterized the phenotypes of these individuals with regard to glucose and HbA1c levels. These results will also allow to refine the classification of pathogenic and likely pathogenic variants for MODY.

## PgmNr 1099: Next generation sequencing in the diagnosis of rare metabolic disorders.

### Authors:

---

**Introduction:** Molybdenum cofactor deficiency, is a very rare autosomal recessive metabolic disorder, first described in 1977. It is characterized by neonatal seizures resistant to treatment, opisthotonus and dysmorphic features. Low uric acid and increased levels of urine sulfites are also present. The disorder is attributed to mutations in *MOCS1*, *MOCS2*, *MOCS3* and *Gephyrin* genes.

**Case report:** We report the clinical presentation of a female newborn, the second child of consanguineous phenotypically healthy parents. The mother was a G5P2 woman, with 3 spontaneous abortions. From the first day of life, the newborn presented with trunk hypotonia and hypertonia of the limbs, opisthotonus, intractable seizures and dysmorphic features such as facial asymmetry, overlapping sutures, prominent occipital bone and narrow forehead. She had a low nasal bridge with a short nose and a high arched palate, retrognathia, low set ears, low posterior hairline and 5<sup>th</sup> finger clinodactyly. Cardiological investigation revealed atrial septal defect. Biochemical and metabolic profile showed low plasma uric acid (0.2 mg/dl), positive urine sulfite test and elevated urine sulfocysteine levels (145.6 mmol/mol creatinine). Brain MRI revealed thin corpus callosum and cerebellar hemispheres atrophy.

**Results:** Chromosomes from peripheral blood by G-banding technique was normal. Whole exome sequencing revealed a homozygous missense mutation in *MOCS2* (c.226G>A, leading to p.Gly76Arg, in exon 4 of the *MOCS2* gene). Both parents were found to be carriers of the above mutation. *MOCS2* is involved in the biosynthesis of the molybdenum cofactor of the complementary group B.

**Conclusion:** Whole exome sequencing technique, is the gold standard method of investigation in cases of an inconclusive phenotype in critically ill newborns. An accurate and prompt diagnosis leads to precise therapy and appropriate genetic counselling of the family to avoid the risk of recurrence.

## PgmNr 1100: Coexistence of two infrequent genetic pathologies: Noonan and renal Fanconi syndromes.

### Authors:

**Introduction:** Genetic diseases are associated with variations in DNA, which it includes single-nucleotide variation or large variations of DNA fragments. The clinical variability of genetic conditions can occur by variable expressivity of monogenic diseases and less frequent coexistence of two conditions. The genetic advances have allowed the application of very useful molecular studies in the diagnosis of patients with uncertain pathology. We present the unusual coexistence of two diseases with different pathogenic mechanisms and different clinical manifestations.

**Case report:** 4-year-old female patient, born of non-consanguineous parents, prenatal history of hydronephrosis, neonatal finding of dilated cardiopathy with interatrial communication and pulmonary hypertension and optic nerve hypoplasia. Since the year of age with persistent hydronephrosis, renal tubular acidosis, height and weight low. Patient with chromosomal complement 46, XX without alteration. array Genomic Comparative Hybridization without evidence of deletions or duplication [arr (1 -22, X) x2]. Sequencing of the CTNS gene negative. Clinical exome sequencing (trio), which evidenced a heterozygous variant pathogenic in the PTPN1: c.236A>G(p.Gln79Arg) associated with Noonan syndrome, and another heterozygous variant c.1861G>T (p. Glu621\*) in the gene EHHADH, probably pathogenic, associated with renotubular Fanconi syndrome 3.

**Discussion.** The power detection of molecular alterations depends on the resolution of the test used and the type of technique. In this patient the staggered study with different diagnostic techniques allowed to identify the coexistence two infrequent conditions explaining the patient's phenotype. Noonan syndrome is a rasopathy characterized by low stature, facial dysmorphism and congenital cardiac anomalies, among others. In addition, Renotubular Fanconi syndrome, type 3, is an alteration of the renal tubular absorption characterized urinary hyperexcretion of electrolytes with secondary symptoms and evidence of hypophosphatemic rickets and acidosis. Both phenotypes could be mistaken in individuals with pathologic short stature

**Conclusion.** The coexistence of these genetic conditions has not been previously reported with different etiology and high comorbidity associated with a late diagnosis; these results emphasize the importance of clinical exome in patients with clinical phenotypes that do not configure for a specific entity.

## PgmNr 1101: Kallman syndrome: A case report.

Congenital hypogonadotrophic hypogonadism is a rare disease caused by deficiency in the production, secretion or activity of gonadotropin-releasing hormone (GnRH), which is the main regulatory hormone of the reproductive axis. The clinical characterization of this disorder and in the setting of an isolated hypogonadotrophic hypogonadism is due to infertility and partial or incomplete puberty.

Congenital hypogonadotrophic hypogonadism may present as an isolated deficiency of GnRH or be associated with other developmental anomalies such as: cleft lip and palate, dental agenesis, ear abnormalities, congenital deafness, renal agenesis, skeletal alterations or bimanual synkinesias.

Kallman syndrome is a congenital hypogonadotrophic hypogonadism associated with anosmia or hyposmia. This alteration results from an abnormal embryogenic migration of the GnRH neurons in the olfactory plaque to the anterior cerebral region. The association of congenital hypogonadotrophic hypogonadism with an alteration in olfactory perception (anosmia or hyposmia) is found in around 50% of cases of Kallmann syndrome. Thanks to advances in mass sequencing techniques, more than 25 genes related to Kallmann syndrome have been identified, including CHD7. We present the case of a 34-year-old female patient with a history of delayed puberty, learning disorder, hypogonadotrophic hypogonadism and hyposmia, with a G-banded karyotype with normal chromosomal complement 46, XX and a clinical-led exome, which reports a heterozygous variant c.1159C> T (p.Q387 \*) in the CHD7 gene. This mutation has been described not only in the Kallmann syndrome together with the association of olfactory alterations, but also in congenital hypogonadotrophic hypogonadism and CHARGE syndrome.

Research on the molecular basis of the disease and the various signaling pathways involved will help improve the diagnosis and management of patients with hypogonadotrophic hypogonadism, as well as develop more precise genetic counseling and screening.

## PgmNr 1102: Rare *BMP4* sequence variants in patients with hypogonadotropic hypogonadism.

*BMP4* is a member of the bone morphogenetic protein family which is part of the transforming growth factor-beta superfamily. *BMP4* is involved in the embryonic development of various organ and tissues including the craniofacial and olfactory structures, pituitary, eyes, heart, and kidneys. Mutations in this gene are associated with orofacial cleft and microphthalmia in human patients. *BMP4* plays an important role in the embryonic development of the GnRH neurons (Forni et al 2013, Layman et al 2011) and anterior pituitary by regulating diverse cellular responses, such as cell differentiation, migration, adhesion, and proliferation (Massague et al 2000). *BMP4* also has been described as inhibiting FSH production particularly (Nicol et al 2008). Recently, a heterozygous truncating mutation was described in a 6 years old prepubertal child with combined pituitary hormone deficiency (Rodriguez-Contreras et al 2019). Mutations in the BMP genetic network including *BMP4* were reported to be found in patients with hypogonadotropic hypogonadism (HH) in a meeting abstract (Cassatella et al ASHG 2013). However, no detailed description of *BMP4* mutations in the etiology of HH has been found in the literature. Here we present three independent patients with isolated HH who harbor rare seemingly deleterious sequence variants in *BMP4*.

Methods: We screened the whole exome sequencing data from 215 HH patients from Turkey.

Patient number	DNA change	Zygosity	Protein change	Minor allele frequency in gnomAD	CADD score
1	NM_001202.3:c.450C>G	Hom	NP_001193.2:p.(Asn150Lys)	0.00001	22.5
2	NM_001202.3:c.41G>A	Het	NP_001193.2:p.(Cys14Tyr)	0.00001	24.9
3	NM_001202.3:c.751C>T	Het	NP_001193.2:p.(His251Tyr)	0.0001	29.6

Results: We identified apparently deleterious rare *BMP4* sequence variants in three independent patients with HH. All patients were normosmic. Interestingly, variant p.N150K has been reported to cause renal hypodysplasia in heterozygosity as well as homozygosity in two independent Turkish patients (Weber et al 2008). Co-occurrence of HH with kidney anomalies are well known, especially with certain anosmic HH genes. In all of the patients both FSH and LH were similarly deficient, i.e. there was not a particularly more pronounced deficiency of FSH over LH.

Conclusions: These results suggest that inactivating variants in *BMP4* may compromise the central

part of the hypothalamo-pituitary-gonadal axis and result in normosmic HH.

## PgmNr 1103: Genomic characterization of *STX16* deletion in pseudohypoparathyroidism.

Pseudohypoparathyroidism type 1b (PHP-1b) is a rare imprinting disorder, characterized by renal parathyroid hormone resistance, but the absence of physical features of Albright hereditary osteodystrophy. A common heterozygous 3-kb deletion of *STX16* gene was previously reported in multiple unrelated probands. This deletion cause isolated loss of methylation at *GNAS* exon A/B. We aimed to identify *STX16* deletion and exact breakpoint and to gain insights into the mechanism of *STX16* deletion. We investigated 10 patients who were diagnosed as PHP-1b but didn't have any pathogenic sequence variants in *GNAS*. Methylation-specific multiplex ligation-dependent probe amplification assay of *STX16* were performed to assess the allelic dosage. Junction PCR and Sanger sequencing around presumptive breakpoint area was carried out to reveal the exact breakpoint. A *STX16* gene deletion was detected in 2 of 9 probands (22.2%). Deletion range was the same for both probands which was from g.57,243,566 to g.57,246,545 (2,979 bp), according to the February 2009 human reference sequence (hg19, build37), consistent with previous reports. The 5' and 3' break points were located in the mammalian-wide interspersed repeat (MIR) sequences suggesting an MIR-mediated non-allelic homologous recombination (NAHR) as the putative mechanism for the common *STX16* 3-kb deletion. To the best of our knowledge, this is the first study to reveal that the MIR was involved in the genomic rearrangement.

## PgmNr 1104: Novel *KMT2D* mutation in Kabuki syndrome with midgut malrotation and hyperinsulinism.

---

Kabuki syndrome (KS) is a heterogeneous phenotypic genetic syndrome, mainly caused by loss of function in *KMT2D* and *KDM6A*. Gastrointestinal anomalies in KS patients have been rarely reported. The present patient was a female infant, born at 37-week gestation. Her growth parameters included weight of 2,714 g (10<sup>th</sup> centiles), length of 49 cm (50<sup>th</sup> centiles), and head circumference of 32 cm (10<sup>th</sup> centiles). At one hour after birth, she developed respiratory distress and found to have hypoglycemia (blood sugar 34 mg/dL). She was treated with bolus dose of 10% dextrose. Critical blood samples showed elevated serum insulin level at 10.4 µU/ml, prompting diagnosis of hyperinsulinism. Due to refractory response to high dose of glucose infusion, diazoxide treatment was started on day of life (DOL) 5 which resulted in gradual improvement of hypoglycemia. On DOL15, the patient developed feeding difficulty, abdominal distension and frequent vomiting. Barium swallowing revealed abnormal position of duodenal and jejunal loops, indicating midgut malrotation, prompting surgical operation with Ladd procedure performed. She was discharged home on DOL 45. Due to her minor dysmorphic features including smooth philtrum, thin vermilion of lips and microretrognathia, genetic evaluation was carried out. There was no specific recognized syndrome was suspected. Cytogenomic and SNP microarray (CytoSNP850, Illumina) analysis was performed which revealed normal findings. Whole exome sequencing revealed a *de novo* novel pathogenic heterozygous *KMT2D* mutation, c.13564A>T (pLys5122\*). *KMT2D* is a transcriptional activator that induces the transcription of target genes by covalent histone modification and involved in adhesion-related cytoskeletal regulation, which might affect cell growth and survival effecting to coupling of apoptosis and Left-Right patterning controls organ looping. Therefore, this might explain the pathogenic mechanism of *KMT2D* mutation leading gut malrotation in the present patient. Retrospectively, the patient did not show typical facial phenotypes of KS such as long palpebral fissure and eversion of the lateral one-third of lower eyelid, probably due the characteristic facial phenotypes of KS was not evident at that young age. In conclusion, we address the benefit of WES in establishing diagnosis of rare disorder in patient without characteristic features of a known syndrome and the rare phenotype of KS namely gut malrotation.

## PgmNr 1105: Molecular diagnosis of osteogenesis imperfecta: Targeted gene panel sequencing.

Osteogenesis imperfecta (OI) is a hereditary disease characterized by increased bone fragility and low bone mass. The incidence is one in 10,000 births. Mutations in the *COL1A1* and *COL1A2* genes that encode type I collagen, are responsible for more than 90 percent of all cases of OI.

To understand the etiology of the disease, to identify the carriers and the underlying genetic cause is extremely important for appropriate genetic counseling. In this study, 29 patients who admitted to our clinic between July 2018 and June 2019 with OI were screened for related genes. Exon and the exon-intron boundaries were amplified using OI Paragon kit (14 genes related with OI) and sequence analysis was performed via Illumina MiSeq™ System. Sophia DDM platform and Sophia Genetics' MOKA software was used for variant analysis and annotations. Pathogenicity of variants were analyzed using online tools (HGMD, ClinVAR, MutationTaster, SIFT, Polyphen) and ACMG criteria. 37 variants in *BMP1*, *COL1A1*, *COL1A2*, *FKBP10*, *LEPRE1*, *PLS3*, *SP7*, *SERPINH1* and *PLOD2* genes were identified. According to ACMG classification, 28 of these variants were variant of unknown significance (VUS), while nine of them were pathogenic and possibly pathogenic. 14 of these variants were novel. Our study affirms that genetic screening of patients with OI symptoms by using multigene panel not only eases the diagnosis but also help to provide accurate and effective genetic counseling for prenatal diagnosis and preimplantation genetic diagnosis options for patients and their family members for the risk of developing the diseases in the future.

## PgmNr 1106: Strong genotype-phenotype correlations in *ACTG2* are the primary determinants of disease severity in visceral myopathy.

Visceral myopathy (MIM #155310) is a disorder manifesting primarily as abnormal intestinal and bladder peristalsis, with a clinical spectrum that includes Megacystis Microcolon Intestinal Hypoperistalsis Syndrome (MMIHS) and Chronic Intestinal Pseudo-Obstruction (CIPO). Symptoms range from intrauterine bladder distension with severe postnatal feeding intolerance and dependence on parenteral nutrition to intermittent constipation with or without bladder dysfunction. A number of genes have been identified underlying these phenotypes with the vast majority of molecularly-diagnosed cases caused by dominant variants in *ACTG2*; however, the overall genetic architecture of visceral myopathy has not been well-characterized.

We report in the clinical features, molecular diagnostic rates and genotype-phenotype correlations in 51 families with visceral myopathy ascertained based on clinical features of megacystis, functional bladder or GI obstruction or microcolon. Targeted *ACTG2* sequencing or exome sequencing yielded a molecular diagnosis in 64% (34/53) of cases, of which 97% (33/34) is attributed to *ACTG2* and 3% (1/34) to *MYLK*. As a group, the *ACTG2*-negative cases had a higher likelihood of having a more favorable clinical outcome and more restricted disease. Strikingly, missense variants in five conserved Arginine residues in *ACTG2* accounted for 49% (26/53) of the disease burden in this cohort; all alleles were due to CpG dinucleotide changes. Poor outcomes, defined as total parenteral nutrition (TPN) dependence, death or transplantation, were invariably associated with one of the Arginine missense alleles within the *ACTG2*-positive cases in the cohort. Further characterization of specific Arginine missense mutations suggests an allelic series with a severity spectrum of p.R178 > p.R257 > p.R40 along with other less frequently reported recurrent sites p.R63 and p.R211.

These results provide a seemingly robust genotype-phenotype correlation for *ACTG2*-related disease and emphasize the important role of Arginine missense variants in visceral myopathy. Our findings potentially have important implications on the diagnostic strategy and patient counseling.

## PgmNr 1107: Expanding the phenotype of inflammatory bowel disease in Hermansky-Pudlak syndrome.

### Authors:

B.R. Gochuico <sup>1</sup>; X. Parisi <sup>1,2</sup>; N.R. Shelman <sup>3</sup>; M.A. Merideth <sup>1</sup>; W.J. Introne <sup>1</sup>; T. Heller <sup>4</sup>; W.A. Gahl <sup>1,5</sup>; M.C.V. Malicdan <sup>1,5</sup>; K.J. O'Brien <sup>1</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) National Human Genome Research Institute, National Institutes of Health, Bethesda, Maryland; 2) Medical Research Scholars Program, Clinical Center, National Institutes of Health, Bethesda, Maryland; 3) Department of Pathology, Boston Children's Hospital; 4) National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, Maryland; 5) NIH Undiagnosed Diseases Program, Common Fund, Office of the Director, National Institutes of Health, Bethesda, Maryland

**Background:** A subpopulation of patients with Hermansky-Pudlak syndrome (HPS) develop inflammatory bowel disease. A paucity of information is available about disease prevalence, clinical characteristics, genotyping analysis, and histologic features. The objective of this study is to expand the understanding of HPS inflammatory bowel disease.

**Methods:** Medical records of all children and adults with HPS evaluated at the National Institutes of Health Clinical Center from 1995 to 2018 were retrospectively reviewed. Their clinical characteristics, genotyping results, and histologic findings were analyzed.

**Results:** Inflammatory bowel disease affected 35 (13.5%; 11 male, 24 female) of 259 patients with HPS. The mean age of onset was 20 years with a range of 1 to 52 years. Six children had very early-onset inflammatory bowel disease. The most common symptoms were hematochezia, abdominal pain, and loose stools. Fistulae or extra-intestinal manifestations developed in 31% or 23%, respectively. Genotyping showed that patients with HPS-1, HPS-3, HPS-4, or HPS-6 were diagnosed with inflammatory bowel disease; HPS-3 was associated with mild symptoms. Seventy-four percent of patients received medical therapy. The most common treatments were systemic corticosteroids, anti-tumor necrosis factor alpha drugs, and systemic non-steroidal immunosuppressants. Seven of 13 patients who received anti-tumor necrosis factor alpha therapy had prolonged clinical responses. Bowel resection was performed in 37%. Active cryptitis, chronic inflammatory changes, granulomas, and ceroid lipofuscinosis were histopathologic findings in three colectomy specimens.

**Conclusion:** Inflammatory bowel disease resembling Crohn's disease affects a subpopulation of patients with HPS-1, HPS-3, HPS-4, or HPS-6. Very early-onset inflammatory bowel disease can develop in children with HPS. Severity of disease is highly variable and is generally mild in patients with HPS-3. Treatment of patients with HPS inflammatory bowel disease was similar to that of patients with Crohn's disease.

## PgmNr 1108: *TRPC6* pathogenic variant in a Japanese boy with infantile nephrotic syndrome.

---

Transient receptor potential channel C6 (TRPC6) coded by *TRPC6* is involved in slit membrane formation in podocytes. Abnormalities in proteins that form slit membranes, including TRPC6, are known to cause glomerular disease. Originally, *TRPC6* variants were reported as the cause of adult-onset focal segmental glomerulosclerosis (FSGS), the main cause of steroid resistant nephrotic syndrome (SRNS). However, pediatric cases of FSGS due to *TRPC6* variants have also been reported. Here, we report a patient with rapidly progressing infantile nephrotic syndrome, in whom a pathogenic *TRPC6* variant was identified.

The patient is a 2-years-old Japanese boy who is the second child from unrelated healthy parents. The pregnancy and delivery were uneventful. At age 8 months, edema appeared and gradually increased, and he was diagnosed with NS. He received prednisolone therapy for four weeks. But the symptom did not improve, and he was admitted to our hospital for further investigation and treatment. Renal biopsy demonstrated diffuse mesangial sclerosis (DMS). Clinical exome analysis, using a MiSeq and TruSight One Sequencing Panel (Illumina, San Diego, CA, USA) including 4813 genes associated with human genetic disorders, revealed a heterozygous missense variant of *TRPC6* (MN\_004621:c.523C>T causing p.Arg175Trp). At age 1 year and 5 months, peritoneal dialysis was introduced because of respiratory failure resulting from overhydration triggered by infection.

The same variant was not found in his parents, nor registered in databases of healthy individuals. The variant was reported to cause childhood-onset SRNS in a patient with a renal pathology as FSGS (Wang et al, 2017). Therefore, it would be a cause of infantile nephrotic syndrome with a renal pathology as DMS in the current patient. Considering that patients with SRNS caused by *TRPC6* variants, though the number is limited, were reported to tolerate renal transplantation without relapse (Santín et al, 2009; Sun et al, 2017), renal transplantation would be a reasonable choice for this patient. Genetic investigation could be useful in evaluating and treating patients with infantile or childhood-onset severe nephrotic syndrome.

## PgmNr 1109: Heterozygous *CTNNB1* and *TBX4* variants in a patient with abnormal lung growth, pulmonary hypertension, microcephaly, and spasticity.

The canonical wingless (Wnt) and fibroblast growth factor (FGF) signaling pathways are essential for regulation of human organ development. Perturbations of these pathways and disruptions from biological homeostasis have been associated with abnormal morphogenesis of multiple organs, including the lung. Components of Wnt and FGF signaling, *CTNNB1* and *TBX4*, respectively, modulate epithelial-mesenchymal interactions required for proper morphogenesis and lung development. *CTNNB1* variants have been identified mainly in patients with neurodevelopmental disorders, visual defects, and different types of cancers whereas *TBX4* variants have been associated with ischiocoxopodopatellar syndrome, pulmonary hypertension (PAH), developmental delay with heart and limb defects (PMID: 20206336), and recently with lethal lung developmental diseases (PMID: 30639323). Using exome sequencing in a term infant with lung growth abnormality, severe microcephaly, and spasticity, who died at four months of age due to progressively worsening of PAH and respiratory failure, we identified a *de novo* heterozygous nonsense variant c.1603C>T (p.Arg535\*) in *CTNNB1* and a heterozygous missense variant c.1198G>A (p.Glu400Lys) in *TBX4* inherited from the unaffected father. Both variants are rare and predicted to be likely deleterious. Interestingly, the *CTNNB1* variant c.1603C>T was reported in two unrelated infants with low oxygen saturation or persistent PAH during the neonatal period coexisting with microcephaly, spasticity, intellectual disability, and behavioral anomalies (PMID: 27915094). While severe microcephaly and spasticity detected in our patient overlap the clinical features in these two subjects, the observed lung phenotype is distinct and includes abnormal lung growth with enlarged simplified alveoli, prominent lymphangiectasia, and PAH with mild venous hypertensive changes. We suggest that perturbations in *CTNNB1* and *TBX4* act synergistically to produce a severe lung phenotype. Our data expand the known phenotypic spectrum of *CTNNB1* and *TBX4* variants, support the contention that

dual molecular diagnoses can parsimoniously explain blended phenotypes, and further implicate a recently proposed complex multi-locus mutational burden underlying the lung developmental diseases (NIH-R01HL137203, NIH-UM1HG006542).

Biliary atresia (BA) is a rare disease of liver and bile ducts that occurs in infancy. Children with BA undergo a surgical procedure to reestablish bile flow, but 70-80% of patients ultimately require liver transplant, making BA the leading cause of liver transplant in children. To investigate the genetic causes of BA, we performed an exome sequencing variant prioritization analysis on 54 case-parents trios recruited as part of the National Birth Defects Prevention Study, with 91% of cases having isolated BA and no other congenital anomaly. Whole-exome sequencing (WES) was performed on Illumina platform using SeqCap EZ Exome capture reagent. After performing standard quality control exclusions, single nucleotide variants and small insertion/deletions were identified using Platypus and annotated using ANNOVAR. In each trio, we prioritized *de novo*, rare homozygous, and rare compound heterozygous (CH) protein-altering variants. On average each trio was found to have one *de novo*, two homozygous and three CH candidate variants. We Sanger sequence validated a *de novo* missense variant in the syntaxin-binding protein 4 gene (*STXBP4*); the same variant was identified in clinical exome data from a child with liver failure. We identified two probands with different rare compound heterozygous variants in the polycystic kidney disease 1 like 1 gene (*PKD1L1*), a recently identified BA candidate gene associated with ciliary calcium signaling and establishing left-right asymmetry. A focused review of ciliopathy genes identified one patient that carried CH variants in inversin (*INVS*), a gene involved in primary cilia function and left-right axis determination. Utilizing StringDB, we have established a significant interaction enrichment ( $p < 0.004$ ) among the 152 genes harboring rare CH variants in cases, with cytoskeleton organization and calcium ion binding as most significantly enriched biological process and molecular function. Our study results suggest that BA is heterogeneous in its underlying genetic etiology. In the future, larger studies utilizing more

comprehensive genome sequencing methods better suited to assay structural and non-coding variants will be needed to better understand the genetic component of BA.

## PgmNr 1111: Identification of two novel pathogenic mutations of *SLC22A12* in two renal hypouricemia families with semidominant phenotypes.

Renal hypouricemia (RHUC, OMIM 220150 and 612076) with clinical presentations of low serum uric acid (UA) concentrations (less than 2.0 mg/dL) tends to complicate with exercise-induced acute renal failure (EIAHF). In patients with RHUC, many loss-of-function mutations have been detected in *SLC22A12* (OMIM: 607096, RHUC1) and *SLC2A9* (OMIM: 606142, RHUC2), which encode two major urate transporters in renal tubules. Here we report two patients from unrelated Taiwanese families suffered from hypouricemia with the initial presentation of EIAHF, and two novel missense variants (NM\_144585.3:c.1376T>G, NP\_653186.2:p.L459R in family I and c.365A>G, p.Y122C in family II) in *SLC22A12* identified via direct sequencing of *SLC22A12* and *SLC2A9*. Both mutations had allele frequencies below 0.01 validated in 200 Taiwanese cohorts and impaired uric acid uptake was revealed in oocyte injection assays. Biochemistry examinations showed hypouricemia in family members heterozygous for each mutation (mean serum UA level: 1.76 mg/dL, 95% CI: 1.50-2.02 mg/dL) and even lower serum UA levels in probands (mean: 0.95 mg/dL, 95% CI: 0.85-1.05 mg/dL, p<0.05). These probands are compound heterozygotes with different possible loss-of-function variants of *SLC22A12*. In conclusion, our results suggest that these two novel mutations lead to RHUC by impairing function of urate transporters and account for biochemically semidominant phenotypes in these two families.

## PgmNr 1112: Very low-level *FOXF1* parental somatic mosaicism in families with alveolar capillary dysplasia with misalignment of pulmonary veins.

---

Alveolar capillary dysplasia with misalignment of pulmonary veins (ACDMPV) is a rare lethal neonatal developmental lung disease. The vast majority of ACDMPV cases are sporadic and causative *de novo* point mutations or copy-number variant (CNV) deletions involving *FOXF1* or its distant lung-specific enhancer have been described. Importantly, in a few familial ACDMPV, the pathogenic *FOXF1* variants were transmitted from the somatic mosaic or heterozygous unaffected parent. To assess the scale and ratio of parental somatic mosaicism, we screened 18 unrelated ACDMPV families with the *FOXF1* variant determined to be apparent *de novo* (n=14), of unknown parental origin (n=1), or inherited from a parent suspected to be somatic and/or germline mosaic (n=3), using highly-sensitivity blocker displacement amplification (BDA), droplet digital PCR (ddPCR), quantitative PCR, long-range PCR, and array comparative genomic hybridization. BDA is a PCR-based technology that preferably amplifies allele with SNVs or CNVs, allowing for rare event quantitation with precision similar to ddPCR (PMID: 29805844). We have identified and characterized four (22%) families with parental mosaicism levels ranging between <0.03% and 19%, confirming that the rate of parental somatic mosaicism in ACDMPV is higher than previously thought. In one family, mosaic allele ratio in different tissues originating from all three germ layers ranged between <0.03% and 0.65%, suggesting that *FOXF1* variant might have occurred during early embryonic development. Comparison between results obtained using BDA and ddPCR for *FOXF1* variants indicates that both methods can accurately and efficiently quantitate low-level mosaicism. Our study further implies the importance of a systematic

screening of parental samples for low-level somatic mosaicism and shows that parents of children with ACDMPV who are found negative for *FOXF1* variants by the routine detection methods may benefit from re-analyses using more sensitive and quantitative methods.

## PgmNr 1113: Overcoming challenges in identification, annotation, and interpretation of variants in DSD genes.

### Authors:

E.C. Delot <sup>1,2</sup>; H. Barseghyan <sup>1,2</sup>; A. Parivesh <sup>1</sup>; H. Lee <sup>3</sup>; E. Vilain <sup>1,2</sup>; the DSD Translational Research

### Affiliations:

1) Center for Genetic Medicine Research, Children's National Medical Center, Washington, D.C., USA; 2) Genomics and Precision Medicine, School of Medicine and Health Sciences, George Washington University Washington, D.C., USA; 3) UCLA Depts of Human Genetics & Pathology and Laboratory Medicine, Los Angeles, CA, USA

Whole-genome sequencing (WGS) of 94 individuals with a wide spectrum of Disorders/Differences of Sex Development (DSD) revealed challenges of variant calling and classification for several well-known DSD genes. Using two different analysis pipelines, pathogenic variants were identified in *AR*, *SRY*, *WT1*, *NR5A1/SF1* and *SRD5A2*, with a 31% diagnosis rate in the non-syndromic 46,XY DSD subcohort.

Sequencing of *AR* proved challenging with low gene coverage and read depth, in particular next to the polyQ or polyG repeats. We were able to identify a complex frameshift variant missed by commercial clinical testing. WGS established a firm diagnosis of 5 $\alpha$ -reductase deficiency in 4 patients with homozygous or compound heterozygous variants in *SRD5A2*. Two of these had undergone clinical exome sequencing, which had missed the diagnosis. We found that *SRD5A2* is incorrectly annotated in ENSEMBL (but not RefSeq) as a non-coding transcript, resulting in ENSEMBL-based annotators filtering out *SRD5A2* variants. We recommend reanalysis of negative exomes for patients with the appropriate phenotypes. Identification of the V89L polymorphism in *SRD5A2* was also difficult because of an error of alignment to Hg19 by some platforms. Availability of larger, more ethnically diverse reference databases (such as ExAC/gnomAD) also prompted reclassification as likely benign of previously published pathogenic variants (e.g. in *MAP3K1*).

To assess evidence available in the databases used by laboratories to determine variant pathogenicity, we examined ClinVar variants in 69 DSD genes. For several of the long-known DSD genes, available proof was obvious, with the highest numbers of variants reported for *AR*, *NROB1/DAX1*, *CYP21A2*, *SRD5A2*, *SRY*, *NR5A1/SF1*, or *WT1*. However, historical variants, with pathogenicity strongly supported by published evidence from *in vitro* or animal models, were often missing, resulting in gross under-estimation of available evidence for several genes (e.g. *AMHR2*, *SRY* or *CYP21A2*). The difficulty of interpreting whether a ClinVar-reported variant is causative of the DSD phenotype is increased for genes causing syndromic disorders where the genital phenotype is incompletely penetrant (e.g. *DHCR7* in CHARGE) or where XY and XX individuals are differentially affected (e.g. *ATRX*).

These challenges highlight the need for standardization of variant annotation tools and expert human interpretation of sequencing data in patients with rare disorders of complex etiology such as DSD.

## PgmNr 1114: Generation of a Zebrafish model to study the role of *GPR101* in embryonic development and somatic growth.

---

**Background:** X-linked acrogigantism is a novel syndrome of early childhood-onset pituitary gigantism caused by duplications of *GPR101*, a gene that is predominantly expressed in the brain.

**Aim:** To elucidate the role played by *GPR101* during embryonic development and its effects on body growth.

**Methods:** *gpr101* knockout (KO) zebrafish were generated by CRISPR-Cas9. Growth was monitored until 9 weeks post-fertilization (wpf) in fish housed both in groups and individually. The mRNA expression of *gpr101*, pituitary and hypothalamic hormones (*gh1*, *prl*, *pomca*, *pomcb*, *trh*), and growth regulators (*igf1a*, *igf2a*, *igf2b*) was measured by qPCR at 7 dpf and 6 wpf (heads). Development of maternal-zygotic *gpr101* KO (MZ*gpr101*) embryos from fertilization to 24 hpf was monitored by time-lapse microscopy. Morphometric analysis of MZ*gpr101* brains was done by staining 6 dpf larvae with lysotracker and imaging with a confocal microscope.

**Results:** Two frame-shifting alleles - a deletion of 5 bp and a deletion of 13 bp - were selectively propagated from F founders. Both frameshifts were present at the mRNA level, and *gpr101* expression between mutants and wild type (WT) controls was similar, excluding genetic compensation triggered by mutant mRNA degradation. A significant decrease in standard length, body weight, and BMI in KOs was seen at 3, 6, and 9 wpf ( $p < 0.05$  for all). Genotype frequencies followed Mendelian distribution. Sex did not influence the three variables at 9 wpf, when fish reach sexual maturity. The smaller size was not accompanied by significant differences in the expression of hypothalamic or pituitary hormones (at 6 wpf). MZ*gpr101* were characterized to investigate the contribution of maternal factors. The majority of embryos died during the blastula-gastrula transition. Pericardial edema was present in about half the surviving embryos. The remaining WT-looking larvae showed decreased expression of *gh1* ( $p = 0.07$ ) and *igf2a* ( $p < 0.05$ ), enlarged hypothalamus and sensory ganglia, and a smaller dorsal diencephalon ( $p < 0.01$  for all). Individually-housed MZ*gpr101* were already smaller before feeding started, excluding its effect on growth.

**Conclusions:** This animal model represents the first *in vivo* evidence that *gpr101* regulates body growth. We also unraveled an essential role for *gpr101* during blastulation/gastrulation. Finally, the morphometric findings suggest that *gpr101* might be a negative regulator of the canonical Wnt pathway. Future studies will validate this hypothesis.

## PgmNr 1115: Investigating *SFRP4* causing Pyle disease in an African child.

### Authors:

C. Oosterwyk <sup>1</sup>; N. Manyisa <sup>1</sup>; G. Agenbag <sup>1</sup>; E. Chimusa <sup>1,2</sup>; A. Wonkam <sup>1,3</sup>

---

Pyle disease (PD) is a rare autosomal recessive disorder leading to widened metaphyses of long bones, cortical bone thinning and genu valgum. Four mutations causing PD in the *SFRP4* gene have been reported in four unrelated families of different ethnic backgrounds worldwide. The aim of this project was to investigate the involvement of mutations in *SFRP4* in a South African (SA) patient. Sanger sequencing was performed for the *SFRP4* gene in the SA patient of mixed ancestry. This was followed-up by targeted sequencing of variants suspected to be pathogenic in the unaffected parents and sibling to confirm heterozygosity. In silico bioinformatics analysis of the putative candidate variants to assess their pathogenicity was performed. The study revealed a novel putative pathogenic variant in intron 5 of *SFRP4* (c.855+4delAGTA) in a homozygous state, in the South African patient with PD. The parents were both heterozygous for the same mutation. The novel variant was present in the splice junction, and in silico prediction provided evidence that may affect the donor site causing aberrant splicing, and therefore pathogenicity. This study has reported for the first time the implication of a mutation in the *SFRP4* gene in an African patient presenting with PD and adds to the evidence that PD is seemingly due to a mutation in the single genes in many world populations. Understanding PD molecular pathophysiology may provide insight and a better understanding of bone remodelling and possible target for new therapeutic approaches, that will impact the treatment of other skeletal dysplasias including osteoporosis.

## PgmNr 1116: Biallelic hypomorphic variants p.Arg1133Cys and p.Arg1379Cys in *COL2A1*: Further delineation of phenotypic spectrum of recessive type 2 collagenopathies.

### Authors:

G.S. Bhavani <sup>1</sup>; H. Shah <sup>2</sup>; A. Moirangthem <sup>1</sup>; A. Shukla <sup>1</sup>; O.H. Kim <sup>3</sup>; G. Nishimura <sup>4</sup>; G.R. Mortier <sup>5</sup>; K.M. Girisha <sup>1</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Department of Medical Genetics, Kasturba Medical College, Manipal Academy of Higher Education, Manipal, India; 2) Department of Orthopedics, Kasturba Medical College, Manipal Academy of Higher Education, Manipal, India; 3) Department of Pediatric Radiology, Woorisoa Children's Hospital, Seoul, Republic of Korea; 4) Center for Intractable Diseases, Saitama Medical University Hospital, Saitama, Japan; 5) Center for Medical Genetics, University of Antwerp/Antwerp University Hospital, Antwerp, Belgium

The phenotypic spectrum of type 2 collagenopathies ranges from lethal achondrogenesis type 2 to milder osteoarthritis with mild chondrodysplasia and all of them are monoallelic except recent two reports on association of biallelic variants in *COL2A1* with spondyloepiphyseal dysplasia congenita in two children.

Two affected brothers aged 26 and 24 years were evaluated for short stature (heights -11 and -10 SD), micromelia, lumbar hyperlordosis and joint hyperlaxity. Platyspondyly, hip dysplasia, short femoral necks, metaphyseal irregularities, short and broad metacarpals, metatarsals and phalanges of both hands and feet were noted on radiographs. Exome sequencing of both siblings revealed a biallelic pathogenic variant, c.4135C>T(p.Arg1379Cys) in exon 53 of *COL2A1*. Healthy, consanguineous parents were heterozygous carriers.

In the second family, proband had difficulty in walking and mild scoliosis by age 7 years. He had pectus carinatum, kyphosis, leg length discrepancy and mild joint laxity. His 10 years-old sister had restricted hip movements and hypermetropia. Platyspondyly, coxa valga, epi-metaphyseal dysplasia, delayed carpal ossification and generalized osteopenia were noted in both. They had a novel homozygous pathogenic variant, c.3190C>T(p.Arg1133Cys) in exon 47 of *COL2A1*. The variant segregated in Mendelian fashion and carriers of the variant were unaffected.

MutationTaster, PolyPhen2 and SIFT predict these variants to be disease causing. p.Arg1379Cys is observed in heterozygous state in 6 individuals in gnomAD with a frequency of 0.00002387 and p.Arg1133Cys is not reported in gnomAD. Both variants were absent in in-house database of 623 exomes.

Though all six patients from four families exhibit a spondylo-epimetaphyseal dysplasia, they demonstrate a wide variation in severity of short stature and involvement of epiphyses, metaphyses and vertebrae. The variant, p.Arg1133Cys (family 2) in the triple helical domain is associated with a mild, p.Arg437Trp (Tham *et al.*, 2015) and p.Pro458Leu (Barat-Houari *et al.*, 2015) in the same domain with moderate and p.Arg1379Cys (family 1) in C-propeptide domain with severe phenotype. We hypothesize the variants are likely to be hypomorphic, given the underlying mechanisms of disease causation for known heterozygous variants in *COL2A1*. With this report, we describe additional four individuals with homozygous hypomorphic variants in *COL2A1* and expand the

phenotypic spectrum of recessive type 2 collagenopathy.

## PgmNr 1117: A case report of recessive aggrecan mutations in a girl with spondyloepiphyseal dysplasia.

### Authors:

E. Carter; J. Davis; C. Raggio

[View Session](#) [Add to Schedule](#)

**Affiliation:** Center Skeletal Dysplasias, Hospital for Special Surgery, New York, New York.

---

Skeletal dysplasias are a heterogeneous group of >400 disorders impacting the size and shape of the skeleton. The aggrecanopathies comprise a single group within the current skeletal dysplasia nosology. We report a child with compound heterozygous *ACAN* mutations and a skeletal dysplasia phenotype less severe than what is reported in the one family with SEMD Aggrecan type (OMIM 612813) but more severe than the changes described in the one family with SED Kimberley type (OMIM 608361). An 11 year-old girl with a history of short stature (height -7 SD), scoliosis, joint abnormalities, and brachydactyly was referred to our service for work-up and genetic analysis. Prior consultations had included a differential diagnosis of acrodysostosis versus a FilaminA disorder. Family history was significant in that both the mother (4'9" tall) and the father (5'3" tall) had a history of chondromalacia patellae. Radiographic review detected short stature, platyspondyly, mild scalloping of the posterior aspects of the lumbar vertebral bodies, thoracolumbar scoliosis, epiphyseal changes, and genu valgum with an osteochondral defect in the left knee. Exome sequencing detected two compound heterozygous mutations in the *ACAN* gene: p.S1396LfsX5 and p.A171V. Our proband's mother was found to carry the p.A171V mutation; paternal DNA was unavailable for confirmatory testing. *ACAN* encodes the protein aggrecan, which plays an important role in development and function of articular cartilage. Aggrecan-related bone disorders include a variety of phenotypes, ranging from dominant idiopathic short stature to recessive spondyloepimetaphyseal dysplasia (SEMD), aggrecan type, which is characterized by marked short stature (66-71 cm final height). We present clinical and X-ray characteristics of a girl with an intermediate skeletal dysplasia phenotype that falls between the recessive, more severe SEMD Aggrecan type and the dominant, milder SED Kimberley. Although the specific mutations detected in our family have not been reported before, we believe they cause our proband's skeletal dysplasia findings, and speculate that carrier status impacts final height in other family members.

## PgmNr 1118: Loss of *Fkbp10* in murine tendons and ligaments recapitulates key features of Bruck syndrome.

Osteogenesis Imperfecta (OI) is a heterogeneous genetic disorder that is characterized by low bone mass, increased susceptibility to fractures and progressive bone deformities. Recently, we and others have reported that loss-of-function mutations in FK506 binding protein 10, 65 kDa (*FKBP10*) can cause progressively deforming OI, with a subset of patients exhibiting joint contractures, also known as Bruck Syndrome. To determine if *Fkbp10* in tendons and ligaments is required for proper joint formation, we genetically ablated *Fkbp10* using *Scx-Cre* transgenic mice. Interestingly, conditional removal of *Fkbp10* in *Scx-Cre*-expressing cells induced hindlimb contractures associated with significant gait defects. In contrast, *Fkbp10* deletion in *Col2-Cre*-expressing cells did not cause hindlimb contractures, indicating that *Fkbp10* may be dispensable in chondrocytes. Furthermore, *Scx-Cre*-mediated deletion of *Fkbp10* markedly reduced telopeptide lysyl hydroxylation of type I collagen and collagen cross-linking. Histological analyses of the knee and ankle joints at multiple postnatal stages revealed that *Fkbp10* mutant mice develop ectopic chondroid lesions in tendons and ligaments, which subsequently undergo heterotopic ossification. Furthermore, mRNA-seq of the developing chondroid lesions in *Fkbp10* mutant mice showed significant enrichment of extracellular matrix organization genes, which overall resulted in increased expression of fibrillar collagens, matrix metalloproteases and small leucine rich proteoglycans. Taken together, our mouse model recapitulates several key features of Bruck Syndrome that may provide a valuable tool for identifying novel therapies.

## **PgmNr 1119: X-linked hypophosphatemia: All eight individuals representing separate American families carrying the *PHEX* 3'UTR mutation c.\*231A>G tested positive for an exon 13-15 duplication.**

### **Authors:**

S. Mumm <sup>1,2</sup>; M. Huskey <sup>1</sup>; S. Duan <sup>1</sup>; V. Wollberg <sup>2</sup>; P. Smith <sup>2</sup>; V. Bijanki <sup>2</sup>; G.S. Gottesman <sup>2</sup>; M.P. Whyte <sup>1,2</sup>

---

In 2008, a single nucleotide change (c.\*231A>G) located 3-bp upstream of the putative polyadenylation signal in the 3'UTR of *PHEX* was associated with X-linked hypophosphatemia (XLH) in seven patients from six unrelated Midwest USA families (Bone 43: 663-6, 2008). In 2015, we reported (JBMR 30: 137-43, 2015) this mutation in six apparently sporadic instances of XLH in Midwest children, but then found mothers carrying the 3'UTR mutation who remarkably appeared unaffected or mildly affected by XLH. Subsequent investigation among > 300 patients with XLH identified several multigenerational American families harboring this unique *PHEX* mutation. Their XLH was distinctly less severe than for those patients carrying a mutation that disrupts the *PHEX* coding region. Furthermore, females compared with males with the 3'UTR defect seemed still more mildly affected, and were often untreated or even undiagnosed with XLH (JBMR 33 Suppl 1: 425-6, 2018). In 2014, a boy with autism and hypophosphatemic rickets (a second cousin to a 3'UTR mutation patient) was referred with copy number microarray performed commercially, showing a copy number gain of *PHEX* exons 13-15. Therefore, we performed copy number real-time qPCR for exons 12-16, (primers failed for exon 13) in four females and four males from apparently “unrelated” families with the 3'UTR mutation. Controls were three sex-matched XLH patients with coding region *PHEX* mutations and a healthy male and female. The six XLH patients with conventional mutations or unaffected controls showed the appropriate copy number for all *PHEX* exons (one copy for males and two for females). In contrast, all eight subjects with the 3'UTR mutation exhibited one extra copy of *PHEX* exons 14 and 15 in their genomic DNA. Thus, the duplication likely resides within or near *PHEX* but its precise location and orientation remain unknown. It may be that all individuals carrying the 3'UTR defect harbor this exon 13-15 duplication. If so, their mild form of XLH would reflect a shared “founder”. However, it also remains to be determined whether this duplication disrupts normal translation or function of *PHEX*. Perhaps the mild XLH phenotype is not from the 3'UTR mutation, but instead due to the exon 13-15 duplication rendering the 3'UTR change a benign variant that co-segregates. Alternatively, the duplication may be a benign variant. Functional assays for *PHEX* mRNA stability and protein function will clarify the etiology of this mild form of XLH.

## PgmNr 1120: Osteogenesis Imperfecta fractures show delayed healing and increased possibility of re-fracture in murine models.

---

Osteogenesis Imperfecta (OI) is the most common genetic bone dysplasia that is phenotypically and genetically complex. It is characterized by bone deformities and fractures caused by low bone mass and impaired bone quality. Roughly 85-90% of cases are dominantly inherited and result from mutations in genes encoding type I collagen (*COL1A1* and *COL1A2*), the major protein of the bone matrix. 10-15% of OI cases are recessively inherited and the majority result from mutations in members of the prolyl-3-hydroxylation complex including Cartilage Associated Protein (CRTAP). OI patients are at an increased risk of fracture throughout their lifetimes and anecdotal evidence suggests successful fracture recovery. However, non-union has been reported in 24% of fractures and 52% of osteotomies and many stabilization techniques result in additional surgery due to re-fracture. Additionally, re-fractures typically go unreported making the frequency of re-fractures in OI patients unknown. Thus, there is an unmet need to better understand the mechanisms by which OI affects fracture healing. It is our hypothesis that OI fractures undergo suboptimal healing and that this process results in ultimately weaker bone leading to the increased possibility of re-fracture. Using an open tibial fracture model, we show a decrease in callus size in both *Col1a2*<sup>G610C/+</sup> and *Crtap*<sup>-/-</sup> OI mouse models post-fracture suggesting impaired healing. Callus cartilage distribution is altered in the OI models suggesting alterations in cartilage formation or differentiation and may be associated with the observed decrease in callus size. Fracture calluses in both models also exhibited a significant decrease in polar moment of inertia (pMOI) indicating a decrease in resistance to torsional stress. Most importantly, via three-point-bending biomechanical testing, we determined that in wild type bone, the healed fracture site resulted in stronger bone compared to the unfractured tibia. However, *Crtap*<sup>-/-</sup> healed fractured tibia show a trend towards being mechanically weaker and exhibiting decreased ductility when compared to the contralateral unfractured bone. This implies the possibility that OI fractures do not heal properly and may be a prime location for re-fracture. These data provide valuable insight into the effect of the ECM on fracture healing, a poorly understood mechanism, as well as support the need for treatment of primary fractures to decrease incidence of refracture and deformity in OI patients.

## PgmNr 1121: Novel pathogenic variants support constitutive dysregulation of the noncanonical WNT pathway gives rise to Robinow syndrome.

---

Robinow syndrome (RS) is a genetically heterogeneous disorder characterized by skeletal dysplasia and a distinctive facial appearance. RS can segregate as an autosomal-recessive (AR) trait (RRS [MIM 268310]) or autosomal-dominant (AD) trait (DRS [MIM 180700]). Previous studies have revealed locus heterogeneity and identified several genes that can cause RS; including *DVL1*, *DVL3*, *FZD2*, *WNT5A* and *NXN*. The aforementioned Robinow genes identified thusfar all play a role in the WNT/planar cell polarity (PCP) signaling pathway. We performed Sanger sequencing and exome sequencing (ES) on a cohort of 12 subjects from 10 families with RS or a RS-like phenotype. Two unrelated individuals were identified to have pathogenic variants in *DVL1*: a recurrent single base pair deletion (c.1519delT;Trp507Glyfs\*142), and a single nucleotide deletion (c.1556del;p.Gly519Aspfs\*130). Two subjects had previously-reported pathogenic variants *FZD2*: a missense variant (c.1300G>A;p.Gly434Ser) and a nonsense variant (c.1644G>A;p.Trp548\*). In addition, three likely pathogenic variants in *WNT5A* were found: a private missense variant (c.461G>T; p.Cys154Phe) in both a patient and his affected father, and a heterozygous missense variant in exon 3 (c.248G>A; p.Cys83Tyr) in an unrelated individual. One subject had variants in *NXN*, including a homozygous nonsense variant (c.817G>A; p.Gln273\*) *in trans* with a ~1Mb telomeric deletion on chromosome 17p containing *NXN*. Such clinical findings can elicit a range of potential differential diagnoses, including other skeletal disorders. In our cohort, pathogenic variants in Aarskog-Scott syndrome (MIM: 305400) related genes were found in three individuals: two hemizygous frameshift variants (c.367del; p.Leu123\*) and a hemizygous 1bp deletion in *FGD1* (c.1422del; p.Phe474Leufs\*34). Plus, we found one subject with a heterozygous missense variant in *PPP1CB* that causes Noonan syndrome-like disorder with loose anagen hair 2 (MIM: 617506) (c.146C>G; p.Pro49Arg). Note that PP1C can stabilize Dvl and sustain Wnt signaling in mammalian cells and zebrafish embryos. In conclusion, individuals in our cohort were found to carry pathogenic or likely pathogenic variants in genes associated with either RS or disorders with phenotypic overlap with RS. Our findings confirm that constitutive dysregulation of the noncanonical WNT pathway in humans gives rise to RS, which has deepened our insight into underlying mechanisms of the skeletal development and WNT signaling.

## PgmNr 1122: *GNPNAT1* variant causes a novel form of rhizomelic skeletal dysplasia due to impaired chondrocyte differentiation.

### Authors:

Glucosamine 6-phosphate N-acetyltransferase GNPAT1 catalyzes transfer of an acetyl residue to D-Glucosamine 6-phosphate in the second step of a four-step pathway yielding UDP-N-acetyl-alpha-D-glucosamine (UDP-GlcNAc). UDP-GlcNAc participates in both N- & O- linked glycosylation of proteins in concert with glycosyltransferases. We identified a consanguineous family with four individuals affected with severe skeletal dysplasia characterized by marked rhizomelia, platyspondyly and short stature with adult heights ranging from 99 to 114 cm (SD -7 to -9.6). Whole genome sequencing was completed for two affected and two unaffected individuals. Computational modeling to predict the variant's effect on GNPAT1 was completed by I-Mutant Suite on the protein crystal structure. To explore its biological role, *Gnpnat1* was knocked down by small interfering RNA (siRNA) in rat epiphyseal chondrocytes and the effects on cellular proliferation, differentiation and apoptosis were studied. Analysis of the whole genome sequencing data revealed a homozygous missense variant in *GNPNAT1* (OMIM 616510) in all affected individuals. The GNPAT1 variant affects an amino acid conserved in all multicellular species examined except mosquitoes. The predicted pathogenic variant was absent from public databases and in DNA of 190 ethnically matched controls. *GNPNAT1* is ubiquitously expressed and the encoded protein is localized to cytoplasmic organelles including endoplasmic reticulum and Golgi bodies. The variant affects the acetyltransferase domain of the protein. Computational modeling of the crystal structure predicted a large decrease in stability (DDG Value Prediction, -0.70 Kcal/mol) of the enzyme due to the effect of variant on GNPAT1. Knockdown of *Gnpnat1* in rat epiphyseal chondrocytes did not have an effect on apoptosis. Cell proliferation was somewhat impaired. However, significantly decreased expression of chondrocyte differentiation markers (*Acan*, *Alpl*, *Col2a1*) was observed, suggesting impaired epiphyseal chondrocyte differentiation in the absence of GNPAT1. Variants in *GFPT1* (OMIM 138292) and *PGM3* (OMIM 172100), encoding enzymes involved in the same pathway as GNPAT1, have previously been associated with different human genetic disorders. Our findings implicate a *GNPNAT1* variant in a severe form of skeletal dysplasia and suggest that the disease represents a novel disorder of glycosylation. Funded by Swedish Research Council, Sweden & Higher Education Commission, Pakistan.

## PgmNr 1123: *IFT172* mutation as the nineteenth cause of oral-facial-digital syndrome.

---

The defects in cilia structures or function cause disease expanding multiple organs associated with cilia, that is called ciliopathy. Ciliopathy is classified into subgroups by its clinical features including Joubert syndrome, Bardet-Biedl syndrome, short-rib thoracic dysplasia, and Oral-facial-digital syndrome (OFD). *IFT172* plays a critical role in intraflagellar transport and its mutations cause various ciliopathy-related syndrome phenotype but not OFD. Herein, we document a male patient with OFD syndrome phenotype who had biallelic mutations in *IFT172* gene. Clinical features compatible with the diagnosis included post-axial polydactyly, laterality defects of the heart tube (i.e., single atrium, an atrioventricular septal defect, and a persistent left superior vena cava), and multiple oral frenula. The patient had compound heterozygous variants c.39+5G>A and c.1478T>G (NM\_01566.2): The former variant changes the guanine nucleotide that is critical for normal recognition of the splicing donor site, and the latter variant changes Leu residue that is highly conserved down to *Chlamydomonas reinhardtii*. This is the first report of biallelic *IFT172* mutations who had an OFD syndrome phenotype. Hence, *IFT172* represents the 19th OFD gene. The documentation of a mutation in *IFT172*, in addition to *IFT57*, confirms the IFT pathway is one of the pathogenetic mechanism for OFD.

## PgmNr 1124: The phenotypical spectrum of BRD4 defects.

The growth of an individual is a variable and highly heterogeneous trait. We performed WES in individuals with short stature. In 2 independent non-consanguineous families we identified 2 heterozygous missense *de novo* variants in *BRD4* (c.1856G>T; c.2513A>T). Screening for further individuals with *BRD4* variants, we identified an individual with a *de novo* frameshift (c.2728delC) variant.

In the 4 previously reported patients with frameshift and missense variants in *BRD4* a Cornelia de Lange-like phenotype, growth deficit, microcephaly and intellectual disability was described. In our study, the patient with the frameshift variant and the patient with the c.1856G>T variant both presented with intellectual disability and Cornelia de Lange-like facial gestalt. Microcephaly was not present in the patient with the frameshift variant. Short stature seems to be a more consistent feature in individuals with missense variants.

*Bromodomain Protein 4* (*BRD4*) is a member of the bromodomain (BET) protein family involved in binding to hyperacetylated genomic regions of promoters and enhancers. *BRD4* mediates CDK9 activity to influence transcription elongation by RNA polymerase II and thus regulates gene expression, cell differentiation and cell cycle. Expression analysis showed that the missense variants lead to reduced expression levels. As the frameshift variant does not alter *BRD4* expression levels we propose a potential shorter, functionally impaired protein. These results indicate a loss-of-function effect of all three identified variants. Immunofluorescence analysis of cells from both patients with missense variants confirmed a significantly reduced cellular growth and smaller cell size when compared to controls. scRNASeq Analysis in HEK293 cells with CRISPR/Cas9 mediated *BRD4* defects highlighted a complex dysregulation of effector proteins (CDK9, CCND1/2, PCNA, DNTTIP1/2, TOP2A and SPA-1).

In conclusion, our findings expand the clinical spectrum of mutations in *BRD4* ranging from idiopathic short stature without distinct facial gestalt to a Cornelia de Lange-like phenotype. Furthermore, we confirm the proposed loss-of-function effects of *BRD4* mutations. We hypothesize that the variability of the phenotype might in part be explained by different effects of the variants on target effector genes.

## **PgmNr 1125: MPS-specific physical symptom score (PSS) and adaptive functions in MPS IVA: A cross sectional study.**

---

**Introduction:** MPS IV or Morquio syndrome is an inherited autosomal recessive lysosomal storage disease caused by deficiency in N-acetylgalactosamine-6-sulphate phosphatase, encoded by GLANS gene mapped to 16q24. Previously an MPS-specific physical symptom scale was developed and introduced a Physical Symptom Score (PSS) (PMC 4864710) by quantifying the somatic disease burden in MPS I, II and VI. Now we investigate the association of PSS with adaptive functions in nine MPS IV patients from a cross-sectional study (NIH-U54NS065768).

**Hypothesis:** The goal of our study was to investigate the physical symptoms in MPS IV patients who have been treated with enzyme replacement therapy (ERT) and to examine the relationship of physical symptoms with adaptive behavior and daily living skills.

**Methods:** Nine patients with MPS IV aged 11.6 to 53.3 years, among them 6 female and 3 male who were enrolled in "Longitudinal Studies of Brain Structure and Functions in MPS Disorders," were recruited from University of Minnesota. Somatic disease burden was measured by the PSS, and adaptive behavior was measured with the Adaptive Behavior Composite standard score and Daily Living Skills (DLS) standard score from the Vineland Adaptive Behavior Scales, Second Edition (VABS-II). Within this sample, 8 MPS IV patients were administered the NIH-developed PROMIS questionnaires to assess pain, anger, anxiety, relationships, support, and fatigue.

**Results and Discussion:** While all nine patients had average adaptive skills, we have found higher/worse PSS score is associated with a lower/worse Vineland composite standard score ( $P=0.021$ ) and DLS score ( $P=0.033$ ). The association between the PSS and age was not statistically significant in MPS IV. The pilot PROMIS data found no significant elevations for MPS IV in areas described above. Limitations include small sample size and lack of control data suggesting the need for further analysis on a larger cohort.

**Conclusion:** Adaptive functions are negatively associated with PSS at a statistically significant level

(See Table 1). Future longitudinal analysis of more patients will provide more detailed information on emotional, social and adaptive outcomes with somatic burden of disease.

Table 1 Linear trend between predictor (predominantly PSS) and adaptive functions

Outcome	Predictor	N	Slope (95% CI)	P-value
PSS	Age (yr)	9	0.04 (-0.03, 0.10)	0.267
Vineland Composite	PSS	9	-7.88 (-14.58, -1.17)	0.021
Vineland DLS	PSS	9	-5.81 (-11.15, -0.46)	0.033

## PgmNr 1126: Mutation spectrum in 147 Chinese patients with craniosynostosis: Findings of a custom sequencing panel study.

---

Craniosynostosis (CS), one or more of the cranial sutures in an infant skull prematurely fuses, is a skeletal disease caused by genetic or environmental factors, or interplay of them. Most genetic studies on CS were carried out in Caucasian populations, while only a few case reports were performed in East Asian populations. In our study, we established a Chinese craniosynostosis patient cohort without prior molecular diagnosis. We aimed to assess the impact of a targeted gene sequencing for the genetic diagnosis, and to describe the characteristics of mutation spectrum in Chinese craniosynostosis patients. We firstly designed a panel to sequence exonic regions of 17 genes based on a comprehensive literature review. We then performed panel sequencing and bioinformatic analysis in 147 probands. The confirmation and inheritance of suspected variants were validated in probands and their available parents by Sanger sequencing. Variants were identified according to the ACMG standards, based on silico prediction and Sanger validation. A total of 80 cases were identified with pathogenic or likely pathogenic variants. In total, we identified 43 different variants in 9 genes (*EFNB1*, *ERF*, *FGFR1*, *FGFR2*, *FGFR3*, *POR*, *TCF12*, *TGFBR2*, *TWIST1*). We further showed that the distribution of variants has no significant differences between Chinese and Caucasian patients of Apert, Crouzon and Pfeiffer syndromes. However, in Crouzon patients, the mutation frequency at the C342 and Y340 residues were significantly different between the two populations. In addition, eleven novel variants were identified, which had never been reported in Caucasian patients. In summary, our custom sequencing panel can provide reasonably high-yield diagnosis in Chinese craniosynostosis patients. The differences and novel findings of our study suggested great potential to carry out systematic genetic studies in Chinese craniosynostosis patients.

## PgmNr 1127: Parental gonosomal *COL2A1* mosaicism contributes to intrafamilial recurrence in a family with type 2 collagenopathy.

---

The *COL2A1* gene encodes the alpha-1 chain of procollagen type 2. Mutations in the *COL2A1* gene are associated with several different types of skeletal dysplasia collectively known as type 2 collagenopathies. The main inheritance pattern of type 2 collagenopathies is autosomal dominant, and in some cases, germline mosaicism and gonosomal mosaicism have been reported. Our patients were 6-years-old boy and 4-years-old girl. They had severe short stature (-8.5SD and -10.0SD, respectively), flat nose, and short limbs. Their radiograph showed abnormality of vertebra and epiphyseal metaphyses. Their parents had no phenotypes. We conducted whole exome sequencing (WES) to the family because autosomal recessive or germline mosaicism of skeletal dysplasia such as spondyloepimetaphyseal dysplasia or kniest dysplasia was suspected. The heterozygous *COL2A1* mutation (c.3121 A>G) was found in the two patients, and then we diagnosed type 2 collagenopathy. Next, to investigate whether gonosomal mosaicism was raised within the family, we conducted target deep sequencing to their parents without mutations by WES. About 1% *COL2A1* mosaicism was identified in the mother's tissues. We assumed that the mother's gonosomal mosaicism would arise in the epiblast, the mutation rate in egg cells would be high, and the intrafamilial recurrence rate of the disease would also be higher than by the germline mosaicism. This study suggests the importance of detecting the low levels of somatic mosaicism in parents whose children have a suspicious germline mosaicism, and the usefulness of target deep sequencing to detect them.

## PgmNr 1128: Anabolic effects of nitric oxide on bone revealed by deficiency of argininosuccinate lyase.

Argininosuccinate lyase deficiency (ASLD) is the second most common urea cycle disorder. Some of the manifestations in ASLD like neurocognitive deficiencies and hypertension are observed even in individuals without documented hyperammonemia and thus are likely caused by mechanisms other than elevated ammonia. ASL is the only mammalian enzyme capable of synthesizing arginine, the sole precursor for nitric oxide synthase (NOS)-dependent nitric oxide (NO) synthesis. Moreover, we have previously shown that ASL is also required for channeling extracellular arginine to NOS for NO production. Hence, loss of ASL leads to a cell-autonomous deficiency of NO production. ASL deficiency is thus a Mendelian model for cell-autonomous, NOS-dependent NO deficiency. NO is an important signaling molecule that influences a wide range of biological processes including bone metabolism. Previous studies have shown that NO donors may prevent bone loss and fractures in postmenopausal women. However, the function of NO in bone formation remains controversial.

Here, we reported that loss of ASL led to decreased NO production and impaired osteoblast differentiation in osteoblastic cell lines and primary osteoblasts derived from a hypomorphic mouse model of ASLD (*Asl*<sup>Neo/Neo</sup>). Osteoblast-lineage specific *Asl* knockout mice (*Osteocalcin Cre; Asl*<sup>f/f</sup>) resulted in decreased bone mass, which was due to reduced bone formation. Mechanistically, the anabolic effect of NO on osteoblast differentiation may be mediated through glycolysis, as indicated by decreased abundance of glycolytic enzymes and reduced glycolytic rate and capacity in *Asl* deficient osteoblastic lineage cells. Caveolin 1 (*Cav-1*) has been reported to be an endogenous negative regulator of NO synthesis. Therefore, we hypothesized that ablation of *Cav-1* may rescue the low bone mass in *Asl*<sup>Neo/Neo</sup> mice. Indeed, we observed that bone mass, NO production, as well as glycolysis were restored in *Asl*<sup>Neo/Neo</sup>; *Cav-1*<sup>+/-</sup> mice as compared to *Asl*<sup>Neo/Neo</sup> mice. Finally, we generated induced pluripotent stem cells (iPSCs) from an individual with ASLD and low bone mass. Consistently, when iPSCs were differentiated into osteoblasts, the mineralization capacity was impaired from the ASL-deficient osteoblasts as compared to three unaffected controls. Taken together, our findings reveal that ASLD is a unique genetic model for studying NO-dependent osteoblast function, and suggest that NO-glycolysis pathway may be a new target for bone anabolism.

## PgmNr 1129: An emerging ribosomopathy affecting the skeleton due to bi-allelic variations in *NEPRO*.

---

Cartilage hair hypoplasia (CHH), anauxetic dysplasia 1 and anauxetic dysplasia 2 are rare metaphyseal dysplasias caused by biallelic pathogenic variants in *RMRP* and *POP1*, which encode the components of RNase-MRP endoribonuclease complex (RMRP) in ribosomal biogenesis pathway. Nucleolus and neural progenitor protein (NEPRO), encoded by *NEPRO* (*C3orf17*), is known to interact with multiple protein subunits of RMRP. We ascertained a six-years-old girl with skeletal dysplasia and some features of CHH. *RMRP* and *POP1* did not harbor any causative variant in the proband. Parents-child trio exomes revealed a candidate bi-allelic variant, c.435G>C, p.(Leu145Phe) in *NEPRO*. Two families with four affected individuals with skeletal dysplasia and a homozygous missense variant, c.280C>T, p.(Arg94Cys) in *NEPRO*, were identified from literature and their published phenotype was compared in detail to the phenotype of the child we described. All the five affected individuals have severe short stature, brachydactyly, skin laxity, joint hypermobility and joint dislocations. They also have short metacarpals, broad middle phalanges and metaphyseal irregularities. Protein modeling and stability prediction showed that the mutant protein has decreased stability. Both the reported variants are in the same domain of the protein. Our report delineates the clinical and radiological characteristics of an emerging ribosomopathy caused by biallelic variants in *NEPRO*.

## PgmNr 1130: The role of COL27A1 in skeletal development: Additional pathogenic variants from Turkish kindreds and mouse modeling of the Steel syndrome Puerto Rican founder allele.

---

Previously we reported the identification of a homozygous p.Gly697Arg variant in *COL27A1* as a founder mutation in Puerto Rico segregating with Steel syndrome (STLS, MIM #615155); a rare osteochondrodysplasia characterized by short stature, congenital bilateral hip dysplasia, carpal coalitions, and scoliosis. Here we report homozygosity and segregation of this variant in five probands from the initial clinical report and an additional family of Puerto Rican descent with multiple affected individuals. These data confirm that the variant allele represents a founder mutation and that it is the molecular cause of the clinically described Steel syndrome. Additionally, we report three novel and distinct homozygous pathogenic variants in *COL27A1* identified in unrelated consanguineous Turkish kindreds where the probands were ascertained due to unusual osteochondrodysplastic phenotypes. We developed an animal model for the p.Gly697Arg orthologous mutation in the murine *Col27a1* that recapitulates some of the major skeletal features observed in Steel Syndrome individuals including reduced length, scoliosis, and a rounded skull shape. Two pathogenic missense variants were functionally characterized *in vitro* and support a cell non-autonomous mechanism of disease. Characterization of the *in vivo* model shows that the phenotype is likely the result of abnormal collagen deposition in the extracellular matrix and disorganization of the proliferative zone of the

growth plate. The hypothesis that carrier states for this autosomal recessive osteochondrodysplasia may contribute to common complex traits is further explored. Our findings augment our understanding of *COL27A1* biology and expand on the allelic architecture that can potentially underlie both rare and common disease phenotypes.

## PgmNr 1131: Respiratory function in the *Crtp*KO mouse model of osteogenesis imperfecta.

---

Respiratory disease is a leading cause of mortality in patients with Osteogenesis imperfecta (OI), a congenital disease that causes severely reduced bone mass and is most commonly caused by dominant mutations in type I collagen genes, *COL1A1* and *COL1A2*. Because type I collagen is present in most tissues, the disease is systemic and patients with moderate or severe OI can suffer from respiratory distress at birth, and then declining respiratory function with increased vulnerability to lung infections in adulthood which can lead to fatal pneumonia. Previous studies proposed that impaired respiratory function in OI patients was secondary to skeletal deformities however recent evidence suggested the existence of a primary lung defect. How collagen defects causing OI negatively affect lung function is not understood and poorly studied. Here, we analyzed the lung phenotype of *Crtp*KO mice, a mouse model of recessive OI with defective collagen synthesis, to corroborate our hypothesis that collagen defects are responsible for their compromised lung parenchyma architecture and consequently alter the respiratory pattern and mechanical properties of the respiratory system. Our results show that lung fibroblasts lacking *Crtp* expression synthesize type I collagen with altered post-translation modifications, consistent with those observed in bone and skin of *Crtp*KO mice. These collagen alterations likely weaken the lung tissue and cause the changes in parenchymal lung architecture and alveolar airspace observed in *Crtp*KO mice. Unrestrained whole body plethysmography showed a significant increase in the ratio of inspiratory time over expiratory time (TI/TE) concomitant with an increase of the diaphragm duty cycle (TI/TCT), the primary inspiratory muscle, in *Crtp*KO compared to WT mice. Closed chest measurements using the force oscillation technique (FOT) showed an increased dynamic resistance but no significant changes in compliance or elastance. Further assessments of lung tissue properties indicated no changes in central airways resistance but significant increases in both lung tissue damping and tissue hysteresivity in *Crtp*KO compared to WT mice suggesting an alteration of the alveolar structure and peripheral lung ventilation heterogeneity. This is the first evidence that collagen defects in OI cause primary changes in several respiratory parameters and thus negatively impact lung function with features of both restrictive and obstructive lung disease.

# PgmNr 1132: Characterization of the Robinow syndrome skeletal phenotype with dual-energy x-ray absorptiometry and genotype-phenotype correlations with osteosclerosis.

## Background

Robinow syndrome (RS) is a genetically heterogeneous skeletal dysplasia with a growing list of associated genes. Recent reports suggest much more phenotypic heterogeneity including a few reports of an osteosclerotic form of RS. We endeavored to investigate the full spectrum of skeletal anomalies in a genetically diverse cohort of RS patients with a focus on the bone structure.

## Subjects & Methods

Seven individuals with molecularly confirmed RS, including four with *DVL1* variants and single individuals with variants in *WNT5A*, *ROR2*, and *GPC4* underwent a musculoskeletal physical exam and dual-energy x-ray absorptiometry (DEXA) scan. Measures in bone mineral content (BMC) and bone mineral density (BMD) of the total body and non-cranial skeleton were taken and compared to height and age matched controls for pediatric and adult subjects.

## Results

Skeletal examination revealed variability in limb shortening anomalies including mesomelia (3/7), rhizomelia (2/7), and micromelia (2/7) as well as limited supination (3/7), genu valgus (1/7), and scoliosis (1/7). DEXA scan measures compared to height-matched controls revealed increased total body BMC (4/7), non-cranial BMC (2/7), total body BMD (6/7), and non-cranial BMD (3/7). DEXA scan measures compared to age-matched controls revealed increased total body BMC (3/7), non-cranial BMC (0/7), total body BMD (3/7), and non-cranial BMD (1/7). Cranial osteosclerosis based on BMD for age was present in 3/7 subjects, one of which also had non-cranial osteosclerosis. One subject had osteopenia.

When comparing the skeletal phenotype based on genotype, cranial osteosclerosis was only observed in *DVL1*-RS (2/4) and *GPC4*-RS (1/1) subjects, while individuals with a *ROR2*-RS and *WNT5A*-RS had normal or low BMD. Notably, the *GPC4*-RS subject's cranial osteosclerosis was complicated by choanal atresia, bilateral conductive hearing loss, and cranial nerve III, VI and VII palsy secondary to stenosis of nerve foramina.

## Conclusion

The spectrum of skeletal anomalies including the micro-architecture of the bones observed in RS has considerable variability with some genotype-phenotype correlations. In particular, osteosclerosis appears to be a feature observed only in those with variants in *DVL1* and *GPC4* based on this study

and prior publications. Additionally, the osteosclerosis has a predilection for the cranium compared to the non-cranial skeleton, which can result in comorbidities like cranial nerve palsy and hearing loss.

## PgmNr 1133: A mouse model of mandibulofacial dysostosis with microcephaly reveals a role for EFTUD2 in the neural tube.

Splicing, the removal of introns from pre-messenger RNA is an essential step for expression of most genes in multicellular organisms and for expanding the number of proteins coded by genomes. Exome sequencing has shown that mutations in splicing factors and small nuclear ribonucleoprotein particles (snRNPs) which form core components of the spliceosome, are responsible for craniofacial malformations. Our group is using a mutant mouse line with conditional mutation in *Eftud2*, the gene mutated in mandibulofacial dysostosis with microcephaly (MFDM) to uncover the etiology of this syndrome. *In situ* hybridization revealed strong expression of *Eftud2* in ectodermal and mesodermal components of the future craniofacial region at embryonic days (E) 7.5 and 8.5, and by E9.5 expression was also found in the body wall and developing heart. To examine the requirement for *Eftud2* in neural crest cells, the Wnt1-Cre2 transgenic line was used to delete exon 2 of *Eftud2*. *Eftud2* flox homozygous mutant embryos carrying the Wnt1-Cre2 transgene displayed hypoplasia of the midbrain and pharyngeal arches starting at E9.5. By E11.5, most embryos also had an open neural tube and all embryos showed exencephaly at E14.5. Cartilage preparations revealed an absence of cartilage in the head, reduction/or absence of Meckel's cartilage, and abnormal inner ear development. Since deletion of exon 2 is predicted to generate a truncated protein with partial function, our data suggest that normal levels of *Eftud2* is crucial in neural crest cells for normal craniofacial development. Future studies are focused on elucidating the molecular and transcriptional basis of MFDM using this mouse model.

## PgmNr 1134: Variants in *ANK2* brain-specific transcript as novel cause of holoprosencephaly.

Loss-of-function mutations in Ankyrin 2 gene (*ANK2*; OMIM 106410) are known as a cause of human arrhythmias and Long QT syndrome (OMIM 600919). Different Ankyrin isoforms encoded by alternatively spliced transcript variants have been described. This includes a brain-specific 440-kD Ankyrin which contains a 200-kD segment encoded by exon 38, not typically found in cardiac *ANK2* transcripts. Whereas *Ank2* null mice show brain structural defects such as hypoplasia of the corpus callosum, dilated cerebral ventricles, extensive degeneration of the optic nerve with death by postnatal day 21, no association between *ANK2* variants and defects of the human forebrain development, including holoprosencephaly (HPE) has been reported to date.

Here we present two unrelated female patients aged 2 years each, diagnosed with lobar holoprosencephaly by Magnetic Resonance Imaging. Thorough phenotyping of each patient revealed no associated feature in the first patient. The second patient had a single central maxillary incisor and cleft of the lip and palate. No extracephalic features were identified in both patients. Using trio-based exome sequencing, novel *de novo* heterozygous variants in exon 38 of *ANK2* were identified. The first patient had a stop-gain variant c.7804G>T (p.E2602\*) predicted deleterious and loss-of-function intolerant (CADD score: 51; pLI score: 1), and the second patient had a deleterious missense variant c.9848C>T (p.S3283L)(CADD score: 29) in addition to a *de novo* frameshift variant in *SIX3* c.613del (p.Asp205Thrfs\*46). While mutations in *SIX3* alone can cause HPE, the low rate of *de novo* variants and the incomplete penetrance frequently observed for this gene are suggestive of a possible digenic etiology for the second patient. It is anticipated that genes regulating forebrain patterning and involved in the pathogenesis of HPE are expressed in the prosencephalic neural folds that give rise to the forebrain vesicle during primary neurulation. Gene expression analysis in mouse embryos by *in situ* hybridization at GD8.25 demonstrated specific *ANK2* expression in the prosencephalic neural folds.

This study presents for the first time an association between variants in *ANK2* brain-specific transcripts and HPE, revealing *ANK2* gene as a potential regulator of human forebrain development and modulator of HPE pathogenesis.

## PgmNr 1135: The refinement of 16p13.3 microdeletion syndrome from a case presentation of a girl with epilepsy, intellectual disability, and distinctive dysmorphic features.

Eight patients have been reported with 16p13.3 microdeletion syndrome demonstrating intellectual disability and epilepsy. The responsible region for this phenotype encompassed five genes (*TBC1D24*, *ATP6V0C*, *AMDHD2*, *CEMP1*, and *PDPK1*). Here, we describe an additional patient demonstrating moderate intellectual disability, epilepsy, skeletal abnormalities, and distinctive dysmorphic features with a minimal overlapping region harboring *TBC1D24* and *ATP6V0C*. The patient was a 10-year-old girl. She developed tonic-clonic seizures at 8 months and was started with an antiepileptic drug. Myoclonic seizures began at 7 years, which were controlled with multiple antiepileptic drugs. She started to walk alone at 30 months and speak recognizable words at 7 years. Dysmorphic features were noted including a wide forehead, arched eyebrows, long palpebral fissures, long eyelashes, bulbous nasal tip, short and prominent philtrum, and pointed chin. She had skeletal abnormalities including chest and spine deformities and metacarpophalangeal joint contracture. Copy number variation analysis from trio exome sequencing data detected a *de novo* microdeletion at 16p13.3. Chromosomal microarray analysis revealed a microdeletion of 284 kb at 16p13.3 (from position 2,280,210 to 2,565,055 bp). The present patient delineated the critical region for intellectual disability and epilepsy for 16p13.3 microdeletion syndrome.

**INTRODUCTION:** Cleidocranial dysplasia, OMIM #119600, is an autosomal dominant disorder characterized by hypoplasia or aplasia of the clavicles with narrow, sloping shoulders that can approximate each other, delayed fusion of cranial sutures, wide-open fontanels at birth that may persist throughout life. It is caused by mutations in *RUNX2* (6p21) involved in differentiation of osteoblasts and bone formation. The prevalence of CDD is 1/1,000,000.

**OBJECTIVE:** Present a family affected with case of CDD and its clinical-radiological correlation.

**CASE REPORT:** Patient 1 (*proposita*): 4 years-old female, product of the 3rd pregnancy. **Physical examination:** weight 15,100kg (pc11), height 104cm (pc21), HC 49cm (pc13), midfacial hypoplasia, hypertelorism, delayed fusion of cranial sutures, wide-open fontanels, hypoplasia of the clavicles with narrow, sloping shoulders that can be approximated one to another; scoliosis and difficulty speaking. **X-ray:** Presence of facio-cranial disproportion, hypoplasia of clavicles, dorsal scoliosis and enlargement of lumbar vertebrae.

**Patient 2** (brother): 9 years-old male, product of 1st pregnancy. **Physical examination:** weight 22,400Kg (pc2), height 125cm (pc4), HC 51cm (pc3), hypertelorism, delayed fusion of cranial sutures, wide-open fontanels, hypoplasia of the clavicles with narrow, sloping shoulders that can be approximated one to another, scoliosis, cognitive and intellectual functions normal. **X-ray:** presence of facio-cranial disproportion, hypoplasia of clavicles, dorsal scoliosis with thickened vertebrae and apparent bifurcation, enlargement of lumbar vertebrae with apparent platyspondyly.

**Patient 3** (mother): 30 year-old female, with familial history of affected mother and half-sister 17 year-old. Physical examination: weight 60kg, height 1.56cm, HC 50cm, broad flat forehead, midface hypoplasia, hypertelorism, hypoplasia of clavicles with narrow, sloping shoulders that can be approximated each other, cognitive and intellectual functions normal. **X-ray:** vertebral anomalies (thickened lumbar vertebrae) and hypoplasia of clavicles.

**CONCLUSIONS:** A family with clinical and radiological manifestations compatible with CDD was studied. The diagnosis was done on basis of clinical and radiological findings. Molecular genetics testing can be used to confirm the diagnosis in patients with atypical clinical and radiological features. Genetic counseling should be provided to affected families, management and treatment is multidisciplinary.

## PgmNr 1137: Variant in *OTUD6B* gene cause intellectual developmental disorder with dysmorphic facies, seizures, and distal limb anomalies: A case report.

### Authors:

J. Rojas Martinez; R. Quero; M. Manotas; M. Guerra; J. Villalta

[View Session](#) [Add to Schedule](#)

**Affiliation:** Instituto de Genética Humana, Facultad de Medicina, Pontificia Universidad Javeriana, Bogotá, Colombia.

---

The syndrome of intellectual developmental disorder with dysmorphic facies, seizures, and distal limb anomalies is a multisystemic disorder of autosomal recessive inheritance with phenotypic variability characterized by microcephaly, global developmental delay, absence of language, hypotonia, growth retardation with prenatal onset, feeding difficulties, structural abnormalities in the brain, and congenital anomalies including heart defects and musculoskeletal abnormalities. It is caused by biallelic mutations in the *OTUD6B* gene that encodes a member of the deubiquitinating enzyme subfamily that contains the ovarian tumor domain (OTU).

We present the case of a 16-year-old male adolescent, product of the second pregnancy of consanguineous parents (first cousins), with severe intellectual disability, focal epilepsy, absence of language, notorious delay in neurodevelopment and bilateral profound sensorineural hearing loss associated with craniofacial dysmorphism due to microcephaly, bilateral palpebral ptosis, right iris coloboma, bifid tongue, winged neck, pectum excavatum, breast hypertelorism, clinodactyly, shortening of the fifth finger in the hands and generalized xeroderma.

Trio whole exome sequencing revealed a pathogenic variant c.433C> T (p.Arg145 \*), in homozygosis in the *OTUD6B* gene, which confirmed the diagnosis in the patient and the status of heterozygous carriers in both parents.

It has been reported fourteen individuals from eight independent families worldwide with homozygous mutations in the *OTUD6B* gene as a cause of the developmental disorder with dysmorphic facies, seizures, and distal limb anomalies. At our knowledge, our patient is the first case reported in America.

## PgmNr 1138: A novel 3 MB deletion on 6p24 excluding *TFAP2A* results in a mild phenotype in a multiplex family with orofacial clefting.

---

Nonsyndromic orofacial clefting (OFC) has a complex etiology but multiplex families are likely to be enriched for high effect variants that reflect novel genetic factors or causal mechanisms. In a previous effort to characterize large copy number variants as genetic risk factors for OFC following a genome-wide association study (GWAS), we identified a novel 3 Mb deletion on 6p24 in three affected members of the same family from Colombia. The reported pedigree had a dominant inheritance pattern and included 5 individuals with cleft lip (CL) or cleft lip and palate (CLP): a female proband (CLP), her brother (CLP), her mother (CL), and a maternal aunt (CLP) and uncle (CL). All affected family members with DNA (4 of 5 individuals, including one not typed in the GWAS) carried the deletion, which was inherited from the proband's unaffected grandmother. Exome sequencing of this family found no segregating single nucleotide variants in OFC candidate genes, supporting the pathogenicity of this deletion. The 3Mb deleted region included 12 genes and a gene desert spanning approximately 840 kb. Two of the deleted genes are notable for their associated phenotypes: *DSP* (woolly hair and keratoderma) and *BMP6* (decreased growth), but neither are strong OFC candidates. The 3' breakpoint of the deletion is located in the middle of a conserved 2.5Mb topologically associated domain (TAD) identified from published Hi-C data in human embryonic stem cells and containing *TFAP2A*. In addition to removing the 5' boundary of the TAD, the deletion includes one enhancer active in human cranial neural crest cells and human fetal craniofacial tissue and a second with activity in neural crest in mouse embryos. *TFAP2A* mutations and deletions cause Branchiooculofacial Syndrome (BOFS), a dominant syndrome that includes OFC as a primary phenotypic feature in addition to branchial and ocular anomalies. Except for OFC and characteristic facial features (broad nasal root and slight hypertelorism), the affected members of this family lack additional features of BOFS. Cumulatively, these data suggest that deletion of distal *TFAP2A* regulatory elements result in a craniofacial phenotype consistent with mild features of BOFS and that these elements are excellent candidates for being involved in nonsyndromic OFCs.

## PgmNr 1139: Phenotypic expansion of *KMT2D*-associated disorder: Beyond Kabuki syndrome.

Pathogenic variants in *KMT2D*, which encodes lysine specific methyltransferase 2D, cause autosomal dominant Kabuki Syndrome 1 (MIM: 147920), associated with distinctive dysmorphic features that include arched eyebrows, long palpebral fissures with eversion of the lower lid, large protuberant ears, and persistent fetal finger pads. Most disease-causing variants described to date are putative loss-of-function alleles, although 15-20% of cases are attributed to missense variants. We describe here four cases (including one previously published case, Sakata et al. 2017) with de novo *KMT2D* missense variants, and who have shared but unusual clinical findings not typically seen in Kabuki syndrome, including athelia (absent nipples), choanal atresia, hypoparathyroidism, delayed or absent pubertal development, and extreme short stature. Two of the four had severe interstitial lung disease. These individuals also lack the typical dysmorphic features found in Kabuki syndrome. All of these missense variants cluster within a 40-amino-acid region of the protein that is located just N-terminal of an annotated coiled coil domain. These findings significantly expand the phenotypic spectrum of features associated with variants in *KMT2D* beyond those seen in Kabuki syndrome and suggest a possible new underlying disease mechanism in these cases.

## PgmNr 1140: Expanding the spectrum of *KLHL7*, novel mutation, and evidence for multilocus pathogenic variation.

**Background:** Mutations in Kelch-like 7 (*KLHL7*) have recently been described to cause a constellation of clinical findings with descriptions of both autosomal recessive Crisponi syndrome (CS)/cold-induced sweating syndrome type 1 (CISS1)-like (CISS3), Bohring-Opitz syndrome (BOS)-like presentation and autosomal dominant retinitis pigmentosa 42 (RP42). CISS3/BOS is mainly characterized by clinical features of severe developmental delay/intellectual disability (DD/ID), hyperthermia, recurrent infections, feeding difficulties, joint contractures, and craniofacial dysmorphism. Heterozygous pathogenic variants in the BACK domain mainly result in RP42 phenotype, whereas biallelic pathogenic variants in the Kelch-repeat domain result in CISS3/BOS.

**Material and Methods:** In this study, we performed exome sequencing and family-based rare variant analyses on 117 families with a shared clinical feature of arthrogryposis.

**Results:** A total of eight affected individuals from four unrelated families were found to have biallelic pathogenic variants in *KLHL7*. The stopgain variant c.565C>T:p.Arg189\* resides in the BACK domain of *KLHL7*, and is novel. The remaining three families had variants that were reported previously. One family showed evidence for multilocus pathogenic variation including rare variants in *HOXA11* and *TNRC6C* in addition to *KLHL7*, each potentially contributing to the proband's phenotype. Subjects from three of the 4 families shared recognizable facial features whereas multilocus pathogenic variation subject had dysmorphic craniofacial features that were distinct from the other 3 families. The syndromic features observed in all individuals were severe DD/ID with brain anomalies (4/4) and arthrogryposis (4/4). Additional features not present in all cases included prematurity (3/4), genitourinary system anomalies (2/4), congenital heart disease (2/4); and nephrolithiasis (1/4), intestinal obstruction (1/4) and cleft palate (1/4), representing a potential expansion of the known clinical features associated with biallelic *KLHL7* pathogenic variants.

**Conclusions:** Our findings confirm that CISS3 is a clinically recognizable disorder with distinctive facial dysmorphic features and we further delineate the syndromic features of this syndrome by describing biallelic variants including one novel potentially pathogenic variant. We further validated that biallelic variants in the *KLHL7* BACK domain can cause CISS3 in addition to RP42.

## PgmNr 1141: Biallelic frameshift variants in *CNKSR1* and a novel deletion in *ZEB2* identified in a patient dysmorphologically diagnosed with Mowat-Wilson syndrome.

### Authors:

---

Mowat-Wilson syndrome (MOWS) is an autosomal dominant disorder characterized by distinctive facial appearance, intellectual disability, delayed motor development, microcephaly and short stature. It is known that most patients with MOWS have de novo heterozygous mutations in the *ZEB2* gene. We encountered a 3-year-old female patient with distinctive facial appearance (narrow bifrontal diameter, frontal bossing, telecanthus, epicanthal folds, prominent antihelices, prominent ears, uplifted earlobes, prominent nasal bridge), intellectual disability, delayed motor development, hypotonia and short stature. She was clinically diagnosed with MOWS. Since direct sequencing for *ZEB2* coding exons displayed no pathogenic variants in the patient, we performed whole exome analysis for trio in the family.

After routine SNV calling and variant filtering procedure, no pathogenic SNVs in *ZEB2* but biallelic frameshift variants (p.Thr282fs from mother and p.Ala503fs from father) in *CNKSR1* were found in the patient. Recently, it has been reported that a recognizable autosomal recessive intellectual disability was caused by defect of the *CNKSR1* gene. The p.Thr282fs was recurrent and the p.Ala503fs was novel. However, the patient's findings did not match the phenotypes of *CNKSR1* mutations, which were previously reported. In addition, a homozygous variant of p.Pro284HisfsTer74 in *CNKSR1*, which was near the p.Thr282, was registered 224/273,674 in the gnomAD. Thus, copy number analysis was performed using whole exome data, which revealed an approximately 360kb deletion around intron 7 of *ZEB2* in the patient. The deletion was confirmed by the breakpoint analysis.

Based on these findings and data, we concluded that the patient's symptoms were caused by the novel deletion in *ZEB2* rather than biallelic variants in *CNKSR1*.

## PgmNr 1142: Phenotype assessment of a Brazilian Cornelia de Lange syndrome (CDLS) cohort.

Introduction: Cornelia de Lange syndrome (CDLS) is a rare genetic disorder caused by mutations in five different genes (*NIPBL*, *SMC1A*, *HDAC8*, *SMC3*, *RAD21*), characterized by dysmorphic features (synophrys, long eyelashes, short nose, hirsutism, microcephaly), limb defects, growth retardation and neurodevelopmental delay. The disorder has a wide clinical variability, thus our objective is to assess the clinical characteristics of 24 Brazilian patients. Materials and Methods: Whole exome sequencing (WES) of the patients and their parents were performed in clinical diagnosis of CDLS. Results: From the 24 cases, pathogenic variants in *NPBL* were found in 22 cases and the other 2 cases were confirmed in *SMC1A*. The main clinical findings in confirmed CDLS patients were: highly arched eyebrows (95.8%), synophrys (91.6%), long curly eyelashes (87.5%), hypertrichosis (79.1%), microcephaly (70.8%), anteverted nostrils (75%), thin upper lip (66.6%), long philtrum (66.6%), downturned corners of the mouth (66.6%), syndactyly (54.1%), abnormal palmar crease (50%), depressed nasal bridge (45.8%), short neck (45.8%), cryptorchidism (41.6%), hypoplastic genitalia (37.5%) and micrognathia (29.1%). Prenatal growth retardation is reported in 79.1%, height or length below 5th percentile for age in 75% and weight below 5th percentile for age in 62.5%. Other secondary features are gastroesophageal reflux (70.8%), epilepsy (33.3%), heart anomalies (25%), hearing loss (25%) and myopia (20.8%). Neurodevelopmental delay were present in 87.5%, intellectual disability in 58.3% and language delay in 70.8%. Behavior problems were reported in all patients, except three, such as attention deficit disorder (75%), anxiety (66.6%) and self-injurious behavior (54.1%), aggression (45.8%). Other findings were abnormal palmar crease (52%), syndactyly (44%) and oligodactyly (12%). The current age varies from 8mo to 40 y (mean 11y5mo, median 8y). Conclusion: The clinical and molecular evaluation were a pioneer in Brazilian CDLS patients and WES is an important exam for these patients and their family for the correct diagnosis, follow-up and genetic counseling.

## PgmNr 1143: Tracheal cartilaginous sleeve in patients with Beare-Stevenson syndrome.

### Authors:

K. Kurosawa <sup>1</sup>; E. Seki <sup>2</sup>; K. Enomoto <sup>1</sup>; K. Tanoue <sup>2</sup>; M. Tanaka <sup>3</sup>

---

Tracheal cartilaginous sleeve (TCS), a life-threatening complication in patients with craniosynostosis syndromes, is a solid cartilaginous tube lacking the pars membranacea, caused by defective C-shaped tracheal rings. Without tracheostomy, it has a 90% mortality by 2 years. To increase knowledge regarding TCS and Chiari malformation for respiratory distress in Beare-Stevenson syndrome (BSS), we report 2 cases with BSS and TCS. Patient 1 was the second child of healthy Japanese parents. After birth, she was intubated for severe respiratory failure caused by airway obstruction and choanal stenosis. Chest computed tomography (CT) and bronchoscopy showed dorsal recession of the tracheal internal wall, suggesting TCS. At 5 years, she developed severe sleep apnea. Although bronchoscopy showed improvements in the tracheal wall deformity, spinal magnetic resonance imaging revealed a hyper-intense signal at the C2 level. Genetic analysis revealed a pathogenic FGFR2 variant c.1124A>G (p.Tyr375Cys). Patient 2 was the third child of healthy parents. At age 10, he developed obstructive respiratory distress. Chest CT showed tracheostomy tube obstruction by a TCS-related dented deformity. At 12 years of age, he died suddenly after respiratory distress caused by tracheostomy tube obstruction. The tip of the tracheostomy tube had caused tracheal wall injury resulting in the formation of a dented deformity. Stacking of the tracheostomy tip into the dented deformity was considered the likely cause for the respiratory distress. Genetic analysis identified a pathogenic FGFR2 variant c.1115C>G (p.Ser372Cys). Early interventions with tracheostomy and cervical cord decompression improved severe respiratory distress. This shows that the mechanism and severity of TCS vary, and early airway evaluation is critical in craniosynostosis syndromes. To our knowledge, this is the first report demonstrating an abnormal tracheal structure due to long-term injury by the distal tip of the tracheostomy tube, leading to airway obstruction in BSS. Our report delineates the potential risks of tracheostomy tube obstruction by TCS and emphasizes the importance of investigations with bronchoscopy for BSS patients.

## PgmNr 1144: Clinical features of individual with Birk Barel syndrome.

### Authors:

---

Birk-Barel syndrome also known as *KCNK9* imprinting syndrome is characterized by congenital central hypotonia, severe feeding difficulties, delayed development, intellectual disability, and dysmorphic features including dolichocephaly with bitemporal narrowing, short philtrum, tented upper lip, palatal abnormalities, and small mandible. It is caused by heterozygous mutation in *KCNK9* on chromosome 8q24. The diagnosis of the *KCNK9* imprinting syndrome is established in a proband with suggestive clinical findings and detection of the heterozygous *KCNK9* pathogenic variant p.Gly 236 Arg (G236R) on the maternal allele. To date 19 individuals with a molecularly confirmed diagnosis have been reported: 15 from an Arab-Israeli family and four cases with different pedigrees [Barel et al., 2008, Graham et al., 2016].

Here we describe a Japanese individual with *KCNK9* imprinting syndrome caused by recurrent mutation in *KCNK9*. The individual was 2 years and 7 months old girl, the third child of healthy 28-year-old mother and 38-year-old father. She was born at the normal delivery at 40 2/7 weeks of gestation. Apgar scores were 7 and 9 at 1 minute and 5 minutes, respectively. At birth, profound hypotonia, high palate, and talipes equinovagum were noted. After birth, she required oxygen inhalation and phenobarbital due to apnea, and needed tube feeding for a year because of poor feeding. Her development has been significantly delayed; she started rolling over and sitting independently at 1 year 2 months old, crawling at 2 years and 2 months old, and speaking a few single words at 2 year 4 months. She has not started standing with support and walking independently at 2 years and 7 months old. Brain MRI at 4 months old did not reveal any structural brain abnormalities. We identified *de novo* c.706G>A variant, (G236R) by whole exome sequence.

The *KCNK9* variant (G236R) reduces the outward current of the TASK3 channel encoded by *KCNK9* gene, and nonsteroidal anti-inflammatory fenaminic acid such as mefenamic acid (MFA) has been reported to stimulate the channel [Veale et al., 2014, Takahira et al., 2005]. To date, only two affected individuals have been treated with MFA, with noted increased energy while on the medication [Graham et al 2016]. To establish the efficacy of the MFA treatment, the further studies of additional individuals of Birk-Barel syndrome with MFA treatment and the long-term observation of them are expected.

## PgmNr 1145: Impact of few rare genetic disorders on oral health.

**Authors:**

E. Severin; S. Albu; C. Albu

[View Session](#) [Add to Schedule](#)

**Affiliation:** Dept Human Genetics, Carol Davila Univ Med Pharm, Bucharest, Romania

---

**Background.** According to the EU definition, accepted by Romanian authorities, a rare disease (RD) is defined as a life-threatening or chronically debilitating condition that afflicts fewer than 5 in 10,000 persons within the general public. It is estimated that 80% of RDs are a result of genetic causes. RDs are characterised by a broad diversity of disorders and symptoms that vary not only from disease to disease but also from patient to patient suffering from the same disease. Craniofacial features, including dental anomalies and diseases, vary considerably from individual to individual as well. Oro-dental findings do not increase the risk of death among people with RDs, but the quality of life becomes worse. **Objectives.** The study based on our experience and a systematic review aimed to study the impact of genetic disorders on oral health in rare diseases and to provide better knowledge of craniofacial problems in some RDs. **Material and Methods.** To collect evidence that genetic disorders play a key role in RDs, an electronic literature search was conducted using different medical databases and additional information resources. The variables studied included craniofacial features, teeth development anomalies, dental occlusion, oral mucosa and oral pathologies. **Results.** The results included few RDs (Cherubism, Cleidocranial dysplasia, Hypohidrotic ectodermal dysplasia and Osteogenesis imperfecta) associated with craniofacial abnormalities and/or oro-dental problems. Genetic causes, signs and symptoms are described. **Conclusions.** Given the high rate of craniofacial, oral and dental abnormalities, people with RDs need a thorough oral evaluation and the pediatric dentist should be familiar with common, rare, and individual findings in people with RDs and anticipate complications which allow better-individualized treatment.

## PgmNr 1146: Whole-exome sequencing analysis of multiplex families with nonsyndromic orofacial clefts identifies variants in genes for Mendelian OFC syndromes.

### Authors:

K.K. Diaz Perez <sup>1</sup>; J.T. Hecht <sup>2</sup>; G.L. Wehby <sup>3</sup>; J.C. Murray <sup>3</sup>; M.L. Marazita <sup>4</sup>; E.J. Leslie <sup>1</sup>

---

Among the most common congenital facial abnormalities worldwide are orofacial clefts (OFCs), which occur when an infants' lip and/or mouth do not form properly during pregnancy leading to an opening in the lip or roof of the mouth. Most OFCs occur in the absence of other significant structural or developmental abnormalities and are thus considered nonsyndromic, with both genetic and environmental influences on etiology. The last decade of OFC research has focused on common genetic variants, but increasing evidence points to a role for rare variants in a subset of cases. We performed whole-exome sequencing (WES) to identify novel, protein-coding variants in a set of 72 multiplex nonsyndromic OFC families from diverse populations with quasi-Mendelian inheritance patterns. Here we summarize three families with mutations in genes previously associated with OFC syndromes. The first was a Guatemalan pedigree with four male siblings affected with cleft lip and palate (CLP); both parents and a female sibling were unaffected. The most likely causal variant was a frameshift mutation of *TP63* (p. His536Thrfs\*18), shared by the affected individuals, the female sibling, and their mother. The second family was a three-generation Hungarian family where two siblings had cleft palate (CP), their father had CLP, and their paternal grandfather had bifid uvula and syndactyly of the hands and feet. These individuals all shared a missense mutation in *IRF6* (p. Leu22Pro). Neither family meets the diagnostic criteria for the known syndromes caused by *TP63* and *IRF6*. The third family was from Pittsburgh with two siblings and their father, all affected with CP. We identified a 32bp deletion that results in a frameshift mutation in *SMC3* (p. Leu676Argfs\*5) shared among all three affected individuals and not found in two unaffected siblings; DNA from a paternal aunt with CLP was unavailable for study. Mutations in *SMC3* cause Cornelia de Lange syndrome but are primarily missense or in-frame indels, so we hypothesize this variant may cause nonsyndromic OFC through a different mechanism. Overall, our study provides evidence that WES can successfully identify likely pathogenic variants in multiplex OFC families and uncover some of the "missing heritability" of OFCs. More importantly, this work highlights the blurring of the distinction between syndromic and nonsyndromic OFCs and may suggest a role for clinical sequencing in patients with a family history of OFCs.

## PgmNr 1147: Complex rearrangements of *CREBBP* detected in patients with Rubinstein-Taybi syndrome (RSTS).

### Authors:

---

Rubinstein-Taybi syndrome (RSTS) is characterized by distinct facial features, short stature, broad thumbs and first toes and moderate to severe intellectual disability. Their distinct facial features include downward slanting palpebral fissures, arcuate eyebrow, beaked nose with nasal bridge, high-arched palate and grimacing smile. RSTS is rare autosomal dominant disease arising in rate of about 1/100,000-125,000. Haploinsufficiency of causative genes including *CREBBP* and *EP300* is the underlying mechanism of the disease. Both genes have similar functions as histone acetyltransferase that regulates transcription via chromatin remodeling. 50-70% of patients have mutation in *CREBBP* and 3% have mutation in *EP300*. Microdeletions in *CREBBP* are found in 10% of patients. Here we report complex rearrangements of *CREBBP* in two patients with RSTS. We performed copy number variation (CNV) analysis using panel-based exome data. Patient 1 showed the dispersed deletions in the region encompassing *CREBBP* and *ADCY9*, suggesting small genomic rearrangements. Patient 2 showed mosaic deletion (deletion allele : about 25%, normal allele : about 75%) in exon 7-13 of *CREBBP*. He showed mild phenotype of RSTS. These results indicate that the underlying mechanism of RSTS are highly variable for genomic rearrangement and suggest that the detection system for complex rearrangements are required in the context of clinical setting for RSTS.

# PgmNr 1148: A biallelic variant in the *DACH1* gene (Dachshund Family Transcription Factor 1) causes postaxial polydactyly type A.

## Authors:

M. Umair <sup>1</sup>; Z. Lin <sup>3</sup>; F. Ahmad <sup>2</sup>; M. Bilal <sup>2</sup>; M. Younus <sup>3</sup>; A. Khan <sup>1</sup>; M. Alfadhel <sup>1, 4</sup>

---

**Background:** Polydactyly or hexadactyly is a very common limbs deformity mostly characterized by having an extra digit/toe with or without a bone. Currently, mutations in nine genes have been implicated in causing a non-syndromic form of polydactyly including *GLI3*, *GLI1*, *ZNF141*, *IQCE*, *MIPOL1*, *STKLD1*, *FAM92A1*, *KIAA0825*, and *PITX1*.

**Methods:** DNA from single affected individual [IV-1] was subjected to whole exome sequencing (WES), followed by Sanger sequencing to verify segregation of the variants in all the available family members. Protein homology modeling and molecular docking were performed using standard methods.

**Results:** A pathogenic disease-causing biallelic missense variant (**c.569G>A; Cys190Tyr**) was identified in the *DACH1* gene that segregated perfectly with the disease phenotype within the family. The variant was absent in 155 exomes from unrelated Pakistani individuals, different online publically available databases, and in 245 ethnically matched controls. Structural analysis of the DACH1 protein revealed secondary structure change that might result in loss of downstream interaction.

**Conclusion:** Taken together, the present study report on the first direct evidence of the involvement of *DACH1* gene in causing nonsyndromic postaxial polydactyly in humans. This signifies impotence and yet unexplored role of *DACH1* in limbs development.

## PgmNr 1149: Severe Noonan syndrome phenotype associated with a germline Q71R MRAS variant.

Activation of the RAS pathway through either the activation of genes that accelerate the pathway or the suppression of genes that inhibit the pathway leads to a group of disorders collectively referred to as RASopathies. The key molecules of the RAS pathway are *KRAS*, *HRAS*, and *NRAS*. Mutations in these three RAS homolog genes have been shown to be associated with RASopathies. Recently, two patients with a Noonan syndrome phenotype were shown to carry mutations in the yet another RASopathy gene, *MRAS* (muscle RAS oncogene homolog). Here, we report a patient with a severe Noonan syndrome phenotype associated with a germline Q71R MRAS variant, which represents a recurrent substitution in RAS homologs in various cancers. The patient's dysmorphic features included relative macrocephaly, a down-slanted palpebral fissure, hypertelorism, a depressed nasal bridge, and low-set ears with thick lobes; these facial features are strongly associated with RASopathy. We confirmed that the *MRAS* gene represents a causative gene for RASopathy.

## PgmNr 1150: Primary immunodeficiency with chronic enteropathy and developmental delay in a boy arising from a novel homozygous *RIPK1* variant.

---

Identification of genetic causes of primary monogenic immunodeficiencies would strengthen the current understanding of their immunopathology. Pathogenic variants in genes in association with tumor necrosis factor  $\alpha$  (TNF $\alpha$ ) signaling including *OTULIN*, *TNFAIP3*, *RBCK1* and *RNF31* cause human congenital autoinflammatory diseases with/without immunodeficiency. *RIPK1*, encoding a receptor interacting serine/threonine kinase 1, is present in protein complexes mediating signal transduction including TNF receptor 1. Biallelic loss-of-function variants in *RIPK1* were recently reported in individuals with primary immunodeficiency with intestinal bowel disease and arthritis. Here we report a novel homozygous *RIPK1* variant in a boy with immunodeficiency and chronic enteropathy. Our patient exhibited severe motor delay and mild intellectual disability, which were previously unknown. The present results are expected to deepen the current understanding of clinical features based on *RIPK1* abnormalities.

## **PgmNr 1151: Unbiased genomic approach to molecular diagnosis in patients with immune system dysfunction leads to unexpected molecular findings, multiple diagnoses and secondary findings.**

### **Authors:**

M. Walkiewicz; M. Similuk; J. Yan; L. Jamal; H. Hullfish; K. Jevtich; C. Lowe; A.P. Hsu; C. Hong; P. Littel; S. Xirasagar; S.M. Holland

[View Session](#) [Add to Schedule](#)

---

**Background:** In the past decade, dozens of new Mendelian disorders of immunity have been recognized. Yet, the genetic contributions to these disorders remain largely unelucidated. Making progress in this area requires a coordinated, systematic, and transparent approach to clinical genomics and research.

**Methods/Design:** We systematically applied genomic evaluation to research participants, including clinical grade interpretation and reporting of primary and secondary findings. We collect genomic data, family medical history, and standardized phenotype. We interpret and report clinical results in the medical record in conjunction with genetic counseling and shared access to data.

**Results:** We have recruited 1798 participants and completed analysis for 721 individuals and finalized 342 cases. We have issued 249 (72.8%) proband reports; 111 were inconclusive and 138 had at least one molecular finding. Of these, 82 (59.4%) had a pathogenic variant, 16 (11.6%) had a likely pathogenic variant, 39 (28.3%) had a variant of uncertain clinical significance (VUS) and 1 (0.72%) had likely benign variants. Four (2.9%) cases had secondary findings including pathogenic variants in *BRCA1* and *BRCA2*. Two (1.4%) cases had dual molecular diagnoses and 2 (1.4%) cases had a molecular diagnosis outside of “immune” phenotypes. Two (1.4%) cases had revised molecular diagnoses. Lastly, we identified several candidate genes requiring further follow up.

**Conclusion:** Unbiased genomic work-up yields molecular diagnoses, multiple or unexpected diagnoses, and secondary genomic findings, personalizing patient care. Process standardization, data integration, and data sharing policy facilitate research and discovery of candidate genes.

## **PgmNr 1152: Updates to the NIAID Genomic Research Integration System (GRIS): Integrated phenotype-genotype search, laboratory test results integration and visualization, variant tagging, and automating clinical reporting workflows.**

---

The NIAID Genomic Research Integration System (GRIS) has established an interactive web-based application to integrate patient clinical phenotype, pedigree, and genomic sequencing data. GRIS is used by clinical molecular geneticists and novice and expert researchers to identify putative causal variants for disorders and explore relationships between diseases and genes. GRIS is being continuously enhanced to integrate new types of content and broaden the use of existing content. A substantive enhancement, the integrated phenotype-genotype search enables identification of variants that segregate in families comprised of individuals with selected phenotypes. With rapid increases in the volume of next generation sequencing, this feature can be especially helpful for identifying causal and modifier variants for Mendelian immunologic disorders as well as elucidating polygenic disorders, which constitute the majority of immune disease cases. Recent enhancements also include the integration of laboratory test results and data visualizations which provide more granular phenotypic context alongside summary Human Phenotype Ontology (HPO) terms. Lab test results are being integrated at the individual patient level and used to compare patients and build cohorts. Integration of these results with clinical notes provides a rich data source for the creation of phenotypic profiles associated with genetic variants. To enhance user collaboration and productivity centered around genetic variants, GRIS has been extended to include variant tagging by categories including biological significance, clinical variant interpretation, and workflow status tracking. Clinical molecular geneticists use variant tags as a mechanism to communicate their clinical variant analysis results to researchers for review and investigation. Data filters have been expanded in GRIS for more robust filtering of variants including additional public and internal reference databases for population frequencies, gene- and sample-level depth of coverage QC metrics, and impact-based filtering options such as pLI and missense Z scores and extensions to HGMD matching. GRIS enables automated generation of draft clinical reports based on the analyzed and tagged data, which has greatly assisted

the task of clinical variant result reporting by the clinical team. As of June 2019, GRIS includes over 6000 records linked to 1200+ whole exomes. The system is currently being updated to integrate and analyse whole genomes.

## PgmNr 1153: Identification of prion protein as a novel human blood group system antigen.

### Affiliations:

1) Genome Medical Science Project (Toyama), National Center for Global Health and Medicine (NCGM), Shinjuku-ku, Tokyo, Japan; 2) Department of Laboratory Testing, Japanese Red Cross Tohoku Block Blood Center, Miyagi, Japan; 3) Institute of Biomedical Sciences, Department of Cell Science, Fukushima Medical University, Fukushima, Japan; 4) Department of Research and Development, Japanese Red Cross Central Blood Institute, Tokyo, Japan; 5) Department of Blood Transfusion and Transplantation Immunology, Fukushima Medical University Hospital, Fukushima, Japan; 6) Blood Group Section, Japanese Red Cross Kanto-Koshinetsu Block Blood Center, Tokyo, Japan

Blood group systems consist of red cell surface antigens and incompatible blood lead to severe and potentially fatal transfusion reactions or red cell hemolysis. Thirty-six human blood system genes have been registered in International Society of Blood Transfusion (ISBT) and genetic variations including single nucleotide variation encoding amino acid substitution mostly determine presence or absence of the antigens. Anti-KANNO, a broadly reactive red cell alloantibody, is found among some Japanese pregnant women, but the genetic basis of the corresponding antigen remains unclear. Here we integrated a statistical approach to identify the coding gene for KANNO antigen by conducting a genome-wide association study (GWAS) on 4 KANNO<sup>-</sup> individuals and 415 healthy Japanese. The GWAS revealed a genome-wide significant association of chromosome 20p13 locus [ $P = 2.76E-08$ , odds ratio  $> 1,000$  (95% confidence interval = 48–23,674)] and identified single nucleotide polymorphism (SNP) located in an intronic region of prion protein (*PRNP*) gene. We also applied whole exome sequencing to them and revealed a missense variant in the *PRNP* gene (rs1800014, E219K), which is in linkage disequilibrium with the SNP identified in GWAS. Independent 14 KANNO<sup>-</sup> individuals also possessed the homozygous genotype of the missense variant. Monoclonal antibody-specific immobilization of erythrocyte antigens assay using anti-KANNO and mouse anti-human prion protein showed a clear difference between KANNO<sup>+</sup> and KANNO<sup>-</sup> red cells, locating KANNO antigen on red cell specific membrane protein. *In vivo* and *in vitro* binding assays of anti-KANNO were further applied to the cells expressing human prion protein and anti-KANNO showed direct binding to CHO-K1 cells expressing wild type PRNP but not to those expressing E219K PRNP.

In conclusion, we established a novel human blood group system through the identification of encoding gene and causative mutation that affects the seropositivity of blood antigen. The risk allele frequencies of identified causative missense mutation are 4% in Asian, but less than 0.5% in other populations and its homozygous genotype was observed in 17 of 8,236 South Asians and 7 of 4,321 East Asians but unobserved in other populations in ExAC database, indicating that the KANNO-negative blood type is likely more frequent in Asians.

## PgmNr 1154: Genetic analysis of families with a rare platelets function disorder.

---

Glanzmann Thrombasthenia (GT) is a rare autosomal recessive disorder that is mainly caused by defects in the platelet function. Mutations in *ITGB2A* and *ITGB3* genes are known to cause GT. For this study, individuals from 15 families were recruited based on their bleeding time and platelet aggregation profiling. Proband showing the platelet dysfunction were subjected to Sanger and exome sequencing which resulted in the identification of a novel and seven known mutations in *ITGB2A* and *ITGB3* genes. In one of the GT families, a novel variant (c.1512T>A) in *ITGB3* gene was identified in the affected individual and in-silico tools predicted that the variant probably produces a truncated protein (p.Y504\*). However, analysis of the platelets cDNAs from the GT patient and her mother revealed the presence of *ITGB3* transcripts of varying lengths. This finding ruled out the involvement of the previously predicted nonsense mediated decay of transcripts carrying c.1512T>A variant as its sole fate. The cDNA sequencing from this patient and her mother indicated the involvement of alternative splicing due to c.1512T>A variant (via a yet unknown mechanism). Intriguingly, the alternatively spliced transcript present in GT patient and her mother lacked 75 nucleotides around the mutation site in exon 10 of *ITGB3* transcript. Relative expression analysis of these samples demonstrated a reduced level of the alternatively spliced transcript in GT patient as compared to the carrier mother and a healthy control. In line with this data, the immunoblotting confirmed the presence of protein in both the samples with a marked reduction in Itgb3 level in GT patient as compared to the mother. Based on these results it can be concluded that *ITGB3* variant (c.1512T>A) lowered the amount of functional protein in the GT patient which might be a possible reason for the platelet dysfunction and disease phenotype. However additional studies are required to further explore the underlying splicing mechanism and protein function defects.

## PgmNr 1155: A single center experience in Turkey in the molecular diagnosis of hemophilia B.

---

Hemophilia B (HB) is an X linked recessive bleeding disorder with a prevalence of 1 in 30,000 live male births. Bleeding symptoms vary according to the level of coagulation factor IX activity. To date, more than 1200 mutations have been defined in the *F9* gene. The aim of this study was to determine the mutation spectrum of the *F9* gene in HB patients from Turkey and to establish a phenotype-genotype correlation.

Thirty-four HB patients, who were molecularly analyzed for *F9* gene mutations in Ege University Pediatric Genetics Laboratory, were included in the study. Clinical and laboratory findings were obtained from hospital records. The Factor IX Gene Variant Database and Human Gene Mutation Database were searched for the identified mutations. Pathogenicity of the variants was classified in accordance with ACMG criteria.

From the 34 HB patients 18 (52.9%) were classified as severe, 13 (38.2%) moderate and 3 (8.8%) mild. Missense, nonsense, splice site, and frameshift mutations were identified in 19 (55.8%), 8 (23.5%), 4 (11.7%) and 1 (2.9%) of the study group, respectively. In one patient, the large deletion was identified. In only one patient, there was no mutation found via sequencing analysis. Five mutations (c. 89-2\_89-1insT, c.521-1G>A, c. 839-1G>T, c. 1088G>T, and c. 1238G>T) were novel. Two of the 5 patients with novel mutations had moderate phenotype while the remaining 3 had the severe phenotype.

In conclusion, in our study group, mutations in the *F9* gene could be found anywhere throughout the entire gene; as in previous studies. This study may contribute to the phenotype-genotype correlation of HB due to the 5 novel mutations mentioned herein.

## PgmNr 1156: A novel molecular indicator for inhibitor development in hemophilia A.

The development of neutralizing antibodies, which is called inhibitor, against factor VIII (FVIII) is a serious complication of the early stages of replacement therapy in hemophilia A (HA). Risk factors for inhibitor development that allow risk stratification are classified simply into two groups: modifiable and unmodifiable. The position and type of substitution of missense mutations may influence the risk of inhibitor development. In this study, we investigated the inhibitor risk of missense mutations and affecting factors including changing in the type of amino acid group.

We evaluated the *F8* gene variant database (<http://www.factorviii-db.org/>) by EAHAD to collect mutation data and clinical findings including the severity of HA and inhibitor development in the patient. The data in the cases with missense mutations recorded in the database were then selected. Twenty amino acids are known to be classified according to their side chains into 2 major groups: nonpolar hydrophobic and polar. Otherwise, the polar group may subclassify into 3 subgroups: basic, acidic and polar uncharged (Table). Each mutation data were noted to be changed or unchanged according to whether substitution caused changes in the amino acid class using these two classifications.

In this study, otherwise, we used CADD, REVEL, M-CAP, and DANN scores to find significant cut-off value and a specific marker indicating inhibitor development.

Among all data in the *F8* gene variation database (<http://www.factorviii-db.org/>), 3248 different case data with 954 different missense mutations were excluded. The data with both clinical phenotype and inhibitor information were in 2207 cases. Of these 2207 cases, 153 (%6.9) had been reported to be positive. Evaluation according to whether substitution caused changes in the amino acid class or not using 4 groups classification showed that unchanged variants are more associated with inhibitor development in overall ( $p=0.012$ ). This result was more significant when the cases differed between clinical severity. While 9.8% of cases with unchanged variants ( $n=44/451$ ) have been reported to have inhibitor of FVIII, this value was 4.8% ( $n=34/709$ ) in the cases with changed variants in mild HA patients ( $p=0.001$ ). In mild HA cases, CADD and REVEL scores have been found to associated with inhibitor development.

In mild HA cases with a missense mutation, amino acid substitution type (unchanged) might be a novel indicator for inhibitor development in hemophilia A.

## PgmNr 1157: Multiple genetic diagnoses in a cohort of patients with Cryopyrin Associated Periodic Syndrome (CAPS).

### Affiliations:

1) Translational Autoinflammatory Diseases Section (TADS), NIAID/NIH, Bethesda, MD; 2) Rochester Regional Health, Rochester, NY; 3) Division of Intramural Research (DIR), NIAID/NIH, Bethesda, MD

**Background.** Cryopyrin associated periodic syndrome (CAPS) is an autosomal dominant autoinflammatory disease caused by mutations in *NLRP3*. CAPS comprises 3 clinical phenotypes of increasing severity: familial cold autoinflammatory syndrome (FCAS), Muckle-Wells syndrome (MWS) and neonatal onset multisystem inflammatory disease (NOMID). Patients with CAPS present with variable severity of systemic inflammation, neutrophilic urticaria, hearing loss and aseptic meningitis. We aimed to identify additional Mendelian diagnoses that may explain phenotypic variability not attributable to CAPS.

**Methods.** Whole exome sequencing (WES) and chromosomal microarray analysis (CMA) were performed.

**Results.** Of the 11 CAPS patients analyzed, 4 (36.4%) had a Mendelian genetic diagnosis in addition to CAPS. **Patient 1** is a 10-year-old female with a somatic mutation in *NLRP3* (NM\_001079821)(c.925G>T, p.G309C, ~12% mosaicism) and classic NOMID manifestations. She was noted to have developmental delay, upslanting palpebral fissures and sparse eyebrows, which were explained by CMA findings compatible with 12q21.2q22 deletion syndrome. **Patient 2** is a 10-year-old female with a germline *NLRP3* mutation (c.916G>A, p.E306K) and clinical features of FCAS/MWS. She presented with clinodactyly, scoliosis, and broad great toes. Height was between the 5<sup>th</sup> and 10<sup>th</sup> percentile. WES revealed a novel heterozygous variant in *NPR2* (c.2T>A, p.M1?), gene associated with epiphyseal chondrodysplasia (MIM#615923). **Patient 3** is an 8-year-old female with a germline *NLRP3* mutation (c.1437C>A, p.N479K) and a NOMID phenotype. She presented with brachydactyly, a round face and a broad nasal bridge. WES showed a novel heterozygous variant in *FBN1* (c.7876C>G, p.L2626V), gene associated with several musculoskeletal syndromes, including Marfan syndrome (MIM#154700) and Weill-Marchesani syndrome 2 (MIM#608328). **Patient 4** is a 19-year-old male with a germline mutation in *NLRP3* (c.983G>A, p.G328E) and a clinical picture of NOMID. WES showed a novel heterozygous variant (c.821T>G, p.M274R) in *NLRC4*, gene associated with macrophage activation syndrome (MIM#616050).

**Conclusions.** Of 11 CAPS patients with pathogenic *NLRP3* mutations, 4 had a secondary genetic diagnosis, which explained clinical features that were not attributable to CAPS. Our data suggest that further genetic testing should be considered to explain “phenotypic variability”.

---

Severe chronic neutropenia is a congenital condition defined as an absolute neutrophil count of less than 500/ $\mu$ L for at least three months. There are three categories according to the onset time or pattern of variation of neutrophil levels: congenital, cyclic, and idiopathic. Among them, severe congenital neutropenia is an inborn disorder with maturation arrest of the early stage of granulopoiesis associated with various genetic abnormalities that has been classified with 26 genes. We here report a 4 year-old boy was admitted due to fever, sepsis, *skin abscesses and gingivitis*. He had a past history of febrile illnesses including septic shock, pulmonary *tuberculosis*, recurrent pneumonia, cutaneous abscesses, oral thrush and isolated neutropenia from birth (  $0.1 - 0.4 \times 10^9/L$  ). Family history was nonspecific and he had no siblings. Initial laboratory revealed severe neutropenia (white blood cells, neutrophils, lymphocytes, monocytes was  $4.73 \times 10^9/L$ ,  $0.17 \times 10^9/L$ ,  $3.68 \times 10^9/L$ ,  $0.68 \times 10^9/L$ , respectively) and increasing of erythrocyte sedimentation rate (112 mm/hr) and C-reactive protein (121 mg/L). A gram-stain and culture of blood showed *Ralstonia pickettii* and culture of abscess fluid showed negative. Bone marrow findings showed normal myeloid cells, reduced granulocyte cell line and no malignant cells. Test of HIV and TB profile were negative. Immunoglobulin quantification results showed normal range of IgG, IgA and IgM. Lymphocyte immuno-phenotyping showed normal count of T lymphocytes, TCD4, TCD8, TCD4, B lymphocytes and natural killer cells. No duplication or deletion in the CGH. Of note, novel mutation of the *ELANE* gene encoding human neutrophil elastase is found via whole exome sequencing and validated by Sanger sequencing. Functional motif Patient were managed with prompt administration of *combination intravenous antibiotic therapy* in two week without granulocyte colony stimulating factor. When he discharged from hospital, white blood cells and neutrophils was  $9.94 \times 10^9/L$  and  $0.43 \times 10^9/L$ , respectively. He received antimicrobial prophylaxis with trimethoprim-sulfamethoxazole and did not accept high cost of *G-CSF* prophylaxis in 6- month follow- up. During the follow-up observation period, he suffered from two times of skin abscesses.

## **PgmNr 1159: Integrative exome analysis of primary immunodeficiency diseases reveals novel pathogenic variants correlated with specific clinical findings among Vietnamese patients.**

### **Authors:**

---

The diagnostic landscape of genetically heterogeneous primary immunodeficiency diseases (PID) has been transformed remarkably by the advent of sequencing. However, no genetic study of PID applying whole exome sequencing has been conducted in Vietnam. This study aims to build effective approach for identifying pathogenic variants in PID exomes and characterizing distinct mutations among Vietnamese patients, which contributes to the genomic database of Asian population. 36 patients with suspected PID and 65 controls were recruited. Mapping, variant calling and annotation was conducted applying BWA, GATK Best Practices and ANNOVAR. Extensive panel of 410 PID genes was developed following Clinical Genomic Database 2019 and IUIS 2017. We applied an in-house bioinformatics pipeline for WES analysis which integrates collaboration between geneticists and physicians. Criteria for variant prioritization were: rare variants with MAF<0.01, predicted deleterious in numerous functional prediction algorithms from dbNSFPv3.5a database. Downstream pathogenicity assessment of top candidates follows 3 conditions: (1) matched correlation of disease causing genes with clinical presentation including key symptoms, (2) comprehensive database search to determine the impact of detected mutations on expression and function of DNA, RNA and encoded protein, (3) internal control database was screened to ensure the absence of concerned variants. The family segregation of all detected variants was validated by Sanger sequencing. A diagnostic yield of 30% was achieved. We identified up to 67% novel pathogenic variants in PID patients: 3 cases with de-novo dominant mutations, 4 cases with compound heterozygous mutations and 4 cases with hemizygous mutations, leaving 25 cases undiagnosed. Causative variants in 10 genes were highly associated with clinical findings of 4 main PID groups: immunodeficiencies affecting cellular and humoral immunity (*ADA*, *CD40LG*, *IL2RG*, *RAG1*), diseases of immune dysregulation (*AIRE*, *LRBA*, *SH2D1A*), congenital defects of phagocyte number or function (*ELANE*, *ITGB2*), and predominantly antibody deficiencies (*NFKB2*). Further functional validation is required to prove the pathogenicity of detected mutations, and hence to share these data in genetic databases. Our results suggest that WES holds great promise as an effective diagnostic strategy for PID and other rare diseases in developing countries like Vietnam.

## PgmNr 1160: *UNC13D* deficiency associated with epileptic seizures and antibody deficiency: The first case from the Iranian national registry.

---

Familial hemophagocytic lymphohistiocytosis (FHL) is a severe life-threatening immunodeficiency that is characterized by proliferation and infiltration of hyperactivated macrophages and T-cells. FHL is a heterogeneous autosomal recessive disorder with five subtypes. Certain mutations in some genes encoding perforin (*PRF1*: FHL2) [11], munc13-4 (*UNC13D*: FHL3), syntaxin-11 (*STX11*: FHL4), and munc18-2 (also known as syntaxin-binding protein 2) (*STXBP2*: FHL5) could result in FHL disease. Perforin is a pore-forming protein that is crucial for target cell lysis, while *UNC13D*, *STX11*, and *STXBP2* encode proteins that are in charge of fusion and trafficking of the granule exocytosis towards the target cells [1, 15, 16]. The clinical symptoms result from decreased or absent cytotoxic T lymphocytes and natural killer cells activities.

Here, we described a fatal case of Iranian infant with prolonged fever, hepatosplenomegaly, cytopenias, hemophagocytosis, skin rash and neurological symptoms. The diagnosis of FHL type3 was confirmed by the identification of homozygous c.1208T>C (p.Leu403Pro) missense mutation in exon 14 of *UNC13D* gene. In contrast to previously reported *UNC13D* deficient patients, immunologic findings indicated a significant decrease in CD19<sup>+</sup> and CD20<sup>+</sup> cells in our patient. It is noteworthy that major humoral immunodeficiency has been reported in FHL so far. Based on our data, *UNC13D* deficiency should be considered in children with phenotype resembling antibody deficiency and lymphoproliferative disorders.

## PgmNr 1161: Biallelic loss-of-function *JAK1* variants detected by whole exome sequencing in a patient with immunodeficiency and multiple congenital anomalies.

### Authors:

J. Ji<sup>1,2</sup>; R.J. Schmidt<sup>1,2</sup>; G. Raca<sup>1,2</sup>; J.A. Biegel<sup>1,2</sup>; J.A. Church<sup>3,4</sup>

### Affiliations:

1) Department of Pathology and Laboratory Medicine, Children's Hospital Los Angeles, Los Angeles, CA; 2) Department of Pathology, Keck School of Medicine of the University of Southern California, Los Angeles, CA; 3) Department of Pediatrics, Children's Hospital Los Angeles, Los Angeles, CA; 4) Department of Pediatrics, Keck School of Medicine of the University of Southern California, Los Angeles, CA

The *JAK1* gene encodes Janus kinase 1, a ubiquitously expressed protein-tyrosine kinase. Previous animal model experiments suggest that *JAK1* plays an essential role in interferon-alpha/beta and interferon-gamma signal transduction. *Jak1* <sup>-/-</sup> cells do not manifest biologic responses to a subset of cytokine receptors. To date, a single patient with recurrent mycobacterial infection and early-onset metastatic bladder carcinoma has been reported to harbor biallelic pathogenic variants in *JAK1* leading to *JAK1* deficiency. However, the *JAK1* gene-disease association has not yet been well-established.

Here, we report a male patient with newborn screen TREC = 1/mcL (reference range >18); CD3+ = <20/mL, CD19+ = 538/mcL, NK = <20, consistent with T-B+NK- severe combined immunodeficiency disease. Other clinical features included hypotonia, pulmonary hypertension, respiratory distress, pneumothorax, patent foramen ovale, ventriculomegaly, tricuspid insufficiency, dysmorphic facial features, wide-spaced nipples, arthrogryposis, club foot, sclerosis of the bones, bowing of the femurs, mesomelia, rhizomelia, single palmar crease, brachydactyly, elevated prothrombin time, elevated partial thromboplastin time, and abnormal brain imaging.

Exome sequencing for the patient detected an apparent homozygous c.1613dupT (p.Met539Hisfs\*21) variant in exon 11 of the *JAK1* gene (NM\_002227.3). Due to the lower depth coverage for this *JAK1* frameshift variant, copy number variant detection was performed using NxClinical. A 58 kb overlapping deletion encompassing exons 9-25 of the *JAK1* gene was identified. This deletion was confirmed by retrospective review of the chromosomal microarray data for this patient. Follow-up parental studies demonstrated that the frameshift variant was inherited from the father and the multi-exon deletion was inherited from the mother, consistent with compound heterozygosity. There were no other clinically significant variants identified from exome sequencing and chromosomal microarray analysis.

This is the second reported patient with inherited bi-allelic *JAK1* loss-of-function variants and human immunodeficiency. Although the bi-allelic *JAK1* mutations are also likely related to this patient's other clinical findings, including congenital cardiac, pulmonary, skeletal and neurological anomalies, the presence of additional pathogenic alterations not detected by whole exome sequencing cannot be ruled out.

## **PgmNr 1162: Pyrin-associated Autoinflammation with Neutrophilic Dermatosi (PAAND): Novel autosomal recessive MEFV mutation and genotype-guided colchicine treatment.**

PAAND is a recently described monogenic auto-inflammatory disorder which shares clinical features with Familial Mediterranean Fever (FMF). PAAND unlike FMF, is not associated with serositis or amyloidosis. Although, different recessive and dominant mutations in *MEFV* can cause FMF, up to now, all reported cases of PAAND were associated with a dominant p.S242R mutation in *MEFV*. The proband was a 5-years old female born to healthy, consanguineous parents. She developed an oral aphthous ulcer at 20 days of age, followed by a maculo-papular and pustular skin rash on the perioral region and upper and lower extremities. Other symptoms included perineal mucosal inflammatory lesions, recurrent episodic fever and abdominal pain. She had failure to thrive and developmental delay, and manifested with episodic myalgias and arthralgias. Her younger brother presented with similar symptoms. High-dose corticosteroid therapy failed to cause symptomatic relief, but both the patient and her similarly affected brother showed dramatic improvement with Colchicine treatment, with complete resolution of symptoms within several months. We sought the genetic cause of this auto-inflammatory disease with whole exome sequencing (WES) of the trio. We detected in the patient a novel homozygous missense mutation, in *MEFV*, which was heterozygous in the parents. Genome-wide homozygosity mapping revealed a number of regions of homozygosity (ROH, <2Mb), in the patient's DNA, including one on chromosome 16 harboring *MEFV*. PAAND is an auto-inflammatory disease with *MEFV* mutation, our family being the first one with documented autosomal recessive inheritance. Colchicine, an effective treatment for FMF, showed promising results in the treatment of PAAND.

## PgmNr 1163: Duplication that involve the *F9* gene such as cause of thrombophilia X-Linked due to factor IX.

### Authors:

Thrombophilia is defined as a predisposition to thrombosis. It is caused by inherited or acquired causes. Establish genetic causes include antithrombin III, protein C, protein S, factor V Leiden, prothrombin 20210A allele, and MTHFR mutations. Other genetic factors causing thrombosis or pulmonary embolism have been identified in recent studies, including elevated factor VIII and plasminogen activator inhibitor-1 (PAI-1) deficiency. However elevated factor IX is actually considered such an indeterminate cause of genetic thrombophilia.

We present the case of a family suffering from recurrent thrombosis and pulmonary embolism due to hereditary thrombophilia. The proband is a 35-year-old male who experienced ten episodes of pulmonary embolism. Thrombophilia was suspected and screening tests for establish genetics factors were negative. Then exome in trio further sequencing analysis identified a duplication that involved the *F9* gene in the patient such as his mother, this duplication was confirmed with comparative genomic hybridization. The mother suffered from one episodes of deep venous thrombosis, pulmonary embolism and ischemic stroke and one sister experienced one episode of pulmonary embolism at 35 years-old.

The present report highlights a very rare case of thrombophilia related with duplication that involve the *F9* gene. Factor IX is a circulating serine protease that serves as an essential component of the blood coagulation pathway. The gain of function is the possible pathogenic mechanism that associates factor IX as a cause of thrombophilia. Our findings suggest the duplication of *F9* gene such as cause of thrombophilia, X-linked, due to factor IX defect.

## PgmNr 1164: *De novo* loss-of-function variants in *CAPRIN1* in patients affected by severe autism and language delay.

---

We report the description of six patients carrying heterozygous *de novo* nonsense or splicing mutations in *CAPRIN1*, identified by whole-genome or whole-exome sequencing, and a case with a 1 Mb *de novo* deletion encompassing the gene.

All cases are characterized by severe non-syndromic autism spectrum disorder and severe language delay without any skeletal anomalies or characteristic facial dysmorphisms.

Caprin-1 is an ubiquitous protein highly expressed in brain and involved in essential cellular processes, such as cell proliferation and migration. The protein localizes at neuronal RNA granules, that are fundamental structures for the proper transport and translation of many mRNAs of key proteins involved in synaptic plasticity. Caprin-1 is able to directly interact with the Fragile X Mental Retardation protein (FMRP) and with the Ras GTPase-activating protein-binding protein 1 (G3BP1). Interestingly, *CAPRIN1*<sup>-/-</sup> mice die perinatally, while *CAPRIN1*<sup>+/-</sup> are characterized by a reduction in social interactions and lower response to novelty (Ohashi *et al.* 2016). In rats and mice, Caprin-1 was shown to be important in the development of dendrites and dendritic spines. Behavioural studies on these models have also shown that the protein is involved in long-term memory formation, through a mechanism mediated by AMPA Receptors.

Given the interesting available information on the gene, we aim at establishing an international collaborative network aims at demonstrating the role of Caprin-1 haploinsufficiency as a mechanism involved in the onset of a specific form of neurodevelopmental disorder.

## PgmNr 1165: Family-based whole exome sequencing allows a 20% diagnostic yield in patients with isolated autism spectrum disorder.

**Introduction:** Neurodevelopmental disorders (ND) are highly heterogeneous conditions, including autism spectrum disorders (ASD) and intellectual disability (ID), characterized by extensive clinical and molecular overlap. Previous studies by whole exome sequencing (WES) in patients with ND indicated a diagnostic yield ranging widely (6-45%), with higher rates in patients with additional clinical features compared to patients with isolated ND.

**Methods:** Trio/quad based WES was performed at ASC consortium on 78 families with one or more probands with ND. Forty-two patients presented ID (10 isolated and 32 syndromic) and 36 ASD (23 isolated and 13 syndromic). ID and ASD were considered syndromic when associated with at least one of the following features: facial dysmorphisms, microcephaly/macrocephaly, growth delay/overgrowth, epilepsy, congenital malformations/skeletal abnormalities.

**Results:** We identified 22 pathogenic or likely pathogenic variants in genes associated with monogenic Mendelian disorders (28.2%): 10 in patients with ASD (28%) and 12 in patients with ID (29%). Five patients presented syndromic ASD with mutations in *ARID1B*, *DSCAM*, *HNRNP2*, *NAA15*, *SRCAP* genes respectively; 5 isolated ASD with mutations in *DEAF1*, *DLG4*, *FOXP1*, *PTEN* genes, 11 syndromic ID with mutations in *BRAT1*, *CDK5RAP2*, *CEP152*, *DDX3X*, *GRIN1*, *H3F3B*, *PIGC*, *PPM1D*, *PRR12*, *PTPN11*, *SON* genes and one isolated ID with mutation in *IQSEC2*. Detection rates in the four subgroups were 38.5%, 21.7%, 34.4% and 8.3%, respectively. All 10 ASD patients presented de novo variants, while patients with ID presented 7 de novo variants and 4 biallelic variants consistent with an autosomal recessive inheritance.

**Conclusion:** These data confirm that trio based WES has a high diagnostic rate in ND. Notably, more than 20% of patients with isolated ASD disclosed a monogenic cause, indicating that trio based WES is a powerful strategy for the molecular diagnosis of isolated ASD. Moreover, these results demonstrate

that several genetic syndromes associated with ND are characterized by a wide phenotype spectrum ending with isolated ASD in the absence of other obvious clinical signs.

## PgmNr 1166: Exome sequencing of a Finnish cohort reveals known and candidate genes for syndromic neurodevelopmental disorders.

---

**Background:** Developmental delay/intellectual disability (DD/ID) is a heterogeneous group of disorders marked by limits in cognitive function, adaptive behaviors, and/or physical functioning. Identification of the genetic contributions to DD/ID is complicated by its extreme genetic heterogeneity. Recessive pathogenic variants contribute to DD/ID, particularly in isolated populations (i.e. bottleneck) due to founder alleles and in populations that have high coefficients of consanguinity and identity-by-descent (IBD) within a clan; both result in absence of heterozygosity (AOH) observable in exome sequencing (ES) data from personal genomes.

**Method:** Samples were collected from 5 Finnish families from a subisolate population in Kainuu with syndromic DD/ID. ES and family-based rare variant analysis included two parent-child trios, one parent-child-sibling quad, one parent-child duo, and one sibship with an affected first cousin. Parental consanguinity (first-cousins) was reported in 1 family.

### Results:

At least 1 known or candidate gene was identified in each of 7 affected individuals from 5 families, and included rare pathogenic or likely damaging variants in established DD/ID genes *ANKRD11* (*de novo*) and *GRIN2A*, consistent with autosomal dominant (AD) inheritance of an apparently sporadic trait, and *KIA2022* consistent with an X-linked (XL) trait in a male proband. Variants in previously reported candidate genes included *SPTBN4* (*de novo*) and *DHX58* (*de novo*). Novel candidates include homozygous variants in *ERGIC3* located in 7.1 Mb of AOH and a heterozygous variant in *NPAT*. Two families were identified to have rare variants in 2 genes: supporting a potential dual diagnosis (*GRIN2A*, *NPAT*) in one proband, and providing an explanation for apparent intrafamilial phenotypic variation between another proband (*ERGIC3*) and her cousin (*KIAA2022*). Despite a high proportion of variants (5/7) suggestive of AD disease, the average total AOH is 172.7 Mb (154.5 – 188.2 Mb), with 29.4 (25 – 36) long AOH tracts (>1.606 Mb) per proband, supporting a high rate of IBD in this small cohort.

### Discussion:

Among the 5 families, most variants were *de novo* (3) or consistent with AD inheritance (2). This observation is notable, given the high average AOH observed in the studied probands (172.7 Mb). Our findings provide additional evidence to support 2 previously reported candidate disease genes (*SPTBN4* and *DHX58*) and reveal *ERGIC3* and *NPAT* as potential novel candidate disease genes.

## PgmNr 1167: Haploinsufficiency of *SPTBN1* is associated with syndromic intellectual disability and autism.

Spectrins are a common component of cell cytoskeletons and function to bind to cytoskeletal elements such as microtubules, and active and intermediate filaments. They are each composed of  $\alpha$  and  $\beta$  subunits, encoded by *SPTA1* and *SPTAN1* ( $\alpha$ ) and *SPTB*, *SPTBN1*, *SPTBN2*, *SPTBN4* and *SPTBN5* ( $\beta$ ). One  $\alpha$  and one  $\beta$  subunit each interact in an antiparallel manner to form rod-shape heterodimers that further organize into tetramers. Spectrins are broadly expressed, notably in the brain, kidney, and muscle. To date, spectrin genes have been associated with erythroid cell disorders (*SPTA1*, *SPTB*) and neurologic disorders (*SPTAN1*, *SPTBN2*, *SPTBN4*), but no disease traits have been identified in association with *SPTBN1* or *SPTBN5*.

Clinical exome sequencing (ES) performed on the index case, a 25-year-old female with autism spectrum disorder, revealed a *de novo* missense variant (c.613G>A [p.G205S]) in the calponin homology domain of *SPTBN1*. Review of the local diagnostic laboratory database and DECIPHER identified 4 additional unrelated individuals with apparently sporadic overlapping neurodevelopmental phenotypes and *de novo* *SPTBN1* variants, including 1 missense variant (c.5641G>A [p.D1881N]) located in the spectrin repeat domain, two canonical splice site variants (c.567-2\_584delins17; c.647+1G>T), and one stopgain variant (exon 5/36). The stopgain variant and both splice site variants are predicted to result in a loss of function. All variants are novel and located at positions that are evolutionarily conserved.

Here, we describe 5 unrelated individuals with *de novo* variants in *SPTBN1* in association with a neurodevelopmental phenotype, supporting the candidacy of *SPTBN1* as a novel neurodevelopmental disorder gene. The observation of a stopgain variant and 2 variants impacting the canonical splice site suggest a loss-of-function mechanism for disease. Genotype-phenotype correlations are limited by the small cohort size, and larger allelic series will further inform the phenotypic spectrum of disease associated with *SPTBN1*.

## PgmNr 1168: Heterozygous loss-of-function variants in *SFMBT1* are associated with intellectual disability.

---

Chromatin remodeling proteins that regulate gene transcription have a well-established role in the pathogenesis of intellectual disability syndromes. These include BAF-related genes such as *ARID1B*, histone demethylases such as *KDM5C*, and components of the mediator complex such as *MED12*, among others. We identified heterozygous, loss-of-function single nucleotide variants or copy number losses encompassing *SFMBT1*, encoding a histone-binding protein, in four unrelated families with intellectual disability of variable severity.

Two subjects had a *de novo* variant leading to a frameshift (c.1445delG, p.Gly482fs) or nonsense (c.1518C>G, p.Tyr506\*) mutation. Two subjects had copy number losses encompassing *SFMBT1*, one of which was found to be *de novo* and the other was a familial variant, inherited from a mildly affected parent and grandparent. Review of the DECIPHER database (<https://decipher.sanger.ac.uk/>) revealed an additional case of chromosome 3p21.1 microdeletion with similar features, further refining the smallest region of overlap to 415 kb in size (chr3: 52811541-53226664). This region includes 7 genes, of which *SFMBT1* is the most compelling candidate to explain the phenotype. Clinically, our subjects share phenotypic features in addition to developmental delay and intellectual disability including mild dysmorphic facial features, short stature in 2/6 subjects, and scoliosis in 3/6 subjects. Because of developmental and speech delay, brain MRI (performed in 3/6 subjects) and audiology exam (performed in 4/6 subjects) were pursued but resulted normal.

*SFMBT1* belongs to a group of highly conserved MBT domain-containing proteins and functions as part of transcriptional corepressor complexes. It is predicted to be intolerant to loss-of function (pLI score 0.94, <https://gnomad.broadinstitute.org>). Interestingly, pathogenic variants in *KDM1A*, encoding a protein known to interact with *SFMBT1*, are the cause of syndromic intellectual disability, further supporting the important role of this complex in neurodevelopment. We suggest that loss-of-function variants in *SFMBT1* should be considered in the diagnostic work up of patients presenting with developmental delay and intellectual disability.

## PgmNr 1169: A novel mutation of *JMJD1C* is involved in epileptic encephalopathy of childhood.

Epileptic encephalopathy is characterized by frequent epileptic seizures associated with developmental delay or regression in infancy or childhood. We present here the first patient with epileptic encephalopathy associated with a novel missense mutation in *JMJD1C* (jumonji domain-containing protein 1C) [MIM 604503] (NM\_032776:exon12:c5347G>A;p.A1783T). The patient was 5-year-old female. She was born at 37 weeks of gestation as a first child to non-consanguineous parents by cesarean section after an uncomplicated pregnancy. Her parents were both healthy with no history of seizures. Her birth parameters were normal. Her developmental milestones were not delayed at 1 year and 6 months: controlling her head at 3 months, sitting at 6 months, walking alone at 12 months. She could speak meaningful words at 12 months. At 1 year and 6 months, she developed a status epilepticus with generalized tonic-clonic seizures and transferred to our hospital. Although her clinical examination indicated to a kind of metabolic encephalopathies, there were no clues of diagnosis after the analysis of amino acids in her blood and cerebrospinal fluid and organic acids in her urine. After this event, her development was regressed. Her seizures remained refractory to treatment with multiple anti-epileptic drugs. She was referred to us for the genetical assessment at the age of 5 years. We performed exome sequence and identified a novel heterozygous mutation in *JMJD1C* that was absent in the gnomAD database. Sanger sequencing confirmed that this mutation was *de novo*. This mutation affects evolutionary highly conserved amino acid and is predicted damaging to protein function. *JMJD1C* encodes a histone demethylase shown to be widely expressed in the brain. Only less than ten pathogenic mutations in *JMJD1C* were identified, which were implicated to cause autism spectrum disorder, intellectual disability or Rett like syndrome. This is the first case of epileptic encephalopathy caused by *JMJD1C* mutation and will expand the phenotypic spectrum of *JMJD1C*.

## PgmNr 1170: Biallelic variants in *IQSEC1* cause intellectual disability, developmental delay, and short stature.

---

We report two consanguineous families with probands that exhibit intellectual disability, developmental delay, short stature, aphasia, and hypotonia in which homozygous non-synonymous variants were identified in *IQSEC1* (NM\_001134382.3). In a Pakistani family the *IQSEC1* segregating variant is c.1028C>T:p.(Thr343Met), while in a Saudi family the variant is c.962G>A:p.(Arg321Gln). *IQSEC1*, 2, and 3 encode ARF-GEFs for ARF6 and their loss affects a variety of actin dependent cellular processes, including AMPA receptor trafficking at synapses. The ortholog of *IQSEC1* in the fly is *schizo* and its loss affects ROBO mediated growth cone guidance at the midline in the CNS, an actin dependent process. Ubiquitous overexpression of the reference *IQSEC1* cDNA in wild-type flies is lethal. However, overexpression of the two variant *IQSEC1* cDNAs does not affect viability, suggesting that they are loss of function alleles. Loss of *schizo* in flies causes embryonic lethality that can be rescued to 2<sup>nd</sup> instar larvae by moderate expression of the human reference cDNA. However, the p.(Arg321Gln) and p.(Thr343Met) variants fail to rescue this embryonic lethality. These data indicate that the variants behave as loss of function mutations in two independent assays. We also show that *Schizo* is expressed and required in photoreceptors for proper function based on Electroretinograms. Finally, mice with a conditional *lqsec1* deletion in cortical neurons exhibited an increased density of dendritic spines with an immature morphology. The phenotypic similarity of the patients and the

functional experiments in *Drosophila* and mice indicate that *IQSEC1* variants are the cause of a recessive disease with intellectual disability, developmental delay and short stature, and that glial growth cone, axonal guidance and dendritic projection defects as well as dendritic spine dysgenesis may underlie disease pathogenesis.

## PgmNr 1171: Genes contributing to brain malformation and neurodevelopmental syndromes in a Turkish population.

**Background:** Approximately 1 in 6 children have a Neurodevelopmental Disorder (NDD) resulting in significant sociocultural and economic burden to the society. We expanded a previously reported study of 128 Turkish families with brain malformations (Phase I of this study had an >85% solve rate and revealed 41 novel disease genes) to determine contributing genes and genetic architecture underlying NDD.

**Material and Methods:** We now report data from 270 families including 142 newly recruited Turkish families (phase II) in addition to the phase I cohort. We implemented family-based exome sequencing (ES) of probands and informative affected and unaffected family members based on pedigree structure. Potentially pathogenic, likely damaging variants of interest underwent Sanger confirmation and segregation analysis. Array Comparative Genomic Hybridization was performed in individuals found to have potential pathogenic copy number variants from ES data. Additionally, 13 of the families who remained undiagnosed during phase I of the study underwent exome re-analyses with expansion of ES to include additional family members.

**Results:** Of the 142 newly enrolled families, we achieved a potential molecular diagnosis in 83 families (58.4%) thus far including 19 new candidate disease genes (13.3%). Amongst the candidate disease genes, we have identified  $\geq 2$  affected unrelated individuals for five genes: *TUBGCP2*, *GRM7*, *PLXNA1*, *NTNG2*, and *TRAPPC4* either within this cohort, through collaborations via GeneMatcher or surveys of the literature. Multilocus pathogenic variation was observed in 8 of the 83 families, driven by absence of heterozygosity (AOH), i.e. AR + AR trait loci, apparently due to the high identity-by-descent (IBD) observed in this consanguineous cohort. Three of 13 families undiagnosed from phase I were resolved with reanalysis and expansion to family-based ES.

**Conclusion:** Our approach allowed us to propose 19 novel candidate NDD genes (phase II) and reiterate the importance of reanalysis for unsolved exome cases and the impact of oligogenic inheritance in a subset of cases with this complex trait. Also, our study further expands the clan genomics hypothesis to multi-locus models, confirming our observations in the arthrogryposis

complex trait, by revealing accumulation of rare homozygous deleterious variants within the clan is driven by IBD in consanguineous populations.

## PgmNr 1172: Copy number variation detection using NGS-based data: Statistics and intellectual disability case report.

São Paulo, SP, Brazil

Deletions, and to a lesser extent, duplications involving a single or multiple exons, or even encompassing several genes, may be the molecular cause of several diseases. However, apart from well studied genes, such as *DMD* or *PMP22*, the frequency of these events is unknown or underestimated. To analyze CNV on NGS data we used XHMM (eXome Hidden Markov Model) and Nextgene (Softgenetics) applications. Some regions were validated by MLPA and currently, both applications are being used in our routine. From 2017 to 2019 we analyzed 578 patients that were divided in three major groups: neuromuscular disorders (NMD), skeletal disorders (SD) and developmental disorders (DD). Based solely on sequencing analysis, we have concluded the diagnosis in 43.9% of the cases (40.6%, NMD, 52.0%, SD and 44.9%, DD). The inclusion of CNV analysis has increased our yield to 53.3% (51.9%, NMD, 60.0%, SD and 51.9%, DD). This considerably improvement in our diagnosis yield is due to the detection of deletions/duplications not only in specific genes (*ATP7A*, *DYSF*, *LAMA2*, *NF1*, *SPG11*), but also in regions not primarily considered (18q deletion, 22q11 deletion).

As an example, we describe a *WAC* gene partial deletion detected in an 11yo girl referred for intellectual disability (ID) genetic testing. She was born to non-consanguineous parents and presented delayed neuropsychomotor development, mild-moderate ID (IQ=50), anxiety, underweight, hearing loss, hypertrichosis, synophrys, macrostomia and mild phenotypic abnormalities. DNA sequencing analysis using a panel containing ~6700 genes (TruSight One Expanded – Illumina) did not reveal SNVs that could explain her clinical features. On a subsequent CNV analysis using NGS data, two CNVs were detected (hg19): an heterozygous deletion encompassing exons 7-14 of *WAC* gene (minimal size chr10:28884662-28908535) and an heterozygous duplication involving exons 30-84 of *HUWE1* gene (minimal size chrX:53560270-53622363). Loss-of-function alterations in *WAC* gene (MIM \*615049) were identified in patients with ID and, to our knowledge, only one partial deletion was described in this gene (exons 5-14). On the other hand, the *HUWE1* partial duplication was not clearly associated with ID and was considered VUS. The patient's phenotype was attributed to *WAC* deletion. Though not all identified CNVs could be validated, we consider an essential step the use of at least two independent tools to detect these alterations.

---

Mutations of the X-linked gene encoding methyl-CpG-binding protein 2 (*MECP2*) cause classical forms of Rett syndrome (RTT) in females. Clinical diagnosis of typical (classical) and atypical forms of RTT requires a period of developmental regression followed by recovery or stabilization. Typical RTT is further characterized by meeting four necessary criteria and all exclusion criteria. Atypical RTT requires two to four necessary criteria, all exclusion criteria, and five of supportive criteria (Neul et al 2010). It is recognized that individuals with other phenotypes (autism, developmental delay, intellectual disability) may harbor *MECP2* mutations or duplications/deletions. Mutations in genes coding for cyclin-dependent kinase-like 5 (*CDKL5*) and forkhead box G1 (*FOXG1*) are more commonly found in patients with atypical Rett syndrome. There does exist a subset of patients who may have features of RTT, without meeting all diagnostic criteria for typical or atypical RTT, and are lacking a mutation in *MECP2*, *NTNG1*, *CDKL5*, or *FOXG1*. We refer to these individuals as having Rett syndrome like (RTT-L) disorder. Whole Exome Sequencing (WES) of eight patients in our cohort with RTT-L disorder revealed mutations in the genes *GABRG2*, *GRIN1*, *ATP1A2*, *KCNQ2*, *KCNB1*, *TCF4*, *SEMA6B*, and *GRIN2A*, which are seemingly unrelated to Rett-related genes. We hypothesized that the phenotypic overlap in RTT and RTT-L is caused by mutations in genes that affect common cellular pathways critical for normal brain development and function. We annotated a list of mutations in genes identified from peer-reviewed articles as causing RTT-L and its associated clinical phenotype, then performing a protein-protein interaction (PPI) network analysis of these genes. We also investigated their molecular interaction of RTT-L genes with *MECP2*, *CDKL5*, *NTNG1*, and *FOXG1*. We find evidence for a significant number of the molecular interaction among the RTT-L genes and with RTT genes. Genes linked to RTT and RTT-L disorder were highly interconnected and enriched in the biological pathways of circadian entrainment, the CREB pathway, and RET signaling, and neuronal processes like synaptic transmission, and transcription. We conclude that mutations in genes that significantly interact with the PPI network established by Rett-related genes often cause RTT-L, explaining the considerable feature overlap between RTT-L genes and Rett-related genes.

## PgmNr 1174: Second *Fxr2* knockout mouse demonstrates more severe *Fmr1/Fxr2* double KO phenotypes: Implications for Fragile X syndrome and *FMR1* function.

### Authors:

Y. Gu; D.L. Nelson

[View Session](#) [Add to Schedule](#)

**Affiliation:** Human and Molecular Genetics, Baylor College of Medicine, Houston, Texas.

Fragile X syndrome results from loss of *FMR1* function due to CGG repeat expansion and loss of mRNA expression. We previously demonstrated that mutation of the *Fmr1* paralog, *Fxr2*, enhanced phenotypes found in either *Fxr2* or *Fmr1* single KO mice, indicating likely compensation that could be relevant to severity of symptoms in fragile X syndrome and potentially to therapeutic strategies. We now report that a more complete ablation of *Fxr2* with a second KO allele provides more severe double KO phenotypes, suggesting a more significant role for *Fxr2* in the compensating for *Fmr1* mutation.

*Fxr2* KO1 showed hyperactivity and impairment of rotarod performance, while *Fmr1/Fxr2* double KO displayed additional phenotypes including aberrant circadian behavior and molecular rhythms and metabolic disturbances. The *Fxr2* KO1 allele has now been shown to encode an *Fxr2* protein lacking 39 amino acids due to an in-frame deletion; residual activity has confounded analysis.

We generated a second *Fxr2* KO (KO2) allele while developing a conditional KO allele. The mRNA is predicted to encode only the N-terminal 79 amino acids of *Fxr2* and appears to represent a *bona fide* *Fxr2* null. Interestingly, *Fxr2* KO2 shows more severe phenotypes than *Fxr2* KO1, supporting the notion that KO1 was incomplete. Of particular note, recovery of *Fmr1/Fxr2* double KO male mice is severely reduced from expectations and fewer than half of the expected *Fxr2* KO2/KO2; *Fmr1* KO/+ females are recovered. These difficulties are much more severe than those found with the *Fxr2* KO1 allele. Efforts to determine where embryos are lost are underway.

We characterized *Fxr2* KO2 along with intermediate *Fxr2* mutant lines (generated to create the conditional KO) for weight, fecundity and behavior. All lines showed reduced weight and all but *Fxr2* KO2 produced fewer than half the expected homozygous pups. Molecular analysis confirmed that the intermediate lines: *Fxr2* Tm2a, Tm2b, Tm2f and Tm2g encode mRNAs that produce truncated *Fxr2* proteins containing the original Tudor domain 1 coupled to a novel chimeric Tudor domain 2. We hypothesize that truncated proteins encoded by the intermediate lines not only have lost *Fxr2* function but also interfere with the function(s) of *Fmr1* and/or *Fxr1*.

Understanding the functions and capacities of all three members of the *FMR1/FXR1/FXR2* family to cross-compensate is important for determining the effects of loss of *FMR1* function in Fragile X syndrome and could suggest therapeutic interventions.

Fragile X Syndrome(FXS) is known to be the main monogenic cause of Intellectual Disability(ID). Despite reported cases of FXS in some African countries, genetic testing remains largely unavailable in most healthcare settings in Africa. We report here FXS in a large polygamous family from Cameroon, with confirmed molecular diagnosis.

We conducted a cross-sectional study in the proband's extended family. Snowball sampling was used to identify and recruit potential participants for FXS testing. Demographic information such as age, sex, clinical characteristics were collected. Pedigrees were drawn using Cyrillic 3.0. DNA were extracted from peripheral blood of any consented family members, or their parents. Molecular diagnosis of FXS was performed at the National Health Laboratory Services, Cape Town, South Africa. Data was analysed using Epi-info7.2.

A total of 46 individuals were tested for FXS. Of these, 58.7%(n=27/46) were females. The mean age was 9.4(±5.0) years for children and 45.9(±15.9) years for adults. Up to 8.7%(n=4) were clinically affected with severe ID, all were males with full mutation (more than 200CGG). 13.0%(n=6) presented with mild ID of which, 3 were females with a full mutation, 2 were females with a premutation(101, 91 CGG) and a normal male(42 CGG). Study of the family pedigree suggested that the founder of these families had more than 20 wives and was likely a FXS normal transmitting male.

No case of Fragile-X-Tremor-Ataxia syndrome was reported. An affected male with a confirm diagnosis of FXS had 3 daughters(112, 120, 120 CGG), while two women aged 63years (101CGG) and 64years (91CGG) reported premature menopause. Among females(n=27), 14.8% had a full mutation, 37.0% a permutation and 48.2% were normal. Moreover, 21.1%(n=4) males had a full nutation and the rest were normal. Being a member of the first normal transmitting male's lineage is a risk factor for having a premutation or full mutation for FXS(P=0.0004).

This study describes the pattern of a genetic transmission of FXS in an exceptionally large Cameroon family, and will inform further retrospective counselling and testing for reproductive risk, and risk for developing premature ovarian insufficiency. The family will also help in exploring challenges associated with the return of an individual genetic results in a rural setting in Africa. The large family could help in exploring potential genetic modifiers of FXS, including differential methylation status in female carriers.

## PgmNr 1176: *In vivo* role of FMRP phosphorylation in fragile X syndrome.

Fragile X syndrome (OMIM 309550), the most frequent cause of inherited intellectual disability and a well-known cause of autism, is due to the loss of functional fragile X mental retardation protein (FMRP), an RNA-binding protein. Previous studies have shown that phosphorylated FMRP can inhibit the translations of its mRNA targets while unphosphorylated FMRP allows translation to proceed. Serine499 is the primarily conserved phosphorylated residue in mouse FMRP, and the mutation *p.Ser499Asp* (S499D) is associated with stalled ribosomes that inhibit downstream translation, thereby mimicking the phosphorylation of FMRP *in vivo*. To further investigate the function and mechanism of FMRP phosphorylation in *FMR1*-related intellectual disabilities, we generated an *Fmr1* S499D (c.1495\_1497TCT>GAC) mutant mice using the CRISPR/Cas9 Engineering System. No phosphorylated FMRP was detected in the mutant line. Using the fibroblasts derived from this mutant line, we determined the half-life of FMRP and found that the mutant S499D FMRP displayed a longer half-life compared to wildtype FMRP. Furthermore, we observed increased anxiety/stress in the *mutant* S499D males. These data together suggest that FMRP phosphorylation could play an important role in FMRP-mediated regulation of neurodevelopment and behaviors.

---

Members of a paralogous gene family in which variation in one gene is known to cause disease, are eight times more likely to also be associated with human disease. Recent studies have elucidated *DHX30* and *DDX3X* as genes for which pathogenic variant alleles are involved in neurodevelopmental

disorders. We hypothesized that variants in paralogous genes encoding members of the DExD/H-box RNA helicase superfamily may also underlie developmental delay/intellectual disability (DD/ID) disease phenotypes. Here we describe 18 unrelated individuals with DD/ID, CNS dysfunction, vertebral anomalies, and dysmorphic features who were found to have likely damaging variants in DExD/H-box RNA helicase genes. In addition, these individuals exhibit a variety of other tissue and organ system involvement including ocular, outer ear, hearing, cardiac, and kidney tissues. Five individuals with homozygous (1), compound heterozygous (2), or *de novo* (2) missense variants in *DHX37* were identified by exome sequencing. We identified ten total individuals with missense variants in three other DDX/DHX paralogs, *DHX16* (4 individuals), *DDX54* (3 individuals), and *DHX34* (3 individuals). Most identified variants are rare, predicted to be damaging, and occur at conserved amino acid residues. Taken together, these 15 individuals implicate the DExD/H-box helicases in both dominantly and recessively inherited neurodevelopmental phenotypes and highlight the potential for more than one disease mechanism underlying these disorders.

## PgmNr 1178: Solving the unsolved: Integrated analysis of genome and transcriptome sequencing data identifies structural variants responsible for rare developmental delay syndromes.

---

Exome sequencing (ES) represents the first-tier diagnostic test in patient presenting with intellectual disability (ID)/developmental delay (DD) with suspected monogenic etiology and negative array-CGH results. Yet, almost 50% of these patients remain unsolved, at the molecular lever, arguing the potential interest to extend the genetic investigations beyond the protein-coding genome. We deployed trio genome (GS) followed by, when available, blood transcriptome sequencing (RNA-seq) as part of an integrated strategy to evaluate the utility of molecular approaches beyond the exome, to solve a cohort of 41 patients unexplained by standard clinical ES and array-CGH analyses. We identified *de novo* balanced inversions disrupting the Topologically Associating Domain regulating the neural expression of *MEF2C*, responsible for the epileptic encephalopathy presented by one patient, and disrupting *BCL11A* in a patient presenting with syndromic DD respectively. Two complex SVs consisting of deletions-inversions affecting *WWOX* and *CASK* were detected in patients presenting with epileptic encephalopathy and syndromic DI respectively. *WWOX* patient was compound heterozygous for the SV inherited from the unaffected father and a pathogenic missense inherited from the mother. The SV caused the inversion of exon 5, which underwent exon skipping as showed by RNA-seq results. No *WWOX* protein was detected by western blot analysis. *CASK* patient was a

female carrying a *de novo* 9.4 Kb variant responsible for the loss of 3 exons. RNA-seq demonstrated the creation of a shorter transcript altering *CASK* reading frame. One patient, clinically compatible with a Simpson-Golabi-Behmel syndrome 1, carried a deep intronic hemizygous deletion of *GPC3*, identified by array-CGH. GS identified a more complex SV involving an intra-chromosomal insertion-deletion disrupting *GPC3* transcriptional unit. RNA-seq demonstrated the absence of *GPC3* expression and a transcriptional profile compatible with a perturbed Glypican pathway. A patient presented a *de novo* partial deletion of *GATAD2B*. Lastly GS identified two *de novo* pathogenic variants affecting nucleotides not covered by ES in *PURA* and *FOXG1*.

Overall, GS followed by non-systematic RNA-seq, allowed the identification of the causative events underlying unexplained DI/DD patients in 8/41 (20%) cases, highlighting the interest in deploying multi-omics approaches to solve unsolved Mendelian disorders.

---

The AUTS2-associated neurodevelopmental syndrome is characterized by mild to moderate intellectual disability, mild microcephaly, variable facial dysmorphism, and feeding difficulty in individuals with chromosomal arrangements, especially deletions, that impact the *AUTS2* gene. We report 8 new individuals with heterozygous *de novo* variants in *AUTS2*, including 5 with missense or indel variants in exon 9 who have more severe clinical features than any of the individuals previously reported with the AUTS2-associated syndrome. Clinical and neuroimaging review uncovered two distinct presentations. The first group included 3 individuals with predicted truncating mutations and clinical features similar to published reports. The second group included 5 individuals with missense mutations or in-frame deletions of exon 9 downstream of a second translational start site for this bicistronic protein and clinical features distinct from the published AUTS2-associated phenotype. This second group included one individual with a severe epileptic encephalopathy and four individuals with a novel, recurrent mutation that have normal head size and dysmorphic facial features similar to Rubinstein-Taybi syndrome, as well as partial agenesis of the corpus callosum and mild to moderate cerebellar hypoplasia. The clinical features observed among individuals in group 2 were much more severe than patients with AUTS2 predicted loss-of-function, suggesting the exon 9 mutations have severe functional consequences, possibly by selectively affecting expression of the short isoform. The spectrum of disease severity, type of AUTS2 aberration, and phenotypic features further delineates the AUTS2-associated syndrome.

Okur-Chung Neurodevelopmental syndrome (OCNDS) is a recently described autosomal dominant condition caused by mutations in *CSNK2A1*, with clinical heterogeneity comprising of intellectual disability, global developmental delays and facial features. Brain MRI anomalies are present in two thirds of published cases, these have included: cortical malformations, delayed myelination, vermian hypoplasia and hydrocephalus. Of the total 27 published cases, 25 are missense mutations while two are splice site in the *CSNK2A1* gene. We identify the first nonsense variant along with novel neuroimaging findings in three out of four newly reported cases of OCNDS.

Our cases range between 22 months to 32 years old (y/o). They all presented with developmental delays, intellectual disability, dysmorphic features and all but one with seizures. Diagnoses were made via Whole Exome Sequencing or Autism/Intellectual Disability panel. Case 1 is a 32 y/o male who is nonverbal with autism and ataxia, the latter correlating with his brain MRI finding of cerebellar vermian hypoplasia. Serial brain images revealed occipital volume loss, which may correlate with his bilateral astigmatism. Case 2, is a 7y/o female with bilateral astigmatism and cataracts requiring surgery, her brain MRI revealed hydrocephalus resulting in optic tortuosity and required shunting.

Case 3 is a 9 y/o female with anxiety and seizures. Brain MRI revealed delayed myelination. She has a missense mutation in p.K198R, which is in a highly conserved region in the activation segment of *CSNK2A1*. Interestingly another published case with the same mutation has similar neuroimaging findings. Case 4 is a 22-month-old female with the first documented nonsense variant in p.R306X. She presented with severe oral motor dysphagia, cardiac malformations and dysmorphic features; cleft lip, hypertelorism with depressed nasal bridge.

Our cases expand the phenotype for ophthalmologic and neuroimaging findings seen in OCNDS. Also for the first time we illustrate genotype correlation with neuroimaging phenotype. Recent evidence indicates that CK2 kinase regulates eye morphogenesis in *Drosophila* indicating a possible role in eye pathogenesis. Since the syndrome is characterized by developmental delays, it may be difficult to ascertain visual changes, thus physicians should be aware. Furthermore, given the recent discovery and paucity of cases, management guidelines such as the need for neuroimaging in OCNDS will need to be developed.

---

**Introduction.** Ubiquitin Specific Peptidase 7 (USP7) is a deubiquitinating enzyme involved in syndromic intellectual disability. Its interaction with ubiquitin-tagged proteins and its once described bond with the proteasome strongly suggest a deeper link, but no evidence of direct interaction has been validated and characterized. Several proteins of the Ubiquitin Proteasome System have already been shown as causative of neurodevelopmental diseases. Our goal was to investigate relation between USP7 and the proteasome structure and function, to guide us in the understanding of USP7 role in neurodevelopmental diseases.

**Material and Methods.** We studied 2 families: one patient and one control (father) in the first, one patient and two controls (father/mother) in the second. Both patients carry a de novo missense mutation in USP7. The first lies in the catalytic domain, and the second in a structurally important domain: UBL-2. We investigated the proteasome using SDS and Native-Page Western Blots as well as chymotrypsin-like activity assays, and begun exploring key protein in neurodevelopmental pathways.

**Results.** USP7 levels differed between our patients: they were normal in patient 1 with a variant in the catalytic domain, and reduced in patient 2 with a variant in UBL-2. Proteasomal catalytic activity was reduced in patient 1, but normal in patient 2. We also identified dysregulated proteins in the Sonic HedgeHog pathway in patient 1. Any such findings were not noted in family 2.

**Discussion.** Interestingly, we highlighted a potential proteasomal dysfunction in a patient with a pathogenic variant in the catalytic domain of USP7, as well as a dysregulated Shh pathway that could both be involved in the neurodevelopmental part of the disease. The absence of similar findings in patient 2 likely relates to its different type of variant and effect on protein levels of USP7. This observation should help to further understand physio/pathological functions of USP7 and establish genotype-phenotype correlations.

## PgmNr 1182: Neuropsychological study in 14 French patients with White-Sutton syndrome and *POGZ* mutations.

**Introduction** – White-Sutton syndrome is a rare developmental disease characterized by a global developmental delay, intellectual disabilities, and neurobehavioral abnormalities secondary to pathogenic *POGZ* variant. Although *POGZ* is described as an intellectual disability gene, some patients may only present learning disability. Thus, the purpose of our study was to describe the neurocognitive phenotype in patients with identified *POGZ* pathogenic variants.

**Materials and methods** – This study is based on a national collaboration through the AnDDI-Rares network, and includes 14 patients from 13 families (10 females, 4 males) with *POGZ* pathogenic variants, with a mean age of 11.7 years. All clinical data and neuropsychological tests have been collected from medical files by the referring physician.

**Results** – In our cohort, we observed 13 *POGZ* variants, including 5 frameshift, 3 nonsense, 2 splice variants and 3 missense. All cases were sporadic except a family following autosomal dominant inheritance. Among 14 patients, 10 patients exhibit intellectual disability: 5 mild ID, 2 moderate ID and 3 severe ID. The 4 remaining patients have learning disabilities with a similar neurocognitive profile, including dysexecutive syndrome, attentional disorders, slowness and difficulties on the affect recognition. 10/14 patients also exhibit a behavioral disorder, including anxiety in 6 patients, stereotypies in 5 patients, inappropriate behavior in 4 patients, and social withdrawal in 5 patients. Sleep difficulties were reported in 4 patients.

**Conclusion** – This study reveals that the cognitive phenotype of patients with *POGZ* mutation may range from learning disabilities to severe intellectual disabilities. This point is of importance for newly diagnosed young patients. It also highlights that same genes can be reported in a large spectrum of

neurocognitive profile, and that children with learning disabilities could benefit from next generation sequencing techniques such as exome sequencing.

## PgmNr 1183: Cause or coincidence: Explore the pathogenicity of *de novo* missense variants in *AHDC1*.

**Background:** Xia-Gibbs Syndrome (OMIM: 615829: XGS) is a Mendelian disorder discovered in 2014 and characterized by hypotonia, sleep apnea, intellectual disability and developmental delay. The disorder can result from *de novo* truncating mutations in the *AHDC1* gene located on chromosome 1p36.11 (Xia *et al.*, 2014). Many missense variants in *AHDC1* were reported in public databases of putatively healthy people and it is unclear whether some missense alleles in *AHDC1* can be pathogenic. Here, we have aggregated data from eight cases with *de novo* *AHDC1* missense mutations and provide guidelines for consideration of missense mutations at this locus, for possible assignment as disease causing variation.

**Methods:** Patients were recruited through the XGS Registry which was hosted in a secure, HIPAA compliant server (Jiang *et al.*, 2018). Families of patients submitted clinical and genetic reports allowing detailed assessment of genotypic and phenotypic information. Additional cases were identified through searching in public databases and literature review. Multiple comprehensive computational algorithms were used to predict the protein damage from missense alleles.

**Results:** We identified eight cases bearing seven different *de novo* missense mutations in *AHDC1* (two were previously reported (Gumus, 2019; Guipponi *et al.*, 2014)). The phenotypes of these missense cases showed overlapping features with classic XGS syndrome, including speech delay, intellectual disability, hypotonia. There are also non-overlapping phenotypes observed such as hypercalcuria, 'molar tooth sign' in MRI images. Multiple computational algorithms predict that three of the *de novo* mutations that are clustered in a region with an AT-Hook binding motif (p.Gly537Asp, Gly792Arg and Asp607Asn) have a high potential of being deleterious. In contrast, one of the *de novo* variants (p.Gly792Arg) is predicted to be not-damaging. That case also is suspected of a diagnosis of Joubert Syndrome based on her phenotype, although not genetically confirmed.

**Conclusion:** The pathogenicity of *de novo* missense mutations in *AHDC1* is still uncertain. However, a preponderance of *de novo* mutations, together with computational models, have suggested that mutations occurring in some regions of *AHDC1* may be damaging. Aggregating case reports of individuals carrying *de novo* missense mutations in the *AHDC1* gene, cellular functional studies and mouse models will lead to better understanding of the pathogenicity of such mutations.

---

CDK8 is a conserved serine/threonine kinase and is a member of the mediator complex that regulates a various transcription regulators including  $\beta$ -catenin and Notch. Mutations in *MED12* and *MED13* as other members of the complex are associated with syndromic intellectual disability (ID) and collectively referred to as “mediatopathies”. As expected, 12 patients with syndromic ID and missense mutations in *CDK8* or one patient with syndromic ID and haploinsufficiency of *CDK19* gene (a homolog of *CDK8*) were reported. The association between *CDK8*-family genes mutations and mediatopathy-resembled disorders is yet to be delineated. Here we report three patients with *de novo* missense mutations in *CDK8*-family genes and the mechanistic basis of *CDK8*-family-associated disorders with zebrafish model. Patient 1 was a 2-year-old male with ID, microcephaly, and congenital heart defects. Hypertelorism, low-set ears, a short philtrum, a high nasal bridge, a high arched palate, and a micrognathia were existed. Patient 2 was an 8-year-old male with ID. Hypertelorism, a short philtrum, a wide nasal bridge, and bifid uvula were existed. Patient 3 was a 12-year-old male with ID and microcephaly. Sparse hair, arched eyebrow, hypertelorism, low-set ears, a short philtrum, a wide nasal bridge, and a broad columella were existed. Exome analysis showed patient 1 and patient 2 had *de novo* missense variants in *CDK8* (p.G28A and p.N156S, respectively), and patient 3 had a *de novo* missense variant in *CDK19* (p.Phe197Leu). Pathogenicity of the variants were evaluated by various assays. 1) *In vitro* kinase assay of human CDK8 showed that enzymes with p.G28A or p.N156S substitution exhibited decreased kinase activity. 2) Zebrafish overexpression analyses showed that p.G28A or p.N156S alleles were hypomorphic alleles *in vivo*. Importantly, inhibition of CDK8 and CDK19 kinase activity in zebrafish embryos using morpholino antisense oligonucleotide or specific chemical inhibitor induced the craniofacial and heart defects related to the patients' phenotype. We suggest inhibition of Wnt/ $\beta$ -catenin signaling in developing neural crest cells may play a role in the pathogenesis of *CDK8*-family-associated disorders because of phenotypic overlap between inhibition of Cdk8 and Cdk19 activity and Wnt/ $\beta$ -catenin signaling. In conclusion, zebrafish studies showed that missense mutations in kinase domain of *CDK8* or *CDK19* cause human congenital defects as hypomorphic alleles.

---

Xia-Gibbs syndrome (XGS, MIM: 615829) is an emerging cause of intellectual disability characterized by delayed speech, autistic features, sleep apnea, and hypotonia. More than 130 cases have been identified worldwide with a wide spectrum of predicted pathogenic mutations in the AT-Hook DNA Binding Motif Containing 1 (AHDC1) protein. We have established a secure patient registry, recording detailed clinical surveys for more than 45 families. The overwhelming majority (113 of 120) of cases are born with a dominant *de novo* truncating mutation in *AHDC1* at chr1p36.11, with age range at diagnosis from birth to 57 years old. RNA expression analysis using two permissive patient samples shows bi-allelic expression of the truncated and wildtype RNA transcripts providing supporting evidence for evasion of NMD. Interestingly, large deletions encompassing *AHDC1* have been reported as pathogenic with no cases providing sufficient evidence of its single involvement. *AHDC1* has three putative AT-hook binding motifs and homology to the catalytic subunit of DNA polymerase zeta (*REV3L*) and the Neurite Extension and Migration Factor (*NEXMIF*), both of which are implicated in developmental and intellectual disability disorders. We investigated a set of 7 clinically predicted pathogenic *de novo* missense or truncating mutations in *AHDC1* in a transfection assay using fluorescent tags. Independent expression and colocalization of wildtype and mutant variants were measured. We observed that the localization patterns of 3 transiently expressed truncated AHDC1 mutants (C791WFs\*57, R925\*, Q970\*) produce hallmarks of nucleolar stress. Specifically, mislocalized protein is shuttling from nucleoplasmic foci to the nucleoli. Such patterns are typically indicative of protein migration from heterochromatic sites surrounding the nucleoli to transcriptionally active euchromatic structures of rDNA transcription and suggest that the truncated proteins produce a disruption in this pattern. Shorter and longer truncation alleles (Q262\*, Q1270RFs\*75) display a spectrum in their localization pattern. This cellular phenotype is not observed with the tested missense mutations thus far (D607N, G792R.) In aggregate, these results are suggestive of a gain of function mechanism underlying cases of Xia-Gibbs syndrome in which the abnormal truncated AHDC1 protein impacts this cellular process and produces downstream developmental abnormalities, delayed developmental milestones and intellectual disability.

---

**Background:** Proteasome-mediated protein degradation is essential to proteostasis in eukaryotic cells. The scarcity of pathogenic variants in the ~50 genes which encode proteasome subunits, assembly helpers and regulatory particle subunits suggests adverse selection pressure associated with compromised cell viability. Whereas recessive variants in genes of the 20S catalytic core particle subunits have been found involved in autoinflammatory diseases, we recently showed that *de novo* variants in *PSMD12* –which encodes the scaffolding subunit Rpn5 of the 19S regulatory particle of 26S proteasome - lead to a syndromic neurodevelopmental disorder, the Stankiewicz-Isidor syndrome (MIM: 617516).

**Methods:** A collaborative international effort allowed us to identify a series of likely pathogenic variants in two additional genes of the regulatory particle 19S, *PSMC3* and *PSMC5*, which encode ATPases involved in unfolding and translocation of the substrate to be degraded into the 20S proteolytic core particle. In cells of affected individuals, we assessed the functional effect of the variants on proteasome 26S function and activity. We examined the possible impact of the variants on main pathways of neurodevelopment by immunoblotting. We used *in vivo* mouse and *Drosophila* models to determine the consequences of *PSMC3* and *PSMC5* variants on neuronal function and behavior.

**Results:** The variants found in *PSMC3* and *PSMC5* are missense, *de novo* and clustered in the ATPase domain. Individuals with *PSMC3* variants present with developmental delay and frequent MRI anomalies, along with cardiac and/or skeletal abnormalities, whereas those with *PSMC5* variants display intellectual disability and behavioral issues. We observed impaired proteasome function with a significant decrease in proteasomal activity, accumulation of ubiquitin conjugates, activation of the unfolded protein response and impaired mTOR activity.

**Conclusion:** We extend the list of neurodevelopmental disorders caused by variants of the 19S proteasome particle. Our preliminary results show that *PSMC3* and *PSMC5* alterations are associated with disruption of protein degradation systems and of the mTOR pathway. Proteomic analyses and development of animal model are in progress and are anticipated to expand our knowledge of the mechanisms of 19S-related disorders.

## PgmNr 1187: *De novo* variant in *FBXO11* gene in a child with neurodevelopmental disorder.

### Authors:

I. Zarante; M. Manotas; R. Quero; M. Guerra; J. Villalta; J. Rojas

[View Session](#) [Add to Schedule](#)

**Affiliation:** Instituto de Genetica Humana, Pontificia Universidad Javeriana, Bogota, Colombia

Neurodevelopmental disorders (NDDs) affect about 400,000 children per year, the novo mutations associated to NDDs have an average prevalence of 1 in 213 to 1 in 448 births according to the age of the parents. Recent studies of complete exome sequencing (WES) in children with undiagnosed developmental disorders is allowing the identification of rare *de novo* heterozygous mutations in genes associated with development as an important cause. A specific diagnosis in neurodevelopmental disorders is and will be useful for the management of the condition, prediction of possible problems, prognosis and genetic counseling.

We report a case of an 5-year-old male child with congenital hypotonia, congenital scoliosis, global developmental delay, sensorineural hearing impairment, dysmorphic features, metatarsus adductus and hypoplasia of the corpus callosum. The karyotype and comparative genomic hybridization which proved to be normal. Due to severe neurodevelopmental delay and facial dysmorphisms we completed the genetic investigations with whole-exome sequencing in trio, showed a probable pathogenic variant heterozygous in the *FBXO11* gene: c.2588C *de novo* and it has not been reported previously as a pathogenic variant nor as a benign variant; 20 cases of patients with neurodevelopmental disorder with variable intellectual disability and various other features associated with pathogenic variants in the *FBXO11* gene have been reported. Clinically, the patient's phenotype is congruent with global syndromic development delay due to allelic mutations in the *FBXO11* gene.

*FBXO11* encodes a member of the F-Box protein family, constituting a subunit of an E3-ubiquitin ligase complex. This complex is involved in ubiquitination and proteasomal degradation and thus in controlling critical biological processes by regulating protein turnover. It is possible that *FBXO11* mutation is the cause of neurodevelopmental disorder in other patients actually without etiology diagnosis.

## **PgmNr 1188: Mitochondrial-processing peptidase subunit beta (*PMPCB*) rare compound heterozygous variants in a patient with developmental delay, neurodegeneration, cerebellar vermis agenesis and cerebellar atrophy.**

---

The *PMPCB* gene encodes the catalytic subunit of the mitochondrial processing protease (MPP). The protein cleaves an N-terminal signal of imported mitochondrial precursor proteins for their maturation. Five individuals from four families with childhood-onset neurodegeneration, absent speech and cerebellar atrophy were reported with pathogenic biallelic variants in *PMPCB*. Functional studies showed the deleterious effect with buildup of mitochondrial precursor proteins and impaired activity in mitochondrial respiratory chain complexes and in mitochondrial/cytosolic enzymes.[PMID: 29576218] This gene was found to be up-regulated and expressed in CD40L-stimulated Acute Lymphoblastic Leukemia (ALL) cells leading to their differentiation to dendritic cells.[PMID: 19580345] *PMPCB* was also up-regulated in colon cancer cells treated with saponin extracts. [PMID: 18425323] A study revealed blocking *PMPCB* lead to tumor suppression and apoptosis of EpCAM+ hepatic carcinoma cells via inactivation of Wnt/ $\beta$ -catenin signaling pathway.[PMID: 30862714]. Our patient is an 18-year-old male with global developmental delay, spastic ataxia and history of a seizure disorder. Brain MRI showed cerebellar vermis aplasia and cerebellar hypoplasia. An EEG revealed slow background for age. Chromosomal microarray was normal, mitochondrial genome analysis negative, and muscle biopsy unremarkable. Whole exome sequencing trio of proband and parents (WES) showed that the patient is a compound heterozygote for two variants, p.R451X and p.I160M, in the *PMPCB* gene (NM\_004279.2), each inherited from one parent. Both parents had learning difficulties as children. No other variants were reported via the WES analysis. Unlike the five cases described in literature, our patient has intelligible speech. His lactate/ pyruvate ratio was normal, suggesting some preserved mitochondrial respiratory function. This contrasts with the abnormal lactate levels and decreased muscular respiratory chain complex and aconitase activities described with the previously reported cases. One previous study showed that biallelic variants in *PMPCB* triggered defects in MPP proteolytic activity leading to mitochondrial dysfunction with early onset childhood neurodegeneration. Since few data are known about this gene beside its significance in neurodevelopment, this report helps to expand the phenotype of *PMPCB*-related disorders. Further studies are warranted to explore the functional impact of these variants.

## PgmNr 1189: Neurochondrin, a novel candidate for autosomal recessive intellectual disability with epilepsy, is required for normal maturation and function of cortical interneurons.

---

The *NCDN* gene encodes neurochondrin, predominantly expressed in neural tissues where it mediates neural growth, synaptic plasticity and signal transduction. Depletion of *Ncdn* in mice causes epileptic seizures, depressive-like behaviors and impaired spatial learning. We identified a rare homozygous *NCDN* missense variant (NM\_001014841.1:c.1246G>C) in three affected family members of a consanguineous Pakistani family characterized by mild intellectual disability (ID) and recurrent seizures. Electroencephalography (EEG) of two affected siblings revealed abnormal patterns. To investigate the cellular and biophysical mechanisms behind neurochondrin deficiency, we applied the CRISPR/Cas9 technology to knockout (KO) *NCDN* in human induced pluripotent stem cells (iPSCs) and neuroblastoma cell line (SH-SY5Y). Both targeted and isogenic wild-type (WT) iPSCs were differentiated into cortical interneurons. Electrophysiological recordings using whole cell patch-clamp analysis revealed that the neurochondrin-deficient neurons exhibited only abortive or single action potentials, with amplitudes significantly reduced, when compared to isogenic WT neurons ( $p=0.0067$ ). Furthermore, cortical interneuron cultures with *NCDN* deletions contained fewer mature neural cells. Moreover, differentiated SH-SY5Y cells with *NCDN* deletions exhibited significantly reduced neurite outgrowth when compared to WT SH-SY5Y cells. Overexpression of WT *NCDN* in neurochondrin-deficient SH-SY5Y cells rescued the neurite outgrowth phenotype. In contrast, overexpression of *NCDN* with the missense variant (*NCDN* c.1246G>C), identified in the three patients, failed to rescue the phenotype. Taken together we identified a *NCDN* missense variant associated with ID and epilepsy. Functional analysis of *NCDN* deficiency in iPSC derived cortical interneuron and neuroblastoma cell lines indicate that the protein is pivotal for neurite outgrowth, neuronal maturation and normal biophysical properties.

## **PgmNr 1190: Alpha-thalassemia X-linked intellectual disability syndrome: A multigenerational family provides additional insights into phenotypic variability within this syndrome.**

### **Authors:**

J. Schymick; N. Dykzeul; D. Matalon

[View Session](#) [Add to Schedule](#)

**Affiliation:** Stanford University, Division of Medical Genetics, Stanford, CA.

---

Alpha-thalassemia X-linked intellectual disability syndrome is a rare disorder with only 168 known cases (Gibbons R, 2006). It is characterized by severe global developmental delay, distinctive craniofacial features, hypotonia, intellectual disability, and a family history suggestive of an X-linked pattern of inheritance. Mild-to-moderate anemia secondary to alpha-thalassemia may also be present. This syndrome results from variants in the *ATR*X gene. Over 90% of pathogenic variants are reported are in regions encoding the zinc finger and helicase domains. Here we report a two generational Hispanic family with three affected individuals carrying a newly described variant in the *ATR*X gene. We describe the clinical characteristics of the affected individuals within our family and review the literature on genotype-phenotype correlations for variants in the *ATR*X gene.

Our proband is a 5-year old male with global developmental delay, microcephaly, short stature, intellectual disability and hypotonia. He has no discernible words and can walk only ten steps independently. Our proband's older brother is an 8-year old male with global developmental delay and hypotonia. He has 20 to 30 words and uses sign language. His first steps were between age 3 and 4 years, and he currently ambulates independently. He does not have microcephaly or short stature. Our proband's maternal uncle is a 39-year old male with a history of intellectual disability and developmental delay. He also has a lack of expressive speech and uses sign language. He ambulates independently. Dysmorphic features include microcephaly and full lips with tented upper vermilion border.

We identified a nonsense variant c.1753G>T (p.Glu585\*) in the *ATR*X gene via an X-linked intellectual disability gene panel. This variant was identified in our proband and subsequently in his older brother and maternal uncle who have relatively milder phenotypes. The glutamine residue at codon 585 is highly conserved and located outside the zinc finger and helicase domains providing additional insights into genotype-phenotype correlations for this gene. Furthermore, our family provides additional evidence for intrafamilial variability and offers additional case examples of milder phenotypes that may be underreported within this syndrome.

## PgmNr 1191: Long-term survival of mice with deletion of BRCA1 as adults.

BRCA1 faithfully repairs damaged DNA by promoting homology-directed repair (HDR). Loss of BRCA1 and other HDR genes is incompatible with viability and causes severe genomic instability. Homozygous loss of *Brca1* is embryonic lethal in mice, and cells lacking BRCA1 are sensitive to cellular stresses such as DNA damage and ionizing radiation (IR). We thus hypothesized that if *Brca1* is deleted in adult mice, genomic stress that is incompatible with life will ensue within days after deletion.

To test this, we administered doxycycline to 10-week old mice containing alleles of an inducible Cre system (Tet Responsive Element – Cre Recombinase [*TRE-Cre*], and the reverse tet transactivator [*rtTA*]), and floxed *Brca1* alleles (*Brca1*<sup>F22-24/F22-24</sup>). Administration of doxycycline resulted in ~1500 fold increase in expression of Cre recombinase in the liver and mammary gland. PCR of genomic DNA at the *Brca1* locus showed recombination and extensive excision of floxed exons 22 through 24 in liver, intestine, mammary, kidney, muscle, and pancreas. *Brca1* mRNA was reduced 85% to 99% after deletion, and more than half of mice had >95% deletion. Contrary to the embryonic lethality observed in all previously tested *Brca1* deletion mouse models, we found that deletion of *Brca1* in adult mice caused no overt phenotypes, was compatible with life, and that recombined mice (*Brca1*<sup>Δ/Δ</sup>) that have extensive, widespread deletion of *Brca1* survived up to 1 year after *Brca1* recombination. We next examined the survival of mice with *Brca1* loss that were exposed to additional cellular stress in the form of ionizing radiation. Surprisingly, mice that lack *Brca1* and are deficient for HDR showed no increased sensitivity to irradiation unless combined with p53 null alleles. Our surprising results show that mice deficient for HDR are viable and not radiation sensitive. Future studies will examine the compensatory mechanism of DNA repair that preserves viability in mice deficient in *Brca1* and HDR.

## PgmNr 1192: Phenylalanine (Phe) level and compliance for patients with phenylketonuria (PKU) - a Quality Improvement (QI) initiative.

### INTRODUCTION AND OBJECTIVES:

Phenylketonuria (PKU) is an inborn error of metabolism caused by the deficiency of phenylalanine hydroxylase enzyme. It is an autosomal recessive disease caused by pathogenic variants in *PAH* gene. PKU is one of the first biochemical genetic diseases identified (Følling, 1934), and is the first genetic disease treated successfully with diet modification (Bickel, 1953). After Dr. Guthrie developed a screening assay in 1963, newborn screen for PKU was soon implemented in all states in the United States and in many other countries around the world.

Here we investigated phenylalanine (Phe) levels and time elapsed since last Phe level, creating benchmark data for compliance and further quality improvement (QI) initiatives.

### METHODS:

This is a single-institution, retrospective longitudinal project that collects all Phe levels in Boston Children's Hospital (BCH) during an 18-year window (3/21/2001 – 1/7/2019). The Phe level was conducted either on-site at BCH's biochemical genetics laboratory, or by the Massachusetts state lab. We captured and calculated the following 2 metrics:

1. "Last [Phe]": The last Phe level on our record (unit:  $\mu\text{mol/L}$ ). This serves as an endpoint evaluation for how well the patients control their PKU.
2. "Last follow-up": The time period between the collection date of "Last [Phe]" and the last project observation date, 1/7/2019 (unit: days). This metric indicated how long the patient has not been checked for Phe, and represents the compliance.

### RESULTS:

During the 18-year interval, we have 16,007 Phe tests from 395 patients in BCH.

For the "Last [Phe]", there are 186 patients (47.09%) who have a level greater than 360  $\mu\text{mol/L}$ , 117 patients (29.62%) greater than 600  $\mu\text{mol/L}$ , and 39 patients (9.87%) greater than 1,200  $\mu\text{mol/L}$ .

For the "Last follow-up", there are 221 patients (55.95%) who have a "Last follow-up" greater than 182 days (6 months), 182 patients (46.08%) greater than 365 days (1 year), and 144 patients (36.46%) greater than 546 days (1.5 year).

### CONCLUSIONS and FUTURE DIRECTIONS:

Using 360  $\mu\text{mol/L}$  as an optimal Phe level cut-off, 47.09% of the patients were out of range. Using 12 months as a follow-up period cut-off, 46.08% of the patients are not compliant. Almost half of the patients cannot keep up with our treatment goal. We will use these 2 metrics to identify patients and

study the reasons for poor compliance to improve the quality of PKU care.

## PgmNr 1193: Intermittent neurologic decompensations: An underrecognized presentation of tyrosine hydroxylase (TH) deficiency.

---

**Introduction.** Tyrosine hydroxylase (TH) deficiency is a treatable autosomal recessive inborn error of dopamine biosynthesis caused by mutations in *TH* and resulting in neurological signs caused by dopamine deficiency. Two main presentations are described. Type A, milder, presents after 12 mo with progressive hypokinesia and rigidity. Type B presents before 12 mo and often neonatally, as a progressive complex encephalopathy.

**Case history.** We report a girl with mild TH deficiency who had recurrent episodes of neurological decompensation following infections or vaccinations. Prior to the first episode, she had normal development except for mild head tremor. The first episode occurred at 12 mo, after 2 weeks of intermittent fever following a vaccination, with marked fatigue, loss of walking/sitting, worsened tremor, severe axial hypotonia, and recuperation over several days. Episodes 2 (19 mo) and 3 (25 mo) followed viral infections by a few days, presenting as lethargy, axial hypotonia, appendicular rigidity and worsening tremor needing several weeks of intensive rehabilitation. She had residual tremor and mild lower limb spasticity. Basal ganglia were normal on cerebral MRI. Exome sequencing revealed two missense variants of unknown significance in *TH*: c.1147G>T (p.G383W, paternal) and c.1084G>A (p.E362K, maternal). Both have gnomAD allele frequencies of <1/50,000 and are classified as deleterious by SIFT, PolyPhen and MutationTaster. CSF analysis showed dopamine metabolite, homovanillic acid (HVA), 160 nmol/L (reference, 233-938) and HVA/5-hydroxyindolacetic acid molar ratio 1.07 (literature reference, 1.5-3.5). The patient responded rapidly to Dopa/carbidopa (currently 2.7 mg Dopa/kg/d) without further episodes.

**Patient series.** Considering this patient plus 4 others discovered by systematic literature review, we identified 7 distinct neurologic episodes. All occurred after infections or vaccinations, between ages 12 mo to 6 yr. Each presented with marked hypotonia and decreased motor function. Tremor occurred in 4/5 patients. Recuperation occurred in all cases. 3/5 patients later developed dystonia.

**Conclusion.** This defines a third clinical category of TH deficiency: episodes of marked hypotonia with recuperation over weeks to months. Because TH deficiency is treatable and important for genetic counselling, this diagnosis should be considered in episodes of marked hypotonia, even after a single episode, especially in patients with dystonia or rigidity.

## PgmNr 1194: Metabolomics analysis of SLC13A5 deficiency in mice.

Early infantile epileptic encephalopathy (EIEE) is a genetically heterogeneous disorder in humans. EIEE is characterized by severe neonate seizures along with developmental delays with intellectual disabilities. One cause of EIEE is mutations in *SLC13A5* (EIEE Type 25), a gene encoding member 5 of solute carrier family 13, a sodium/citrate cotransporter. Reduction of *SLC13A5* expression alters metabolism with weight loss in several species. In humans, *SLC13A5* is expressed predominantly in the liver, brain, salivary gland and testis. Citrate plays essential role in energy homeostasis and is detectable in plasma, cerebral spinal fluid (CSF) and seminal fluid. Citrate is produced in the mitochondrion as a product of oxaloacetate and acetyl-CoA condensation by citrate synthase in the tricarboxylic acid (TCA) cycle. Besides its role in mitochondrial energy metabolism, cytosolic citrate is a substrate for fatty acid and sterol biogenesis, and extracellular citrate plays a role in determining the availability of divalent cations in CSF and seminal fluids through chelation. A recent study suggests that loss of *SLC13A5* disrupts oncogenic signaling in human liver cells. A previous study of a small cohort of patients with *SLC13A5* deficiency demonstrated altered TCA metabolites by mass spectrophotometry in CSF, plasma and urine. These results suggest disruption of TCA cycle/energy metabolism due to *SLC13A5* loss. In the present study, we carried out a pilot experiment examining the metabolites in the brain, liver and plasma of a pair of mice (one male and one female) with *Slc13a5* deficiency. Overall, initial data demonstrates a reduction in amino acid metabolites and elevations of free fatty acids in brain and liver. Interestingly, it also suggests potential sexual dimorphism with significant differences between the male and female samples for several diacylglycerol (DGA) species. Metabolomic evaluation of a larger cohort of animals (12 per genotype, including 6 males and 6 females) is currently underway.

## PgmNr 1195: Multi-omics analysis of a new cellular model of Barth syndrome uncovers mechanisms of mitochondrial dysfunction and highlights the importance of tissue-specific modeling.

Barth syndrome (BTHS) is an X-linked disorder caused by defects in tafazzin (TAZ), a transacylase involved in the final remodeling step of cardiolipin (CL), which results in increased monolysocardiolipin (MLCL) and decreased remodeled CL on the inner mitochondrial membrane. TAZ is ubiquitously expressed in all tissues, however the CL acyl chain composition is tissue specific; brain CL is characterized by a diversified array of acyl chains including polyunsaturated chains, whereas in cardiac and skeletal muscle CL is predominantly in the tetralinoleoyl form. Clinical features of BTHS include cardiomyopathy, skeletal myopathy, and neutropenia. In order to explore novel areas of cellular dysfunction and identify potential targets for therapeutic intervention we applied a multi-omics discovery approach to a TAZ-deficient HEK293 cell line that was developed and phenotypically validated in our laboratory, TAZ<sup>745</sup>. Lipidomics analysis of TAZ<sup>745</sup> cells showed the characteristic CL abnormalities seen in BTHS including a decrease in remodeled CL, a shift towards unsaturated CL, and an increase in MLCL. Proteomics analysis comparing wild type (WT) and TAZ<sup>745</sup> cells revealed differential expression of proteins involved in the dynamic response to mitochondrial stress (i.e. machinery of fission, fusion, and mitophagy), and of proteins of the mitochondrial respiratory chain, including decreased expression of several subunits of complex I and complex I assembly factors. Metabolomics analysis revealed decreased NAD<sup>+</sup> and increased AMP in TAZ<sup>745</sup> compared to WT, further highlighting respiratory chain dysfunction as a key feature of TAZ deficiency. The most significantly reduced complex I assembly factor in TAZ<sup>745</sup>, NDUFAB1, was also present at lower abundance in BTHS patient-derived lymphoblast cell lines (LCLs) compared to controls. These changes in steady state levels resulted in reduced complex I activity in TAZ<sup>745</sup> and patient derived LCLs compared to their respective controls. Due to the tissue specific-nature of the clinical symptoms in BTHS (i.e. severe cardiac and skeletal muscle dysfunction, with minimal neurological effects), we developed an iPSC model of TAZ deficiency, and differentiated these iPSCs into neural progenitor cells and cardiomyocytes in order to determine if complex I dysfunction is more prominent in tissues with severe clinical effects. These findings have significance for targeted therapeutic development in BTHS aimed at improving complex I function.

## PgmNr 1196: Unraveling AADC deficiency: Clinical, biochemical, and molecular genetics findings in Latin-American patients.

**BACKGROUND:**Aromatic L-amino acid decarboxylase (AADC) is central in the synthesis of biogenic monoamine neurotransmitters. AADC deficiency is a severe neurometabolic disorder, usually underrecognized, presenting early in life with hypotonia, hypokinesia, oculogyric crises, autonomic dysfunction, dysphoric mood, and sleep disturbance **METHODS:**Clinical, biochemical and molecular genetics data retrospective analysis from 5 patients with AADC deficiency **RESULTS:**Neurological symptoms became evident in all patients during the first 6 months of life. Severe hypotonia, hypokinesia and hypomimia, dystonic movements and typical oculogyric crises were present in all patients. Ptosis occurred in 4 patients, hyperhidrosis in 3, hypersalivation in 4 and nasal congestion in 4 patients. Two patients suffered from temperature instability in the first year of life and two from hypoglycaemia **DISCUSSION:**AADC deficiency is a neurotransmitter disorder with features presenting as early as in the first month of life. Hypotonia, hypokinesia, oculogyric crises and autonomic are clinical hallmarks of the disease and may lead to clinical suspicion. Clinical phenotype severity is variable, but the majority of patients show minimal motor development in the absence of treatment. Since gene therapy has been shown to bring greater improvement for such patients, early diagnosis in this disease is essential for better clinical outcome

## PgmNr 1197: Characterization of multiple spontaneous novel variants in the human *NPC1* gene.

---

Niemann Pick disease type C (NPC) is an autosomal recessive lysosomal storage disease resulting from abnormal cholesterol and sphingolipid trafficking within the endosomal/lysosomal pathway. The disease is due to a variant in the *NPC1* or *NPC2* genes, with both variants presenting identical clinical pathologies. We characterized 29 patients with variants in the *NPC1* gene. Following DNA isolation, exons with flanking intronic regions were sequenced. Our results determined 8 novel unpublished variants;

6 were due to point mutations resulting in codon replacements, 2 were small deletions/insertions leading to frameshift mutations. The novel variants were investigated by bioinformatics using online databases 1000 genomes; SIFT polyphen, and mutation taster. Variants were analyzed computationally using SoftGenetics: Nextgene, Geneticist Assistant, Mutation Surveyor; and Alamut Visual with HGMD to predict potential detrimental effects of each variant. The purpose of this report is to consider these novel variants for relevance for diagnostic purposes, or disease progression in NPC.

## PgmNr 1198: Mouse models of, and AAV gene therapy for, propionic acidemia (PA).

### Authors:

C.P. Venditti; S.N. Smith; R.J. Chandler

[View Session](#) [Add to Schedule](#)

**Affiliation:** NHGRI, NIH, Bethesda, MD

Propionic Acidemia (PA) is a rare autosomal recessive metabolic disorder caused by reduced activity of the enzyme propionyl-CoA carboxylase (PCC). The PCC enzyme is composed of two subunits, alpha and beta, encoded by the *PCCA* and *PCCB* genes, and is responsible for the catabolism of propiogenic amino acids, as well as odd-chain fatty acids and cholesterol. PA is equally likely to be caused by mutations in the *PCCA* or *PCCB* gene. Patients diagnosed with PA typically present in the early newborn period with a metabolic crisis, which can be fatal if not promptly recognized and treated. Hypotonia, lethargy, growth retardation/failure to thrive, cardiomyopathy and seizures are variably present but overall are common complications in the patients. PA is chronically managed via dietary restriction, and antibiotic therapy is used in some patients to decrease propionate derived from gut bacteria. Medical management can decrease the severity of symptoms, but the high rates of morbidity and mortality still persist in many with PA, driving care teams to offer elective liver transplantation as a surgical treatment option. Because of suboptimal outcomes observed in PA, there is a pressing need to develop new therapies.

We have generated new mouse models of *Pcca* and *Pccb* deficiency. Two loss of function alleles in exon 5 of *Pcca*, as well as one knock-in (A134T), and 4 in exon 14 of *Pccb* were recovered after CRISPR Cas-9 gene editing, and bred to homozygosity. Other than the *Pcca*<sup>A134T/A134T</sup> mice, homozygotes for all *Pcca* and *Pccb* mutations displayed neonatal lethality and massively increased 2-methylcitrate, very much like severely affected PA patients. Next, a series of AAV cassettes designed to express the human orthologues of PCCA or PCCB in the liver of the mutant mice were prepared, and pseudoserotyped with an AAV8 or AAV9 capsid. *Pccb*<sup>-/-</sup> or *Pcca*<sup>-/-</sup> mice were treated at birth, and followed for survival, growth and metabolic correction. Both lines of mice could be rescued from lethality with systemic AAV gene therapy, and the rescued mutants had improved metabolic parameters and prolonged survival. In summary, we have created new murine models of severe PA caused by *Pcca* or *Pccb* deficiency, developed a suite of candidate AAV vectors that express the human orthologues, and tested them for efficacy in the mutant mice. Our results provide critical preclinical steps in the pathway to develop AAV gene therapy for patients with propionic acidemia.

## PgmNr 1199: Genotype and phenotype analysis of 12 Chinese children with treatable valine-metabolism-related Leigh syndrome.

### Authors:

J. Wang; F. Fang; X. Han; Z. Liu; M. Xu; D. Shen; L. Dai; W. Zhang; J. Li

[View Session](#) [Add to Schedule](#)

**Affiliation:** Neurology, Beijing Children's Hospital, Capital Medical University, National Center for Children's Health, Beijing, China

**Background** 3-Hydroxyisobutyryl-CoA hydrolase (HIBCH) and short-chain enoyl-CoA hydratase (SCEH) are involved in valine metabolism, encoded by *HIBCH* and *ECHS1*, respectively, and any mutation can cause Leigh syndrome. Mitochondrial function can be improved clinically by limiting valine intake.

**Methods** The clinical data and genetic mutations of patients from 2013 to 2019 were retrospectively analyzed to discuss the genotype and phenotypic characteristics.

**Results** There were 160 genetically diagnosed cases with Leigh syndrome. The *HIBCH* and *ECHS1* mutations were 6 cases respectively, accounting for 7.5% (12/160). The onset age was 0 to 4 years and the median age of onset was 0.33 years. 4 cases were triggered by infection, and 1 was triggered by vaccination, all of which were *HIBCH* mutations. The initial symptoms were mainly developmental regression, acute encephalopathy (mostly in *HIBCH* defect) and dystonia (mostly in *ECHS1* defect). The main clinical symptoms were developmental retrogression (n=9), dystonia (n=8), nystagmus (n=5). Basal ganglia lesions were found in all 12 patients, and 7 were complicated with brainstem lesions. Organic acid screening revealed increased 2,3-dihydroxy-2-methylbutyrate (23DH2MB) in samples from the 10 patients (83%), and the *ECHS1* mutation and *HIBCH* mutation were 5 cases respectively. Blood tandem mass spectrometry analysis showed that 5 patients (42%) of 3-hydroxybutyryl carnitine (C4OH) increased, 3 cases were *HIBCH* mutations. Seventeen mutations were identified in *HIBCH* and *ECHS1*, consisting of 13 novel mutations and 4 mutations reported previously. thirteen novel mutations included 10 missense mutations (*HIBCH*: c.977A>C, p.L326R; c.452C>T, p.S151L; c.1036G>T, p.V346F; *ECHS1*: c.607C>T, p.A203T; c.463G>A, p.G155S; c.557C>T, p.S186L; c.310C>G, p.Q104E; c.554T>C, p.K185R; c.542C>T, p.R181H; c.712G>C, p.A238P)?2 splicing mutations (*HIBCH*: c.750+1G>A; *ECHS1*: c.414+5G>A); 1 nonsense mutation (*HIBCH*: c.469C>T, p.R157X).

**Conclusion** Leigh syndrome caused by *HIBCH* and *ECHS1* mutations was rare and premature. The head MRI showed Leigh-like changes, involving basal ganglia, with or without brainstem involvement. The increase of 23DH2MB in urine may be a biomarker of *HIBCH* and *ECHS1* defects, while the increase of C4OH in blood is more common in *HIBCH* defects. We identified 5 novel *HIBCH* and 8 novel *ECHS1* mutations, enriching the genotype of Leigh syndrome in Chinese children.

## PgmNr 1200: Collaborative development of therapeutics for sialic acid storage disease.

---

Lysosomal sialic acid (SA) storage disease (SASD) is an autosomal recessive, neurodegenerative, multisystemic disorder caused by defects in the lysosomal SA membrane carrier *SLC17A5* (Sialin). *SLC17A5* defects cause free SA and secondary metabolites to accumulate in lysosomes. The clinical spectrum ranges from severe infantile onset in infantile sialic acid storage disease (ISSD; elevated urine SA; ~40 reported cases), to a mild, adult form, called Salla disease (moderate elevation of urine SA; ~120 cases).

Although sialic acid metabolism, membrane transport, and lysosomal biology have been extensively studied, the pathobiology of SASD remains poorly understood. Moreover, SASD is likely underdiagnosed; known patients have experienced a diagnostic delay due to the rarity of the disorder, non-specific clinical symptoms and absence of routine urine SA testing. There is no approved therapy for SASD.

As is typical for orphan diseases, the small population of patients makes it difficult to motivate industries to invest in performing the pre-clinical and clinical studies necessary to develop therapies. On the other hand, multidisciplinary collaborative efforts involving the NIH, academic clinical scientists, and patient advocacy groups have successfully overcome the scientific, clinical and financial challenges facing the development of new drug treatments for rare diseases.

Encouraged by these successes, we have initiated a collaborative effort for SASD. This has allowed us to start creating cell and mouse models, perform basic/translational research, initiate a natural history study to aid in the identification of biomarkers and treatment endpoints, raise awareness for SASD, and investigate leads on drug candidates. We aim to collect data that incentivize industry to further develop, obtain approval, and commercialize SASD treatments.

## PgmNr 1201: The laboratory approach to the diagnosis of Krabbe disease.

### Authors:

Gelb <sup>4</sup>; M. Escolar <sup>5</sup>; D. Gavrilov <sup>1</sup>; D. Oglesbee <sup>1</sup>; K. Raymond <sup>1</sup>; S. Tortorelli <sup>1</sup>; P. Rinaldo <sup>1</sup>; A. Guenzel <sup>1</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Biochemical Genetics Laboratory, Mayo Clinic, Rochester, MN.; 2) Department of Pediatrics, Duke University Medical Center, Durham, NC; 3) New York State Department of Health, Albany, NY; 4) University of Washington, Seattle, WA; 5) Children's Hospital of Pittsburgh, Pittsburgh, PA

Newborn screening (NBS) for Krabbe Disease (KD) is currently performed in six US states. High frequency of pseudodeficiency alleles in the galactocerebrosidase (GALC) gene has led to a large number of false positive cases. Psychosine (PSY), a substrate of GALC, has been found to be elevated in the blood in KD patients. To facilitate close monitoring and rapid identification of patients at risk of KD based on an abnormal NBS result or suspicious clinical presentation, we developed assays to measure PSY in dried blood spots (DBS), erythrocytes (RBC) and cerebrospinal fluid (CSF), and adapted a new GALC enzyme assay in leukocytes (WBC).

**Specimens:** Specimens were obtained from at risk patients based on the primary NBS test result or because of a phenotype suggestive of KD.

### Results:

	PSY (DBS) [nmol/L]	PSY (RBC) [pmol/g Hb]	PSY (CSF) [nmol/L]	GALC (WBC) [nmol/h/mg prot]
IKD	25-111 (n=23)	54-356 (n=3)	1.3-4.3 (n=6)	<0.01 (n=12)
LOKD	2.6-9.9 (n=8)	37-43 (n=3)	0.02-0.30 (n=6)	0.03-0.07 (n=5)
GALC Pseudo	0.35-1.3 (n=55)	-	-	0.1-0.3 (n=5)
GALC Carrier	0.36-1.5 (n=27)	-	-	0.09-0.55 (n=14)
Controls	<1.5 (n=205)	<4.5 (n=152)	<0.03 (n=124)	>0.87 (n=130)

IKD, Infantile KD; LOKD, Late Onset KD; ranges represent 1st to 99th percentiles.

**Conclusions:** The new GALC enzyme activity assay along with PSY measurements in various specimen types may allow a differentiated diagnosis of KD which is specifically important when asymptomatic cases are identified by NBS. Testing of PSY in RBC was implemented to allow normalization of PSY values to hemoglobin, thereby avoiding potential collection artifacts common to DBS. The PSY assay in RBC may therefore allow for monitoring of asymptomatic patients with LOKD in preparation for potential hematopoietic stem cell transplantation.

## PgmNr 1202: Extensive Mongolian spots in GM1 gangliosidosis: A pictorial report in Indian population.

---

GM1 gangliosidosis (MIM# 230500) is a lysosomal storage disorder, usually characterized by progressive psychomotor deterioration, visceromegaly, facial coarseness, macular cherry-red spots, and skeletal abnormalities. Cutaneous lesions are not frequently reported in the literature. In this study, we have described five unrelated patients of GM1 gangliosidosis with persistent and extensive Mongolian spots on the trunk and extremities that provided a clue towards their clinical diagnosis. The cutaneous lesions were present at birth, before the appearance of characteristic features of the disease. Four out of five patients were from our previously reported cohort of 46 patients with GM1 gangliosidosis in which 30 patients (65%) had Mongolian spots. Of the five reported patients, four patients presented with psychomotor retardation and one had only extensive Mongolian spots as the presenting complaint. Apart from extensive Mongolian spots, they exhibited coarse facies, hepatosplenomegaly, generalized hypotonia, and features of dysostosis multiplex. Three patients had cherry-red spots on the retina. The condition was confirmed by identification of biallelic pathogenic variants in the *GLB1* gene and very low activity of beta-galactosidase enzyme in peripheral leukocytes. Biallelic pathogenic variants in *GLB1* were identified in all of them. These include one novel missense variant p.(Lys493Asn) and two reported variants, a splicing variant c.75+2dup and a nonsense variant p.(Arg457Ter), in *GLB1*.

We ascertain that extensive Mongolian spots are the unique cutaneous phenotype of GM1 gangliosidosis. Unusual extensive Mongolian spots can be used as a diagnostic handle for early recognition of GM1 gangliosidosis. Extensive Mongolian spots, particularly in the context of neurodevelopmental deterioration and macular cherry-red spots, helped in differentiating GM1 gangliosidosis from other similar neurodegenerative conditions.

## PgmNr 1203: Acid ceramidase deficiency due to mutations in *ASAH1*, presenting as Farber disease: Diagnostic data from the first-ever natural history study.

**Introduction:** Farber disease is a rare lysosomal storage disorder caused by mutations in both alleles of the *ASAH1* gene. The resulting deficiency of the lysosomal enzyme acid ceramidase, and accumulation of the pro-inflammatory sphingolipid ceramide, causes a broad spectrum of symptoms and disease severity which may delay diagnosis or lead to misdiagnosis. The ongoing study described here is the first comprehensive, systematic clinical study of the natural history of Farber disease.

**Methods:** The Observational and Cross-Sectional Cohort Study of the Natural History and Phenotypic Spectrum of Farber Disease (NCT03233841) is designed to collect retrospective and prospective data including demographics, clinical presentation, phenotype, and diagnostic history of patients diagnosed with Farber disease who have or have not undergone hematopoietic stem cell transplantation (HSCT), along with specific prospective clinical evaluations in living patients.

**Results:** 44 patients, including 24 living non-HSCT, 3 living HSCT, 13 deceased non-HSCT, 4 deceased HSCT, have been enrolled in the study since November 2017. Diagnostic modalities included genetic testing (95%), enzyme activity testing (14%), and nodule biopsy (36%). The average age of the living non-HSCT patients at enrollment was 6.7 years (range 1 to 28 years). Average time from onset of first symptoms to diagnosis was 2 years (range < 1 to 12 years). Patient countries of origin included Afghanistan, Argentina, Canada, Egypt, Germany, India, Iraq, Italy, Mexico, Sweden, Syria, Turkey, and the USA.

**Conclusions:** Patients representing the breadth of the phenotypic spectrum of Farber disease, from rapidly progressive (severe) to slowly progressive (attenuated), have been enrolled from 15 centers in 9 countries. The majority of patients were diagnosed by *ASAH1* mutational analysis. Demographic data and numbers of patients enrolled indicated that Farber disease is likely not as rare as previously thought.

## PgmNr 1204: The prevalence of *GALM* mutations that cause galactosemia: A database of functionally evaluated variants.

Galactosemia is a metabolic disorder that affects the appropriate metabolism of  $\beta$ -D-galactose. Deficiencies in three of the enzymes of the Leloir pathway, namely, GALT, GALK1, or GALE, are characterized as type I, II, and III galactosemia, respectively. Recently, we reported a novel type of galactosemia (type IV galactosemia) due to biallelic *GALM* mutations. Genetic diagnosis is indispensable for diagnosing *GALM* deficiency because no biochemical diagnosis method has been established. Given that apparently pathogenic variants in *GALM* are found in public variant databases, we presumed the presence of pathogenic variants that have not been reported. In this study, we explore 67 *GALM* variants that are prevalent in the ExAC database, including 57 missense variants, 7 stop-gain variants, 2 frameshift variants, and 1 splice-site variant. We performed an in vitro expression assay and an enzyme activity assay. Among the 66 variants except for 1 splice-site variant, 29 produced no or faint protein expression and were judged as pathogenic variants. Furthermore, the remaining 37 variants were evaluated by enzyme activity assay. Two showed mildly reduced enzyme activity and were classified as benign. Based on our study, the estimated incidence of *GALM* deficiency is 1:228,411 in all populations, 1:10,388 in the African population, and 1:80,747 in the Japanese population. Our *GALM* mutation database is useful for the genetic diagnosis of *GALM* deficiency.

## PgmNr 1205: 1-<sup>13</sup>C-Propionate oxidative capacity predicts clinical outcomes in propionic acidemia.

---

Propionic acidemia (PA) is a severe metabolic disorder characterized by significant multiorgan involvement. There are no FDA-approved genomic therapies or validated disease biomarkers. We explored the role of *in vivo* whole-body oxidation of 1-<sup>13</sup>C-propionate as a surrogate endpoint for clinical outcomes in propionic acidemia

All study participants were enrolled in a natural history protocol (The Natural History, Physiology, Microbiome and Biochemistry Studies of Propionic Acidemia, ClinicalTrials.gov ID NCT02890342). To identify parameters associated with 1-<sup>13</sup>C-propionate oxidation, we selected variables meeting a univariate criterion of coefficient  $r < -0.4$  or  $> 0.4$  (99 of 343 parameters). Of these, a subset of 9 variables representative of key disease characteristics (height z-score, full scale IQ (FSIQ), optic nerve atrophy, sensorineural hearing loss, left ventricular ejection fraction (LVEF%), cystatin C-based estimated glomerular filtration rate (eGFR), serum erythropoietin, complete and incomplete protein as a percent of recommended daily allowance) were used to specify a clinical prediction model of propionic acidemia in non-transplanted patients.

We enrolled 34 participants, ages 3-53 years (mean age 16 years, 56% females, including 1 kidney- and 3 liver-transplanted individuals); 30 completed the stable isotope study. Participants with biallelic null variants (frame shift, premature stop codons, and exon deletions) in *PCCA* or *PCCB* had lower 1-<sup>13</sup>C-propionate oxidation (mean = 6.2%) compared to those with at least one non-null variant (mean = 20.2%,  $P < 0.0001$ ). Oxidation was normal in liver transplant recipients (mean = 64.7%,  $P < 0.0001$ ). In non-transplanted participants, 120-minute 1-<sup>13</sup>C-propionate oxidation was associated with height z-scores ( $r = 0.48$ ,  $P < 0.05$ ), FSIQ ( $r = 0.74$ ,  $P < 0.0001$ ), sensorineural hearing loss (odds ratio = 0.8, 95% CI 0.67 – 0.98), cystatin C eGFR ( $r = 0.46$ ,  $P < 0.05$ ), erythropoietin ( $r = 0.55$ ,  $P < 0.01$ ), complete protein intake ( $r = 0.43$ ,  $P < 0.05$ ), and incomplete protein intake ( $r = -0.44$ ,  $P < 0.05$ ). LVEF% ( $P = 0.06$ ) and optic nerve atrophy (odds ratio = 0.73, 95% CI 0.5 – 1.04) showed statistical trends.

Lower 1-<sup>13</sup>C-propionate oxidation was associated with severe genotypes and more adverse clinical outcomes helping define the clinical prediction model of propionic acidemia. These data support the role of *in vivo* metabolic profiling as a surrogate endpoint in clinical trials aimed at restoring propionate oxidation in the liver.

## PgmNr 1206: The *Ornt1* KO mouse: A disease model for the HHH (Hyperornithinemia-Hyperammonemia-Homocitrullinuria) syndrome.

---

**Introduction:** The Hyperornithinemia-Hyperammonemia-Homocitrullinuria (HHH) syndrome is a disorder of the urea cycle (UC), ornithine degradation pathway and cationic amino acid transport caused by mutations in the mitochondrial ornithine transporter, *ORNT1*. In contrast to most disorders of the UC that present as neonatal hyperammonemic coma (i.e. OTC deficiency), HHH syndrome has a later onset and more variable and mild clinical phenotype. We hypothesize that the HHH syndrome phenotype is influenced by the existence of two additional mitochondrial cationic amino acid transporters, *ORNT2* (non-functional in mouse) and *ORNT3* (SLC25A29). To understand the mechanisms of disease for HHH syndrome, we studied an available *Ornt1* KO mouse that was generated by replacing a region of intron 4 and exon 5 with a neomycin  $\beta$ -galactosidase cassette.

**Results:** Two phenotypes of homozygous (HMZ) pups (n=65) were observed: one group expired by 24-36 h (45%) and the second group developed severe neurological disease by 14-15 days of life before dying (55%). HMZ pups, significantly smaller in size at birth, exhibited marked growth delay. Progressive neurological symptoms (ataxia, loss of righting reflex, spasticity) started at day 10 of life. Hyperammonemia was observed in 10-14 d/o pups (Wild-type 258  $\pm$  43  $\mu$ m vs HMZ 872  $\pm$  182  $\mu$ m). Fatty liver was evident in  $\sim$ 50% of 10 d/o HMZ pups. Significant elevation in plasma ornithine (5X) and urinary excretion of cationic amino acids, homocitrulline, lactate and citrate were also observed. At non-saturating ornithine concentration, residual ornithine transport was measured in skin fibroblasts from HMZ pups when compared to WT.

**Conclusions:** The *Ornt1* KO mouse presents a phenotype similar to patients with HHH syndrome that includes spasticity, liver disease, growth delay and mild hyperammonemia. Despite a non-functional mouse *Ornt2*, *in vivo* gene redundancy is evident in the *Ornt1* KO mouse implying that *Ornt3* (Slc25a29) or another mitochondrial cationic amino acid transporter is responsible for the residual ornithine transport and variable phenotype in this murine disease model. Previous *in vitro* studies showed that SLC25A29 acts as an ornithine transporter whereas SLC25A20 (carnitine/acylcarnitine transporter) and SLC25A45 (two members of the ORNT1 subfamily) did not rescue the deficient ornithine transport in ORNT1 deficient fibroblasts.

## PgmNr 1207: High-dose hydroxocobalamin injection achieves biochemical correction and clinical improvement in adults with late-onset cobalamin C disease.

---

Cobalamin C (cblC) disease is the most common inborn error of intracellular cobalamin metabolism caused by pathogenic variants in *MMACHC*. It is characterized biochemically by accumulation of homocysteine (Hcy) and methylmalonic acid (MMA). cblC disease is classified into early- and late-onset forms. The late-onset form is rare and could present from late childhood to adult with neurological deteriorations, psychiatric disturbances, and thromboembolic complications. Hydroxocobalamin injection is a standard treatment. Its optimal dosing has not been systematically evaluated in adults. We report three adult siblings with a biochemically and molecularly confirmed cblC disease. The 28-year-old proband presented with severe psychosis, deep venous thrombosis with pulmonary embolism, and progressive neurological deterioration associated with extensive lesions in the spinal cord, periventricular white matter as well as basal ganglia. Serum total homocysteine and methylmalonic acid were markedly elevated. Serum Hcy and MMA levels were markedly elevated. Hydroxocobalamin injections, together with betaine and folic acid, were prescribed at standard (1 mg/day) and escalated (25 mg/day) doses in an attempt to maximize therapeutic benefits. This regimen led to a rapid normalization of serum Hcy and MMA levels, resolution of psychiatric symptoms, and improvement of neurological functions and brain and spinal cord lesions. Two biochemically affected but clinically asymptomatic siblings received hydroxocobalamin injections at 25 mg/day, which normalized serum MMA and Hcy in 2-3 weeks. Their injections were successfully spaced out to 25 mg/week for maintenance therapy. All three patients are compound heterozygotes for a known variant, Arg91LysfsX14, and a novel variant, Tyr130Cys, in *MMACHC*. This case highlights a need to evaluate defects of intracellular cobalamin metabolism in adults with severe neuropsychiatric manifestations. A longer follow up is needed to determine the optimal dosing regimen for acute (25 mg/day) and maintenance (25 mg/week) therapy in adult patients with late-onset cblC disease but the clinical and biochemical responses we have documented suggest that high doses hydroxocobalamin injections are beneficial.

# PgmNr 1208: Newborn screening program by tandem mass spectrometry for inborn metabolic disease in Hunan Province: Incidence, genetic characteristics, and clinical outcomes.

## Affiliations:

1) Department of Genetic Medicine, Maternal and Child Health Hospital of Hunan Province, Changsha, Hunan, China; 2) Department of Health Care, The Maternal and Child Health Hospital of Hunan Province, Changsha, Hunan, China;; 3) Department of Health Care, The Maternal and Child Health Hospital of Hunan Province, Changsha, Hunan, China

This study sought to investigate the prevalence, mutation characteristics and clinical outcomes of inborn metabolic disorders (IMD), detected by tandem mass spectrometry (MS/MS) newborn screening in Hunan province. We studied 565,182 newborns who underwent MS/MS screening for 26 IMDs, including fatty acid oxidation disorders (FAODs), amino acid disorders (AAs), and organic acidemias (OAs) between March 2013 and September 2017. For patients with positive results, a recall screening test was performed, and the results were further confirmed by specific biochemical and genetic analysis. For all patients with IMD, guideline-directed medical treatment was administered, and the follow-up outcomes were evaluated. A total of 107 newborns were diagnosed with IMDs, with an overall prevalence of 1:5,282, including 65 newborns with FAODs (1: 8,695), 29 with AAs (1:19,489), and 13 with OAs (1:43,476). The Primary carnitine deficiency (PCD) (1:12,845), Hyperphenylalaninemia (HPA) (1:33,246), Short-chain acyl-CoA dehydrogenase deficiency (SCADD) (1:47,099), Citrine deficiency (NICCD) (1:94,197) were the four most common IMDs in Hunan province. The hotspot mutation in SLC22A5 gene of PCD were c.51C>G (25.3%), c.1400C>G (23.0%), and c.760C>T (13.8%); in PAH gene of HPA were c.728G>A (22.2%) and c.721C>T (14.8%); in ACADS gene of SCADD was c.1031A>G (38.9%); and in SLC25A13 gene of NICCD was c.851\_854delGTAT (50.0%). The remaining IMDs were rare, and the hotspot mutations were unclear right now. During a mean follow-up of 26.1±5.6 months, 7 patients died, 4 were suffered an intelligent disability, whereas the remaining 96 subjects had normal physical and intelligent development. **Conclusion** The overall prevalence of IMDs is not fairly low in Hunan province. The spectrum of these disorders presents with typical regional characteristics, and the hotspot mutation profile is consistent with that detected in the Chinese population. Newborn screening by MS/MS enables the early detection of IMDs. Early appropriate management can significantly improve the outcomes of these patients.

## PgmNr 1209: Novel mutation in *MT-ND1* m.3955G>A related to neonatal onset Leigh syndrome with spinal lesion.

---

**Introduction** Leigh syndrome is subacute necrotizing encephalomyelopathy characterized by symmetrical lesion of basal ganglia and brain stem. *MT-ND1* gene mutation causes the functional decline of respiratory chain complex I activity and is associated with Leber hereditary optic atrophy, MELAS and Leigh encephalopathy. *MT-ND1* mutation related to neonatal onset lethal lactic acidosis was also reported. **Case report** ??The patient was born at 38 weeks gestation to nonconsanguineous healthy parents. At the age of 2 weeks she came into coma and was admitted to the hospital. Laboratory test revealed elevated serum lactate (9.5 mmol/L), and pyruvate (0.27 mmol/L). Cerebrospinal fluid lactate and pyruvate also elevated. MRI showed restriction of diffusion bilaterally in the cervical spinal cord, brain stem and cerebral white matter. Magnetic resonance spectroscopy showed elevation of lactate peak. At the age 3 weeks, MRI showed the diffusion restriction area were extended and cerebellar tonsillar herniation was present. She didn't recover from coma and couldn't breathe. She received a tracheostomy at the age 8 of weeks. Her condition came stable. At 3 months old, infection exacerbated her condition and she died. Whole mitochondrial genome sequencing detected homoplasmic *MT-ND1* m.3955G>A, p.Ala217Thr in her blood and muscle, which is not detected in her mother's blood. Whole exome sequencing detected no mutations associated with her symptoms. Enzyme activity of respiratory chain complex I was decreased in skin fibroblasts and muscle. **Discussion** We concluded *MT-ND1* variant was the cause of Leigh syndrome because decreased enzyme activity of respiratory chain complex I was consistent with *MT-ND1* mutation. Spinal cord and brain were involved in our case. Spinal lesion involvement has been reported in some patients with Leigh syndrome, but genetic causes have been identified in only a few cases including *NDUFA1*, *MTTK*, *MTRNR2*, *SURF1* mutation. This is the first case of *MT-ND1* mutation related to Leigh syndrome with spinal lesion. These results suggest that *MT-ND1* could be one of the causes of Leigh syndrome with spinal lesion.

## PgmNr 1210: Next generation sequencing analysis for mitochondrial disorder in Japanese patients.

---

Mitochondrial disorders have a reported incidence of 1 in 5000 live births and are clinically and genetically heterogeneous group of diseases. A correct diagnosis is challenging, mainly because of the absence of clear phenotype-genotype correlations, and these diseases are attributed to mutations in the 16.6 kb mitochondrial genome and approximately 1500 genes encoded in the nuclear genome. The development of Next Generation Sequencing (NGS) has revolutionized the diagnostic approach. New approaches make genetic analyses much faster, more sensitive and more efficient. We have developed a targeted NGS-based assay of the mitochondrial DNA (mtDNA), which include 179 nuclear genes reference to the Human Gene Mutation Database (HGMD®) associated with mitochondrial disorders. Specifically, we designed and performed a 3-step strategy, comprising of clinical and pathological screening, long-range PCR using muscle DNA and whole mtDNA sequencing with Illumina MiSeq, and gene-targeted analysis following whole-exome sequencing (WES). A total of 150 suspected mitochondrial diseases cases were analyzed in five years from 2014 to 2019. Mutations were found in mtDNA in 15 of the 150 analyzed cases. Miseq was performed for 144 cases, and deletion of mtDNA was observed in 85 cases out of 144 cases (59%). WES was performed in 65 cases, 17 of which revealed mitochondrial related nuclear gene abnormalities (25.7%). Multiple cases have mild renal failure, external ophthalmoplegia, and neuropathy. Further study should investigate more nuclear genes and pathological study to clarify the pathophysiology. These symptoms were underestimated or undetected before diagnostic confirmation. Our results indicate that neuropathy might be an important symptom of adult mitochondrial disease caused by mutations in nuclear genes. We speculate that a noticeable number of mildly symptomatic patients with an adult mitochondrial disease existed.

## PgmNr 1211: The phenotypic spectrum of 43 Czech patients with single mitochondrial DNA deletion.

### Authors:

The single mitochondrial DNA deletion (del-mtDNA) is associated with sporadic clinical syndromes of varying severity ranging from Pearson syndrome, Kearns-Sayre syndrome (KSS) spectrum to isolated progressive external ophthalmoplegia (PEO). We present clinical and molecular data of Czech patients with single del-mtDNA. Results: Since 1992, a total of 43 patients have been diagnosed. Single del-mtDNA was detected in 85 DNA samples obtained from our patients (more than one tissue was tested in each patient), mtDNA deletion break-points were unequivocally characterized in 29 samples. The single del-mtDNA lengths were 1835-7827 bp, the single del-mtDNA heteroplasmy levels ranged from 31% up to 90%. The age of onset varied from weeks after birth to 79 years, 67% patients developed symptoms before the age of 20. Ptosis was the most common presenting symptom (36 patients), following by PEO, muscle weakness and dysarthria. Five patients were classified as having Pearson syndrome, 25 patients KSS spectrum (58%) and seven PEO. Six patients suffered from atypical phenotype manifesting myalgia and muscle weakness (3/6), isolated dysarthria or ptosis and muscle atrophy (2/6) and dysarthria and epilepsy (1/6). Conclusion: Six (14%) individuals manifested different clinical features further expanding the clinical spectrum associated with SMD phenotype. *Supported by AZV17-30965A and RVO-VFN64165.*

**BACKGROUND:** Newborn screening (NBS) using tandem mass started all over Japan in 2014. Since then the number of NBS target diseases increased from 6 to 20. We have been conducting a follow-up project of patients with inherited metabolic diseases (IMD), who were positively screened in NBS, after confirming their genotypes since 2014. This will provide us phenotype/genotype correlations in these NBS target IMD and important evidence for evaluation of NBS efficacy and genotypes-adjusted clinical guidelines.

**METHODS:** We designed a gene panel covering the NBS target IMD and the related diseases. Gene panel analysis was performed at Kazusa DNA Research Institute. In 2014-2016, we did mutation analysis on research basis with parents' informed consent, after 2017 mutation analysis for a large part of NBS-target IMD were covered by public medical insurance. We obtained written consents from parents for follow-up study. These studies were approved by the Ethical Committee of our institutions. This research was supported in part by AMED under Grant Number JP17ek0109276 and Health and Labour Sciences Research Grants (H29-nanchitou(nan)-ippan-051) for Research on rare and intractable diseases.

**RESULTS:** More than 340 cases were enrolled in this gene panel study for five years (January 2014 to March 2019). Among them, the number of patients with IMD detected by NBS were 260, as follows: Propionic acidemia (49), Hyperphenylalaninemia (37), Methylcrotonylglycinuria (27), VLCAD deficiency (19), Methylmalonic acidemia (18), Galactosemia (17), MCAD deficiency (16), Maple syrup urine disease (14), primary systemic carnitine deficiency (12), Glutaric acidemia type 2 (9), Homocystinuria(8), Others (34). Most of other 70 cases were symptomatic patients who were previously diagnosed. In most cases, we could find the gene mutations in their corresponding genes. We also started clinical follow-up studies.

**DISCUSSION:** In some NBS-target IMD, we found specific mutations only identified in NBS. For example Y435C was predominantly identified in Japanese patients with propionic acidemia who were identified in NBS. Clinical phenotype of patients with Y435C in PCCB (propionic acidemia) has been asymptomatic or mild. Similar findings were also seen in VLCAD deficiency. It is challenging to distinguish patients with high risk from those with no symptom or low risk and make genotype-

adjusted clinical guidelines at this moment. We need further long-term follow-up studies.

## PgmNr 1213: Modulation of the gut microbiome in a mouse model of isolated methylmalonic acidemia induces a therapeutic biochemical and hepatic response.

### Authors:

Cobalamin A deficiency (cblA), caused by pathogenic variants in *MMAA*, is a form of isolated methylmalonic acidemia (MMA), a severe disorder of intermediary metabolism. MMA is characterized by multiorgan pathology including hepatic mitochondrial dysfunction. Clinical management of MMA involves a protein restricted diet, aggressive management of disease related symptoms, and, in some patients, intermittent antibiotic treatment to minimize the production of propionate. Although previous reports suggest antibiotic treatment could reduce serum methylmalonic acid concentrations by as much as 25% in human subjects with MMA, there is no experimental evidence to prove the beneficial effects of antibiotic treatment.

In the current study, we assessed the effects of antibiotic therapy in a mouse model of cblA deficiency. Vancomycin was administered in the drinking water of affected (*Mmaa*<sup>-/-</sup>) and unaffected (*Mmaa*<sup>+/-</sup>) mice for two weeks and resulted in drastic improvements in the mutant phenotype: weight increased 2-fold (multiple t-test:  $p < 0.05$ ), plasma MMA decreased 4-fold (Mann-Whitney test:  $p < 0.01$ ), and plasma Fgf21 decreased nearly 30-fold (Mann-Whitney test:  $p < 0.05$ ).

To explore the mechanisms underlying antibiotic effects, we performed RNA-seq on liver mRNA and bacterial 16S rRNA metagenomic sequencing on stool samples from affected and unaffected mice. Comparison of affected and unaffected liver transcriptomes revealed 9,632 differentially expressed genes in the disease state, of which vancomycin treatment restored expression in 83% (8,007) of these dysregulated genes (Fisher's exact test:  $p < 0.001$ ). Comparison of dysregulated genes to mRNA and proteomic datasets from MMA patients and MMA murine models identified a core set of 4 dysregulated pathways including mitochondrial energy homeostasis and proliferation, xenobiotic metabolism, and host-bacterial interactions ( $p < 0.001$ ). 16S sequencing of stool samples collected during and after vancomycin treatment revealed a loss of *Bacteroidetes*, *Firmicutes*, and *Actinobacteria* communities in both affected and unaffected mice.

This study is the first to clearly establish a therapeutic effect of antibiotics in isolated MMA and explore the gut microbiome effects on the liver transcriptome. The understanding of the gut-liver axis in MMA can point to new targets for small molecule therapeutics and disease-specific probiotics.

## PgmNr 1214: Novel mutations identified by whole exome sequencing in *ECHS1* from three Chinese patients with Leigh syndrome.

### Authors:

M. Wu <sup>1</sup>; Z. Liu <sup>2</sup>; Y. Liu <sup>3</sup>; D. Sun <sup>4</sup>; F. Fang <sup>2</sup>; Z. Liu <sup>4</sup>

### Affiliations:

1) School of Medicine, Jiangnan University, Wuhan 430056, China; 2) Department of Neurology, Beijing Children's Hospital, Capital Medical University, National Center for Children's Health, Beijing, 100045, China; 3) Aegicare (Shenzhen) Technology Co., Ltd., Shenzhen, 518110, China.; 4) Department of Pediatric Neurology, Wuhan Children's Hospital, Tongji Medical College, Huazhong University of Science & Technology, Wuhan 430016, China

**Background:** Mitochondrial short-chain enoyl-CoA hydratase-1 deficiency (ECHS1D, OMIM 616277) is a rare inborn metabolic disorder whose clinical presentations are consistent with Leigh Syndrome (LS, OMIM 256000), a clinically and genetically heterogeneous disorder that commonly onset within the first months or years of life. It was first characterized to be caused by biallelic mutations of gene *ECHS1* (OMIM 602292) in 2014. The genetic errors in *ECHS1* gene affects the fourth step of valine degradation and leads to the accumulation of toxic intermediates, methacrylyl-CoA and acryloyl-CoA, to further cause brain pathology. To date, more than 30 different pathogenic mutations have been identified from over 40 patients.

**Methods:** We implemented whole-exome sequencing in three Chinese patients diagnosed as LS to precisely identify the disease-causing variants. During the diagnosis, other examinations and biomedical measurements such as metabolic measurement, mitochondrial respiratory chain (MRC) enzyme activity measurement, oxygen consumption rate (OCR) measurement and brain magnetic resonance imaging (MRI), were also carried out.

**Results:** WES analysis of three patients identified four distinct mutations in *ECHS1* to be the pathogenesis. Among the detected mutations, only one, c.583G>A (p.Gly195Ser), has been reported in previous studies; the other three, c.463G>A (p.Gly155Ser), c.557C>T (p.Ser186Leu) and c.476\_c.477delAGinsGGCATAGA (p.Gln159delinsLeuTyrAla), are all novel. It is worth noting that one of the novel variants, c.463G>A (p.Gly155Ser), was detected in all three patients from unrelated families, indicating a potential founder effect, which has already been previously reported to be existing in LS in other mutations. Clinically, despite different initial presentations, all studied patients were with similar clinical syndromes such as development regression, paroxysmal exercise-induced dystonia, as well as common radiological features like symmetrical bilateral brain abnormalities, similar metabolic results like consistently elevated plasma. The presence of the marker metabolite 2-methyl-2,3-hydroxybutyric acid in urine organic acids have also been detected.

**Conclusion:** Our findings enriched the pathogenic mutation spectrum of *ECHS1* gene and confirmed the clinical and phenotypic presentations of ECHS1D in LS. Further studies are required to look into the noteworthy novel mutation c.463G>A (p.Gly155Ser), especially in Chinese origin population.

## PgmNr 1215: The G6PD-mediated mechanism of inhibiting the invasion and proliferation of *plasmodium falciparum* by dehydroepiandrosterone and nicotinamide.

### Authors:

W. Jiang; P. Du; C. Jiang; J. Yan; Q. Hu

[View Session](#) [Add to Schedule](#)

**Affiliation:** Department of Medical Genetics, Zhongshan School of Medicine, Sun Yat-Sen University, 74# Zhongshan Road, Guang Zhou, Guangdong, China

**Background:** New drugs are urgently needed to control artemisinin-resistant *Plasmodium* strains. Our previous study revealed that plasmodium multiplication would understandable inhibited in G6PD deficient erythrocytes because the plasmodium organelles could not obtain enough NADPH. However, we rare know the effect of insufficient ribose-5-phosphate on plasmodium multiplication in G6PD deficient erythrocytes and the potential mechanism of dehydroepiandrosterone and nicotinamide decreases G6PD activity to inhibit the invasion and proliferation of *Plasmodium falciparum*.

**Methods:** Late parasites were isolated from infected RBCs using flow cytometry. The R-5-P was transferred to erythrocyte by electrorotator, followed R-5-P was determined quantitatively by mass spectrometry. The infection and proliferation of *P. falciparum* were detected by Giemsa staining and real-time FQ PCR. After the infected erythrocytes were treated by DHEA and nicotinamide, G6PD activity was assayed by standard method, Young's modulus of erythrocyte membranes was measured to observe the mechanical properties by atomic force microscopy and the invasion and proliferation of *Plasmodium falciparum* were observed by Giemsa staining and real-time FQ PCR.

**Result:** The invasion and proliferation of *P. falciparum* in G6PD deficient erythrocyte were significantly reduced. When ribose-5-phosphate was transferred into G6PD deficient erythrocyte, proliferation of *P. falciparum* will be rescued. After the infected erythrocytes were treated by DHEA and nicotinamide, G6PD activity decreased and Young's modulus of erythrocyte membranes decreased with the altered mechanical properties. The minimum effective concentration of DHEA to inhibit *P. falciparum* was 12.5  $\mu\text{mol/L}$ , and nicotinamide was 2mM/L.

**Significance:** G6PD activity decreased after dehydroepiandrosterone and niacinamide treated, which mediated to inhibit invasion and proliferation of *P. falciparum* in host erythrocyte. The mechanism is not only involved in modulation of the redox state due to reduced NADPH, but also in decreased nucleotide synthesis due to reduced ribose-5-phosphate in pentose phosphate pathway, which is main source for nucleotide synthesis of *P. falciparum* in host erythrocyte. G6PD may be the target of the new drug for fighting against malaria. Our results also showed that both dehydroepiandrosterone and niacinamide have anti-malaria effect mediated by G6PD and the drug combination more effectively and less adverse effects.

## PgmNr 1216: Natural course of auditory function in Takenouchi-Kosaki syndrome.

**Authors:**

T. Takenouchi; K. Kosaki

[View Session](#) [Add to Schedule](#)

**Affiliation:** Keio Univ, Tokyo, Japan

---

**Background:** We recently established a novel multi-system disorder caused by mutations in *CDC42*, which was eponymized as Takenouchi-Kosaki syndrome (OMIM# 616737). All reported cases exhibited sensorineural hearing loss.

**Methods:** We retrospectively analyzed auditory brainstem response (ABR) and imaging data in two patients with Takenouchi-Kosaki syndrome. Both patients had hearing aids and had a de novo heterozygous mutation in *CDC42*, i.e., p.Tyr64Cys.

**Results:** patient 1: ABR at the age of four years showed clear waves I, III and V at 80dB, whereas ABR at the age of 21 years showed a blurred wave I at 80dB. Compared to audiometry, the patient showed a decreased response in ABR and otoacoustic emission. Patient 2: ABR at the age of seven years showed a clear wave V at 60dB on the right and at 70dB on the left. At the age of twelve years, her ABR showed a clear wave V at 80dB bilaterally, and a barely recognizable wave I at 90dB. The results were compatible with those in audiometry. A computed tomography scan of the inner ear showed a decreased number of rotations of cochlear and was compatible with 'incomplete partition type I', according to the classification of cochleovestibular malformations by Sennaroglu and Saatci.

**Discussion:** Our retrospective analysis on the natural course of auditory function in two patients with Takenouchi-Kosaki syndrome showed a possible progressive hearing loss from childhood through adulthood. These clinical observations appeared compatible with existing findings in *cdc42* knock-out mice that exhibited progressive hearing loss and loss of inner hair cells. The anatomical changes of the inner ear of the patient 2 suggested developmental arrest during the fetal period.

## PgmNr 1217: Metaphyseal enchondromatosis with D-2-hydroxyglutaric aciduria and variants in *IDH1*, *IDH2*, and *EXT2*.

### Authors:

---

Metaphyseal enchondromatosis with D-2-hydroxyglutaric aciduria (ME-HGA; OMIM 614875) is a rare disorder characterized by enchondromas and elevated levels of D-2-hydroxyglutaric acid (D-2HG). Vissers et al. (2011) reported the somatic mosaic *IDH1*-R132 variant in two unrelated patients with ME-HGA. Heterozygous, somatic, gain-of-function (GOF) variants of *IDH1* (R132C, R132G, R132H, R132L, and R132S) and *IDH2* (R172S) have been reported in a variety of cancers as well as Ollier disease (OD; OMIM 166000) and Maffucci syndrome (MS; OMIM 614569). OD and MS are related conditions characterized by enchondromas with a 30% risk of chondrosarcoma transformation. While wild-type *IDH1* and *IDH2* catalyze the oxidative carboxylation of isocitrate to  $\alpha$ -ketoglutarate ( $\alpha$ KG), the GOF variants instead cause  $\alpha$ KG to be converted to D-2HG. The conversion of  $\alpha$ KG to D-2HG leads to inhibition of  $\alpha$ KG-dependent reactions promoting increased histone and DNA methylation as well as impaired cell differentiation. Here, we present a 4-year-old boy with delayed tooth eruption, bilateral multiple enchondromas (shoulders, arms, elbows, wrists, hands, ribs, spine, hips, knees, ankles, and feet), and D-2HG aciduria. He had a normal CGH array. We performed WES of his blood and two enchondroma biopsies and identified a germline, heterozygous *IDH2*-T435M variant in all samples tested. We also identified a somatic mosaic, heterozygous *IDH1*-R132C GOF variant in both enchondromas but not in the blood sample. The proband also had a germline, heterozygous *EXT2*-T620M variant in all samples tested. Parents' samples are now being tested to determine if the germline *IDH2*-T435M and *EXT2*-T620M variants are *de novo*. The *IDH2*-T435M variant is of unknown significance with a gnomAD MAF of 3.61e-3. Loss of function variants in *EXT2* are known to cause autosomal dominant multiple exostoses (OMIM 133701). The *EXT2*-T620M variant is of unknown significance but is predicted to be pathogenic by DANN, dbNSFP, FATHMM, GERP, LRT, MetaLR, MetaSVM, MutationAssessor, MutationTaster, PROVEAN, and SIFT and has a gnomAD MAF of 6.62e-4. Herein we suggest that these *IDH1*, *IDH2*, and *EXT2* variants interact in this patient to cause his severe multiple enchondromas phenotype with D-2HG aciduria, supporting our hypothesis that these are tumor disposition syndromes characterized by locus heterogeneity with germline (or early post-zygotic) and additional tumor variants leading to tumor formation.

## PgmNr 1218: The CHD4-related syndrome: Investigation of the clinical spectrum, genotype-phenotype correlations and molecular basis.

---

**Purpose:** Sifrim-Hitz-Weiss syndrome (SIHIWES) is a recently described multi-systemic neurodevelopmental disorder caused by *de novo* variants in chromodomain helicase DNA-binding protein 4 (*CHD4*). This condition is part of an increasingly recognized group of Mendelian disorders involving chromatin remodeling abnormalities. In this study, we investigated the clinical spectrum of

the disorder, genotype-phenotype correlations and the effect of different missense variants on CHD4 function.

**Methods:** We collected detailed clinical and molecular data from 32 individuals with mostly *de novo* variants in *CHD4*, identified through next generation sequencing. We performed 3D protein modeling, ATP hydrolysis and nucleosome remodeling assays on variants from five different CHD4 domains.

**Results:** The majority of participants had global developmental delay and mild to moderate intellectual disability. However, a few participants had an IQ score in the normal range. Abnormal brain imaging was seen in 69% overall, and in 96% of the participants that underwent brain MRI. A range of findings were reported including ventriculomegaly, hydrocephalus requiring shunting, Chiari 1 and a thin corpus callosum. Two participants were diagnosed with moyamoya disease and subsequent stroke; Congenital heart defects were present in 65% and macrocephaly was seen in 40%. Additional common abnormalities included hypogonadism in males, skeletal and limb anomalies, hearing impairment and ophthalmic abnormalities.

The majority of variants were non-truncating and affected the SNF2-like region of the protein. We did not identify genotype-phenotype correlations based on the location of variants. For the 3 individuals with truncating variants, the phenotype involved fewer systems and the facial features were not similar. Alterations in ATP hydrolysis and chromatin remodeling activities were detected in missense variants from five different domains.

**Conclusion:** The CHD4-related syndrome is a multi-systemic neurodevelopmental disorder. Missense substitutions in different protein domains alter CHD4 function in a mutation-specific manner, but result in a similar phenotype in humans. Further research is required in order to better understand the disease mechanism and to determine the pathogenicity of truncating variants in this condition.

## PgmNr 1219: Distinct alterations in tricarboxylic acid cycle metabolites are associated with cancer and autism phenotypes in Cowden syndrome and Bannayan-Riley-Ruvalcaba syndrome.

---

While detecting germline mutations to identify heritable disease risk is utile, not all individuals with predisposition alleles will develop identical phenotypes. Thus, identifying factors for individual-level risk stratification is necessary even among those with germline mutations in an identical gene. Cowden syndrome (CS) and Bannayan-Riley-Ruvalcaba syndrome (BRRS) are autosomal dominant disorders characterized by a high risk of breast, thyroid and other cancers, and in a subset, autism spectrum disorder (ASD). In *PTEN*<sup>MUT</sup> CS/BRRS patients, up to 10% have germline *SDHx* (succinate dehydrogenase, mitochondrial complex II) variants, which modify cancer risk. *PTEN* contributes to metabolic reprogramming, a well-established role in a cancer context. Relatedly, *SDH* sits at the crossroad of the electron transport chain and tricarboxylic acid (TCA) cycle, two central bioenergetic pathways. Here, we conducted a TCA targeted metabolomics study on 511 CS/BRRS individuals with various genotypes (*PTEN* or *SDHx*, mutant or wildtype) and phenotypes (cancer or ASD), and a series of 98 population controls. We generated immortalized lymphoblastoid cell lines from peripheral blood samples (n=609) following standard methods, and cultured *in vitro* for subsequent metabolic profiling using liquid chromatography tandem mass spectrometry (LC-MS/MS). To evaluate correlations among genotypic/phenotypic features and normalized metabolite levels, we applied linear regression models controlling for age and gender. We found consistent TCA metabolite alterations in patients with various genotypes and phenotypes compared to controls, with unique correlations of individual metabolites with particular genotype-phenotype combinations. Notably, increased isocitrate ( $p=1.2 \times 10^{-3}$ ) but reduced citrate ( $p=5.0 \times 10^{-4}$ ), associated with breast cancer in *PTEN*<sup>MUT</sup>/*SDHx*<sup>WT</sup> patients. In contrast, increased lactate associated with ASD regardless of genotype ( $p=9.7 \times 10^{-3}$ ), which replicated in an independent validation series (n=171) enriched for idiopathic ASD (*PTEN*<sup>WT</sup>,  $p=5.6 \times 10^{-4}$ ). Importantly, we identified fumarate ( $p=1.9 \times 10^{-2}$ ) as a pertinent predictive biomarker to distinguish individuals who will develop ASD versus those who will develop cancer. Our data suggest TCA cycle metabolite alterations are germane to the pathobiology of *PTEN*-related CS/BRRS and to that of ASD (latter regardless of genotype), with potential implications for risk prediction for the individual and for therapeutic metabolic correction.

---

Cornelia de Lange syndrome (CdLS) is a rare multisystem disorder with specific dysmorphic features. Pathogenic genetic variants encoding cohesion complex subunits and interacting proteins (e.g., *NIPBL*, *SMC1A*, *SMC3*, *HDAC8*, and *RAD21*) are the major cause of CdLS. However, there are many clinically diagnosed cases of CdLS without pathogenic variants in these genes. To identify further genetic causes of CdLS, we performed whole exome sequencing in 57 CdLS families, systematically evaluating both single nucleotides variants (SNVs) and copy number variations (CNVs). We identified pathogenic genetic changes in 36 out of 57 (63.2 %) families, including 32 SNVs and four CNVs. Two known CdLS genes, *NIPBL* and *SMC1A*, were mutated in 23 and two cases, respectively. Among the remaining 32 individuals, four genes (*ANKRD11*, *EP300*, *KMT2A*, and *SETD5*) each harbored a pathogenic variant in a single individual. These variants are known to be involved in CdLS-like. Furthermore, pathogenic CNVs were detected in *NIPBL*, *MED13L*, and *EHMT1*, along with pathogenic SNVs in *ZMYND11*, *MED13L*, and *PHIP*. These three latter genes were involved in diseases other than CdLS and CdLS-like. Systematic clinical evaluation of all patients using a recently proposed clinical scoring system showed that *ZMYND11*, *MED13L*, and *PHIP* abnormality may cause CdLS or CdLS-like.

## PgmNr 1221: Co-occurrence of two syndromes resulting in a mixed phenotype-Prader Willi syndrome and KBG syndrome.

### Authors:

P. Gupta; H. Salhah; L. Tambini King; A. Gomez; L. Fried; K. Harwood

[View Session](#) [Add to Schedule](#)

**Affiliation:** St. Joseph's University Medical Center, Paterson, New Jersey.

---

**Introduction:** Prader-Willi syndrome (PWS) is the most common syndromic form of obesity and affects between 350,000 and 400,000 individuals worldwide. KBG syndrome has been reported in about 100 cases worldwide and is due to a mutation in the *ANKRD11* gene. We present the first case of a child with the co-occurrence of both syndromes.

**Case Presentation:** The patient was born via C- Section to a 39-year-old G2P1 female at 38 weeks gestation. He was the product of an IVF pregnancy with a frozen embryo. Prenatal ultrasounds noted single umbilical artery, breech presentation, polyhydramnios, and growth delay. Amniocentesis was declined. His birth weight was 4 pounds. He was admitted to the NICU due to an aspiration event. He continued to exhibit hypotonia and poor weight gain and underwent G-tube placement with Nissen fundoplication and muscle biopsy. He was discharged from NICU after one month. FISH for Prader Willi/Angelman syndrome and microarray were normal but a subsequent methylation analysis confirmed the diagnosis of PWS. He was evaluated in the genetics clinic around one year of age and was noted to have multiple dysmorphic features in addition to severe hypotonia, developmental delay, and failure to thrive. He has been treated with growth hormone since one year of age. Now at nine years of age, he is mostly nonverbal but occasionally uses some repetitive phrases. He does not display food-seeking behavior and has remained below the 5<sup>th</sup> percentile in weight for age. Due to many phenotypic features that seemed to be unexplained by PWS alone, a whole exome trio test was performed, which was positive for a pathogenic mutation in the *ANKRD11* gene.

**Discussion:** This is the first reported case of a patient with the simultaneous diagnosis of PWS and KBG syndrome. KBG syndrome is characterized by macrodontia of the upper central incisors, a distinct craniofacial appearance, skeletal abnormalities and neurological involvement that includes developmental delay, intellectual disability, and seizures. Our patient has prominent central incisors, distinct dysmorphic features, severe developmental delays and failure to thrive, likely resulting from KBG syndrome.

**Conclusion:** When the phenotype of a patient cannot be explained by one diagnosis alone, it is imperative to consider additional possibilities. Obtaining an accurate diagnosis not only helps in understanding the present symptoms, but it also brings closure to previously unanswered questions.

## PgmNr 1222: Review of the phenotypic spectrum associated with haploinsufficiency of *MYRF*.

---

The myelin regulatory factor gene (*MYRF*) encodes a transcription factor that is widely expressed. There is increasing evidence that heterozygous loss-of-function variants in *MYRF* can lead to abnormal development of the heart, genitourinary tract, diaphragm, and lungs. Here, we searched a clinical database containing the results of 12,000 exome sequencing studies. We identified three previously unreported males with putatively deleterious variants in *MYRF*: one with a point mutation predicted to affect splicing and two with frameshift variants. In all cases where parental DNA was available, these variants were found to have arisen de novo. The phenotypes identified in these subjects included a variety of congenital heart defects (hypoplastic left heart syndrome, scimitar syndrome, septal defects, and valvular anomalies), genitourinary anomalies (ambiguous genitalia, hypospadias, and cryptorchidism), congenital diaphragmatic hernia, and pulmonary hypoplasia. The phenotypes seen in our subjects overlap those described in individuals diagnosed with PAGOD syndrome [MIM# 202660], a clinically defined syndrome characterized by pulmonary artery and lung hypoplasia, agonadism, omphalocele, and diaphragmatic defects that can also be associated with hypoplastic left heart and scimitar syndrome. These cases provide additional evidence that haploinsufficiency of *MYRF* causes a genetic syndrome whose cardinal features include congenital heart defects, urogenital anomalies, congenital diaphragmatic hernia, and pulmonary hypoplasia. We also suggest that individuals with a clinical diagnosis of PAGOD syndrome could be screened for pathogenic variants in *MYRF*, and that individuals with *MYRF* deficiency who survive the neonatal period should be monitored closely for developmental delay and intellectual disability.

## PgmNr 1223: Bottom-up approach: An efficient workflow for the characterization of rare genetic diseases.

---

Rare diseases constitute one of the major global health issues that cumulatively affect nearly 10% of the world's population. These are progressively disabling and life-threatening and usually precipitate due to a single, highly penetrant genetic background at fault. Though such diseases are individually less prevalent, yet some of these have a relatively higher incidence in endogamous and consanguineous population groups such as the Ashkenazi Jews, the Finnish population, the Indian Agarwal community, and many others. A higher burden of rare diseases among the heterogeneous, highly endogamous population groups and consanguineous families of Jammu and Kashmir (J&K), located in the northern Himalayan ranges of India, is anticipated. The geographical isolation of these population groups in the difficult-to-reach mountainous terrains along with a higher incidence of endogamy and consanguinity has led to a relatively higher burden of genetic diseases, most of which have remained uncharacterized for years owing to the lack of genetic studies based on the population genetic profile and genetic disorders prevalent in J&K. We have designed a workflow namely the "Bottom-up Approach" for delineation of patho-genetics of genetic disorders prevalent in J&K. This strategic workflow is based on different study designs and is carried out with the aid of state-of-the-art biological techniques including targeted Sanger sequencing of candidate genes and high-throughput Next-Generation sequencing technologies and several *in silico* tools for the analysis of the raw sequencing data and functional/pathogenicity prediction of the potential disease-causing variants. The success of the designed "Bottom-up Approach" is boasted by the precise delineation and reporting of three rare diseases namely Progressive Pseudorheumatoid Dysplasia (PPD), Pantothenate Kinase-Associated Neurodegeneration (PKAN) and Leigh Syndrome (LS) prevalent in different regions in J&K for the first time. These cases were found to be associated with some novel and rare genetic variants that are individually restricted to highly extended, endogamous or consanguineous families. In conclusion, Bottom-up Approach is a powerful workflow that holds relevance in the characterization of less frequent monogenic Mendelian diseases and identification of potential genetic markers and could prove useful in future for precise diagnosis of such diseases and their timely therapeutic management in the affected individuals.

## PgmNr 1224: Inhibition of G-protein signaling in cardiac dysfunction of Intellectual Developmental Disorder with Cardiac Arrhythmia (IDDCA) syndrome.

### Authors:

P. De Nittis <sup>1</sup>; A. Sarre <sup>2</sup>; J. Chrast <sup>1</sup>; W.F. Simonds <sup>3</sup>; T. Pedrazzini <sup>4</sup>; A. Reymond <sup>1</sup>

### Affiliations:

1) Center for Integrative Genomics, University of Lausanne, Lausanne, Vaud, Switzerland; 2) Cardiovascular Assessment Facility, University of Lausanne, Switzerland; 3) Metabolic Disease Branch/NIDDK, National Institutes of Health, Bethesda, MD, USA; 4) Experimental Cardiology Unit, Department of Cardiovascular Medicine, University of Lausanne, Switzerland

Inactivating and hypomorphic mutations in the  $\beta 5$ -subunit of guanine nucleotide-binding protein (GNB5), respectively cause severe and mild forms of IDDCA syndrome, an autosomal recessive disorder associated with cognitive disability and cardiac arrhythmia. Whereas mice *Gnb5* knock-out (KO) showed structural and functional abnormalities of the brain, little was known about possible cardiac conduction anomalies. Of note, IDDCA individuals present bradycardia and sinus arrhythmias. Our mice study shows that *Gnb5*-inhibitory signalling is essential for parasympathetic control of heart rate. We monitored i) heart electrophysiology in KO (n=11), heterozygous (HET, n=8) and wild-type (WT, n=10) mice using *in vivo* electrocardiography (ECG) telemetry, and ii) cardiac function by echocardiography. 24-hours ECG recordings unearthed a high number of arrhythmias in KO animals, including escape beats (n=130 in KO vs. n=0.7 in WT), atrioventricular block (42 vs. 0.6) and tachycardia/bradycardia episodes (25 vs. 0.1), all signs of sinus arrhythmia and conduction problems. Moreover, KO mice were smaller than WT and HET mice, and had a smaller heart, but exhibited better cardiac function, as judged by increased fractional shortening and ejection fraction. Consistent with this observation, comparison of transcriptome profiling of atria and ventricles from WT, HET and KO mice revealed overexpression of genes involved in cardiac muscle contractility (e.g. *Tnnt1* (P=0.002), and *Lrrc10* (P=0.005) in ventricles, and *Myh7* (P=0.01) in atria) along with reduced ventricular expression of genes required for development of pacemaker cells (e.g. *Tbx18* (P=0.0001)) in KO animals. Additionally, KO mice treated with carbachol, a parasympathomimetic, presented significant carbachol-induced bradycardia. In contrast, the anti-parasympathetic drug atropine had the same effect in KO, HET and WT.  $\beta$ -adrenergic activity of KO mice was unaltered, suggesting a normal sympathetic modulation of the cardiac stimulation. We hypothesize that the disease mechanism responsible for heart rate perturbations is the loss of negative regulation on the inhibitory G-protein signalling, resulting in enhanced parasympathetic activity.

Overall, our work highlights that *Gnb5* KO mice not only recapitulate IDDCA's neurologic manifestations, but also mimic the cardiac perturbations, allowing for future screening of drugs modulating the parasympathetic branch of the autonomic nervous system, in view of patients' therapy.

## PgmNr 1225: Expanding the phenotype of mosaic tetrasomy 5p: Female patient with severe scoliosis and Wolff-Parkinson-White syndrome.

### Authors:

C. Chang <sup>1</sup>; J. Chernos <sup>1,2</sup>; M.A. Thomas <sup>1</sup>

[View Session](#) [Add to Schedule](#)

---

**Background:** Supernumerary Isochromosomes are made up of two copies of the same arm of a chromosome leading to tetrasomy for that region. Mosaic tetrasomy of the whole 5p resulting from an isochromosome 5p, or i(5)(p10), has been described in 5 affected children to date, with features including developmental delay, seizures, hypotonia, dysmorphic features, structural brain anomalies, and streaky hyperpigmentation of the skin. Less frequent findings include cardiac anomalies, renal anomalies, musculoskeletal anomalies, and early death due to cardiorespiratory compromise. In addition, mosaic isochromosome 5p has been described in one unaffected adult with infertility, and there are also several reports of partial tetrasomy of distal 5p, with a total of 15 patients with mosaic tetrasomy 5p reported. Due to the rarity of the condition (incidence estimated < 1 in 1,000,000), there are few reports of long-term outcomes.

**Methods/results:** We describe the 6<sup>th</sup>, and oldest reported affected child to date, with a mosaic finding of tetrasomy 5p resulting from a supernumerary isochromosome 5p at a 5% level in peripheral blood. Parental karyotype demonstrated the de novo origin of this finding. We report clinical features, including developmental outcomes at 12 years of age. We compare the features seen in our patient to those of patients reported in the literature. Our patient did not have skin pigmentary findings, but had developmental delay/ID, seizures, hypotonia, cardiac anomaly, and dysmorphic features. In addition, she had severe scoliosis requiring surgery with Harrington rods, and Wolff-Parkinson-White syndrome not reported in other patients to date.

**Conclusion:** We expand and further delineate the reported phenotype of patients with mosaic tetrasomy 5p resulting from a supernumerary isochromosome 5p. The main clinical features of this condition include developmental delay, seizures, hypotonia, dysmorphic features, and additional features. Tetrasomy 5p is typically found as a mosaic anomaly, and may be missed on routine testing (e.g. by microarray or standard karyotype on blood) because there is typically a lower level of mosaicism in peripheral blood. Genetic counselling is challenging because the phenotypic spectrum and clinical severity depend in part on the level and distribution of mosaicism.

## **PgmNr 1226: Phenotype-agnostic versus phenotype-driven analysis of exome (ES) or genome sequence (GS) data: Experience in a clinical site of the undiagnosed diseases network (UDN).**

The UDN utilizes ES and GS in undiagnosed diseases. The sequencing core labs generate sequence data and analyze these. Each clinical site independently analyzes these as well. Variants from both pipelines are reconciled by the clinical site for outcome determination. This dual analysis of every patient's ES or GS is a unique feature of the UDN. We examined its utility at the Duke/Columbia clinical site.

The analytical pipeline at the Duke/Columbia site is phenotype-agnostic, but without a specific CNV caller. In contrast, the core labs integrate phenotype with sequence data and use a specific CNV caller. In 25 of 41 (60%) diagnosed cases, the core labs and the Duke/Columbia site were concordant in diagnostic variants. In five cases (12%) the core labs missed the diagnosis, including variants not reported due to poor phenotypic fit, missing a phenotypic expansion (n=2), missed mosaicism (n=1) and missed CNVs (n=2). The Duke/Columbia site did not diagnose 11 individuals (28%). These included missed CNVs (n=6), not reporting heterozygous variants in phenotypically relevant AR genes in which further targeted testing, revealed a second variant (n=2), missed variants in an alternate transcript (n=2) and not reporting an AD inherited variant (n=1).

Sub-analysis showed that the total number of reported variants (including diagnostic) across both pipelines were  $23.7 \pm 7.8$  with only  $6.1 \pm 5.0$  variants overlapping between the two. These differences were because the research variants reported by the core labs ( $15.5 \pm 6.8$ ) were in genes of interest to the phenotype and the clinical site reported research variants ( $11.1 \pm 6.8$ ) that were bioinformatically prioritized. Of interest, among undiagnosed patients, only the clinical site detected candidate genes (n=4) that are being pursued. The core labs did not report these due to limited information about the genes.

Running two distinct complementary pipelines for ES or GS analysis enhances diagnosis. A phenotype-agnostic pipeline prioritizes variants that can result in phenotypic expansion of a known disorder, as well as new candidate genes. A phenotype-driven pipeline can flag variants in phenotypically relevant genes, leading to targeted investigations and diagnoses. CNV callers for GS also increase diagnostic capabilities. The disadvantage of a dual pipeline is the increased time and effort for personnel due to the larger number of variants. However, overall the dual analyses provide an improvement in

outcomes.

## PgmNr 1227: Expanding the spectrum of novel *ARID1B* mutations in Coffin-Siris syndrome.

### Authors:

**Affiliation:** KK Women s & Children s Hospital, Singapore, Singapore

Mutations in the *ARID1B* (AT-rich interaction domain 1B) gene is recognized as the most common cause of Coffin-Siris syndrome and intellectual disability. The gene encodes a DNA-binding non-catalytic protein that is part of the human Brahma-associated factor (BAF) complex. It is found predominantly in neural tissue and thought to be essential for early brain development. To date, more than 170 pathogenic variants have been documented in the Human Gene Mutation Database but the variants in association with CSS are mostly from patients of European ancestry.

We used next-generation sequencing on genomic DNA extracted from venous blood samples from five unrelated patients (2 Chinese, 2 Indians, 1 Malay) who had developmental and speech delay, coarse facies and thick eyebrows. Four had hypertrichosis, low frontal hairline and prominent eyelashes, while only one had hypotonia and ACC. All were full-term births from non-consanguineous parents.

Using the TruSight One targeted panel, a heterozygous variant in the *ARID1B* gene was identified in each of the five patients, with no other pathogenic candidate variants in other genes. All are truncating variants: three were nonsense substitutions (NM\_020732.3 c.3304C>T, c.4216C>T, c.2881C>T) while the other two were deletions of 1 and 8 nucleotides (c.4272delG and c.1153\_1160del) which are predicted to result in frameshifts leading to premature termination of translation from a nonsense codon downstream. Four cases had DNA samples from both parents while the fifth only had the maternal sample. All five variants were not found in the corresponding parental samples tested. Only one variant (c.2881C>T) had been reported previously in three different studies. It is a nonsense mutation and had only one parental sample. There is no existing report in the scientific literature for the remaining four variants, which were also not found in the Genome Aggregation Database, dbSNP, Human Gene Mutation Database, ClinVar, and the Exome Sequencing Project (ESP) databases.

Our finding unveils *ARID1B* variants in association with CSS among multiple ethnic groups from three major ethnic groups in Southeast Asian populations, with phenotypic features highly resembling their Caucasian and Japanese counterparts. Our finding adds to the mutation spectrum of *ARID1B* and confirms that the variants resulting in CSS1 are mostly *de novo* and truncating.

## PgmNr 1228: Global metabolomics facilitates discovery of a novel disorder of the kynurenine pathway.

### Authors:

L.C. Burrage <sup>1</sup>; C.R. Ferreira <sup>2</sup>; N. Ehmke <sup>3</sup>; J.A. Rosenfeld <sup>1</sup>; H. Dai <sup>1</sup>; B. Lee <sup>1</sup>; S. Lalani <sup>1</sup>; S.H. Elsea <sup>1,4</sup>; Undiagnosed Diseases Network

---

Disorders of the kynurenine pathway, which cause NAD (nicotinamide adenine dinucleotide) deficiency, have been associated with multiple congenital malformations reminiscent of VACTERL association. Biallelic variants in *HAAO* and *KYNU*, which encode enzymes (3-hydroxyanthranilic acid 3,4 dioxygenase and kynureninase, respectively) in the tryptophan catabolic pathway and *de novo* NAD synthesis pathway, are associated with cardiac, renal, vertebral, and limb malformations. Embryonic deficiency of NAD is the suspected mechanism underlying these congenital malformation syndromes, and supplementation with niacin during pregnancy prevents the defects in a mouse model of this disorder. We tested whether plasma and urine global metabolomic profiling (Global MAPS™) identifies defects in the kynurenine pathway using samples from two individuals with congenital cardiac defects, vertebral abnormalities, limb abnormalities and biallelic variants in *KYNU*. Marked elevations in metabolites upstream of the metabolic block were identified in urine (mean 3-hydroxykynurenine Z score = 8.03; mean xanthurenate Z score = 5.84; mean kynurenine Z-score = 2.8) and in plasma (mean Z score xanthurenate = 7.54). A reduction of metabolites downstream of the metabolic block was also confirmed in urine (mean picolinate Z score = -3.81; mean quinolinate Z score = -5.25). We have recently identified two siblings enrolled in the Undiagnosed Diseases Network with complex congenital cardiac defects, vertebral and rib anomalies, short stature, and small kidneys. Exome sequencing revealed that these siblings share biallelic variants in the gene encoding kynurenine 3-monooxygenase (*KMO*), which catalyzes the enzymatic step upstream of kynureninase. Global metabolomic profiling in plasma from one of these siblings revealed elevations in kynurenine (mean Z score = 6.35) and kynurenate (mean Z score = 8.84) and a reduction in quinolinate (mean Z score = -2.73), confirming that this deficiency in kynurenine 3-monooxygenase likely represents a novel defect in the kynurenine pathway that also causes embryonic NAD deficiency and complex congenital malformations. Overall, our studies demonstrate that global metabolomic profiling in plasma and urine may facilitate the diagnosis of kynurenine pathway defects and supports the discovery of a novel defect in this pathway. Future studies are necessary to test whether niacin rescues this congenital malformation syndrome caused by congenital NAD deficiency.

## PgmNr 1229: *De novo* missense variant in the kinetochore-associated *NUF2* gene in a male patient with intra-uterine growth retardation and microcephaly.

---

Mutations in proteins involved with cell division and chromosome segregation, such as microtubule-regulating, centrosomal and kinetochore-associated proteins, have been reported to be associated with microcephaly and/or intra-uterine growth retardation (IUGR). In particular, the kinetochore plays a critical role for mitosis and cell division by mediating interactions between chromosomal DNA and spindle microtubule to direct proper chromosome alignment and segregation. To date, a few genes encoding for proteins of the kinetochore complex have been identified as causes of syndromes that included microcephaly and/or IUGR, namely *CENPE*, *CASC5*, *CHAMP1* and *BUB1B*. Here we report a male patient detected with a rare *de novo* *NUF2* missense variant after trio whole-exome sequencing analysis. The patient was born with IUGR and microcephaly, with additional features including low-set ears, micrognathia and atrial septal defect. *NUF2*, located at 1q23.3, encodes a component of the outer kinetochore-associated NDC80 complex, a highly conserved complex crucial for proper microtubule binding and spindle assemble checkpoint. The mutated residue is located at the N-terminal domain superfamily of *NUF2*, which is known to interact with the N-terminus portion of the NDC80 protein. Analysis with a patient-derived lymphoblastoid cell line showed that *NUF2* is decreased at protein levels. Moreover, NDC80 is downregulated in lysates from patient-derived cells. The variant detected in the proband is predicted *in silico* to cause loss of hydrophobic interactions in the core of the protein, thereby the stability of the N-terminal interaction of *NUF2*-NDC80 might be impaired. Functional *in vitro* assays are being carried out in order to establish a causal role of the mutation in the patient's phenotype. *NUF2* might be a candidate for IUGR/microcephaly, and if so, it would be the first component of the NDC80 complex to be implicated with such features.

## PgmNr 1230: Genome sequencing analysis of a family with a child displaying severe abdominal distention and recurrent hypoglycemia.

**Authors:**

J.L. Liu; G.L. Ding; M.F. Wangler; Z. Sun

[View Session](#) [Add to Schedule](#)

**Affiliation:** Baylor College of Medicine, Houston, TX.

---

We report a boy who developed severe progressive abdominal distention due to a dramatic adipose mass from the age of 7 months. He developed recurrent hypoglycemia that led to seizures at the age of 4 years. Imaging studies supported tumor development from the abdominal white adipose tissue. We performed whole-genome sequencing using blood DNA from the child and his parents. The child inherited a single-nucleotide deletion NM\_000314.6:c.849delA (p.Glu284Argfs) in the tumor suppressor gene *PTEN* (phosphatase and tensin homolog) from his father. The paternal family members have a history of cancers. It is conceivable that *PTEN* loss-of-function induced the adipose tumor growth and hypoglycemia, although the proband did not meet the usual diagnosis criteria of Cowden syndrome or Bannayan-Riley-Ruvalcaba syndrome that are characterized by germline mutations of *PTEN*. This case underlines the variability of phenotypes associated with *PTEN* germline mutations and provides useful information for diagnosis and genetic counseling of *PTEN*-related diseases for pediatric patients.

# PgmNr 1231: Knockdown of *pgap3* in zebrafish uncovers an early neural tube phenotype associated with hyperphosphatasia and mental retardation syndrome in humans.

## Authors:

S. Da'as <sup>1</sup>; W. Aamer <sup>1</sup>; W. Hasan <sup>1</sup>; K. Zamel <sup>1</sup>; M. Stotland <sup>1</sup>; K. Fakhro <sup>1,2,3</sup>

Recessive mutations in Post-GPI attachment to proteins 3 (*PGAP3*), encoding glycosylphosphatidylinositol (GPI)-specific phospholipase protein cause the rare neurologic disorder hyperphosphatasia with mental retardation syndrome 4 (HPMRS4). HPMRS4 is characterized by severely delayed psychomotor development, seizures, hyptonia and dysmorphic facial features. Here, we report a novel homozygous *PGAP3* nonsense mutation, c.265C>T - p. Gln89\*, in a 3-year-old boy, presenting with global developmental delay, speech impairment, seizures, hypotonia, dysmorphic features, cleft palate, low sets of ears, partial agenesis of corpus callosum and elevated alkaline phosphatase serum levels. Given that complete loss of GPI anchors in mouse cause embryonic lethality, we examined the functional consequences of transient knockdown of *pgap3* by morpholino in developing zebrafish embryos. Morphants displayed a HPMRS4-like features of developmental delay, brain abnormalities, dysmorphic head features, hyptonia and seizure. Notably, we observed defective neural tube formation during early stages of development, a phenotype never documented before in humans, which may play a yet uncharacterized role of *pgap3* pathogenesis at early stages of nervous system development. Significantly, *pgap3* loss disrupted midbrain and hindbrain formation by creating a separation of the left and right tectal ventricles, and defects in cerebellar corpus and caudal hindbrain formation. Finally, assessment of neuromuscular response revealed epileptic-like movements during the initial phases of development, followed by seizure-like symptoms, loss of touch response and hypotonia, all mimicking human patients' clinical phenotypes. In conclusion, we investigated *pgap3* knockdown genetic model in a vertebrate species and reveal new and important roles of this gene that may have during the nervous system development and wiring of the brain.

**Keywords:** Hyperphosphatasia mental retardation syndrome 4 (HPMRS4), Post-GPI attachment to proteins 3 (PGAP3), zebrafish model, neural tube defect, corpus callosum.

## PgmNr 1232: Characterization of phenotype - genotype of a cohort of patients with Fanconi anemia in Colombia.

---

**Introduction:** Fanconi anemia is a hereditary disease that presents with congenital malformations and affect different system; has bone marrow failure and predisposition to develop malignant tumors, which affect the patient's prognosis. The diagnosis is based on clinical suspicion and confirmation in genetic studies, where the chromosomal fragility test and sequencing of genes through next-generation sequencing (NGS) are preferred. Clinical expressivity, genetic heterogeneity and limited information in Colombia are factors that make it difficult to diagnose.

**Objective:** Characterization of phenotype-Genotype of a cohort of individuals diagnosed with Fanconi anemia by cytogenetic test and molecular study.

**Methodology:** Patients were recruited from several hospitals in the country and signed a consent to participate in the study. They underwent the cytogenetic test of hypersensitivity to the crosslinking agent (diepoxybutane). In all positive cases, MLPA was performed for the FANCA gene and/or analysis of FANC genes by Next-generation sequencing. We took the clinical and paraclinical data from the medical history, and patients were cited to complete physical examination.

**Results:** 191 individuals were analyzed by DEB sensitivity test; 42 had a positive sensitivity test. 19 patients were positive for a pathogenic variant in FANCA gene and 1 in FANCD2. In the cohort 24 men (57%) and 18 women (43%) were found, with an average age of 9.3 years, the age range was 10 months to 57 years. 26% of the patients were children of consanguineous parents. The most common clinical feature was hematological involvement, followed by alterations in the skeletal system, mainly in the thumbs; in the skin with hyper and hypopigmented lesions and anomalies in the facial phenotype. The age of onset of the hematological involvement was at 6.8 years, started with a commitment of a single cell line and progression to bone marrow failure.

**Conclusion:** The cohort studied with Fanconi anemia presents similar characteristics to those reported in the literature worldwide. We didn't have a phenotypic characterization of our population. Cytogenetic and molecular studies allow to confirm diagnoses of diseases with shared symptoms, facilitated the development of knowledge of the phenotype-genotype relationship, as well as that of physiopathology, which drives new research for the development of new drugs, which impacts in morbidity and mortality.

## PgmNr 1233: Linked-read whole genome sequencing identifies biallelic mutations in *DONSON* as a novel cause of Meier-Gorlin syndrome.

---

Linked-read whole genome sequencing presents a new opportunity for cost-efficient singleton sequencing in place of traditional trio-based designs, while generating informative phased variants – effective for recessive disorders when parental DNA is unavailable. We have applied linked-read WGS to identify novel causes of Meier-Gorlin syndrome (MGORS), a condition recognised by short stature, microtia and patella hypo/aplasia. There are eight genes associated with MGORS to date, all encode essential components involved in establishing and initiating DNA replication. Our successful phasing of linked-read data led to the identification of biallelic rare variants in four individuals (24% of cohort) in *DONSON*, a recently established DNA replication fork surveillance factor. The variants include five novel missense variants and one deep intronic variant. All were demonstrated to be deleterious to function; the missense variants all disrupted the nuclear localisation of *DONSON*, while the intronic variant created a novel splice site which generated an out-of-frame transcript with no residual canonical transcript produced. Variants in *DONSON* have previously been associated with extreme microcephaly, short stature and limb anomalies (MISSLA) and perinatal lethal microcephaly-micromelia syndrome (MIMIS). Our novel genetic findings extend the complicated spectrum of phenotypes associated with *DONSON* variants and promote novel hypotheses for the role of *DONSON* in DNA replication. While our findings reiterate that MGORS is a disorder of DNA replication, the pathophysiology is obviously complex. This successful identification of a novel disease gene for MGORS highlights the utility of linked-read WGS as a successful technology to be considered in the genetic studies of recessive conditions.

## PgmNr 1234: 1p36 deletions: One cytogenetic band, multiple genetic syndromes and disease genes.

---

Deletions of chromosome 1p36 are the most common terminal deletions in humans and affect approximately 1 in 5000 newborns. 1p36 deletion syndrome is characterized by intellectual disability, a spectrum of functional and structural birth defects, and characteristic dysmorphic features. Distal and proximal critical regions for 1p36 deletion syndrome have been defined. Individuals with deletions that do not contain these critical regions do not have the characteristic features of 1p36 deletion syndrome and should be considered to have distinct genetic syndromes. The heterogeneous nature of 1p36 deletions, and an incomplete understanding of the role of individual 1p36 genes, makes it difficult for physicians to provide accurate prognostic information to families, and to create personalized medical plans for affected individuals. To overcome these obstacles, we have generated deletion/phenotype maps using clinical and molecular data from over 200 individuals with isolated 1p36 deletions. Using these maps, we have delineated non-overlapping 1p36 critical regions for seizures, sensorineural hearing loss, cleft lip/palate, congenital heart defects, cardiomyopathy, and renal anomalies. Many of these critical regions encompass genes that have been previously associated with these phenotypes in humans and/or mice. Using this information, physicians can readily identify individuals who are at risk for these phenotypes. We have also annotated the locations of 1p36 genes that have high loss-of-function intolerance scores (pLI > 0.8). Many of these genes have yet to be associated with a particular human phenotype. However, data from mouse models, and the clinical phenotypes of individuals with small deletions and/or loss-of-function variants suggest that haploinsufficiency of a subset of these dosage-sensitive genes may contribute to important 1p36 deletion phenotypes including intellectual disability (*SPEN*, *TP73*, *DNAJC11*, *CLSTN1*, *UBE4B*, *UBR4*, *WASF2*), seizures (*KCNAB2*), orofacial clefting (*SKI*), congenital heart defects (*CASZ1*, *SPEN*, *UBR4*, *ELOA*, *WASF2*), cardiomyopathy (*UBE4B*), and obesity (*WDFC1*). We conclude that many 1p36 deletions are associated with unique genetic syndromes whose phenotypic patterns are distinct from those described by 1p36 deletion syndrome. The distinctive phenotypic patterns of 1p36-related syndromes are caused by haploinsufficiency of dosage sensitive genes that can be identified using a combination of mouse models and human data.

## PgmNr 1235: Identification of a *TP63* pathogenic variant (c.797G>A) in a Mexican family with ADULT syndrome in the father and EEC syndrome in his son.

### Authors:

*TP63* gene pathogenic variants (MIM 603273) causes the syndromes acro-dermato-ungual-lacrima-tooth (ADULT, MIM 103285), Rapp-Hodgkin (MIM 129400), ectrodactyly, ectodermal dysplasia, and cleft lip/palate (CLP) 3 (EEC3, MIM 604292), Hay-Wells (MIM 106260), limb-mammary (MIM 603543), orofacial cleft 8 (MIM 618149), and split-hand/foot malformation 4 (MIM 605289). Overlapping phenotypic features between these syndromes hamper the genotype-phenotype correlation in some families. Here, we report a Mexican family with ADULT syndrome in the father and EEC syndrome in his son due to a *TP63* mutation (c.797G>A). The father had only subtle features of ADULT syndrome, which included dental anomalies (agenesis of the right upper permanent lateral incisor, and a conical-shaped left upper lateral incisor), surgically treated nasolacrimal duct obstruction (NLDO) during infancy, and repetitive episodes of urinary retention until adolescence, with otherwise normal physical exam. His son showed tetraectrodactyly, chronic conjunctivitis, bilateral NLDO, lacrimal fistulae, and mild ectodermal signs (thin and sparse hair, brittle nails), indicative of EEC syndrome without CLP. In both, transpiration was referred as normal. By direct sequencing, the father and his son showed the same *TP63* pathogenic variant (c.797G>A). This family showed striking similarities with those included in the molecularly unconfirmed entry of “NLDO and cleft hands syndrome” in the London Medical Databases. The mutation found in our family has been previously reported in three families with EEC syndrome, and in another with ADULT syndrome. A common feature reported to this mutation is the micturition problems beginning in infancy and improving during adolescence, as in the father of our family. This report confirms that the c.797G>A *TP63* mutation can produce variable and subtle intrafamilial manifestations of the ADULT (lacrimal, tooth anomalies and urinary retention) and EEC3 (ectrodactyly and ectodermal manifestations) syndromes, and probably, also explains the proposed entity previously denominated as “NLDO and cleft hand syndrome”.

## PgmNr 1236: Functional characterization of lymphatic anomaly-associated, ERK-activating mutations in primary lymphatic endothelial cells.

Central conducting lymphatic anomaly (CCLA) is a rare, congenital, and progressive disorder in development of lymphatic vessels and architecture. The standard therapy for lymphatic anomaly is rapamycin (Sirolimus). We recently published a report of a subject unresponsive to rapamycin, in whom we identified an activating mutation in *ARAF*. This mutation strongly activated ERK signaling when retrovirally transduced into lymphatic endothelial cells, causing morphological changes that were reversible through treatment with MEK inhibitors. The patient showed dramatic improvement upon treatment with a MEK inhibitor. As a follow up to this report, we are continuing analysis of mutations discovered in exomes of CCLA patients that fail to respond to rapamycin. Several mutations have been found in genes that influence the ERK signaling pathway. Preliminary results from analysis of mutations in the *KRAS*, *BRAF*, and *RAF1* genes indicate activation of ERK signaling, changes in cell morphology, and reversibility with inhibitors of the ERK pathway, consistent with observations with the *ARAF* mutation. We have also observed a lack of activation of signaling pathways downstream of mTOR, possibly providing a molecular explanation for the failure to respond to rapamycin. Our results suggest the existence of a category of CCLA patients that would benefit from treatment with inhibitors of ERK signaling.

## **PgmNr 1237: Bifid nose with or without anorectal and renal anomalies (BNAR) syndrome: Congenital heart disease belongs to the clinical spectrum.**

*FREM1*-related autosomal recessive disorders include Manitoba oculotrichoanal (MOTA) syndrome, bifid nose with or without anorectal and renal anomalies (BNAR) syndrome and isolated congenital anomalies of kidney and urinary tract (CAKUT). It is a very rare group of disorders with only a few cases reported so far. To date, the authors are aware of 10 published individuals presenting as BNAR syndrome (Al-Gazali, 2002; Alazami, 2009). All of them belong to three consanguineous families of Egyptian, Afghani, and Pakistani ancestry. We report here 2 additional cases in siblings born to Turkish consanguineous parents. Both have the characteristic facial appearance with a bifid nose, unilateral renal agenesis in one of them, and no anorectal anomalies. Interestingly, one of them, a boy has a hitherto unreported congenital heart disease, namely Ebstein malformation. A homozygous *FREM1* exons 18-30 deletion has been identified in brother and sister. By virtue of so-called congruence, two additional autosomal recessive conditions segregate independently in this endogamic family: a nephrotic syndrome due to biallelic *ADCK4* mutation in four first cousins and autoimmune polyendocrinopathy syndrome type I (APECED) due to biallelic *AIRE* variant in two other cousins. Apart from expanding the clinical spectrum of BNAR syndrome, the current family report illustrates the burden of autosomal recessive conditions in endogamic populations.

## PgmNr 1238: A genetic two-hit mechanism drives vascular malformation in hereditary hemorrhagic telangiectasia.

---

Hereditary Hemorrhagic Telangiectasia (HHT) is a Mendelian disease characterized by vascular malformations including visceral arteriovenous malformations and mucosal telangiectasia. HHT is caused by loss-of-function (LOF) mutations in one of 3 genes; *ENG*, *ACVRL1* or *SMAD4* and is inherited as an autosomal dominant condition. Intriguingly, the constitutional mutation causing HHT is present throughout the body, yet the multiple vascular malformations in HHT patients occur focally, rather than manifesting as a systemic vascular defect. This disconnect between genotype and phenotype suggests that a local event is necessary for the development of vascular malformations. We investigated the hypothesis that one trigger for HHT-associated vascular malformations is somatic mutation resulting in biallelic loss of *ENG* or *ACVRL1*. We performed targeted deep sequencing on 20 punch biopsies of telangiectasia, followed by amplicon resequencing, to identify and validate LOF somatic mutations. Somatic mutations were identified in 9/20 telangiectasia with allele frequency ranging from 0.5 to 9%; 5 in *ENG* and 4 in *ACVRL1*. The mutations consisted of 5 indels causing frameshifts, 3 in-frame deletions, and 1 variant predicted to affect splicing; all consistent with LOF. Notably, across our capture panel of 16 vascular malformation-related genes, somatic mutations were exclusively present in the same gene as the constitutional mutation. We established phase for 7 of 9 samples using long-read sequencing, which confirm that the germline and somatic mutations in all 7 samples exist in *trans* configuration; consistent with a genetic two-hit mechanism. Additionally, multiple telangiectasia removed from singular patients contain unique somatic mutations; providing evidence that telangiectasia do not arise from a metastasis-like mechanism but rather from independent mutation events. Although somatic mutations were only found in 9/20 samples, the technical limitations of targeted short-read sequencing preclude the discovery of large indels, mitotic recombination, or epigenetic alterations; any one of which would generate loss of heterozygosity. These common molecular events may seed vascular malformation in a significant portion of telangiectasia. These combined data suggest that biallelic loss of *ENG* or *ACVRL1* may be a required event in the development of telangiectasia, and that rather than haploinsufficiency, vascular malformations in HHT is caused by a Knudsonian two-hit mechanism.

---

The advent of next generation sequencing has a tremendous impact on the study of rare mendelian diseases, which a large proportion has no defined genetic cause. Furthermore, opportunities emerge in populations that experienced long history of genetic and cultural isolation, where the successive accumulation of recessive traits provides favorable ground for studying rare monogenic disorders. As many of the Middle-Eastern populations fit into these criteria, we have established an integrated clinical and research program that focuses on recruiting families of cases with undiagnosed phenotypes or uncommon clinical presentations, including structural deformities and developmental disorders. The program utilizes the power of whole genome sequencing technology and a computational pipeline with the capacity of identifying, both, single nucleotide variants (SNVs) and copy number/structural variants (CNVs/SVs). The potential variants then undergo a prioritization scheme to narrow down the list of candidate genes, which is further prioritized, either by evidence from medical literature, or experimentally validated through functional studies. This collaborative effort of clinicians, geneticists, bioinformaticians, and experimental biologists, so far, has recruited fifty-five families (264 subjects), forty-five (~80%) of which are already sequenced and analyzed. Among those analyzed, a known causative gene was identified in eight families (18%) and in another two (4%), novel genes are being verified through functional studies in zebrafish. The translational impact and the multidisciplinary nature of the program offers ample opportunity for collaboration, education of junior clinicians and biologists, and ultimately it establishes Sidra Medicine as a regional hub of genomic medicine.

## PgmNr 1240: Nucleolar alterations and premature senescence in *POLR3A*-mutated Wiedemann-Rautenstrauch syndrome fibroblasts.

### Authors:

---

**Introduction:** Recently mutations in *POLR3A* have been described as the cause of a rare neonatal progeria known as Wiedemann-Rautenstrauch syndrome (WRS). *POLR3A* is one of the two catalytic subunits of RNA polymerase III, which have important roles in the regulation of transcription of small RNAs, including transference RNA (tRNA), the 5S subunit of ribosomal RNA (5S rRNA), U6 small nuclear RNA (U6 snRNA), between others. However, the contribution of *POLR3A* mutations to cellular senescence and aging remains largely unknown. **Aim:** to describe diverse cellular features of fibroblast derived from one WRS patients and compared it with control fibroblasts. **Materials and methods:** Cultures of primary fibroblasts from one WRS patient [monoallelic *POLR3A* variant c.3772\_3773delCT (p.Leu1258Glyfs\*12)] (Paolacci et al., 2018) and one control were grown. Senescence was analysed by B-galactosidase and P16 expression. Morphology and volumetric analysis of nucleus (lamin A and hoescht staining) and nucleolus (fibrillarin) were analysed by immunostaining using confocal microscopy. Expression of proteins (*POLR3A*, Lamin A, P53, H2A) was evaluated by Western blot and inmunohistochemistry. **Results:** WRS fibroblasts become senescent (increased expression of beta/galactosidase, P16 and P53) in earlier culture passages as compared to control cells, and not associated with changes in nuclear morphology (nuclear blebs and progerin expression) as observed in HGPS cells. However, WRS nuclei are significantly larger. Mutation in *POLR3A* in the present case is associated to deletion of 5 amino acids, which causes changes in the expression of the protein. These changes were associated to an increase number of nucleoli and P53 expression. **Conclusions:** Mutations in *POLR3A* associated to WRS cause an early senescent phenotype in fibroblast associated to alterations in the number and structure/area of nucleolus. The present observations add to our understanding of the differences between HGPS and WRS, and opens new alternatives to study cell senesce and human aging.

## PgmNr 1241: Using suppressor tRNA to rescue protein production in rare genetic diseases caused by nonsense mutations.

### Authors:

---

Genetic diseases can be caused by a variety of mutation types including missense, nonsense, frameshift, and splice site alterations. Of these, nonsense mutations account for about 11% of all inherited diseases and are particularly hard to treat due to absence of protein for the affected gene allele. We have tested a nonsense suppressor tRNA for its ability to rescue protein production for a single base pair substitution in the *CLDN1* gene [MIM 603718] which is reported to cause the ultra-rare Mendelian disease neonatal ichthyosis-sclerosing cholangitis syndrome (NISCH [MIM 607626]), and are evaluating its potential in other rare diseases.

Nonsense suppressor tRNA's are modified transfer RNA's that can incorporate an amino acid at a stop codon. Our construct causes an amino acid residue to be inserted at UGA stop codons, suppressing termination and allowing full-length protein to be produced. To test *CLDN1* protein production, transgenes encoding a fusion protein of *CLDN1* with mCherry were expressed in liver (HepG2) and intestinal (Caco2) cell models. Two versions, wild-type *CLDN1* and *CLDN1* harboring a premature stop codon (c.192 C>A, p.C64X), were compared along with negative controls. The transgenes were expressed with and without suppressor tRNA treatment and assessed for mCherry fluorescence and cellular localization using a high content imaging system.

With nonsense suppressor tRNA treatment, the p.C64X mutant *CLDN1*-mcherry expression was rescued to 42.73% of wild type levels. Further analysis will be done to determine if the newly produced protein is functional as it now contains a different amino acid at position 64. These results indicate that suppressor tRNA therapy has potential to increase protein production in diseases caused by nonsense mutations. This work is currently being expanded to include other mutations and diseases including cystic fibrosis (CF [MIM 219700]) and glycogen storage disease type 1a (GSD1a [MIM 232200]). Additional work is being done to develop suppressor tRNA constructs that target other nonsense mutations and deliver different amino acids so that they can be applied to a broader range of nonsense mutations.

## PgmNr 1242: A homozygous TANGO2 deletion identified in a Brazilian patient.

---

The etiology for a significant fraction of recurrent rhabdomyolysis is still unclear, with a few known genetic causes. Using whole exome sequencing (WES), we identified a homozygous TANGO2 gene deletion in a Brazilian 8 years old girl. She presented recurrent episodes of flaccid tetraparesis and rhabdomyolysis with extreme hyperCKemia (highest known level 147,780 U/L) since 2 years of age, worsening with aging. She also presented global developmental delay, moderate intellectual disability and seizures. No prenatal and birth issues. She was born from a consanguineous couple from southern Brazil, with German ancestry. At age 7, she was evaluated by a medical genetics team. Initial workup was directed to the major differential diagnosis of episodic rhabdomyolysis (Fatty acid beta-oxidation disorders, Glycogen storage disorders), but the extreme hyperCKemia led to TANGO2-related disorder suspicion. Hypothyroidism and severe cardiac dysfunction due to arrhythmias, especially ventricular tachycardia, were also observed, establishing the clinical diagnosis, confirmed then by WES. PCR and SNP array data confirmed the previously reported exons 3-9 deletion in homozygosis. TANGO2-related disorder is a recently reported autosomal recessive condition, which phenotypic spectrum has been expanded since the first reports in 2016, by two independent groups. Several cases have been reported since then, most relying on next-generation sequencing (NGS) strategies. The approximately 34-kb deletion was observed in many cases, and the authors found a minor allele frequency (MAF) of 0.0026-0.13% in European populations and 0.26% in Hispanic/Latino population from control subjects databases. MAF in the Brazilian population is not available, but due to the high ethnic diversity, it is probably different from those previously stated. TANGO2 function and TANGO2-related disorder pathogenesis are not fully understood, although the TANGO family is predicted to contribute in secretory protein loading from Golgi to the endoplasmic reticulum; in mouse tissue culture cells, however, TANGO2 protein co-localizes with a mitochondrial protein. Probably the complex molecular genetics leads to the heterogeneous phenotype. To estimate the common deletion carriers frequency, a 1,000 healthy individuals from southern Brazil screening is ongoing.

## PgmNr 1243: A biallelic *TMEM251* variant in patients with severe skeletal dysplasia, coarse facial features, and early lethality.

---

Skeletal dysplasias are a clinically and genetically heterogeneous group of disorders ranging in severity from mild to lethal forms. Several metabolic disorders, such as lysosomal storage disorders and congenital disorders of glycosylation, include skeletal dysplasia as part of their clinical manifestations. We investigated a consanguineous family with five individuals affected by a recessively inherited progressive disease involving skeletal dysplasia similar to dysostosis multiplex and severe short stature (height SD score <-8.5). Two oldest affected individuals died during the course of this study before the age of 30 years while the others were less than twenty years old. The disorder was reminiscent of mucopolysaccharidosis and mucopolysaccharidosis, with affected individuals manifesting increasing coarsening of facial features, protruding abdomen, and progressive worsening of skeletal dysplasia with age. The patients had gradual loss of mobility, with the oldest being bed ridden. Using whole-exome sequencing we identified a biallelic missense variant affecting both isoforms of *TMEM251* which co-segregated with the disorder in the family. Variants in all other known genes for mucopolysaccharidosis and mucopolysaccharidosis were excluded by the sequencing data. *TMEM251* is an evolutionary conserved (0.69 Z score and 21.351 GDI score), ubiquitously expressed gene. The identified variant was predicted to be damaging by all used software, affected an amino acid which is conserved in diverse vertebrate species, and was absent from public databases and DNA of 190 ethnically matched controls. We determined that *TMEM251* is a transmembrane protein which localizes to the Golgi complex and plasma membranes in human osteosarcoma cell lines. However, mutant *TMEM251* protein with the identified variant was targeted less efficiently to the membranes and the localization was punctate as compared to the wild-type protein. In addition, *Tmem251* knockdown with small interfering RNA induced dedifferentiation of rat epiphyseal chondrocytes without significantly affecting apoptosis of these cells. Our findings implicate *TMEM251* in genetics of a new disorder and suggest a possible role of the encoded protein in differentiation of chondrocytes. Funded by Swedish Research Council, Sweden, Koshish Foundation USA & Higher Education Commission, Pakistan.

## PgmNr 1244: Detailed clinical description of hyaline fibromatosis syndrome patients in Japan.

### Authors:

H. Futagawa <sup>1</sup>; S. Ito <sup>2</sup>; M. Honda <sup>3</sup>; H. Yoshihashi <sup>1</sup>

---

**Introduction** Hyaline Fibromatosis Syndrome (HFS; MIM#228600) is a rare autosomal recessive congenital disorder of the connective tissue caused by (the loss-of-function mutations) mutation in the anthrax toxin receptor-2 (*ANTXR2*) gene (located on chromosome 4q21). It is characterized by accumulation of the hyalinized fibrous tissue with cutaneous, mucosal, osteoarticular and systemic involvement including painful multiple joint stiffness and gingival hyperplasia. Although more than 70 cases have been reported worldwide, reports from Japan are scarce. Here, we report four cases of HFS presented to our hospital.

**Cases** The four Japanese subjects aged between eight months and eight years are presented here. Three cases were genetically diagnosed. Their birth weight ranged from 2546g to 3228g. All cases had failure to thrive (present body weight is between -3.1SD and -2.3SD), arthrogryposis multiplex congenita (multiple joint stiffness), skin nodules, gingival hyperplasia, trismus and bone lesions of X-ray as previously reported. In three cases, chronic pain due to physical stimulation, susceptibility to infection and curly nails were also observed. Interestingly, most of our cases (3/4) had pruritic skin nodules although they could not scratch because of arthrogryposis. Half of the subjects had chronic diarrhea. A single case diagnosed as protein losing gastroenteropathy died at three years of age due to multiple organ failure. None had intellectual disability or verbal communication problem.

**Discussion** In all cases, progressive arthrogryposis preceded the appearance of skin nodules and gingival hyperplasia and thus, compatible with HFS. The pruritis of skin nodules which the present cases suffered has not been previously reported and should be noted during the management. As presented, there should be more emphasis on deteriorating the living quality of subjects with HFS due to the pruritis.

**Conclusion** Recognizing the gradually progressive physical symptoms are essential in total health management of HFS.

## PgmNr 1245: Familial cases of DeSanto Shinawi syndrome with previously unreported nonsense and missense variants in *WAC* .

### Authors:

M. Shinawi <sup>1</sup>; J. Fleischer <sup>2</sup>; H. Andersson <sup>3</sup>; L. White <sup>1</sup>; S. Hughes <sup>4</sup>; T. Hsu <sup>1</sup>

---

**Background:** DeSanto Shinawi (DESSH) syndrome is an autosomal dominant disorder caused by loss of function pathogenic variants in *WAC*. It is characterized by variable degree of developmental delay/intellectual disability (DD/ID), behavioral abnormalities, hypotonia, and recognizable facial features. Up until now, 20 patients were reported with *de novo* variants (10 nonsense, 7 frameshift, 1 splicing, 1 deletion) with 1 familial recurrence due to a presumed germline mosaicism.

**Methods:** Clinical and molecular characterization of two families with predicated pathogenic variants in *WAC* detected via exome sequencing. Clinical data were obtained by retrospective chart review and direct patient interaction with providers.

**Results:** The proband in Family I is a 6-year-old female who presented with DD, dysmorphic features, microcephaly and poor weight gain and later diagnosed with autism and ADHD. Exome sequencing revealed a maternally inherited nonsense variant in *WAC*: c.25C>T;p.Gln9\*. The proband's brother and maternal grandmother were carriers for same variant. All affected family members exhibited DD/ID, ADHD, autism or autistic traits and a few dysmorphic features. The proband in Family II is an 8-year old female who presented with ID/DD, ADHD, and autistic features. Her 29-year-old mother exhibited ID, ADHD, bipolar disorder and depression. The proband and her mother had eye refractive errors and shared a few dysmorphic facial features. Exome sequencing found a maternally inherited heterozygous missense variant in *WAC*: c.1738G>A;p.Glu580Lys. Glu580 is evolutionary conserved and the variant is absent from population databases and predicted to be deleterious based on *in silico* tools (CADD score of 41).

**Conclusion:** To our knowledge, these are the first reported cases of familial DESH syndrome and the first reported family with a missense variant in *WAC*. The patients exhibited similar neurobehavioral profile to previously reported case but facial features and lack of hypotonia were different. The implications of our results: 1) pathogenic variants in *WAC* can be inherited and therefore testing parents is recommended for genetic counseling purposes; 2) reduced penetrance for certain phenotypes and variable expressivity should be thoroughly discussed when families are counseled; 3) patients with DESH syndrome can be fertile and conceive children; 4) adult patients with DESH syndrome exhibit no signs or symptoms of developmental regression or neurodegeneration.

## PgmNr 1246: The challenge of recognizing phenotype-genotype correlations in prenatal exome sequencing.

Whole exome sequencing (WES) has been used recently to identify genetic etiology of fetal structural abnormalities which other diagnostic methods failed to uncover. We report WES analyses of two fetuses in a family in which the mother had three adverse pregnancies. The first fetus was stillbirth at 24 weeks of gestation. The second had abnormal posture of both hands and feet, skin edema, polyhydramnios, and micrognathia at 27 weeks. The third fetus was similarly affected with fetal scalp edema, asymmetrical lower limbs, large hands and feet, and micrognathia at 22 weeks. WES analysis of the POC sample from the third fetus and the parents identified compound heterozygous variants c.512G>T (p.R171L) and c.511C>T (p.R171W) in the ALG3 gene. Sanger studies showed that the second fetus is compound heterozygous for the ALG3 variants too. ALG3 is associated with congenital glycation disorder (CDG-Id), an autosomal recessive disorder caused by glycoprotein biosynthesis defect resulting in multiple affected systems particularly nervous system. The two rare variants have not been previously reported in patients. Another variant affecting the same codon, c.512G>A (p.R171Q), was reported as disease causing in multiple patients; in addition, multiple in silico prediction programs indicate that the two variants in this study are possibly damaging. So far only about 10 patients have been reported to have CDG-Id in the literature. No prenatal phenotype of CDG-Id is available in the OMIM database, and the postnatal phenotype summarized in OMIM does not seem to overlap well with those of fetuses in this study. Further literature search identified two sisters affected prenatally with CDG-Id. The phenotypic features overlap well with those in our fetuses, including prenatal development delay, micrognathia, multiple skeletal abnormalities, skin edema, cerebellar hypoplasia and partial corpus callosum agenesis and pontocerebellar hypoplasia. Based on collective data, we determined that the two variants may be related to the prenatal phenotype. This case highlights the challenge of phenotype correlation in prenatal WES analysis due to lack of information of prenatal phenotype for genetic disorders. The current disease databases usually only include postnatal phenotypes. It would be beneficial to integrate both prenatal and postal phenotypes in such databases, which will greatly facilitate fetal WES analysis.

## PgmNr 1247: Glutamic acid residue in basic domain of *BHLHA9* regulates transcription efficiency.

Embryonic limb development is a highly co-ordinate and complex process involving growth and apoptosis in synchronization. Regulation of multiple genes through transcription and dosage dependent signals are involved in regulation of molecular and cellular activities during limb development. We reported c.220\_221delinsTT variant in *BHLHA9* responsible for Complex Camptosynpolydactyly (MIM: 607639) a complex type of hand (limb) malformation characterized by grossly malformed hands, digits arising from dorsum of hand, polydactyly and soft tissue syndactyly of toes. This is an only report on such hand malformation till date of study. *BHLHA9* located on chr17p13.3 encodes for bHLH (basic helix loop helix) transcription factor and previously associated with Split Hand and Foot Malformation with Long bone Deficiency 3 (SHFLD3; MIM : 612576) in cases of duplication and Mesoaxial Synostotic Syndactyly with Phalangeal reduction (MSSD; MIM: 609432) for missense variations. Phenotypically MSSD and Complex Camptosynpolydactyly are remarkable different from each other, even though our variants p.Glu74Leu and MSSD variants p.Asn71Asp, p.Arg73Pro, p.Arg75Leu are neighboring location in basic domain of *BHLHA9*. We report on importance of Glutamic acid residue in basic domain of *BHLHA9* in fine tuning of transcription activity. Glutamic acid at 74<sup>th</sup> position in *BHLHA9* is highly conserved across species and other bhlh transcription factors, is the only acidic amino acid present in basic DNA binding domain. *BHLHA9* known to form heterodimer with other transcription factors such as TCF3, TCF4 etc and regulates gene expression by binding to E-box sequences (diverse group of enhancer sequences which are binding site for bHLH transcription factors). Using luciferase assay we demonstrated that MSSD variants show reduced luciferase activity compared to wild type *BHLHA9* and Glu74Leu variant of Complex Camptosynpolydactyly shows elevated activity than wild type *BHLHA9*. Our study highlights the unique property of Glutamic acid residue in basic DNA binding domain in regulation of transcription. We propose that MSSD is caused by loss of function variants and Complex Camptosynpolydactyly is caused due to gain of function variant.

## PgmNr 1248: Clinical exome sequencing data reveals high diagnostic rates and new susceptibility genes for congenital diaphragmatic hernia plus (CDH+).

---

Congenital diaphragmatic hernia (CDH) is a life-threatening birth defect with an incidence of approximately 1 in 4000 newborns. In approximately 40-60% of cases, CDH occurs in conjunction with other non-hernia-related anomalies (CDH+). Although array-based copy number variant analyses are routinely ordered on individuals with CDH+, exome sequencing has not been universally adopted as a diagnostic test in this disorder. Here, we analyze a clinical database of approximately 12,000 cases to determine the diagnostic efficacy of exome sequencing in individuals with CDH+ and to identify new CDH susceptibility genes. In this database, exome sequencing provided a molecular diagnosis in 45 out of 82 CDH+ cases, yielding a diagnostic rate of 47%. When CDH co-occurs with cardiovascular malformations (CVMs), the mortality rate increases from 30 to 60%. In the subset of individuals with this life-threatening combination of defects, the diagnostic rate was also 47% (21/45). We identified multiple individuals with positive exome results who carried putatively pathogenic variants in *KMT2D* (n = 4 Kabuki syndrome 1), *EP300* (n = 2; Rubinstein-Taybi syndrome 2), and *ALG12* (n = 2; congenital disorder of glycosylation 1G). This suggests that these genes/genetic disorders are likely to be associated with an increased risk of developing CDH. We also identified individuals with putatively pathogenic variants in *ANKRD11*, *BRCA2*, *FOXC2*, *FOXP1*, *MED12*, *MCPH1*, *RASA1*, *SMARCA4*, *SMARCC2*, and *TCF12*, all of which have been previously associated with genetic syndromes in humans. Published case reports and/or CHD-specific pathogenicity scores generated using a validated machine learning algorithm provided additional evidence in support of their association with CDH. We conclude that exome sequencing can be used to identify a molecular diagnosis in a high percentage of individuals with CDH+. We have also identified several new genes/genetic disorders that may be associated with increased risk of developing CDH.

## PgmNr 1249: Case report: Compound heterozygous loss of function variants in *MYL9* in a case of megacystis-microcolon-intestinal hypoperistalsis syndrome (MMIHS).

---

Megacystis-microcolon-intestinal hypoperistalsis syndrome (MMIHS), also referred to as “visceral myopathy”, is a severe early onset disorder characterized by impaired muscle contractility in the bladder and intestines. The most well-studied gene associated with cases of MMIHS is *ACTG2*. To date, four other genes have also been linked to MMIHS among children born to consanguineous parents, including *LMOD1*, *MYH11*, *MYLK*, and *MYL9*. Here we present the case of a two-year-old girl with a prenatal diagnosis of bilateral hydronephrosis at 20 weeks and congenital mydriasis (both of which have been previously observed among cases of MMIHS) and a suspected clinical diagnosis of MMIHS based on her presentation with megacystis, lack of urinary bladder peristalsis, and intestinal pseudo-obstruction. After initial sequencing and deletion/duplication analysis of the *ACTG2* was negative, further sequencing and deletion/duplication testing was performed on the *LMOD1*, *MYH11*, *MYLK*, and *MYL9* genes. Our laboratory identified two heterozygous loss of function variants in *MYL9*, an exon 4 deletion and a 9 base pair deletion that removes the canonical splicing donor site at exon 2 (NM\_006097.4:c.184+2\_184+10del). Subsequent parental testing confirmed these variants to be *in trans* in our patient. *MYL9* is located on chromosome 20 and encodes a regulatory myosin light chain protein that is necessary for normal cellular contractility. Of note, the patient's mother (who carries the exon 4 deletion) has a history of chronic constipation. Further, one of the patient's siblings was lost at 20 weeks gestation. The sibling's autopsy results showed a urethral valve anomaly and enlarged bladder, potentially consistent with early signs of MMIHS (the sibling's sample was not available for molecular testing). To our knowledge, only 1 other case of MMIHS has been linked to *MYL9* variants: a homozygous deletion encompassing exon 4 in *MYL9* which was discovered during whole exome sequencing, then confirmed by chromosomal microarray analysis and Sanger sequencing. Furthermore, we were unable to find any previous clinical reports of the splicing variant in our patient. Although this report of a second proband with genetically-confirmed *MYL9*-associated MMIHS does not yet move the gene-disease association beyond “limited” per ClinGen guidelines, we suggest *MYL9* be considered for inclusion on genetic testing panels for MMIHS and perhaps other myopathies.

## PgmNr 1250: Bi-allelic pathogenic variants in *COX6A2* cause a striated muscle-specific cytochrome oxidase deficiency.

---

Cytochrome oxidase (COX) deficiency is genetically and phenotypically heterogeneous disorder characterized by mitochondrial respiratory chain defect. Two unrelated Japanese individuals were suspected to have congenital myopathy but pathologically diagnosed with COX deficiency. Both patients presented limb and facial muscle weakness and hypotonia and one also had cardiomyopathy. Neither patient exhibited involvement from other organs. To isolate a causative gene for COX deficiency which presents with only striated muscle-specific symptoms, we performed an exome sequencing in the patients and identified bi-allelic missense variants in *COX6A2* including a homozygous c.117C>A (p.Ser39Arg), and a compound heterozygous c.117C>A (p.Ser39Arg) and c.127T>C (p.Cys43Arg). *COX6A2* is exclusively expressed in the skeletal muscle and heart. We found the specific reduction in complex IV activities among the enzymes in mitochondrial respiratory chain, complex IV activity in skeletal muscles from both individuals. Assembly of complex IV and its supercomplex formation were impaired in muscles. In muscles of *Cox6a2* knockout mice, both complex IV activities and assembly of complex IV were also diminished. In the patient with *COX6A2* pathogenic variants, the symptoms are theoretically restricted to be seen only in striated muscles due to its expression pattern. Therefore, we proposed that our patients had distinctive characteristics from conventional COX deficiency.

In conclusion, this study indicates that bi-allelic variants in *COX6A2*, as a novel causative gene for COX deficiency, cause a muscle-specific form of COX deficiency.

## PgmNr 1251: Biallelic novel variants in *SPEG* causing arthrogryposis and neuromuscular phenotype.

*SPEG* encodes striated muscle preferentially expressed protein kinase (*SPEG*), which plays an important role in myocyte cytoskeletal development. Biallelic rare *SPEG* missense, nonsense and frameshift variants have been previously reported in 9 individuals in association with centronuclear myopathies (CNM) and dilated cardiomyopathy (DCM). CNMs are a type of congenital myopathy characterized by myopathy, weakness, cardiomyopathy, and ophthalmoplegia in individuals with biallelic *SPEG* variants.

In our study, trio exome sequencing (ES) was performed on three families with probands clinically diagnosed with neuromuscular disorders. The first individual (BAB8532) is a 3 month old girl whose exome showed variants in three genes; a homozygous missense change (c.6971T>A:p.Ile2324Asn) in *SPEG*, a compound heterozygous variant in *MYOM3*, and a *de novo* potentially deleterious heterozygous variant in *CIT*. Phenotypically, she presented with muscle weakness and arthrogryposis. She also had DD/ID and ophthalmoplegia. The second individual (BAB9744) is a 22 year old male with compound heterozygous variants (c.[3941-5G>T];[8026+5G>A]) in *SPEG*. BAB9744 was diagnosed with neuromuscular weakness and DCM. The third individual (BAB10708) is a 4 year old male with muscle weakness and arthrogryposis. Exome sequencing results showed *de novo* variants (c.9575C>A:p.[Thr3192Asn]) in *SPEG* and *TPM2*, and additionally compound heterozygous variants in *ABCA7*; of note, no second variant in *SPEG* was identified in this case, suggesting that *SPEG* may be associated with both dominant and recessively inherited conditions. Though the second variant was not identified it could be due to the deep intronic state of the variant not covered by ES.

Here, we provide 3 additional families with deleterious *SPEG* variants which support *SPEG* as a neuromuscular disorder gene and provide evidence to suggest that *SPEG* may be associated with both dominant and recessive segregation of disease. Variants in *MYOM3* and *CIT* in BAB8532, and *TPM2* and *ABCA7* in BAB10708 contribute to the additional phenotypes presented in each individual. The major presenting features in these cases include muscle weakness (3/3), ophthalmoplegia (1/3), arthrogryposis (2/3) and cardiomyopathy (1/3). The variability in clinical presentation and observed

mode of inheritance illustrate the potential contribution of development of a *SPEG* allelic series to fully elucidate genotype-phenotype correlations.

## PgmNr 1252: VCP inhibitor as a potential therapy for VCP myopathy and ALS.

### Authors:

V. Kimonis; L. Weiss; C. Cheng; L. Ta; G. Bonesteele; T. Ton

[View Session](#) [Add to Schedule](#)

**Affiliation:** Div Gen, Dept Pediatrics, Univ CA Irvine, Orange, California.

**Background:** Valosin-containing protein (VCP) disease mutants cause inclusion body myopathy with early-onset Paget disease and frontotemporal dementia (IBMPFD) through a gain of function activity of the VCP gene. Studies in drosophila models as well as in patient fibroblasts indicate that VCP inhibitors improve the disease pathology. CB-5083 is a reversible and competitive specific inhibitor of AAA ATPase p97/VCP and has a documented safety, and is well tolerated in human studies for cancer treatment. Thus, we hypothesize that normalizing the gain of VCP function in patient myoblasts and VCP mutant mice will correct the disease phenotype.

**Objectives:** Correction of muscle and spinal cord pathology in vivo in the homozygous VCP<sup>R155H/R155H</sup> disease mouse model with VCP inhibitor CB-5083.

**Approach:** The VCP<sup>R155H/+</sup> knock in mouse model developed by our lab displays pathological features of human VCP-associated disease however is a slow model of the disease. The homozygous VCP<sup>R155H/R155H</sup> mouse (2-month old, both sexes) were divided into 2 randomly assigned groups of 12 mice each for daily gavage treatment with selected doses of CB-5083 (½ of the maximum tolerated dose) and vehicle group, for 2-4 months. Findings were compared with wild type mice.

**Results:** Homozygous VCP mice tolerated the CB-5083 treatment well with normal behavior and body weights. They also showed improvement of muscle strength when compared with vehicle group and wild type littermates.

**Conclusions:** VCP inclusion body myopathy with early-onset Paget disease and/or frontotemporal dementia (IBMPFD) is caused by a gain of function mutation of the VCP gene. Preliminary studies show that Homozygous VCP mice tolerated the CB-5083 treatment well with improvement of muscle strength when compared with littermates. If successful in patients with VCP disease, ALS and other sporadic IBM could be treated using this strategy.

## PgmNr 1253: Reaching the proper diagnosis of patients with muscular dystrophy through exome sequencing.

### Authors:

B. Azab <sup>1,3</sup>; S. Swedan <sup>2</sup>; Z. Dardas <sup>1,2</sup>

---

**Background:** Muscular dystrophies (MDs) are a heterogeneous group of inherited disorders that are characterized by progressive skeletal muscle weakness and dystrophic changes on muscle biopsy. The broad genetic and clinical heterogeneity of MDs make the accurate diagnosis difficult via conventional genetic and clinical approaches. Exome sequencing (ES) is an efficient, time-saving, and cost-effective tool, enabling disease-causing variant (DCV) detection in affected individuals.

**Aim of the study:** we aimed to investigate the use of the ES for the accurate designation of MD types for 24 patients from 8 unrelated consanguineous Jordanian individuals.

**Methods:** Thorough clinical examination and ES were performed to identify the DCVs in affected individuals from each family, followed by segregation analysis if candidate variants in affected individuals and unaffected family members by Sanger sequencing.

**Results:** We achieved 8 remarkable diagnostics success rate of 75% (6 out of 8 families), identified novel pathogenic variants in DYSF gene, conformed the pathogenicity of recurrent variants and added new phenotypes in patients with these variants.

**Conclusion:** To our knowledge, this is the first study applying an ES-based comprehensive molecular diagnosis to Jordanian patients with MDs. Our findings confirmed that ES as a powerful approach for the diagnosis of MD patients. This efficient method of molecular diagnosis is crucial for guiding patient clinical care, genetic counseling and most importantly, paving the way for gene therapy in the future.

## PgmNr 1254: Compound heterozygous *TRAPPC11* mutations in a Chinese patient with limb girdle muscle dystrophy-18.

---

Limb-girdle muscular dystrophy (LGMD) is a heterogeneous group of neuromuscular disease characterized primarily by progressive proximal myopathy. Due to clinical and genetic heterogeneity, it is often challenging to diagnose subtypes due to phenotype overlap. Recently, *TRAPPC11* (Transport protein particle complex 11) gene mutations were reported to cause autosomal recessive limb-girdle muscular dystrophy-18 (LGMD2S). To date, there have been only 19 patients reported in the literature, and the molecular basis for the wide phenotypic heterogeneity remains poorly understood. In this case report, we describe the role of whole exome sequencing (WES) in identifying pathogenic mutations in *TRAPPC11* gene to resolve diagnosis for a Chinese patient who presented early onset symptoms of global developmental delay at 1 year of age, with gross motor delay being most prominent. Subsequently over time, he showed symptoms of proximal and progressive muscle weakness, early onset scoliosis as well as early cataracts. Serum creatine kinase level was elevated (10800 IU/L). There was no hepatic steatosis. Muscle biopsy revealed mild loss of dystrophin and patchy loss of  $\alpha$ -dystroglycan. Due to clinical overlap with dystrophinopathies, screening for abnormalities in *DMD* gene was performed at time of presentation but was found negative. Trios whole exome sequencing revealed two compound heterozygous variants in *TRAPPC11* gene in proband inherited in trans from parents. Both variants have been previously observed, one was reported as a pathogenic missense mutation in exon 26 c.2938G>A;(p.Gly980Arg), while the other was a nonsense mutation in exon 2 c.142C>T (p. Arg48Ter) with unspecified pathogenicity. While results of WES should be interpreted cautiously taking into account the complete clinical picture inclusive of biochemical and pathological information, it has proved useful in resolving many diagnostic odysseys for rare disorders. The genotype-phenotype correlate for our patient is consistent with LGMDR18 as further advanced symptoms of scoliosis and early cataracts are now observed in patient after the molecular diagnosis. This case further expands the ever-growing spectrum of limb-girdle muscular dystrophy associated with *TRAPPC11* mutations.

## PgmNr 1255: Congenital myopathy: Two candidate genes in a Malian family.

### Affiliations:

1) Neurology, Teaching Hospital of Point G, Bamako, Mali; 2) Service de Rhumatologie, CHU du Point "G", Bamako, Mali; 3) Neurogenetics Branch, NINDS, NIH, Bethesda, MD; 4) Service de Neurologie, CHU de Gabriel Touré, Bamako, Mali; 5) Service de Cardiologie, CHU de Gabriel Touré, Bamako, Mali

**Introduction:** Muscular dystrophies are heterogeneous disorders that are characterized by proximal weakness and progressive disability. Several entities have been reported, but cases with molecular diagnosis are scarce in sub-Saharan Africa.

**Objectives:** To characterize a family with congenital muscular disease and to identify the genetic defect causing the disease.

**Methodology:** Participants were enrolled after giving consent. Neurological examination was performed, and patients were seen by a cardiologist to determine cardiac involvement. DNA was extracted for genetic analysis. Whole exome sequencing using one patient, the parents and an unaffected sibling was performed. Putative variants were checked in SNP databases.

**Results:** This is a consanguineous family in which three affected siblings presented with congenital myopathy. Symptoms started with motor delay with walking at age 2. While the oldest patient never walked, the other two presented with a waddling gait that deteriorated progressively. On examination there was no cognitive impairment but they had generalized muscle atrophy and weakness more prominent in proximal limbs and skeletal deformities including scoliosis and thoracic kyphosis. The patients had hypotonic muscles with absent reflexes, joint hyperlaxity and ankyloses at the elbows and knees. In addition, they had dental crowding but no cardiac involvement. CK levels were normal. EMG showed myopathic features. Whole exome sequencing identified two homozygous variants in different genes. The first is in *C21ORF2*, a gene associated with autosomal recessive axial spondylometaphyseal dysplasia. The variant was not found in 178,834 alleles, including 15,500 African in gnomAD. The second variant is in the *MYOF* gene, and was not seen in SNP databases. *MYOF* is not associated with a disease but previous reports suggested it as candidate gene for myopathy. The first variant segregated with the disease in the family; sequencing for the second variant in the family is not yet complete.

**Conclusion:** Our study has identified two candidate genes for congenital myopathy. The unusual symptoms presented by the patients could indicate a novel entity or a variant of the disease previously described with mutations in *C21Orf2*. Further studies may shed light into these hypotheses.

## PgmNr 1256: A case of tuberous sclerosis complex with pathological mutations in intron of TSC2 gene.

### Authors:

G. Furukawa <sup>1,2</sup>; N. Ishihara <sup>2</sup>; M. Kato <sup>3</sup>; T. Kato <sup>3</sup>; H. Kurahashi <sup>3</sup>

---

**Introduction:** Tuberous Sclerosis Complex (TSC) is a multi-system disorder, typically involving cutaneous manifestation, various tumors and neurological symptoms, such as epilepsy, cognitive deficit and autism. TSC is inherited in an autosomal dominant pattern and is caused by mutations in either TSC1 or TSC2 genes. We have previously reported that more than 70% of the patients in our cohort have nonsense or frameshift mutations in TSC2 gene. Here we report a case of intronic mutation in TSC2 gene with clinical features of definite TSC.

**Subject:** Subject is a 1-year-old boy who was born to non-consanguineous parents. His father has nonspecific cutaneous manifestation on his back, but cannot even diagnose with possible TSC. Subject had symptoms of cardiac rhabdomyoma, hypomelanotic macules, subependymal nodules and cortical tubers at birth, and was diagnosed as definite TSC. He developed focal epilepsy at 2 months of age, became West syndrome at 4 months of age and vigabatrin treatment was administrated. Subject and his parents were underwent for genetic testing after standard genetic counseling.

**Methods:** Genomic DNA was extracted from white blood cell, and made ready to use for next generation sequence library preparation. Trio-based target exome sequencing was performed using TruSight One sequencing panel (Illumina, Inc. San Diego, CA, USA). Annotation and filtering of variants were performed using Variant Studio software (Illumina). Putative candidate variants were validated using Sanger sequencing.

**Result:** We found heterozygous 8 bases deletion in 20th intron of TSC2 gene (c.2220+2\_2220+9delTACCATGG) in the subject, and validated with Sanger sequencing. According to the peak flow of the Sanger sequencing data, we found a same mutation with 40% mosaic ratio in his father. We predicted it splicing abnormalities due to loss of function of splicing donor site using Human Splicing Finder (<http://umd.be/HSF3/>).

**Discussion:** As our case has an intronic deletion, the effect of splicing due to the mutation is expected to be different for each organ. Both TSC1 and TSC2 are tumor suppressor genes that function according to the two-hit theory, and are autosomal dominant in patients' organs. They become autosomal recessive in cell units, therefore clinical features are considered to be diverse. It is a valuable case leading to the elucidation of the mechanism of TSC and the abnormality of splicing, hence it is necessary to advance to the analysis of cell units.

## PgmNr 1257: Clinical and neuropathological features of four familial and two sporadic cases of Neuronal Intranuclear Inclusion Disease (NIID).

---

**Background :** Neuronal intranuclear inclusion disease (NIID)(MIM 603472) is a neurodegenerative disorder characterized by eosinophilic intranuclear inclusions in neuronal cells. Such inclusions are also found in non-neuronal cells. The clinical features and pathological findings in patients with NIID are highly varied.

**Objective:** Here, we present seven NIID cases. Two of them, autopsy was performed.

**Cases :** 5 cases are adult onset NIID (aNIID) and 2 cases are a juvenile onset (jNIID). Case 1 is diagnosed as familial, and case 2, 4 is sporadic adult onset Parkinson disease with dementia. Case 2 and 5 is diagnosed as sporadic mild Parkinsonism with dementia and severe psychosis. Case 6 and 7 is a sister of juvenile onset familial cases and diagnosed as oculopharyngeal muscular dystrophy with mental deterioration by muscle biopsy. Autopsy was performed after sudden death at age 42 and 43.

**Results :** In MRI imaging, diffuse cerebral atrophy was observed in all cases. High intensity of the cortico-medullary junction in diffusion-weighted imaging (DWI), which is characteristic findings in NIID, was seen in aNIID but not seen in two jNIID. In neurological examination, all 5 aNIID showed laterality or severely increased Pulmomenal Reflex (PMR). Ante-mortem diagnosis was made by identification of intranuclear inclusions with skin biopsy in five aNIID. Post-mortem diagnosis was made in two jNIID. In this case, acidophilic intranuclear inclusion body with positive p62 immune staining was observed, not only in neuron and glia cell, but all other organ tissues.

**Conclusion :** Intranuclear accumulation of abnormal proteins and/or dysfunction of protein degradation might underlie in the pathogenesis of NIID. However, NIID is considered as a heterogeneous disease entity and shows various clinical features. Especially, there are different pattern of neuroimaging examination between aNIID and jNIIS. Not only neurologist, but also psychiatrist and pediatrician should pay attention to this heterogeneous disorder.

## PgmNr 1258: VWA2: Novel autosomal recessive candidate gene in Alzheimer's disease (AD).

---

**Background** Up to 90% of Alzheimer's disease (AD) patients remain genetically unexplained. As several AD families do not show clear autosomal dominant inheritance patterns, we investigated if recessive inheritance might explain part of the missing genetic etiology.

**Methods** Whole-genome sequencing (WGS) was performed for 19 Belgian unrelated AD patients (mean AAO:  $56.7 \pm 6.6$  years) without mutations in AD genes. We analyzed the WGS data searching for homozygous variants altering protein sequences with a minor allele frequency (MAF)  $\leq 5\%$  in available databases. Targeted resequencing of candidate variants/genes was performed using multiplex-amplification resequencing.

**Results** Among the 113 investigated variants, homozygous p.V366M in VWA2 was the most promising candidate variant, since p.V366M was also present homozygous in one extra AD patient, was absent in control individuals, has a CADD score of 26.8 and VWA2 is a brain-expressed gene. We performed full exonic resequencing of VWA2 in a Belgian AD cohort (n=1253) and identified one patient homozygous for p.R69M and two patients compound heterozygous for p.V366M/p.L715F. In the Belgian control cohort (n=802) we observed one person heterozygous for p.L715F/p.R69M. To replicate our findings, we resequenced VWA2 in a European AD cohort (n=814) and identified two patients homozygous for p.L715F and two patients compound heterozygous for p.L715F/p.V728L and p.D79G/p.V366M. Heterozygous p.V366M/p.L715F, present in the Belgian AD cohort, was also observed in one European patient and one European control individual. In the European control cohort (n= 423), we identified two Spanish control individuals homozygous for p.H456Y. Taken the high 3.7% allele frequency of p.H456Y in the Spanish subgroup of the European control cohort, compared to 0.6% in the gnomAD database, we expect that p.H456Y might be a population specific polymorphism.

**Conclusion** Our data suggest that VWA2 might contribute to AD risk in an autosomal recessive manner. VWA2 is present in extracellular exosomes known for their contribution to neuronal interaction. We are using long read sequencing to check whether in heterozygous VWA2 carriers the variants are located *cis* or *trans*. Additionally, we are studying expression of VWA2 in brain material to analyze the effect of the genetic variants in VWA2 on expression.

## PgmNr 1259: Mutations in SORL1 R904W as a pathogenic mechanism in the development of Alzheimer's disease in a multigenerational Colombian family.

---

Alzheimer's disease (AD) is a complex and heterogeneous neurodegenerative disease and it is the most common cause of dementia in the elderly. Dementia due to Alzheimer's disease is characterized by noticeable memory, thinking, and behavioral symptoms that impair a person's ability to function in daily life. The genetics (AD) is heterogeneous. Early or familial forms, (EOAD, onset before 65 years), exhibit an autosomal dominant inheritance pattern while late or sporadic forms (LOAD, onset after 65 years) exhibit a complex inheritance pattern. Both early onset and late onset forms have been shown a strong genetic component. In familial forms, highly penetrating causal mutations have been identified in three specific genes, APP, PSEN1, and PSEN2, supporting the major role of amyloid  $\beta$  peptide in the development of the disease. In sporadic forms genome-wide association studies (GWAS) have found more than 30 risk genes such as APOE, BIN1, CLU, ABCA7, CR1, PICALM, MS4A6A, CD33, MS4A4E, CD2AP and SORL1 among others that are involve in new pathways related to the disease, like lipid metabolism, immune system and synaptic functioning mechanisms. We used whole-exome sequencing (WES) to evaluate a Colombian multigenerational family spanning three generations with a diagnosis of EOAD and with an inheritance pattern suggestive of autosomal dominant without mutations in APP, PSEN1 (included the most prevalent mutation in the Antioquia's population, E280A) or PSEN2 genes. We identified possibly pathogenic rare variants in SORL1 gene (R904W) and MAPT gen (R163P) segregating in the family with other potential risk variants in APOE (C130R) and ABCA7 (A877T) genes suggesting an oligogenic inheritance in this family. Also, we build a structural model to try to determine the effect on the structure and function. SORL1 Arg904Trp produces a polarity change that favors hydrophobic interactions and produces a separation between the cell membrane and the mutated protein with respect to the wild type which can generate a structural change that can affect the receptor function and in this way destabilize the normal metabolism of the protein which could explain the development of the disease in this family.

## PgmNr 1260: A coexisting case of Eaton Lambert disease and Charcot Marie Tooth Type 20 syndrome.

Neuromuscular disorders comprise many different clinical conditions that involves the injury or dysfunction of peripheral nerves or muscles. They have different etiopathogenic mechanisms that can correlate with clinical symptoms in patients. Most of them has a genetic cause, but there can be other causes for example immunological etiology in some neuromuscular junction diseases. Because of the spread spectrum of symptoms that can be shared between them, diagnosis in neuromuscular diseases can become a challenge.

In this case report we present a 64-year-old female patient, with onset of symptoms at age of 54 years old, consistent in muscular weakness in lower limbs predominantly proximal, difficulty on climbing stairs, gait abnormality, spasticity, areflexia and dry mouth. Electromyography and neuroconductions were performed at that moment, reported as normal. Then clinical symptoms progressed with increase in muscular weakness, fatigue and difficulty standing, so further exams were performed. Rheumatologic, renal and hepatic profile were reported as normal. Also, enzymatic probe for Pompe disease were negative. CPK levels were lightly high. Three years later electromyography and neuroconductions were performed again, with abnormal result showing sensorimotor axonal polyneuropathy. Then the patient had worsening of symptoms and required wheelchair for ambulation during long walks. One year later she assisted to physiatry and started clinical therapies. A Single-Fiber EMG showed presynaptic neuromuscular junction disease. Repetitive stimuli test was consistent with Eaton Lambert disease. Due to inconsistent findings in electromyography's, molecular studies were considered. Clinical exome sequencing reported a heterozygote *missense* variant of uncertain significance in gene DYNC1H1: c.1976C>T p. (Thr659Met), not previously reported in the literature and classified by bioinformatic predictors as pathogenic, related to Charcot-Marie Tooth type 2o disease. It is possible that clinical and paraclinical findings are caused by coexistence of two neuromuscular diseases.

## **PgmNr 1261: A novel GTPBP2 splicing mutation in two siblings affected with microcephaly, generalized muscular atrophy, and hypotrichosis.**

One of the challenging pitfalls in the genetic counseling of patients with syndromic microcephaly is a definite clinical diagnosis to determine its etiology. Any unknown syndromic microcephaly necessitates piling up of clinical and molecular genetics data in the hope of getting a genotype-phenotype correlation. In this study, we identified a novel splice site mutation in *GTPBP2* gene by Whole Exome Sequencing in two siblings with microcephaly and progressive generalized muscular atrophy associated with hypotrichosis. This mutation is predicted to disrupt the highly conserved acceptor splice site of exon 4 in *GTPBP2* gene. We describe a syndromic microcephaly related to *GTPBP2* gene in two siblings with an autosomal recessive pattern of inheritance, and to the best of our knowledge, is the first report of *GTPBP2* related hypotrichotic microcephaly with generalized muscular dystrophy.

Keywords: Microcephaly, Muscular dystrophy, Hypotrichosis, *GTPBP2* gene

## PgmNr 1262: Pre-symptomatic training improves motor and memory defects in a mouse model of Rett syndrome.

Rett syndrome is a debilitating childhood neurological disease that affects 1:10,000 young girls. Patients typically reach their developmental milestones for the first 12-18 months before rapidly regressing. Over time, Rett syndrome robs patients of their motor, learning, and social skills. Although the genetic basis of Rett syndrome was discovered two decades ago, the precise molecular mechanism by which mutations in *MECP2* cause Rett syndrome remains elusive. Nevertheless, many labs are exploring ways to augment the function of MeCP2 and improve brain function in Rett syndrome. However, these experimental therapies are many years away from clinical use. Right now, patients and their families are desperate for effective therapies.

Work from our lab has shown that deep brain stimulation rescues aspects of the disease in mice. These results indicate that enhancing neural function is sufficient to overcome the defects caused by MeCP2 dysfunction. With this knowledge, we sought to determine whether prolonged training in Rett mice could provide a similar benefit. Extended motor training in symptomatic Rett mice resulted in a modest improvement on the rotating rod, a test of balance and coordination. However, the memory performance of Rett mice did not improve with extended training in the Morris water maze, a test of spatial learning and memory. Because Rett syndrome in humans and mice begins with a period of normal development, we next assessed whether the initiation of training before symptoms develop could enhance the benefit. Surprisingly, pre-symptomatic training dramatically improved the motor and memory defects of Rett mice to near wild-type levels. The benefits were task-specific because pre-symptomatic training did not improve other motor or memory behaviors. Currently, we are using high-resolution microscopy, calcium imaging, electrophysiology, and RNA sequencing to uncover the molecular basis of this improvement.

Because patients with Rett syndrome are diagnosis after the onset of symptoms, there are significant therapeutic implications to this study. The data suggest that pre-symptomatic diagnosis and early rehabilitation may be the key to modifying aspects of Rett syndrome.

---

Acute encephalopathy following a febrile illness is an uncommon finding and often thought to be autoimmune. Several genetic causes have been described, most associated with specific infectious agents. However, heterozygous missense variants in RANBP2, a component of the nuclear pore complex, cause an autosomal dominant susceptibility to acute infection induced encephalopathy (MIM 608033). We report two unrelated families identified through GeneMatcher, one consanguineous family of Palestinian descent in which cousins were homozygous for a missense variant and one US family of Northern European descent in which two sisters were compound heterozygous for a missense and a frameshift pathogenic variant in the gene encoding human nucleoporin NUP214 causing acute infection-induced encephalopathy. Clinical symptoms include fever-induced neurodevelopmental regression, seizures, myoclonic jerks, progressive microcephaly and cerebellar atrophy. Patients made some post-infection recovery, but not to baseline state. Over time there was progressive neurodegeneration. One patient died at 11 years. Assays in primary fibroblasts from affected individuals showed reduced NUP214 and NUP88 protein levels, while the total number and density of nuclear pore complexes was comparable to control fibroblasts. Nuclear transport assays exhibited defects in the classical protein import and mRNA export pathways in affected cells. Using scanning electron microscopy to perform direct surface imaging of fibroblast nuclei revealed a large increase in the presence of central particles ("plugs") in the nuclear pore channels of affected cells. Heat shock exposure of fibroblasts from affected individuals resulted in a marked delay in their stress response, followed by a surge in apoptotic cell death. These studies suggest that decreased cell survival seen in cell culture is the pathogenic mechanism underlying severe fever-induced brain damage in affected individuals. While defects in nucleoporins are implicated in several kidney and other tissue-specific diseases, this study provides evidence by direct imaging at the single nuclear pore level of functional changes in a severe neurologic condition.

---

The blood brain barrier (BBB) acts to ensure central nervous system (CNS) homeostasis and protects it from injury. Claudin-5 (CLDN5) is an important component of tight junctions which are critical for the proper formation of the blood brain barrier. We have identified through whole exome sequencing six unrelated patients with *de novo* mutations in *CLDN5* who present with a common constellation of features including microcephaly, developmental delay and seizures. Brain MRI are notable for brain calcifications. Generation of loss of function mutants in zebrafish *claudin5a* resulted in animals with growth restriction and seizures. Furthermore, these mutants were found to exhibit defects in the blood brain barrier. We find evidence that sequence variants in *CLDN5* cause a novel genetic disorder likely caused by the disruption of the blood brain barrier. Elucidation of the mechanisms by which variants in *CLDN5* result in abnormal brain development will have broad implications for our understanding of neurological disease.

## PgmNr 1265: Phenotype variabilities of the patients with *GABRB1* variants.

[Introduction] *GABRB1* has been reported as a causative gene for epileptic encephalopathy. Epileptic encephalopathy is a disease that develops intractable epilepsy early in infancy and is accompanied by severe developmental delay. Here we report that we identified variants of the same gene in a case in which comprehensive genetic analysis was performed for the purpose of differentiating congenital hypotonia.

[Subject] Subject was a 2-year-old girl born to healthy non-consanguineous parents. She had weakness of crying and difficulty for feeding since at birth. At 2 months, she was diagnosed as laryngomalacia and oxygen supply became necessary during feeding. She developed focal seizures at 3 months, in which were well controlled by carbamazepine (CBZ) administration. Her developmental milestone revealed as following; head controlled at 7 months, able to sit at 15 months, and stand with support at 20 months of age.

[Methods] Whole exome sequencing analysis was performed with trio DNA samples extracted from white blood cells of subject and her parents. Annotation and filtering of variants in which were *de novo* and autosomal recessive (AR) forms were performed by comparing to human reference sequences, and extracted variants with less than one percent allele frequency from the frequency information of the healthy human database.

[Results] One *de novo* and 4 AR variants were filtered as candidate. Among these, we identified *de novo* variant of *GABRB1* c.860C>T (p.Thr287Ile) as a causal gene of the disease. Thr287 is completely conserved in vertebrates, and in silico analysis revealed as pathogenic.

[Discussion] *GABRB1* is a gene encoding GABA<sub>A</sub> receptor  $\beta$ 1 subunit and has been reported as a causative gene for infantile spasm related diseases (Janve et al. Ann Neurol 2016). The variant (p.Thr287Ile) was first reported by Lien et al. (Ann Neurol 2016) as a pathogenic cause of epileptic encephalopathy. In our case, the epileptic seizures had been well controlled by CBZ, thus the main phenotype was hypotonia. Although the pathogenesis of hypotonia is various, the therapeutic intervention based on the genetic variants also leads an important role for developing brain, the value of the pathogenesis identification has been increasing in recent years. Since variants in *GABRB1* alter function of GABAergic neurons in which has an important role for inhibition of epileptic activities, early antiepileptic intervention would be require for appropriate brain development.

## PgmNr 1266: Mutations in *PIGB* cause an inherited GPI biosynthesis defect.

---

Proteins anchored to the cell surface via glycosylphosphatidylinositol (GPI) play various key roles in the human body, particularly in development and neurogenesis. As such, many developmental disorders are caused by mutations in genes involved in the GPI biosynthesis and remodeling pathway. We describe ten unrelated families with bi-allelic mutations in *PIGB*, a gene that encodes sphosphatidylinositol glycan class B that transfers the third mannose to the GPI. Ten different *PIGB* variants were found in these individuals. Flow cytometric analysis of blood cells and fibroblasts from the affected individuals showed decreased cell surface presence of GPI anchored proteins. Lentiviral expression of wildtype *PIGB* rescued the cellular phenotype in fibroblasts, supporting the pathogenicity of the *PIGB* variants. Most of the affected individuals have global developmental and/or intellectual delay, all had seizures, two had polymicrogyria, and four had a peripheral neuropathy. Eight children passed away at a young age. Some of them had a clinical diagnosis of DOORS syndrome (Deafness, Onychodystrophy, Osteodystrophy, mental Retardation, Seizures), a condition with sensorineural deafness, shortened terminal phalanges with small finger nail and toenails, intellectual disability, and seizures, which overlaps with the severe phenotypes associated with inherited GPI deficiency. However, the main causative gene for DOORS syndrome is *TBC1D24*, which is involved in synaptic-vesicle trafficking. Most individuals tested showed elevated alkaline phosphatase, which is a characteristic of the inherited GPI deficiency, but not DOORS syndrome. It is notable that some severely affected individuals showed 2-oxoglutaric aciduria, which can be seen in DOORS syndrome, suggesting that severe cases of inherited GPI deficiency and DOORS syndrome

might share some molecular pathway disruptions.

**Introduction:** Cerebral small vessel disease (CSVD) is the most important cause of vascular cognitive impairment (VCI). Vascular dementia (VaD) is the most severe form of VCI and it is the second most common cause of dementia after Alzheimer's disease. Most CSVD cases are sporadic but familial monogenic forms of the disorder have also been described. CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy), caused by mutations in *NOTCH3* gene, is the most common type of familial CSVD. CARASIL (cerebral autosomal recessive arteriopathy with subcortical infarcts and leukoencephalopathy) is an autosomal recessive CSVD caused by mutations in *HTRA1* gene, although autosomal dominant form of the disease has been recently identified. Furthermore, mutations in *COL4A1* and *COL4A2* have been identified as a cause of CSVD. Despite the mutations identified, many familial and sporadic CSVD cases remain unexplained genetically. We used whole exome sequencing in an attempt to identify novel genes underlying CSVD by studying 35 Finnish VaD patients without genetic diagnosis.

**Materials and methods:** A cohort of 35 unrelated Finnish patients with suspected CADASIL was selected from an initial cohort of 385 patients referred for diagnostic testing for *NOTCH3*. Patients were screened negative for at least the most common mutations in *NOTCH3* in Finland (R133C and R182C). After examining the medical records of all the patients, 35 patients were selected for whole exome sequencing. The inclusion criteria included the presence of vascular cognitive impairment with white matter changes in magnetic resonance imaging, age at onset up to 76 years and/or family history of dementia. Whole exome sequencing was performed to search for a genetic cause of CSVD.

**Results:** Our study resulted in the detection of pathogenic or possibly pathogenic variants or variants of unknown significance in genes associated with CSVD in seven patients, accounting for 20 % of cases. Those genes included *NOTCH3*, *HTRA1*, *COL4A1* and *COL4A2*. We also identified variants with predicted pathologic effect in genes associated with other neurological conditions in five patients.

**Conclusions:** This study revealed the genetic background of vascular cognitive impairment and further supports pathogenic roles of the mutations in *COL4A1*, *COL4A2* and *HTRA1* in CSVD. Our study also showed that whole exome sequencing is a useful tool for diagnosing familial cerebral small vessel disease.

## PgmNr 1268: Screening of over 1500 Indian patients affected with neurological disorders by multi-gene testing showed an improved diagnostic yield.

**Background:** Neurological disorders are clinically heterogeneous group of disorders and are major causes of disability and death. Several of these disorders are caused due to genetic aberration. A precise and confirmatory diagnosis in the patients in a timely manner is essential for appropriate therapeutic and management strategies. Due to the complexity of the clinical presentations across various neurological disorders, arriving at an accurate diagnosis remains a challenge.

**Methods:** We sequenced 1521 unrelated patients from India with suspected neurological disorders, using TruSight One panel. Genetic variations were identified using the Strand NGS software and interpreted using the StrandOmics platform.

**Results:** We were able to detect mutations in 197 genes in 405 (40%) cases and 178 mutations were novel. The highest diagnostic rate was observed among patients with muscular dystrophy (64%) followed by leukodystrophy and ataxia (43%, each). In our cohort, 26% of the patients who received definitive diagnosis were primarily referred with complex neurological phenotypes with no suggestive diagnosis. In terms of mutations types, 62.8% were truncating and in addition, 13.4% were structural variants, which are also likely to cause loss-of-function.

**Conclusion:** In our study, we observed an improved performance of multi-gene panel testing, with an overall diagnostic yield of 40%. Furthermore, we show that NGS (next-generation sequencing)-based testing is comprehensive and can detect all types of variants including structural variants. It can be considered as a single-platform genetic test for neurological disorders that can provide a swift and definitive diagnosis in a cost-effective manner.

## PgmNr 1269: Novel mutations of *COL4A1* in four Japanese patients with variable CNS involvements.

### Authors:

---

*COL4A1* encodes collagen type IV alpha 1, the main component of basement membranes. The mutation causes severe CNS abnormalities including porencephaly and schizencephaly. Despite large-scale studies, the genotype-phenotype correlation remains unclear. Here, we report novel *de novo* *COL4A1* mutations in four Japanese patients with typical or atypical CNS involvements, representing phenotypic diversity of the disorder.

All the patients were males with absence of abnormal events in the fetal period. They were admitted for developmental delay, growth retardation, and microcephaly. They presented the CNS symptoms, including spastic paralysis and epilepsy. Brain MRI revealed porencephaly (n = 1), ventriculomegaly associated with brain bleeding (n = 3), and atretic encephalocele (n = 1), respectively. Additionally, three patients had cataract, hydronephrosis, and hematuria. Using the clinical exome sequencing, we identified *COL4A1* mutations: two patients with missense mutations resulting in a glycine substitution (exon32:c.G2555A:p.G852D, exon40:c.G3407A:p.G1136D) and two with small in/del variants resulting in frameshift (exon32:c.2603\_2609delinsATCCTGA:p.A868\_G870delinsDPG, exon36:c.3054delinsTGTAGAT:p.L1018delinsFVD). Notably, the two patients with in/del mutation showed severe CNS involvements, porencephaly and more severe hydrocephaly. Further, the atretic encephalocele was a rare distinctive phenotype, which has never been described among the *COL4A1* related diseases.

These results indicate that *COL4A1* mutations show highly variable phenotype in cerebral hemorrhage and porencephaly. The molecular analysis using exome sequencing could expand the related phenotype of *COL4A1* mutations. Further analysis is required to clarify the underlying mechanisms of the clinical spectrum in the *COL4A1* related diseases.

Malformations of cortical development (MCD) are a group of predominantly genetic disorders due to abnormal formation of cerebral cortex during fetal brain development. Examples are lissencephaly, heterotopia, and polymicrogyria. MCD place a significant burden on affected individuals, their families and society, as patients often suffer from lifelong symptoms including drug-resistant epilepsy, cerebral palsy, and intellectual disability. Although next-generation sequencing has become broadly available worldwide, marked differences in diagnostic yield remain due to broad genetic and clinical heterogeneity and lack of guidelines in the recognition and classification of these rare disorders.

The international network on brain malformations NeuroMIG ([www.neuromig.org](http://www.neuromig.org)) has formed a multidisciplinary task force with the aim to develop a diagnostic strategy for individuals with MCD. Through literature search, expert input and the Delphi consensus method we have established recommendations on the optimal work flow. This includes a flow chart for the clinical work-up, laboratory standards, and a curated MCD gene panel list. In addition, we discuss the differential diagnosis, possible diagnostic pitfalls and special recommendations for specific MCD subtypes.

These recommendations will aid clinicians in providing the optimal diagnostic strategy, which will improve genetic and prognostic counseling and patient care.

## PgmNr 1271: Idiopathic basal ganglia calcification linked to a SLC20A2 gene mutation.

---

Idiopathic basal ganglia calcification (MIM 213600) is a neurodegenerative disorder characterized by calcium deposits in the basal ganglia, the dentate nucleus, and other brain areas. It appears in the fourth decade of life with progressive movement disorders, which begin with bradykinesia, slow gait, parkinsonism, chorea, tremor, dystonia, athetosis, ataxia, dyskinesia, and neuropsychiatric disorders such as difficulty in concentration, lack of memory, changes of personality or behavior and dementia. We describe a 61-year-old female patient with no family history with 6 months of the onset of symptom onset consisting of vertigo, lingual fasciculations, dysarthria, bradykinesia, memory impairment, and parkinsonism. Diagnostic studies were performed and ruled out toxic, traumatic, infectious, and metabolic etiology. Magnetic resonance showed hyperintensities of the striated, dentate nuclei, the periventricular region and the white matter of the cerebellar hemispheres. Investigations with a multigene panel, including *PDGFB*, *PDGFRB*, *SLS20A2*, *XPR1*, reported a probable pathogenic variant in the heterozygous state in *SLC20A2* c.1794+1G>T associated with idiopathic basal ganglia calcification type 1 which confirms the diagnosis of this patient. Currently, the patient is in treatment and clinical and symptomatic monitoring of neurological and neuropsychiatric status. Idiopathic basal ganglia calcification type 1 is caused by mutations in the *SLC20A2* gene that encodes the sodium-dependent inorganic phosphate transporter type III associated with phosphate homeostasis, which can lead to the accumulation of inorganic phosphate in the brain. Based on the low prevalence of this disease, it is important to know the frequent findings of this entity and consider the possible etiologies of neurological and/or neuropsychiatric unspecific symptoms, in order to control the morbidity and complications due to neurological damage of this pathology.

## PgmNr 1272: MECP2 duplication syndrome resulting from X:7 translocation in a 9-month-old female with severe failure to thrive and developmental delay.

---

**INTRODUCTION:** MECP2 microduplication syndrome is a severe neurodevelopmental syndrome that has been primarily described in males with the cardinal features of hypotonia, global developmental delay, gastrointestinal symptoms, and recurrent respiratory infections. So far only about 20 cases of symptomatic MECP2 duplication syndrome have been reported in females with variable clinical symptoms. **CASE DESCRIPTION:** This is a 9-month-old girl who was admitted for acute respiratory failure with hypoxia, RSV infection. Genetics was consulted for hypotonia, failure to thrive and severe developmental delay. Her previous evaluation at age of 44 days due to positive newborn screen for X-linked adrenoleukodystrophy revealed normal levels of VLCFA and plasminogen although the decreased muscle tone was noticed. The patient had history of neglect prior to the admission. She appeared severely malnourished, with a weight of 5.5kg (Z= -3.47). No obvious dysmorphic features except the ears were relatively big. She had no psychomotor skills, and muscle tone was low. She had mild to moderate laryngomalacia, L>R hearing loss. Comprehensive metabolic workup, SMA test, Russell Silver methylation study were negative. MRI was suggestive of hypomyelination. The chromosome microarray result showed 2.6Mb terminal duplication on Xq28 and a 22kb terminal deletion on 7q36.3. Metaphase FISH indicated an unbalanced X:7 translocation. **DISCUSSION:** The MECP2 duplication syndrome caused by duplication on X28 is an established disorder. Methyl CpG binding protein 2 (MECP2), functions as a transcription regulator for gene expression is associated with central nervous system development. Loss-of-function mutations in MECP2 results in the Rett syndrome, whereas gain-of-function mutations are associated with the MECP2 duplication syndrome. Different from male cases, female cases caused by X;autosome translocation are reported with more severe phenotypes due to random X chromosome inactivation (XCI). **CONCLUSIONS:** Variable clinical symptoms and poor correlation between the genotype and phenotype can cause misleading and delayed diagnosis. By literature search, this exact duplication has not been previously reported in females resulting from an X;7 translocation. The further investigation of the XCI study will help to delineate the underlying mechanism. In the clinical setting of failure to thrive with other symptoms that cannot be explained, chromosome microarray should be offered.

## PgmNr 1273: Characterization of *de novo* variants in *PPP2R5C* expands the spectrum of PP2A-related neurodevelopmental disorders.

---

**Background:** Protein phosphatase 2A (PP2A) is a ubiquitously expressed serine-threonine phosphatase with widespread involvement in multiple cellular processes. Its function is, in part, determined by its composition, with variable catalytic, scaffolding, and regulatory subunits. Of the 19 genes encoding PP2A subunits, six have been implicated in human disease. A single case report describes an overgrowth phenotype in association with a *de novo* variant in *PPP2R5C*, which encodes the PP2A-B56γ regulatory subunit. **Methods:** Through international collaboration facilitated by Matchmaker Exchange, we identified six additional individuals with candidate missense variants in *PPP2R5C*. Retrospective clinical data were collected. The functional impact of *PPP2R5C* variants was evaluated in a HEK293 cell model, in which GFP-tagged PP2A-B56γ variants were ectopically expressed. Following isolation of GFP-tagged proteins, co-precipitation of endogenous PP2A catalytic C and structural A subunits was evaluated by immunoblotting. Associated PP2A catalytic activity was measured on a general PP2A phospho-peptide substrate using a malachite green assay. **Results:** We describe and characterize four novel *PPP2R5C* missense variants in six individuals. We also include functional characterization of a previously reported variant described above. Our cohort, along with the previously published individual, have a consistent clinical presentation that includes: (relative) macrocephaly (4/7), developmental and/or intellectual disabilities (7/7), and congenital hypotonia (7/7). One subject also has refractory epilepsy. All described missense variants are absent from large population databases and affect highly conserved residues; six were confirmed to occur *de novo*. A recurrent variant, p.E122K, was observed in three unrelated individuals; the E122 residue has been previously shown to form direct interactions with the catalytic subunit, and the corresponding residue

in PP2A-B56 $\beta$  is required for target dephosphorylation. Accordingly, we detected significantly impaired binding of scaffolding and catalytic subunits and reduced PP2A catalytic activity compared to wildtype. The impact on subunit binding and phosphatase activity was also evaluated for the remaining variants. **Conclusions:** *De novo* missense variants in *PPP2R5C* cause impaired function of PP2A, providing evidence for a novel neurodevelopmental disorder with a consistent clinical phenotype.

## **PgmNr 1274: Bi-allelic variants in the autophagy gene *ATG4D* are associated with a pediatric-onset neurological disorder characterized by hypotonia, dysarthria, impaired coordination, and gait abnormalities.**

---

**Introduction:** Macroautophagy is a dynamic and highly conserved process that regulates the degradation and recycling of cellular components. Double-membraned organelles known as autophagosomes deliver cellular components to the lysosomes for degradation. Defective autophagy has been shown to contribute to the pathogenesis of various human diseases. We describe two unrelated individuals with a neurological disorder and identify a candidate gene encoding *ATG4D*, one of the four *ATG4* isoforms that process the LC3 and GABARAP proteins required for autophagosome biogenesis and dynamics. Interestingly, homozygous missense variants in *ATG4D* in a canine model are also associated with a neurological disease.

**Methods:** Clinical evaluation was performed on each proband. Exome sequencing and family-based genomics were performed, and variants were prioritized based on their frequency in population databases, level of conservation, and predicted deleteriousness. Expression analyses were performed on primary dermal fibroblasts using quantitative PCR. Autophagic flux was assessed by western blot of autophagy markers p62 and LC3-II and transmission electron microscopy (TEM) on a skin biopsy and primary dermal fibroblasts from one proband.

**Results:** Two probands presented with a neurological phenotype characterized by hypotonia, dysarthria, impaired coordination, and gait abnormalities. Rare, conserved, and likely deleterious bi-allelic missense or frameshift variants were identified in *ATG4D* in both probands segregating with the disease. TEM of skin from one proband revealed occasional accumulation of autophagosomes,

suggesting an upregulation of basal autophagy that is similar to findings from the canine model. Primary dermal fibroblasts from one proband showed decreased *ATG4D* mRNA expression, suggesting instability of the *ATG4D* mRNA. However, no significant differences in the expression of the autophagy markers p62 or LC3-II were identified at baseline or upon treatment with Bafilomycin A<sub>1</sub> (an autophagy inhibitor) and/or starvation (an autophagy inducer). Cellular morphological changes and the formation of autophagosomes in response to these treatments were also comparable to an unaffected control.

**Conclusion:** We report two unrelated individuals with a neurological disorder and hypothesize that bi-allelic variants in *ATG4D* may underlie the pathogenesis of this disorder. Further functional studies are required to delineate the molecular consequences of *ATG4D* deficiency.

## PgmNr 1275: Genetic analysis of autosomal dominant paroxysmal kinesigenic dyskinesia (PKD).

---

PKD is estimated to occur in one in 150,000 individuals, and characterized as involuntary movement at the start of motion. The age of disease onset is typically in childhood but the symptoms gradually ameliorates after puberty. Three genes have been reported so far to be responsible for PKD, *PRPT2*, *SLC2A1* and *MR1*. We ascertained one Japanese pedigree with PKD. This pedigree consists of two patients with five unaffected family members, suggesting an autosomal dominant inheritance. The aim of this study is to elucidate genetic basis responsible for the current familial case of PKD. We identified total of 314,953 single nucleotide variants (SNVs) by exome sequencing of two patients and two unaffected family members. First, we confirmed the absence of exonic SNVs in the three genes known to be responsible for PKD, suggesting that a novel gene is associated with the current PKD pedigree. Then we filtered SNVs detected by exome sequencing by the following fourth criteria: (i) the inheritance pattern consistent with the autosomal dominant model, (ii) deduced functional consequence, (iii) frequencies being zero or extremely low in public databases and in our in-house control samples. Through the filtering process, we selected three nonsynonymous SNVs as candidates for PKD, c.8976G>C [p.Gln2992His] in *FAT2*, c.5435T>C [p.Ser1672Pro] in *NUP98*, and c.8596C>T [p.Arg2866Trp] in *NBEA*. The SNVs in *FAT2* and *NBEA* are located in highly conserved regions among vertebrates, while the SNV in *NUP98* is located in a less conserved region among mammals. According to GTEx, the expression of *FAT2* in the cerebellum is much higher than those of *NUP98* and *NBEA*. *FAT2* and *NBEA* have been reported to be responsible for spinocerebellar ataxia 45 (SCA45) and familial epilepsy, respectively, suggesting the partial overlap of pathogenic mechanisms of PKD with the one of SCAs and/or epilepsy.

## PgmNr 1276: Analysis of DNA repair protein encoding gene, *RFC4*, as a candidate gene in two individuals with a novel neurological disorder.

### Introduction:

DNA replication and repair play critical roles in cellular division and tolerance to DNA damage. Multiple accessory proteins are required to facilitate the binding and function of DNA polymerases during these processes. Variants in several genes encoding these DNA repair accessory proteins are associated with neurological disorders such as cerebellar ataxia, neuropathy, Vestibular Areflexia Syndrome (CANVAS) and Ataxia-Telangiectasia (AT). We present probands with an undiagnosed neurological disorder and identify a candidate gene encoding a DNA repair protein that may be associated with this novel disorder.

### Methods:

Probands were evaluated at the National Institutes of Health Clinical Center through the Undiagnosed Diseases Network's NIH clinical site, the Undiagnosed Diseases Program (UDP). Clinical genome sequencing was performed on probands and available family members. RNA sequencing identified possible splicing variants, and Sanger sequencing was used to validate candidate variants. Splicing variants were confirmed by cDNA sequencing. mRNA and protein expression were analyzed in dermal fibroblasts from probands using quantitative PCR and western blot analysis.

### Results:

Two NIH UDP probands presented with cerebellar neurodegeneration, ataxia, photophobia, dysarthria, and other striking phenotypic similarities to known DNA repair disorders. A UDN initiated collaborative analysis identified splicing variants from RNA sequencing in one proband. Research re-analysis of genome sequences revealed compound heterozygous variants in *RFC4*, including likely-deleterious splicing variants, in both probands segregating with disease. *RFC4* encodes a subunit of replication factor C (RFC), a DNA repair accessory protein that loads and activates DNA polymerases  $\delta$  and  $\epsilon$ . *RFC4* mRNA expression was either unchanged or slightly increased in patient fibroblasts compared to an unaffected control suggesting possible overcompensation of transcription. cDNA sequencing

confirmed splicing variants resulting in deletions of exons 4 or 10, respectively, in fibroblasts from the two probands.

**Conclusion:**

The changes in *RFC4* splicing seen in fibroblast cDNA from our probands, in combination with the phenotypes similar to those of AT, CANVAS, ATLD2, and other DNA repair disorders, suggest that the bi-allelic variants in *RFC4* are pathogenic. Our report implicates *RFC4* as a gene involved in a novel DNA repair disorder.

## PgmNr 1277: Deficient pseudouridylation activates autophagy resulting in postnatal microcephaly, developmental delay, and metabolic abnormalities in two siblings with *PUS7* loss of function variants.

---

Delineating the mechanism underlying disease pathology is critical for informing clinical care and remains a challenge for many genetic disorders. This is especially true for newly identified genetic disorders caused by variants in genes not previously associated with disease. In these cases, identification of pathogenic variants is often insufficient to inform clinical care. Mechanistic studies are necessary to understand normal function of candidate genes as well as the consequences of their dysfunction. Very recently, pathogenic variants in pseudouridine synthase 7 (*PUS7*) were shown to be associated with postnatal microcephaly, aggressive behavior, speech delay, and developmental delay in several unrelated individuals from consanguineous families. We report two siblings in a non-consanguineous family from the mid-western United States who are compound heterozygotes for rare splice and missense variants in *PUS7*. While these siblings showed phenotypic overlap with published reports, they also presented with hearing loss, hypoglycemia, hyperuricemia, and self-injurious behavior.

Loss of *PUS7* function was confirmed in these siblings using RNA and protein from fibroblasts. *HPRT1* was also evaluated for its possible role in the hyperuricemia and self-injurious behavior unique to our patients. Exome sequencing, SNP array, and qPCR ruled out *HPRT1* deficiency as the explanation for these Lesch-Nyhan syndrome-like findings. We therefore focused on the role of *PUS7* in disease pathophysiology. Pseudouridine synthases catalyze the conversion of uridine to pseudouridine of many RNA molecules. *PUS7* can modulate a wide range of RNAs but has been shown to predominantly target specific tRNAs, which then regulate protein translation through the action of pseudouridylated tRNA fragments (tRFs). We observed that loss of *PUS7*-generated tRFs in patient fibroblasts increased global protein synthesis, consistent with published *in vitro* studies. Incidentally, patient cells also exhibited increased expression of transcription factor EB (*TFEB*), a master regulator of autophagy. While studies are underway to confirm and better understand these findings, our results suggest that global upregulation of protein translation has aberrantly activated autophagy in patient cells, manifesting a phenotype most clearly in the CNS. These cases add to a growing body of literature describing deficient tRNA modification as a genetic cause of neurological diseases that often include microcephaly.

## PgmNr 1278: *DYNC1H1*-related disease: Reviewing the literature, describing three novel *de novo* variants, and expanding the phenotypic spectrum.

### Authors:

The *DYNC1H1* gene is associated with different phenotypes, chiefly intellectual disability (ID), spinal muscular atrophy (SMA), Charcot-Marie-Tooth (CMT) and other hereditary neuropathies (HN), congenital myopathy (CM), and malformations of cortical development (MCD). Other phenotypes have also been described, primarily in single reports or small case series. Overlap of features has been readily observed.

Here, we report four patients identified at our institution. Three have novel, *de novo* variants (p.V1116A, p.P1511L, and p.H1412Y). One has a recurrent variant, p.G3658E, which was identified previously in a proband with similar unusual findings, such as corpus callosum hypoplasia and congenital cataracts. Our patients all fell variably within the described spectrum of *DYNC1H1*-related illnesses. One (with p.H1412Y) is the first well-described patient to present primarily with autism (ASD) and mild ID; interestingly, this patient is only the second to have documented gut dysmotility associated with *DYNC1H1*, and the first with omphalocele.

Additionally, we review previously-reported *DYNC1H1* variants and have identified 143 unique families and/or probands harboring 103 different variants associated with neurological or developmental phenotypes. Variants are found throughout the protein in the stem and motor domains and in the connecting neck/linker. We classified phenotypes into 6 major groups: SMA, CMT/HN, ID without explicit neuromuscular (NM) disease, MCDs without explicit ID, and CM. We analyzed data for phenotype/genotype relationships. Phenotypes largely cluster amongst affected family members and those with the same variant; however, there are exceptions, and other phenotype/genotype relationships are elusive. Most CMT/SMA variants are in the stem domain, while most ID variants are in the motor domain. However, there are many exceptions, and most subdomains contain at least two variants: at least one associated with NM symptoms and at least one associated with primarily MCDs.

We conclude that *DYNC1H1* can present with multiple overlapping neurodevelopmental phenotypes. *DYNC1H1*-related CMT, SMA and CM are likely a spectrum of the same disorder. We also establish gut dysmotility and confirm cataracts, arthrogryposis, congenital hip dislocation, contractures, scoliosis or other spine deformities, ADHD, ASD, dysmorphia, microcephaly, seizures, and foot deformities as recurrent features of *DYNC1H1*-related disease.

## PgmNr 1279: Development of clinical and model organism platforms to inform the phenotypic spectrum and functional characteristics of newly-identified variants in *IRF2BPL*.

---

**Introduction:** *IRF2BPL* was identified in 2018 as a new disease gene that causes Neurodevelopmental Disorder with Regression, Abnormal Movements, Loss of Speech, and Seizures (NEDAMSS MIM# 618088). *De novo* truncating mutations in *IRF2BPL*, a single-exon gene of unknown function leads to severe neurological regression after an initial period of unremarkable development in affected individuals. These patients initially present with deterioration of gait and loss of intentional movements, and subsequently develop dysarthria, loss of speech, movement disorder, seizures, and loss of fine motor skills. Individuals with missense variants lack the neuroregression but may display milder symptoms of developmental delay, autism spectrum disorder, and seizures. As a newly-described condition, it is important to develop an understanding of the phenotypic spectrum of disease complications. We describe here our efforts to collect phenotypic data on newly identified cases and characterize the impact of new variants on protein function.

**Methods:** With input from various lab and clinical partners, we developed an IRB-approved protocol to collect longitudinal prospective and retrospective phenotypic data. We developed a data-collection tool that relies on participant-led data entry. Recruitment is based on online advertisements. *In vivo* functional studies using *Drosophila* as a model organism assessed *IRF2BPL* variant function.

**Results:** As a new disease gene, knowledge regarding the phenotypic spectrum is understandably limited. Our most common source of queries and referrals was from ordering physicians who had read our initial publication. In addition, we had introductions to treating clinicians through the clinical exome labs that had identified variants in *IRF2BPL*. Questions regarding known and potential complications and management were common, and we had frequent requests for additional information regarding additional observations not included in the original cohort. A recurrent question was whether variants of unclear significance in *IRF2BPL* could explain the patient's symptoms. This presented a valuable opportunity for functional analysis from model organisms to inform the biological effect of the variants. *IRF2BPL* overexpression in fruit flies allows for a variety of functional assessment depending on the tissue-specific expression of the construct. Our work illustrates the utility of prospective data collection and model organism data in phenotypic characterization.

## PgmNr 1280: Prodromal manifestations of Parkinson's disease in adults with 22q11 microdeletion syndrome.

22q11 microdeletion syndrome (22q11DS) has been recently recognized as a cause of early onset Parkinson's disease (PD), presenting in approximately 4% of adult series, with onset at 35-40 years of age. Multifactorial PD usually presents after 60 years of age, and the classical motor symptoms are preceded by a prodromal phase by about a decade. This prodromal phase is characterized by anosmia, dysautonomia, REM sleep behavior disorders (RBD) and gradual loss of dopaminergic neurons in the basal ganglia.

The aim of this study was to assess the presence of prodromal PD in 22q11DS through a cross-sectional study in adults with MLPA-proven deletions, using the Movement Disorder Society (MDS) research criteria for prodromal PD (Berg et al 2015). Specifically, RBD was evaluated by polysomnography; olfactory dysfunction by Sniffin' Sticks test; dysautonomia by COMPASS31 questionnaire; subtle motor signs by the MDS-UPDRS scale, and integrity of dopaminergic pathways by PET/CT imaging with [<sup>18</sup>F]PR04.MZ, a highly selective dopamine transporter (DAT) ligand. Results of these assessments were used to calculate likelihood ratio (LR) of having prodromal PD according to the MDS criteria. In addition, psychiatric evaluation with the MINI-International Neuropsychiatric Interview version 5.0 (MINI) and cognitive assessment using WAIS-IV were performed. To date, 21 adults (11 women and 10 men) have completed the evaluations, with a median age of 22.5 years (range 18-50 years). One participant (4.1%) had a very high positive LR (>1000) for prodromal PD, based on mild motor signs and decreased DAT signaling in caudate and putamen by PET/CT (specific binding ratio < 65% of age-matched controls). In addition, reduced DAT signaling was most severe in posterior putamen and asymmetric, as seen in early or prodromal PD. This study identified a 22q11DS patient with features highly indicative of prodromal PD and suggestive of neurodegeneration. A larger number of patients and longitudinal follow up are needed to assess the progression to PD and to identify high-risk individuals who may benefit from potential neuroprotective strategies. Funded by Fondecyt Chile grant 1171014.

---

Biallelic *WWOX* pathogenic variants are reported to cause severe infantile onset epileptic encephalopathy (WOREE syndrome), or spinocerebellar ataxia. Here we present clinical and molecular data on four subjects with WOREE syndrome who were referred for clinical evaluation. All four patients were detected to have biallelic loss of function pathogenic variants and/or exonic deletions in the *WWOX* gene. WOREE syndrome is characterized by refractory epilepsy, generalized hypotonia, cerebral atrophy, hypoplastic corpus callosum, delayed myelination on brain MRI, and premature death which were also observed in our patients. Two of our patients died around 2 years of age. The causes of death were related to recurrent infections and aspiration pneumonia in early life. Moreover, our patients present additional clinical features that expand the clinical phenotypic spectrum of WOREE syndrome. Even though anticonvulsants do not control the epilepsy found in this neurogenetic syndrome, the use of a ketogenic diet improved seizure control in two of our patients. None of our patients presented with facial dysmorphic features in contrast to what has been reported in the published literature. Moreover, although these subjects exhibited normal birthweight and head circumference at birth, all of them eventually developed failure to thrive and three manifested acquired microcephaly with progressive deceleration of head growth. Unlike previously reported patients, there was an absence of prenatal findings except for club feet in one patient. Two patients also presented bilateral sensorineural hearing loss which has not been frequently reported in this syndrome. Recurrent pancreatitis was seen in one of the patients which has not been observed before. In summary, we report four patients with WOREE syndrome to further document and delineate the clinical phenotypes of this disorder. This case series expand the clinical phenotype associated with this condition as some patients responded to a ketogenic diet, facial dysmorphic features were absent and prenatal findings were not present, pancreatitis presented in one of the patients, sensorineural hearing loss was observed in two subjects, and most of these subjects developed failure to thrive and presented acquired microcephaly. Long term follow-up of a larger cohort of survivors with WOREE syndrome will provide further clinical insight into the cardinal features of this syndrome.

## PgmNr 1282: Bi-allelic *PDXK* mutations cause polyneuropathy with optic atrophy responsive to PLP supplementation.

---

**Aim:** To identify disease-causing variants in autosomal recessive axonal polyneuropathy with optic atrophy and provide targeted replacement therapy.

**Methods:** We performed genome-wide sequencing, homozygosity mapping and segregation analysis for novel disease-causing gene discovery. We used circular dichroism to show secondary structure changes and isothermal titration calorimetry to investigate the impact of variants on ATP-binding. Pathogenicity was further supported by enzymatic assays and mass spectroscopy on recombinant protein, patient-derived fibroblasts, plasma and erythrocytes. Response to supplementation was measured with clinically validated rating scales, electrophysiology and biochemical quantification.

**Results:** We identified bi-allelic mutations in *PDXK* in five individuals from two unrelated families with primary axonal polyneuropathy and optic atrophy. The natural history of this disorder suggests that untreated, affected individuals become wheelchair-bound and blind. We identified conformational rearrangement in the mutant enzyme around the ATP-binding pocket. Low *PDXK* ATP-binding resulted in decreased erythrocyte *PDXK* activity and low pyridoxal 5'-phosphate (PLP) concentrations. We rescued the clinical and biochemical profile with PLP supplementation in one family, improvement in power, pain and fatigue contributing to patients regaining their ability to walk during the first year of PLP normalization.

**Interpretation:** We show that mutations in *PDXK* cause autosomal recessive axonal peripheral polyneuropathy leading to disease via reduced *PDXK* enzymatic activity and low PLP. We show that the biochemical profile can be rescued with PLP supplementation associated with clinical improvement. As B<sub>6</sub> is a cofactor in diverse essential biological pathways, our findings may have direct implications for neuropathies of unknown aetiology characterised by reduced PLP levels.

## PgmNr 1283: Mutational screening of genes associated with hereditary sensory and autonomic neuropathy in a Brazilian population.

---

Hereditary sensory and autonomic neuropathies (HSAN) are a group of rare genetically and phenotypically heterogeneous disorders characterized by axonal atrophy and degeneration often complicated by ulcers and amputations, with variable motor and autonomic involvement. To date, at least 17 different genes have been associated with HSAN (*SPTLC1*, *SPTLC2*, *ATL1*, *DNMT1*, *ATL3*, *SCN11A*, *HSN2/WNK1*, *FAM134B*, *KIF1A*, *SCN9A*, *IKBKAP*, *NTRK1*, *NGF-β*, *DST*, *PRDM12*, *ZFHX2*, *CLTCL1*). The relative frequency of these disorders varies among ethnic and geographical populations probably due to founder effects. However, the epidemiology of HSAN in Brazil is still unknown, since a systematic study has not been conducted yet. In order to evaluate the frequency of mutations in these genes, we performed a systematic mutation screening of their coding sequences in 25 unrelated Brazilian patients diagnosed with HSAN. We identified 10 patients belonging to three unrelated families with mutations in three HSAN disease associated genes: *ATL3* (p.Tyr219Cys), *SCN9A* (p.Trp714Ter; p.Glu982Ter) and *SPTLC2* (p.Asn177Asp). The clinical features associated with mutations in *ATL3* and *SPTLC2* typically consisted of dominant inheritance, frequent traumas in toes with repeated painless infections, including deep foot ulcerations, osteomyelitis, osteonecrosis and acromutilations. We detected a novel mutation in *SCN9A* (p.Trp714Ter) in compound heterozygous state with the previously described p.Glu982Ter pathogenic variant, leading to an early-onset HSAN phenotype with impairment of pain, temperature and touch sensation, and autonomic involvement, such as urinary incontinence, intestinal constipation and hypohidrosis. We thus identified a pathogenic mutation in 12% of HSAN Brazilian families, which suggests that the vast majority of the cases would be explained by other unknown mutated genes that remain to be discovered. We are currently performing whole genome studies on all remaining cases. Our study characterizes the spectrum of HSAN mutations found in Brazilian patients, and provides additional insights for genotype-phenotype association of the identified mutations.

## PgmNr 1284: After the clinical exome: Identifying the genetic etiology of refractory pediatric epilepsies.

---

The majority of early-onset, refractory epilepsies are due to *de novo* or inherited genetic variation. Genetic testing has demonstrated that pathogenic single nucleotide variants, indels and structural variants account for ~30-50% of early-onset epilepsies. Despite this strong prevailing genetic contribution, the majority of pediatric epilepsy patients never receive a genetic diagnosis. We developed a tiered approach utilizing exome reanalysis and genome sequencing to enable genetic diagnosis in exome negative trios.

We recruited a cohort of 25 exome negative pediatric epilepsy cases primarily consisting of individuals with early-onset, drug refractory seizures. By reanalysis of clinical exome data we identified likely pathogenic or candidate variants in 7 probands. The majority of these were variants in novel genes or genes recently implicated in epilepsy and/or related neurodevelopmental disorders. For instance, we identified a patient carrying a *de novo* missense variant of uncertain significance in *MAST3*. Through an international collaboration we identified an additional seven individuals with *MAST3* missense variants, two of which were recurrent and all were located in the ST kinase domain.

We have pursued genome sequencing in the remaining 18 trios to identify non-coding pathogenic variants. We have developed computational pipelines to detect all major classes of genetic variants and prioritize these with appropriate inheritance models. We hypothesize that genetic variation disrupting functional neuronal *cis*regulatory modules (CRMs) contributes to epilepsy susceptibility by modulating expression of genes involved in neuronal development or function. Promoter capture Hi-C is performed to generate neuronal CRMs in human induced pluripotent stem cell derived neuronal cell types, including neuronal progenitor cells, excitatory and inhibitory neurons. Genetic variants ablating or disrupting neuronal CRMs will be prioritized as candidates.

In summary, we applied a tiered approach to identify genetic variants in epilepsy patients with negative clinical exomes. In this cohort 7/25 (28%) individuals carried likely pathogenic or candidate variants in genic regions. We have designed a computational framework implementing CRMs to prioritize variants outside the exome. Future work will allow us to determine whether variants in CRMs account for the unsolved (72%) cases in our cohort. This framework may have applications to neurodevelopmental disorders more broadly.

## PgmNr 1285: Novel homozygous variants in *CACNA2D2* in patients with epileptic encephalopathy and cerebellar atrophy.

**Background:** Developmental and epileptic encephalopathies (DEE) constitute a spectrum of disorders characterized by intractable epilepsy with prominent epileptiform activity and electroencephalography, developmental delay/intellectual disability, and neurodevelopmental regression. Many patients with DEE have an underlying genetic etiology with now more than 100 genes identified to date. Implicated genes have been shown to participate in synaptic transmission, ion channel function, transcriptional regulation, DNA damage repair, and metabolic pathways. Genes implicated in ion channel functioning are the most common etiology of DEEs, leading to channelopathies. Identification of an underlying channelopathy has important therapeutic implications. Specifically, voltage-gated calcium channel subunits encoded by the family of *CACNA* genes has been linked to epileptic encephalopathy and/or ataxia. To date, four unrelated cases with *CACNA2D2* variants have been reported. Here, we report two additional families with DEE and cerebellar atrophy who were found to have novel homozygous variants in *CACNA2D2*.

**Materials and Methods:** Two affected individuals from family #1 with clinical features of early onset epileptic encephalopathy were recruited for exome sequencing at the Centers for Mendelian Genomics to identify their molecular diagnosis. We identified family #2 through collaboration via GeneMatcher. the index had undergone panel testing for the underlying epilepsy.

**Results:** We found three individuals in two unrelated families with novel homozygous rare variants in *CACNA2D2* with clinical features of DEE and cerebellar atrophy. Family #1 includes two affected siblings with a likely damaging homozygous rare missense variant c.1778g>c.p.(Arg593Pro) and family #2 includes a proband with a homozygous rare nonsense variant c.485\_486del;p.(Tyr162Tyr) in *CACNA2D2*. We compared clinical and molecular findings from all individuals from six unrelated families reported to date and noted that cerebellar atrophy is shared among all.

**Conclusion:** Our study supports the candidacy of *CACNA2D2* as a disease gene associated with DEE

and cerebellar atrophy.

## PgmNr 1286: *GRM7* causes a severe neurodevelopmental disorder characterized by microcephaly, refractory epilepsy, and global developmental delay.

### Introduction:

Defects in ion channels and neurotransmitter receptors are implicated in neurodevelopmental disorders (NDDs) and epilepsy. One such receptor is metabotropic glutamate receptor 7 (mGluR7) encoded by *GRM7*. MGLuR7 is the most highly conserved mGluR receptor and is broadly expressed in the brain. This presynaptic G-coupled receptor is critical for synaptic transmission and is recruited under high neurotransmitter concentrations to inhibit further release of excitatory neurotransmitter glutamate and the inhibitory neurotransmitter GABA.

MGLuR7-/- knockout mice develop spontaneous stimulus-provoked seizures and have reduced seizure threshold. We have previously proposed *GRM7* as a novel candidate disease gene in 4 individuals from 2 unrelated families with NDDs. One additional family has been reported since.

### Methods:

By performing family-based exome sequencing on a cohort of 185 mostly consanguineous Turkish families with NDDs, we identified 2 additional unrelated individuals with rare biallelic *GRM7* variants. Gene query to Baylor Genetics Laboratory yielded 2 more families with rare *GRM7* variants. We compare the observed clinical features and variants of 12 individuals from all 7 unrelated families, providing additional evidence to support *GRM7* as a disease-causing gene in NDDs and epilepsy.

### Results:

Novel deleterious variants in the 4 newly described families include two homozygous missense variants (c.2671G>A:p.E891K and c.1973G>A:p.R685Q), one homozygous stop-gain variant (c.1975C>T:p.R659\*) and compound heterozygous frameshift and missense variants (c.37\_38delTT:p.L13fs and c.895G>A:p.A299T). All 3 new homozygous variants were within a large Absence of Heterozygosity block (>5Mb). All 7 families had unique variants and were of different ethnicities.

Of the 12 affected individuals, neurodevelopmental delay was present in all, refractory epilepsy in 11/12 (92%), microcephaly in 9/12 (75%), and axial hypotonia in 8/12 (67%). Brain imaging showed cortical atrophy in 10/12 (83%), corpus callosum hypoplasia in 7/12 (59%), cerebellar atrophy in 5/12 (42%), and hypomyelination in 4/12 (33%) individuals. Four subjects died due to either Sudden Infant Death Syndrome, aspiration, or due to an unknown cause.

**Conclusion:**

We provide detailed clinical characterization in 7 unrelated families with rare biallelic *GRM7* variants, including 5 novel *GRM7* variants. Our study establishes *GRM7* as a potential disease-causing gene in NDDs, microcephaly, and epilepsy.

## **PgmNr 1287: *De novo* ZBTB47 missense variants in two individuals with generalized epilepsy, developmental delays, and movement abnormalities.**

### **Authors:**

---

Genetic abnormalities are thought to cause a majority of epilepsies, and next-generation sequencing technologies are providing an increasing number of discoveries of such genetic causes. Genes causing epilepsies and movement disorders encode a variety of proteins that play important roles in the central nervous system, including ion channels, neurotransmitters and receptors, transcriptional regulators, and regulators of mTOR. Through trio exome sequencing we identified *de novo* missense variants in *ZBTB47*, which encodes a minimally characterized transcriptional regulator, in two females with generalized epilepsy, developmental delays, and movement abnormalities. The severity of epilepsy was variable, with one girl experiencing up to ~60 tonic seizures per day, despite the use of anti-epileptic medications. This patient also experienced chorea with onset in infancy, while the other patient showed choreiform movements, shuddering attacks and an ataxic gait. Both experienced significant hypotonia. MRIs were normal. The *ZBTB47* variants both affect conserved residues within zinc finger domains of the protein, suggesting that they may disrupt the protein's ability to properly bind DNA. Therefore, *ZBTB47* may provide yet another example of transcriptional dysregulation causing an abnormal neurodevelopmental phenotype.

## PgmNr 1288: A case of UDP-galactose transporter deficiency (SLC35A2-CDG) response to ketogenic diet to control intractable seizures.

### Authors:

---

**Background:** Congenital disorders of glycosylation (CDG) are a group of genetic disorders characterized by abnormal glycosylation of a variety of proteins and lipids. Defects of the X-linked gene SLC35A2, which encodes the Golgi-localized UDP-galactose transporter, result in decreased UDP-galactose transport into the Golgi apparatus leading to abnormal glycosylation. Patients with this condition (formerly CDG-IIIm) show varying degrees of neurological impairments, epilepsy, and congenital anomalies. So far, approximately 60 cases have been reported. Some of the patients had early-onset epileptic encephalopathy. **Case Study:** A 23 year-old Hispanic female with a pathogenic variant of the SLC35A2 gene (c.348delA) has been followed since age 18 Mo. Hypotonia was noted at birth. Microcephaly, and fingers/toes anomalies were noted at age 18 Mo. She experienced her first seizures at age 2 Mo and did not gain any milestones for the first 18 months. She had normal transferrin glycosylation at age 14 y. Developing breakthrough tonic/convulsive seizures with recurrent status epilepticus requiring hospitalization at age 18 y, ketogenic diet was introduced emergently after failure of multiple antiepileptic drugs. The diagnosis of CDG-IIIm was made by the NGS at age 22 y. Brain MRI at age 18 y revealed diffuse, chronic cerebral/cerebellar volume loss prominent in the frontal/temporal lobes bilaterally, bilateral hippocampal dysplasia, with hyperintense MRI signal in the basal ganglia on T2 sequences. The patient's frequent and drug-resistant, generalized tonic seizures responded very well to 2.4:1 ketogenic ratio diet. Her seizure frequency dramatically improved from several tonic seizures each day to very brief spells lasting seconds occurring a few times each week on the ketogenic diet. She continued to have well-controlled tonic seizures for 3 years until age 22 y, with some improvement in attention and interactiveness, with later re-emergence of more prolonged and frequent seizures necessitating escalation of anticonvulsant interventions. **Discussion:** Galactose supplementation showed an improved glycosylation of transferrin in a case of SLC35A2. An additional UDP-galactose transporter was suggested. It is unclear why the ketogenic diet significantly improved seizure control in this patient. Collection and further investigation of other cases of SLC35A2 treated with the ketogenic diet are needed to understand the potential mechanisms of dietary therapy in this CDG.

## **PgmNr 1289: X-linked recessive Chronic Intestinal Pseudo-Obstruction (CIPO): Male patient and his unaffected mother with a frameshift/truncating variant in exon 1 of *FLNA*.**

### **Authors:**

J. Pappas <sup>1</sup>; J. Levy <sup>2</sup>

---

Pathogenic variants in *FLNA* have been associated with different X-linked syndromes. Loss of function (LoF) variants are associated with periventricular nodular heterotopia (PVNH) in females and embryonic lethality in males (Eksioglu, Y Z et al, 1996). There are rare reports of males with LoF variants in *FLNA* in the medical literature with a combination of PVNH, cardiovascular abnormalities, Ehlers Danlos and Chronic Intestinal Pseudo-Obstruction (CIPO) or Congenital Short Bowel Syndrome (CSBS) (Gargiulo A et al., 2007; Kapur RP et al 2010; van der Werf CS et al., 2012; Oda H et al 2016; Jenkins ZA et al 2017). We present a 5 year old boy with CIPO and mild neurodevelopmental delays. He was referred to us at 2 months of age because of unexplained distention and diarrhea after feeding, treated with parenteral nutrition. He presented at 3 days with vomiting and he had surgery for pyloric stenosis. He was diagnosed with intestinal malrotation treated with exploratory laparotomy and Ladd's bands release in infancy. Two maternal uncles had similar histories. Parenteral nutrition discontinued at 14 months and his bowel function started improving. At age 5, his height was at the 23<sup>rd</sup> centile while his weight was at 93<sup>rd</sup>. He tolerated different foods by mouth with no vomiting but occasional diarrhea. His neurological examination was normal. The family resembled the report by Gargiulo A et al., 2007 and *FLNA* (NM\_001110556.1) genetic testing performed in infancy revealed an insertion of T in exon 1: c.10dupT (p.Ser4Phe\*102) by Sanger sequencing. The unaffected mother carried this variant. Our patient's variant and clinical presentation was similar to the two families reported in the medical literature with two base deletion in exon 1 leading to frameshift and stop codon (Gargiulo A et al., 2007; Jenkins ZA et al 2017). CIPO was the main abnormality of affected males in our family and both families in the literature and all the carrier females were unaffected. The frameshift variants in our family and both of the families in the medical literature were in exon 1 and predicted to disrupt the expression of *FLNA*<sup>+1</sup> isoform; the expression of *FLNA*<sup>+28</sup> was predicted normal (Jenkins ZA et al 2017). *FLNA*<sup>+1</sup> is predominantly expressed in the intestines and *FLNA*<sup>+28</sup> in many tissues including the brain. Our patient and his family provide additional evidence that frameshift/truncating variants in exon 1 of *FLNA* are associated with CIPO in males and cause no abnormality in females.

## PgmNr 1290: Identification of novel variants causing leukodystrophies in Sudan.

### Authors:

Abubakr <sup>1</sup>; D. Mustafa <sup>1</sup>; M. Osman <sup>1</sup>; Y. Hasan <sup>1</sup>; A. Elshafea <sup>1</sup>; M. Siddig <sup>1</sup>; S. Haron <sup>1</sup>; L. Elsayed <sup>1</sup>; A. Ahmed <sup>1</sup>; O. Boespflug-Tanguy <sup>2,3</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Faculty of Medicine, University of Khartoum, Khartoum, Sudan; 2) INSERM UMR 1141 PROTECT, Université Paris Diderot- Sorbonne Paris Cité, France; 3) Neuropediatrics and Metabolic Disorders Department, reference center for leukodystrophies and rare leukoencephalopathies (LEUKOFRANCE), CHU APHP Robert-Debré, Paris, France

---

**Background:** Leukodystrophies are inherited disorders primarily affecting the white matter of the CNS with or without peripheral nerve involvement. There are currently 30 recognized forms of leukodystrophies with distinct clinical, biochemical and radiological characteristics. However, the genetics of these classical forms of leukodystrophies remain unknown in many parts of the world especially in Sub-Saharan Africa. This study aimed to shed the light on the clinical and genetic characteristics of leukodystrophies in Sudanese families.

**Methods:** Fifty two families with suspected leukodystrophy from different regions of Sudan were analyzed in the study. Genomic DNA was extracted and screened for mutations using NGS panel testing 153 leukodystrophies and leukoencephalopathies causing genes (NextSeq500 Illumina).

**Results and Discussion:** Nine novel variants were discovered: four variants causing Megalencephalic leukodystrophy with subcortical cysts (which was found to be the most common type of leukodystrophy in Sudan), two variants causing Metachromatic leukodystrophy, two variants causing Leukoencephalopathy with brain stem and spinal cord involvement and lactate elevation and one variant causing Spastic paraplegia 51. We hypothesized that the higher percentage of MLC is caused by the adaptation of heterozygous genotype to hot, dry environments like Sudan (heterozygote superiority).

**Conclusion:** This is the first study to highlight the genetics of leukodystrophies in Sudan. Analysis of additional families is in progress in order to establish the whole spectrum of genetic variations causing inherited leukodystrophies in Sudanese families.

## PgmNr 1291: Nonsense and missense variants in *CAMTA1* gene are associated with developmental delay/intellectual disability, gait abnormalities, and hypotonia.

---

Calmodulin binding transcription activator 1 (*CAMTA1*) encodes a transcription factor and a tumor suppressor. Pathogenic intragenic copy number variation (CNVs) in *CAMTA1* have been associated with nonprogressive cerebellar ataxia with mental retardation (CANPMR; MIM# 614756). The clinical manifestations include development delay (DD)/intellectual disability (ID), ataxia, dysarthria, and poor fine motor skills with/out brain abnormalities. Here, we describe 6 additional patients from unrelated families with overlapping phenotypic features, but who were found to have missense, nonsense variants, or an intragenic duplication in *CAMTA1* gene.

### Patients:

All patients in our cohort (F/M:3/3; 4 Caucasians, 1 Arab and 1 Russian) had motor and speech delay and/or ID with variable severity as well as gait abnormalities ranging from "clumsiness" to ataxia. Five patients had hypotonia and 4 had minor dysmorphic features but without recognizable facial gestalt. Four patients had eye abnormalities, 3 had brain MRI abnormalities, and 2 had difficulties in fine motor skills. The two carrier parents (one of whom is mosaic) had overlapping but milder phenotypes.

### Material and Methods

Exome sequencing was performed on patients (1-4 and 6) and chromosomal microarray analysis was performed on patients 1-3, 5-6.

### Molecular results

Patients 1 and 2 had *de novo* missense variants (p.Y1525C and p.K141N) and patient 3 had a paternally inherited missense variant (p.G500A). The CADD scores and p values for VEST analysis for these variants were 26.2, 23.9 and 26, and 0.0060, 0.019 and 0.077, respectively. The father carrying the p.G500A variant exhibits ID and tremor. Patients 4 and 5 had a *de novo* frameshift and a maternally inherited stop-gain variants (p.E1368GfsX11, p.Gln772\*), respectively, and patient 6 had a duplication of exons 12-16 of *CAMTA1* gene resulting in a frameshift and stop codon after introducing 21 novel amino acids.

### Conclusions

The identification of pathogenic nonsense variants in *CAMTA1* gene in patients with DD/ID, hypotonia, gait and balance abnormalities provides additional evidence that *CAMTA1* has a role in normal brain and cerebellum function and is dosage-sensitive. We speculate that the missense variants cause loss of function as well but this is less clear. Larger cohorts are needed to examine the full spectrum of clinical manifestation and genotype-phenotype correlation. Further studies are required to investigate

the exact role of CAMTA1 in brain development.

## **PgmNr 1292: 11-year-old male with cerebral palsy, seizures, microcephaly, and intellectual disabilities with compound heterozygosity in the *SRCIN1* gene: Candidate gene for a new syndrome.**

### **Authors:**

S. Berger; A. Iglesias

[View Session](#) [Add to Schedule](#)

**Affiliation:** Columbia University Medical Center , New York, NY.

---

Our patient initially presented to clinic at age 11 with spastic cerebral palsy, intellectual disabilities, seizures, microcephaly, contractures, strabismus, emaciation, and reduced muscle bulk. He was born full term after an uneventful pregnancy. He is of Dominican descent and consanguinity was denied. He has a history of seizures since shortly after birth, with profound developmental delay and intellectual disability since an early age, without regression. He is nonverbal and unable to stand without support.

At the time of our consult, he was not seeing any other specialists or receiving any services. He had failure to thrive and poor seizure management with seizures 4-5 times per day. We referred him to multiple specialists at our medical center. He now has a G-tube for feeding and medication, is followed by multiple specialists, and is on multiple anti-epileptics, with an average of 1 seizure per day. Brain MRI shows encephalomalacia. EEG shows epileptic encephalopathy, likely Lennox-Gastaut syndrome.

Physical exam was positive for micro-dolicocephaly, long face, synophrys, strabismus, high arched palate, mild scoliosis, contractures of elbows, knees, wrists and fingers, reduced muscle bulk, axial hypotonia and distal spasticity.

WES identified compound heterozygous variants of uncertain significance in the *SRCIN1* gene. This is currently a candidate gene with no known genetic condition associated with variants in this gene and no known mode of inheritance. Studies have shown that this gene is expressed in the spinal cord and the brain, but further research is needed to clarify if there is a relationship between variants in this gene and his phenotype. We have reached out to a group who is researching this gene and compiling cases.

Incidentally, a microarray showed a 1.7Mb duplication of Xp22.31 which is classified as a variant of uncertain significance. Similar or larger duplications of Xp22.31 have been reported in individuals with neurodevelopmental phenotypes, congenital anomalies, and dysmorphic features. However, these duplications have also been reported in clinically healthy individuals. Therefore, the clinical significance of this variant remains uncertain at this time. No maternal sample is available to determine inheritance.

In summary, we are reporting a patient with a unique phenotype and compound heterozygosity in a

candidate gene. Further assessment of similar patients, as is currently done, will clarify the true nature of this finding.

## PgmNr 1293: Identification of a novel candidate gene in a patient presenting with a neuromuscular disease.

---

Pediatric neuromuscular disorders (NMD) are characterized by a genetically heterogeneous etiology with diverse pathomechanisms. NGS techniques have allowed for the discovery of novel causative genes in this family of disorders. However, many patients still remain genetically unresolved. Here we describe an adolescent patient from consanguineous, unaffected parents who clinically presented with a muscle dystrophy in a limb-girdle pattern at the age of 11. While being asymptomatic in her first decade of life, her symptoms quickly progressed to her requiring assistance with walking and eating. MRI of spine and brain were unremarkable, however EMG studies showed chronic diffuse disorder of her motor neurons. Her lab work, including creatine kinase, was normal. Targeted genetic testing of suspected genes (including *SMN1*, *SMN2*) and microarray analysis was negative. Whole-exome sequencing identified a homozygous missense variant (c.637T>G p.Phe213Val) in exon 2 of *ZNF106*, mapped to chromosome 15q15.1. The p.Phe213 residue is highly conserved across species and *in silico* analysis predicts the Val substitution to be deleterious; with a CADD score of 24.3. *ZNF106* has not been associated with disease, however, recent studies have shown that homozygous loss in mice causes a progressive degeneration of motor neurons and overexpression partially rescues the phenotype in a fruit fly model of *C9orf72* ALS. Furthermore, gene expression is largely restricted to skeletal muscle and recent studies have shown that the ZNF106 protein interacts with RNA, RNA binding proteins and is putatively involved in RNA splicing. Interestingly, pathway analysis of significantly dysregulated genes ( $P \leq 0.05$ ) from patient blood RNAseq data compared to unaffected individuals showed an association to familial amyotrophic lateral sclerosis ( $P = 0.000251$ ), further indicating the role of *ZNF106* in neuromuscular disease. Nonetheless, it is not known whether the p.Phe213Val missense variant in our patient disrupts its putative function and causes disease. We are modeling our patient's missense variant in mouse and zebrafish to understand its putative pathogenicity. In addition, *in vitro* studies will be performed to test the effect of the missense variant on localization, interactome and function of the ZNF106 protein. These studies may bring about a new genotype-phenotype correlation into the spectrum of NMDs and thereby reveal novel pathomechanisms.

## PgmNr 1294: GGC repeat expansion in *NOTCH2NLC* is the cause of neuronal intranuclear inclusion disease.

---

Neuronal intranuclear inclusion disease (NIID) is a slowly progressive neurodegenerative disease characterized by eosinophilic intranuclear inclusions in the central and peripheral nervous system, and in the visceral organs. These intranuclear inclusions were ubiquitin and p62 positive by immunohistochemistry, and without limiting membrane under electron microscopic findings. These histopathological feature has been the hallmark of NIID and the basis of NIID diagnosis.

We started genetical study of NIID with familial NIID patients from two families diagnosed by autopsy. First, we studied linkage analysis with micro satellite markers and identified a peak showing highest LOD score 4.82 at 1p31.1-1q21.3, encompassing 68 Mb. We need to add another familial NIID patients to narrow down. But, the number of newly diagnosed NIID patients were few because autopsy was the only one means of diagnosis. To overcome this situation, we minutely examined NIID histopathological samples and find that skin biopsy was useful to the antemortem diagnosis of both familial and sporadic NIID patients.

After that, we diagnosed many NIID patients by skin biopsy and included them. We engaged in all exome and whole genome sequence with short-read next generation sequencer, but we could not find any nonsynonymous variations that segregate with NIID. We studied linkage analysis again with SNV data from short-read NGS, and its results showed highest LOD score 4.21 in almost same position of the result of linkage analysis with micro satellite markers. We concluded that the genetical cause of familial NIID must not be SNV and be exist within this high LOD score position, and we promoted long-read NGS study. Finally we include familial NIID patients from 9 families, and 40 sporadic NIID patients, and identified a GGC repeat expansion in *NOTCH2NLC* in all and only affected NIID patients.

We can now diagnose NIID more precisely with clinical, pathological and genetical means with the diagnostic flowchart of NIID we made of before. We will promote molecular biological study and radical treatment of NIID.

Aknowledgments: Drs. Haruki Koike, Akihiro Hashiguchi, Hiroshi Doi, Shigeru Koyano, Hideyuki Takeuchi, Michi Kawamoto, Nobuo Kohara, Tetsuo Ando, Toshiaki Ieda, Yasushi Kita, Norito Kokubun, Yoshio Tsuboi, Takeshi Mizuguchi, Kohei Hamanaka, Kazutaka Katoh, Yoshihiro Kino, Masahisa Katsuno, Ikuo K. Suzuki, Martin C. Frith are very much appreciated for their participation to this study.

---

The paternally imprinted *KCNK9* gene encodes a two-pore-domain potassium ion channel expressed primarily in the brain. A Gly236Arg variant in *KCNK9* has been reported to cause *KCNK9* imprinting syndrome in several families, as has a nearby Ala237Asp variant in an additional individual. Here, we

describe a cohort of 18 affected individuals from 14 families with one previously reported (Gly236Arg) and 11 novel *KCNK9* alterations. Phenotypes in these patients are generally consistent with, but demonstrating greater variability, compared to published patients with *KCNK9* imprinting syndrome. The most common phenotypes include motor delay, speech delay, intellectual disability, facial dysmorphism, hypotonia, and behavioral concerns (aggressive or compulsive behavior, ADHD, anxiety).

Protein modeling and dynamics simulations predict variants affect protein structure, dynamics, and K<sup>+</sup> ion distribution. Compared to WT, a subset of variants demonstrate an increased probability of K<sup>+</sup> near the channel pore and are associated with more K<sup>+</sup> transport events. This is in stark contrast to the decrease seen with previously described Gly236Arg, suggesting distinct channel dysregulation by these novel variants. Patient variant characterization using electrophysiological techniques showed seven of thirteen variants cause a gain of conductance compared to WT. Three variants result in a loss or reduction in conductance, and three variants show conductance similar to WT. Ten of the thirteen variants were outwardly rectifying with reversal potentials close to the WT equilibrium potential. Three variants had significantly depolarised reversal potentials. Computational modeling and molecular dynamic simulation results were consistent with experimental assays. Further, we have identified two additional families with variants impacting channel function, but for which additional evidence suggests reduced penetrance.

We describe a cohort of patients with *KCNK9* imprinting syndrome caused by novel *KCNK9* variants with varied functional impact. Both loss of function, like the classical Gly236Arg, and gain of function effects were observed. Based on this observation, we predict that channel agonists, which have been reported as efficacious in patients with the Gly236Arg variant, may not benefit patients with gain-of-function variants.

## PgmNr 1296: Multi-omic analyses in a family with Gaucher and Gaucher-Parkinson diseases reveal several potential modifier genes in *GBA1*-associated Parkinson disease.

---

Gaucher disease (GD) is an autosomal recessive lysosomal storage disorder caused by mutations in *GBA1*. Although GD is a rare disorder, mutations in *GBA1* are also the most common genetic risk factor for the more prevalent neurological disorder Parkinson disease (PD). Focusing on a nuclear family with several informative members, we performed multi-omic analyses including epigenetic studies to identify potential modifiers impacting the association between GD and parkinsonism. The proband in this family had type 1 GD and was evaluated at age 20 when she presented with typical Gaucher manifestations, and again at age 56 after she developed PD, and fibroblasts were collected on both occasions. We analyzed DNA methylation in both sets of fibroblasts, as well as fibroblasts from her two older sisters, one with GD but without PD, and the other without PD or *GBA1* mutations. Bisulfite-treated DNA extracted from the fibroblast lines and an Illumina HumanMethylationEpic BeadChip were used to analyze the methylation of CpG islands. RNA, extracted from fibroblasts from the proband at both ages and from her two sisters, was analyzed by microarray using an Affymetrix Human Clariom S Assay and by 3'-Poly(A) tail RNA-seq. Several methylated and demethylated candidate genes, identified in the proband at age 56, were confirmed in the expression array and by RNA-seq. Illumina GenomeStudio, Affymetrix Transcriptome Analysis Console, Limma and R were employed to elucidate biologically significant genes for further evaluation. Whole Exome Sequencing was also performed on DNA from each family member, and homozygous and compound heterozygous variants identified in the proband only were confirmed by Sanger sequencing and are currently undergoing further evaluation. Integrating the data from methylation studies, whole genome expression arrays, RNA-seq and whole exome sequencing using functional and protein-network analyses may help to determine whether the observed changes are directly or indirectly related to the development of parkinsonism in this patient with GD.

## PgmNr 1297: Novel variants in *LYST* associated with Chediak-Higashi disease.

---

**Introduction:** Chediak-Higashi Disease (CHD) is a rare, recessive disorder characterized by hematologic, pigmentary, neurologic and immunologic features, and can involve life-threatening hemophagocytic lymphohistiocytosis. CHD results from bi-allelic mutations in the lysosomal trafficking regulator gene (*LYST*). *LYST* contains 55 exons, encoding a large 429 kDa protein with an unknown function. *LYST* has an N-terminal ARM/HEAT domain and a C-terminal BEACH domain with WD-40 repeats. More than 75 *LYST* variants causative of CHD have been reported to date, scattered throughout the gene.

**Methods:** In our CHD Natural History study, we extensively investigated 17 CHD patients. Molecular and cellular studies were performed on fibroblast, leukocyte, natural killer (NK) cell and melanocyte cultures. Clinical, genetic and cell biology studies were used to evaluate the correlation between phenotypes and the molecular genotypes of patients with CHD.

**Results:** The patients in our cohort had variable clinical features of CHD, bi-allelic *LYST* variants and enlarged lysosomes within cell cultures. We identified 28 novel *LYST* variants. Genotype-phenotype correlations were noted. Most cases with classic severe CHD clinical features had two truncating *LYST* variants and markedly enlarged lysosomes in cultured fibroblast that were perinuclear clustered, while individuals with a milder clinical presentation had at least one homozygous missense *LYST* variant and milder enlargement and perinuclear accumulation of lysosomes. NK cells of subjects with ARM/HEAT domain mutations had larger lysosomes that polarized to the immune synapse but failed to fuse with the plasma membrane. NK cells of subjects with BEACH domain mutations had smaller and more numerous lysosomes, with impaired migration of lysosomes to the immunologic synapse. In all subjects, NK lytic activity was markedly decreased.

**Conclusion:** Our molecular studies increased the total reported number of *LYST* variants to over 100. CHD clinical severity correlates with severity of the *LYST* protein variant and cellular phenotype. Cellular studies suggest a role of *LYST* in localization and size of lysosomes as well as lytic activity of NK cells. CRISPR cell lines and mouse models are now being investigated to aid our basic investigations and design therapeutic approaches. These results are valuable for understanding the spectrum of disease in CHD and the underlying biological mechanisms of disease.

## PgmNr 1298: Correlation between HPO terms and diagnostic yield in neurodevelopmental disorders.

HUG-CELL has implemented targeted massively parallel sequencing for diagnosis of several diseases and currently offers tests and genetic counseling for families affected with different conditions. We are conducting a preliminary analysis to verify the correlation between specific terms described in medical request and our diagnostic yield. To accomplish this goal, we have included 18 patients exhibiting features of neurodevelopmental disorders, who were referred to our center for molecular testing throughout the last 2 years with clinical indications presenting the terms: global developmental delay (**GDD**) (HP:0001263), developmental regression (**DR**) (HP:0002376) and seizures (**Se**) (HP:0001250). Using a panel with ~6700 genes (TruSight One Expanded - Illumina), we have concluded the molecular diagnosis for 9 individuals (50%) (pathogenic/likely pathogenic alterations in *ACTB*, *AHDC1*, *CTNNB1*, *DEAF1*, *DHDDS*, *DYRK1A*, *HDAC8*, *KCNB1*, *RAC1*, some of them not previously reported in the literature); 6 patients (33%) presented at least one variant of unknown significance - *VUS* (*ARID1B*, *CACNA1H*, *KCNQ3*, *SCN2A*, *SMARCC2*) or one pathogenic/likely pathogenic alteration in genes previously associated with autosomal recessive mode of inheritance (*COG1*, *COG5*); in 3 individuals (17%) no alteration was detected. In spite of the relevant sensitivity rate obtained by our laboratory, the relative frequencies taking into account the abovementioned terms are highly discrepant: considering patients who presented **GDD** (HP:0001263) associated or not with **Se** (HP:0001250) (N=8), the positive detection was attained for 75% (N=6); for individuals whose reasons for request included **DR** (HP:0002376) associated or not with **Se** (HP:0001250) (N=4), the conclusive diagnosis was achieved for 50% (N=2); nevertheless, for patients with clinical indications containing the term **Se** (HP:0001250) without stated **GDD** (HP:0001263) or **DR** (HP:0002376) (N=6) the molecular diagnosis was concluded in 17% (N=1). Although the limited size of our cohort, the low rate of positive diagnosis in the third group (**Se** without **GDD** or **DR**) could suggest that several associated-genes remain to be identified and/or its etiology is complex and fits a polygenic model instead of a Mendelian trait. Once confirmed in a large cohort, these results will be significant to prioritize patients to be investigated using whole exome sequencing, particularly when their tests are paid by public funding.

Financial support: Fapesp/CEPID and CNPq/INCT.

## PgmNr 1299: Genetics of a novel neonatal neuromuscular disorder in dogs.

---

Neuromuscular disorders are a group of rare heterogeneous diseases in humans and animals including dogs. In our research on the causes of high neonatal mortality in Norwich Terrier breed, we have discovered a neonatal neuromuscular disorder in two consecutive litters by the same unaffected parents. In the first litter, a five-week-old puppy was euthanized due to progressive weakness and consequent difficulties in ambulation. In the second litter, a puppy was euthanized at the age of 1.5 weeks due to dyspnea and failure to thrive. A full necropsy was performed on both puppies. Histologically both affected puppies had mild to moderate neurogenic atrophy of the striated muscles. In addition, the 1.5 weeks old puppy had severe thoracic dysplasia. Whole-genome sequencing (WGS) was performed of both affected puppies and their unaffected parents. An in-house pipeline was used for the calling of SNVs, indels, SVs, CNVs and mobile elements. The variants were filtered under recessive, de novo and compound heterozygous models against 868 whole-exome and WGS data from unaffected dogs from other breeds including seven Norwich Terriers. We also analyzed the data as two independent trios that resulted in discovery of candidate variants not shared by the affected puppies suggesting the muscle phenotype is genetically different in them. The found variants were first prioritized by in silico prediction and deleterious candidate variants are currently being validated and screened by Sanger sequencing, using DNA samples from a large cohort of Norwich Terriers stored in our (over 70.000 samples) canine biobank at the University of Helsinki. The functional consequences will be studied by utilizing tissue samples that were collected during necropsy. As dogs have emerged as an important natural model for human inherited diseases with clinicopathological and genetic similarities, our study will bring new insights to the neuromuscular disease spectrum in humans.

## OBJECTIVE

Inherited peripheral neuropathies (IPNs), as represented by Charcot-Marie-Tooth disease (CMT), are clinically and genetically heterogeneous. To date, more than 100 causative genes have been identified. Unexpectedly, the mutation detection rate of IPNs remains low, suggesting the necessity of further exploring unidentified disease causing genes. The purpose of this study is to identify new causes of IPNs in patients with autosomal recessive (AR) IPNs.

## METHODS

Using whole-exome sequencing (WES), we sequenced 303 unrelated patients clinically diagnosed with IPNs. We concentrated on all the recessive variants/genes shared among multiple patients manifesting with comparable clinical phenotypes. We identified cytochrome oxidase assembly factor 7 (*COA7*) gene as a novel causative gene for AR-IPNs and performed mutation screening of the *COA7* gene in 1024 additional patients with IPNs. Furthermore, we provide clinical, genetic, histopathological, and functional data to support the contention that the recessive mutations in the *COA7* gene are responsible for neurological impairment.

## RESULTS

We identified recessive mutations in the *COA7* gene in six unrelated patients. Validated mutations were located at highly conserved residues among different species and segregated with the disease in each family. All six patients with *COA7* mutations had characteristic neurological features of axonal neuropathy, and some patients showed cerebellar ataxia, extrapyramidal symptoms, cognitive impairment, spasticity or subclinical mitochondrial myopathy. MRI scans showed white matter lesions, cerebellar or spinal cord atrophy. Sural nerve biopsies showed chronic axonal degeneration with a marked loss of large and medium myelinated fibres. Mitochondrial respiratory chain enzyme assay in skin fibroblasts from the three patients showed a definitive decrease in complex I or complex IV. In addition, *Drosophila COA7* (*dCOA7*) knockdown models showed rough eye phenotype, reduced life span, impaired locomotive ability and shortened synaptic branches of motor neurons.

## CONCLUSIONS

Our results suggest that loss-of-function *COA7* mutation is responsible for the phenotype of the

presented patients, and this new entity of disease would be referred to as spinocerebellar ataxia with axonal neuropathy type 3 (SCAN3)[MIM 618387]. Mutations in *COA7* may also lead to heterogeneous neuromuscular involvement, manifesting phenotypic diversity in the future.

---

Since inception in 2011, the Centers for Mendelian Genomics have recruited 23K families and generated data for more than 45K individuals from 80 countries. This effort has been a collaboration among four funded centers and >4K collaborators worldwide. The Baylor-Hopkins Center for Mendelian Genomics (BHCMG) has enrolled more than 18K individuals and contributed WES data for 10K samples. For the BHCMG, the BCM:Human Genome Sequencing Center and JHU:Center for Inherited Disease Research have generated ~90Tb of WES data. Using a multiplex strategy with an in-house developed exome capture with custom spike-in has yielded 10Gb of data per exome with 97% at ≥20X coverage. Implementation the NovaSeq platform has decreased the cost by 50% per sample.

Molecular diagnostic rates vary by phenotype/cohort from 37-85%. For undiagnosed cases several strategies are used to ascertain a molecular diagnosis including: sequencing additional family members, searching for additional patients with the same candidate genes/variants in publically accessible databases including GeneMatcher (32K submissions, 130K matches and 10K genes), VariantMatcher and internal databases; and/or alternative sequencing approaches. A large-scale re-processing effort for the BHCMG dataset is underway including alignment and variant calling on GRCh38 for a more comprehensive analysis. Also several families are being piloted for a combined approach using both short/long read WGS to identify coding/non-coding variation, copy number and copy neutral structural variants. BHCMG continues to engage private diagnostic labs to reflex undiagnosed clinical cases into research studies utilizing existing sequencing data for further analysis.

Cumulative analysis of the BHCMG dataset has yielded discoveries in 741 genes including 267 novel and 176 phenotypic expansion genes. Reported discoveries including allelic series, multi-locus pathogenic variation and other mutational burden/oligogenic models for complex traits have been published in >250 papers. BHCMG has established valuable sample acquisition approaches; generated ethnicity-specific data resources, enhanced sequencing methodology, developed PhenoDB, a highly curated, searchable database currently with 8.7K entries and encouraged collaborative efforts. Each discovery has highlighted the diagnostic capabilities in using WES and has taught

lessons in the genomics of disease that continue to drive investigation into cases that remain undiagnosed.

---

The *CADM* family of proteins consists of four neuronal specific adhesion molecules (*CADM1*, *CADM2*, *CADM3* and *CADM4*) that mediate the direct contact and interaction between axons and glia. In the peripheral nerve, axon-Schwann cell interaction is essential for the structural organization of myelinated fibers and it is primarily facilitated via *CADM3*, expressed in axons, binding to *CADM4*, expressed by myelinating Schwann cells. We have identified by whole exome sequencing (WES) three families with axonal Charcot-Marie-tooth disease (CMT2) sharing the same private variant in *CADM3*, Tyr172Cys. This variant is absent in 230,000 alleles in gnomAD and predicted to be pathogenic. Although these *CADM3* families have been diagnosed with CMT2, they all share the same peculiar phenotype consisting of axonal motor neuropathy affecting mainly the upper limbs with pyramidal signs. High-resolution mass spectrometry analysis detected a new disulfide bond created in the mutant *CADM3* potentially modifying the native protein conformation. This result was supported by significant increased protein retention of the mutant in the endoplasmic reticulum leading to activation of the unfolded protein response (UPR). In addition, Stochastic Optical Reconstruction Microscopy (STORM) imaging revealed decreased co-localization of the mutant *CADM3* with *CADM4* at the plasma membrane between cell-cell contact sites. Our findings indicate a novel molecular pathway in patients with CMT involving axon-glial interaction abnormalities.

## **PgmNr 1303: Cofactors biotin, pantothenic acid, and lipoic acid dramatically improved the health of a child with *SLC5A6* gene defect, but not natural killer T-cell function, leading to an ALTE with brain damage and loss of gained skills.**

Mutations in the gene *SLC5A6* are a newly described treatable genetic disorder in the SMVT protein, leading to decreased transport of biotin, pantothenic acid, and lipoic acid across cell membranes (Subramanian, VS, et al; Mutations in *SLC5A6* associated with brain, immune, bone and intestinal dysfunction in a young child. Human Genetics 2017 Feb;136 (2):253-261). Our patient's treatment began at age 15 months with high dose cofactors biotin, pantothenic acid, and lipoic acid to overcome the joint transport defect by diffusion. There was a dramatic improvement in areas of growth and development, head size, bone density and health (ibid). Here we report that frequent infections in this child did not improve and natural killer (NK) cell numbers and functions remained low. A year and a half after start of therapy, the child experienced a viral infection that led to an acute life threatening event (ALTE) with fever, shock, hypotension and devastating central nervous system effects. A virus was not identified. Dramatic hypoperfusion effects were found on an MRI scan in spin of inotropic measures to increase blood pressure and maintain life. The patient recovered after 2 weeks of intensive care, but he suffered loss of skills and intellectual performance. He could no longer walk or talk. Immunologic factors, including immunoglobulins which did improve after therapy, and NK cells which did not, were part of the expression of *SLC5A6* defects in this case. The defect in NK cells was a risk factor for the viral infection experienced by this child, and earlier diagnosis may have altered the outcome.

## PgmNr 1304: Novel *SON de novo* mutation in a patient with a severe neurodevelopmental disorder.

---

*SON* is one of serine and arginine-rich (SR) proteins which contain a long repeat of serine and arginine as a characteristic domain, known as the RS domain, and play as splicing regulators. A heterozygous mutation of *SON* in patients with ZTTK syndrome can lead to splicing errors, such as exon skipping and intron retention. There are 29 reported mutations, and most of the mutations (28/29) are detected in exon 3 of *SON*, which is the largest exon and contains RS domain. These mutations are located in the RS domain or the upstream of RS domain; therefore, these mutations may lead to the dysfunction of RS domain. We detected a novel *de novo* heterozygous mutation in *SON* at the downstream of RS domain by whole exome sequencing, and our case shows the clinical features of ZTTK syndrome. We also detected new two *de novo* heterozygous mutations in *SON* exon 3 at the upstream of RS domain, and these are suggested the dysfunction of the RS domain as well as reported cases with ZTTK syndrome (case 2: c.2977\_2980dup and case 3: c.1881\_1882delAG, NM\_138927.2). Here, we report a novel *SON* mutation and propose that a *SON* mutation in the downstream of RS domain is associated with clinical features of ZTTK syndrome by genotype-phenotype analysis.

Our novel case showed a severe intellectual disability, motor developmental delay, hypotonia, brain malformation, autistic features, and dysmorphic features. The other two cases with a hotspot mutation in *SON* exon 3 showed the characteristic features of ZTTK syndrome patients. Compared to reported cases with *SON* hotspot mutation, our three cases mimic the phenotype of ZTTK syndrome. We also performed expression analysis using patient RNA samples, which is isolated from PBMC of our three cases. All samples showed the changes of alternative splicing patterns in several genes, such as *ADA* and *TUBG1*, which are reported the association with *SON* mutation and splicing errors. The previous report showed only the splicing errors of the mutations in the RS domain. Therefore, this is the first evidence that both mutation types of the RS-upstream and RS domain induce *SON*-mediated splicing errors; moreover, the novel mutation in the RS-downstream of *SON* also lead to splicing errors. Our data will help to understand the gene function of *SON* and the molecular mechanisms of RNA-mediated neurodevelopmental disorders.

## PgmNr 1305: Clinical features of KIF1A-related disorder: A Japanese patient with a novel missense variant and literature review.

---

[Background] Kinesin superfamily proteins (KIFs) play an essential role in neuronal development and survival by transporting membranous organelles and protein complexes along microtubules. Kinesin family member protein 1A (KIF1A) belongs to the kinesin-3 and is a microtubule plus end-directed motor protein. Here, we report clinical and genetic findings of a patient with multiple system neurodegeneration, who was found to have a novel heterozygous missense variant in *KIF1A* (c.833T>C, p.L278P). [Method and Results] The patient is a 33-year-old Japanese man. His motor and intellectual development were delayed. At 36 months, his full-scale IQ assessed by Tanaka-Binet test was 34. At age 7, his neurological examination showed distal dominant muscle atrophy and weakness. Deep tendon reflexes were brisk in the upper and lower extremities, except Achilles tendon reflexes, which were absent. Both planter responses were extensor, and he had pes cavus. Both limb and truncal ataxia were evident. He could not walk without walking assist tools. Routine blood and cerebrospinal fluid examinations were normal. Magnetic resonance imaging (MRI) of the brain showed atrophy in the cerebellar hemispheres and vermis. An ophthalmological examination demonstrated bilateral optic neuropathy and cataract. Serial radiological studies revealed progressive cerebral cortical atrophy. Clinical exome analysis, using a MiSeq and TruSight One Sequencing Panel (Illumina, San Diego, CA, USA) including 4813 genes associated with human genetic disorders, revealed a novel de novo heterozygous missense variant in *KIF1A*. [Discussions] Our patient showed multiple system neurodegeneration, including infantile or childhood onset, intellectual disability, upper and lower motor neuron signs, and cerebellar ataxia. To date, 70 patients with genetically-confirmed KIF1A-related disorders, including ours, have been reported. Most of patients showed various degrees of neurological manifestations, including upper (89%) and lower (45%) motor neuron signs, intellectual disability (66%), cerebellar ataxia (45%), and optic neuropathy (39%), while epilepsy (13%) and microcephaly (10%) were less frequent. This study suggests the clinical utility of using panel-based TES. KIF1A-related disorder is very rare and poorly understood. Molecular genetic analysis of *KIF1A* should be considered in patients who show a combined phenotype of both upper and lower neuron sign, intellectual disability and cerebellar ataxia.

## PgmNr 1306: Disease severity in *KIF1A* Associated Neurological Disorders (KAND) is correlated with variant location.

### Authors:

---

### Background

*KIF1A* Associated Neurological Disorders (KAND) comprise a recently identified group of rare neurodegenerative conditions caused by mutations in *KIF1A*. *KIF1A* is a member of the kinesin-3 family of microtubule (MT) motor proteins. The phenotypic spectrum of KAND includes neurodevelopmental delay, intellectual disability, autism, microcephaly, progressive spastic paraplegia, peripheral neuropathy, optic nerve atrophy, cerebral and cerebellar atrophy, and seizures. Diagnosis is complicated by the large number of disease-causing mutations identified, predominantly heterozygous missense mutations occurring within the motor domain of the protein, many of which are unique mutations. Even among dominant variants within the motor domain, there is currently no way to predict prognosis.

### Methods

We collected caregiver or self-reported medical history and Vineland Adaptive Behavior Scales from individuals with clinically-identified *KIF1A* variants. We also aggregated data on all 82 KAND cases described in the literature, and developed a heuristic severity score by a weighted sum of common symptoms which we applied to all cases with sufficient data. To compare variant severity across dominant motor domain mutations, we further characterized genetic variants using deleterious scores, disease severity, (averaged across a given mutation) and location in the 3 dimensional protein structure.

### Results

Our cohort includes 71 individuals, 58% male and 42% female, 2m-37y old (mean: 10 years, median: 7 years). We describe 32 mutations not previously published. Our analysis of motor domain mutations focused on 133 cases (54 from our cohort, 79 from the literature). We saw a modest but significant correlation between disease severity and CADD scores ( $p=0.27$ ,  $p\text{-value}=0.002$ ), and found that disease severity is strongly associated with location in MT-binding regions, P-loop, switch I, switch II, and neck linker. We found 23 out of 28 (82%) of the most severe KAND cases (score  $>5$ ) had mutations located in the MT-binding regions (vs 10/30 of the least severe), and cases with mutations in these regions had significantly higher severity scores ( $p=2.1e-5$ ;  $\Delta\text{mean}=3$ ) than those with mutations outside the MT-binding regions.

### Discussion

We describe the largest natural history study of KAND to date and the first KAND severity score. We identified the functional subdomains of the protein associated with the most severe disease, providing useful targets for future therapeutic development.

---

Coffin-Siris syndrome (CSS) is a rare but severe neurodevelopmental disorder that is characterized by developmental disability, hypoplasia of the fifth digit, coarse facial features, and a variety of other rarer symptoms. Mutations in the members of the SWI/SNF chromatin remodeling complex are thought to cause CSS, although there is little to no functional data characterizing the patient mutations. Through the Undiagnosed Disease Network (UDN) we identified a patient with symptoms similar to CSS, who carries a *de novo* frameshift allele in the gene BRD4 Interacting Chromatin Remodeling Complex Associated protein (*BICRA*), a non-canonical member of the SWI/SNF complex. Here we present the first functional characterization of the *Drosophila* homolog of *BICRA*, *CG11873*, and correspondingly the first functional characterization the non-canonical SWI/SNF complex *in vivo*. We demonstrate that, like other SWI/SNF complex members, loss of *CG11873* is a dominant enhancer of position effect variegation. *CG11873* mutants also exhibit climbing defects at day 1 and live only for one week, both of which can be rescued by the genomic locus. Finally, we show that *CG11873* binds to other SWI/SNF complex members. Together our data show that *CG11873* is a SWI/SNF complex member whose loss leads to a less severe version of CSS in humans.

## PgmNr 1308: Upstream missense variants approximately located in *Hikeshi* gene cause hypomyelinating leukodystrophy.

### Authors:

**Background:** A founder Ashkenazi missense variant, Chr11:86017416 G>C (p.Val54Leu), in *Hikeshi* gene (*C11ORF73*), encoding HSP70 nuclear transporter protein was found to cause hypomyelinating leukodystrophy, associated with spasticity and intellectual disability. At present, no further pathogenic variants in the gene have been described. We detected two additional missense variants in the gene causing similar phenotype.

**Methods:** We have performed trio exome sequencing of patients with leukodystrophy and their parents as part of a clinical evaluation.

**Results:** We have detected a missense variant, CHR11: 86017488 T>C (p.Pro78Ser) in homozygous state in an 18 year-old male of Christian Arab origin, with leukodystrophy, severe intellectual impairment and spasticity.. His healthy consanguineous parents were found to be heterozygous to the variant, while his healthy two sibs were detected to be heterozygous for the variant as well. A compound heterozygous for the founder Ashkenazi variant and the CHR11:86017330 T>C (p.Phe25Ser) variant has been detected in a Russian boy of partial Ashkenazi Jewish origin), presented with similar albeit milder phenotype. The two novel variants detected, were detected only very rarely among normal population (Allele frequency of 4.064e-6 for both , gnomAD browser). Brain MRI showed a similar characterization of the leukodystrophy in all cases.

**Conclusion:** We have detected two novel missense variants in *Hikeshi* gene among patients with a characterized leukodystrophy, adding to the one pathogenic variant, previously described. These approximately located variants, suggest that this region may have a functional importance. We suggest to add *Hikeshi* gene sequencing in each gene panel related to leukodystrophy.

## PgmNr 1309: The V122I mutation in hereditary transthyretin-mediated amyloidosis is significantly associated with polyneuropathy in UK Biobank.

### Authors:

Hereditary transthyretin-mediated (hATTR) amyloidosis is a progressively debilitating, fatal disease caused by mutations in the transthyretin (*TTR*) gene. Historically, patients were identified by their predominant phenotype (polyneuropathy or cardiomyopathy), but evidence now suggests that a majority develop a mixed phenotype with both polyneuropathy and cardiomyopathy. The V122I (Val122Ile; p.V142I) variant is the most common pathogenic *TTR* mutation, primarily found in individuals of West African descent, and is thought to be predominantly associated with cardiomyopathy. We aimed to test the association of the V122I genotype and all available ICD10 diagnosis codes in the black subpopulation of UK Biobank (UKB) with replication in the Penn Medicine Biobank (PMBB).

The UKBB is a prospective cohort study with genetic, physical and health data on ~500,000 individuals across the United Kingdom. A phenome-wide association study was performed to test for association between the V122I genotype and 1,229 clinical diagnoses in the black subpopulation of UKB (n=6,063).

387 individuals heterozygous or homozygous for V122I were identified and were primarily of African or Caribbean descent (minor allele frequency in black subpopulation = 2%; baseline age: 40-70 years). This analysis revealed a significant association between the V122I genotype and a clinical diagnosis of polyneuropathy (OR = 11.2; 95% CI: 3.7-26.6; p=1.08x10<sup>-6</sup>). Replication analysis was performed in 5,737 black participants of the PMBB, of whom 190 individuals carried the V122I variant. The association of V122I with polyneuropathy was replicated (OR = 1.6; 95% CI: 1.2-2.4; p=0.006). In addition, there was nominally significant evidence that V122I carriers are at increased risk of other symptoms of hATTR amyloidosis, including carpal tunnel syndrome (OR = 2.0; p=0.02) and urinary retention (OR = 2.1; p=0.05) within the UKB.

These data indicate that carriers of the V122I mutation, historically assumed to cause a cardiac phenotype, have a significantly increased risk of polyneuropathy. This highlights the utility of phenome-wide association studies of known pathogenic variants to identify previously under appreciated manifestations of Mendelian disease. Additionally, this finding supports physicians having a clinical suspicion for the multisystem manifestations of hATTR amyloidosis, including both cardiomyopathy and polyneuropathy.

## PgmNr 1310: Development of a haploid mouse embryonic stem cell model of neuronal ceroid lipofuscinosis to enable forward genetic screens for disease modifiers.

---

Neuronal Ceroid Lipofuscinosis (NCL), also referred to as Batten disease, is an autosomal recessive neurodegenerative disease and a type of lysosomal storage disorder. The classical form of Batten disease, juvenile onset NCL3, is caused by mutations in *CLN3*. Loss of *CLN3* cause numerous abnormalities in endolysosomal trafficking, leading to accumulation of autofluorescent storage material in lysosomes. Despite considerable study of *CLN3*, its function and pathways remain unknown, and there is an urgent need to identify new therapeutic targets. To enable forward genetic screens for modifiers of the NCL phenotype, we are developing models of NCL using mouse haploid mouse embryonic stem cells (mESCs). In these cells, the common *CLN3*<sup>Δex7/8</sup> mutation deleting exon 7 and 8 is introduced using CRISPR/Cas9 gene editing. We present our characterization of NCL phenotypes in neurons derived from *CLN3*<sup>Δex7/8</sup> haploid stem cells. These phenotypes are the basis for selection methods using fluorescence activated cell sorting (FACS) to isolate wild type and mutant genotypes from a population of cells based on the accumulation of autofluorescent storage material. Simulated genetic screens, using mixtures of patient-derived *CLN3*<sup>-</sup> and control induced pluripotent stem cell derived neurons, provide a proof-of-concept for future screens in mutagenized haploid mESC neurons. The haploid mESC *CLN3*<sup>Δex7/8</sup> stem cell model will enable forward genetic screens using mammalian neurons, to identify genetic modifiers of the NCL disease phenotype, disease-related pathways and potential drug targets.

## PgmNr 1311: A mix of 'old-school' and up-to-date familial genetic approaches led to identify a new genetic modifier of the age at onset in *C9orf72* frontotemporal dementia.

Frontotemporal dementia (FTD) is a rare neurodegenerative disorder, and the second cause of early onset dementia after Alzheimer's disease. FTD patients suffered from major behavior dysfunctions, associated with amyotrophic lateral sclerosis (ALS) in 15% of cases. Genetics architecture of autosomal dominant FTD has been almost completely defined. Since the major genes of FTD has been now discovered, the search for genetic modifiers, especially modifiers of Age at Onset (AO) has developed. Indeed, individuals carrying FTD associated mutations can develop symptoms from the third decade of life to nearly incomplete penetrance in elderly mutation carriers. This extensive variability of AO remains largely unexplained so far, especially in patients with *C9orf72* mutations, the major cause of familial FTD and ALS as well.

We previously showed that AO of FTD in *C9orf72* families was highly heritable using familial observations and variance component analyses. We took advantage from the availability of familial data and samples to perform linkage and association analyses among *C9orf72* relatives with either concordant or discordant AO. Genome-wide linear mixed models adjusted for sex, kinship, and covariates were notably used to assess the association between SNPs and AO. A suggestive p-value ( $p \leq 1.10^{-5}$ ) was observed for twelve SNPs, but only one was located on a region of positive linkage (LOD score = 2.1).

Independent association analyses of these twelve SNPs were performed thanks to data from the International FTD-Genomics Consortium including unrelated *C9orf72* patients. Only the association of the SNP located in the region of linkage was replicated ( $p = 0.009$ ). Extreme phenotype sampling was considered as an additional replication. Again, the same trend was observed for this SNP in a third cohort of *C9orf72* unrelated patients with early or late onset (logistic regression,  $p = 0.004$ ).

All of these converging results prompted us to focus on this strong candidate and the neighbor gene

which encodes for a synaptic adhesion protein. Through functional studies including the use of cerebral tissue, and *in vitro* models, we are defining the effect of this variants and we try to understand how this synaptic protein can influence the disease onset of FTD/ALS.

Altogether, this work illustrates how, in the context of a rare disease, family-based designs as first-line analyses may represent an alternative approach to detect genetic variants influencing disease-related traits.

## PgmNr 1312: Metachromatic leukodystrophy: Clinical, genetic, biochemical, and neuroradiological findings in a cohort of Brazilian patients.

**Background:** Metachromatic leukodystrophy (MLD) is a lyso-somal disorder affecting mainly peripheral and central nervous system, caused by arylsulfatase A (ARSA) deficiency. Usually It is classified into three forms according to the age of onset of symptoms (late infantile, juvenile, and adult). **Material and Methods:** Retrospective clinical, biochemical and neuroimaging data analysis of 15 MLD patients (9 male, 6 females). **Results:** Mean ages at onset of symptoms and at biochemical diagnosis were, respectively, 19 and 24 months (late infantile form). The most frequently reported first clinical symptom/sign of the disease was gait disturbance and other motor abnormalities infantile form) and behavioral and cognitive alterations (adult form). Diagnosis was achieved only after 2-3 years of symptoms onset (late infantile form). Leukocyte ARSA activity level did not present significant correlation with the age of onset of symptoms. All patients had high levels of sulfatides in urine (chromatography studies). Early dementia was the main feature of the two adult patients (with no motor feature associated). **Discussion:** Our results suggest that there is a considerable delay between the age of onset of signs and symptoms and the diagnosis of MLD in Brazil. Correlation between ARSA activity and MLD clinical form was not seen. Further understanding of MLD natural history, especially with larger samples, are necessary, in particular with the availability of specific treatments in a near future.

## PgmNr 1313: Recessive variants in Lithuanian hereditary neuropathy patients.

---

**Aim:** Charcot-Marie-Tooth disease (CMT) is a heterogeneous group of hereditary neuropathies (HN) that share common phenotypic features. Here, we describe genetic and phenotypic characteristics of patients with autosomal recessive CMT in a group of Lithuanian patients.

**Materials and methods:** Among 46 previously molecularly undiagnosed patients with CMT screened using multigene NGS panel during past 5 years, recessive variants have been identified for 9 unrelated patients. The phenotypes of all of them have been well-defined using HPO codes.

**Results:** Seven patients showed homozygous or compound heterozygous variants in *HINT1* gene, including previously reported pathogenic variant c.110G>C and a novel variant c.299A>G: i) four patients harboured a homozygous pathogenic variant c.110G>C, ii) two patients had compound heterozygous variants (c.110G>C and c.299A>G), and iii) one patient had a homozygous novel variant, which was also identified in affected brother. Additionally, one patient harboured compound heterozygous variants in *FIG4* (the most common pathogenic variant c.122T>C and novel deletion c.1703\_1704delAA), and one patient showed a homozygous pathogenic variant c.844C>T in *GDAP1*. Co-segregation of these variants in affected sibs or healthy relatives confirmed a recessive inheritance. Patients with homozygous novel and previously reported *HINT1* variants shared pure axonal motor neuropathy. A patient with biallelic *FIG4* variants presented an early onset severe demyelinating sensorimotor neuropathy. A patient with homozygous *GDAP1* variant had a severe axonal sensorimotor neuropathy.

**Conclusions:** The most prevalent recessive gene in Lithuanian patients with CMT is *HINT1*. Our data expand the spectrum of variants in *HINT1* and *FIG4* and their significance in molecular diagnosis.

## **PgmNr 1314: NeuroChip analysis of patients with Gaucher disease with and without Parkinson disease reveals potential protective variants in *CTSD* and *ACP2*: A pilot study.**

Gaucher disease is an autosomal recessive genetic disorder which results from mutations in *GBA1*. These mutations lead to the deficiency of the enzyme glucocerebrosidase and the consequent accumulation of the enzyme's substrates. Mutations in *GBA1* are the most prevalent risk factor for Parkinson disease (PD), the second most common neurodegenerative disease. The discovery of the link between Gaucher disease (GD) and Parkinsonism has led to new insights that have the potential to enable earlier diagnosis and better management of the disease. Despite this established connection, it is still not clear why only a minority of patients with GD develop PD, and it is likely that other genes or factors are involved in the GD-PD progression. The identification of causal or protective genetic variants is one approach to identify these factors. We collected DNA from patients with GD with and without PD. We then used NeuroChip genotyping and PLINK whole genome association analysis software to screen our GD and GD+PD cohorts for genetic variants in different lysosome-related genes. By performing Principle Component Analysis (PCA) we identified and removed the outliers to create a more homogeneous cohort. Conducting logistic regression corrected for sex and age, we identified two candidate genetic variants, rs17571 in *CTSD* and rs2167079 in *ACP2*, that we suggest may be protective against progression from GD to PD. Both rs17571 and rs2167079 were significantly more common in the GD group than in the GD+PD group (p-value <0.032 and <0.00524 respectively). GeneMANIA pathway and Protein-Protein network analyses confirmed potential interactions between the two genes and other established genes involved in GD and PD pathogenesis, either directly or through intermediate proteins. It will be important to further evaluate our findings in larger cohorts and to determine the impact of the identified variants at the RNA and protein level using RNA seq, quantitative PCR, immunoprecipitation, and Western blotting. Nonetheless, this work highlights the applicability of cheap and efficient genetic screening platforms such as NeuroChip in conducting genome-wide association analyses.

## PgmNr 1315: Movement-associated and developmental phenotypes of *MBD5*-associated neurodevelopmental disorder (MAND).

### Authors:

S.R. Gillipelli <sup>1,2</sup>; S.H. Elsea <sup>1</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Biosciences, Rice University, Houston, TX

---

*MBD5*-associated neurodevelopmental disorder (MAND) is caused by abnormalities involving *MBD5*, a dosage-sensitive gene within chromosome 2q23.1. Individuals may have deletion, duplication or pathogenic variants that alter expression or function of *MBD5*. While initial studies of MAND included limited data for large cohorts of patients, the natural history of this rare condition is not well-described due to the limited young age range of these initial cohorts. Clinical features of MAND include global developmental delay/intellectual disability, severe speech impairment, seizures, sleep disturbances, and abnormal behaviors. Some individuals in the current patient population, now mostly in the teen and adolescent stage, recently presented with movement-associated phenotypes that were not present in the initial studies. In this study, we investigated how phenotypes of MAND have evolved over time and their overlap with symptoms of other movement-related disorders. A survey of patient caregivers (n=59) was developed to investigate current patient characteristics, including all aspects of the patient's movement, in order to address clinical features of cerebral palsy, ataxia, and factors of movement in MAND that cause obstacles for accurate diagnosis of possible underlying movement-associated disorders. Individuals with microdeletion of *MBD5* (n=42) were 50% female and ranged from age 1-24 years. Regression from developmental milestones was reported for 26% of patients, while 72% of patients were reported to have difficulties understanding their bodies within space. Of patients over age 2, 46% cannot run, while 47% of patients who cannot run had a BMI categorized as either overweight or obese by the Center for Disease Control. While 86% of patients reported full gross limb movement, 90% reported difficulty with fine motor tasks, such as eating, writing, or buttoning a shirt, and 79% reported poor coordination. Only 74% of patients were referred for occupational therapy, illustrating a therapeutic need for this population. Results revealed pronounced neurodegenerative effects of MAND, pointing to novel phenotypes related to movement difficulty and developmental regression. These data show that fine motor tasks are generally lost in the early teen years and that patients are not currently receiving sufficient therapeutic interventions to address developmental concerns. Additional studies are necessary to further investigate the neurodegenerative effects of MAND.

## PgmNr 1316: Singleton exome sequencing is an efficient tool for diagnosis of inherited white matter disorders.

---

Inherited white matter disorders (IWMDs) are a group of neurodegenerative conditions that include leukodystrophies and genetic leukoencephalopathies. Leukodystrophies primarily involve defects in glial cells or myelin sheath. Genetic leukoencephalopathies (gLEs) have significant white matter abnormalities but do not meet inclusion criteria of a leukodystrophy. The true prevalence and incidence remain unknown worldwide. Cost-effectiveness, increasing accessibility and growing expertise have led to widespread application of whole exome sequencing (WES) in the clinic. We evaluated ninety-five individuals from eighty-eight families with white matter abnormalities. Among them, fifty-four were males and forty-one were females with age range of new-born to forty-two-years. Ten families (11.36%) had hypomyelination while other white matter pathologies were noted in remaining seventy-eight (88.63%). Nine families with specific clinical diagnosis underwent targeted genetic testing. Seventy-nine families, in absence of clinical diagnosis, underwent exome sequencing with singleton WES being performed in seventy-five families. Molecular diagnosis was established for fifty-five families (73.33%). Nine families (16.36%) were diagnosed with leukodystrophies and forty-six families (83.63%) with gLEs. Congenital muscular dystrophies (n=3, 6.52%), metabolic (n=17, 36.95%), mitochondrial (n=18, 39.13%), and other neurodegenerative disorders (n=8, 17.39%) accounted for gLEs. Thirty-three (63.46%) among the fifty-two disease-causing variants in this cohort are novel. Majority (39, 75%) of the observed variants are homozygous, eight (15.38%) are compound heterozygous, four (7.69%) are hemizygous and one (1.92%) is heterozygous (*de novo*). Three novel conditions with pathogenic variants in *ISCA1*, *AIMP2* and *TFIP11*

were identified. Possible founder events were noted in three genes, *ISCA1*, *AIMP2* and *BCKDHA*. Our population with background of consanguinity, inbreeding and founder effect, offers a high diagnostic yield for singleton WES in individuals with IWMDs, which are mostly autosomal recessive disorders. This is in line with our earlier observations on recessive Mendelian disorders. This approach appears to be highly cost-efficient for determining allelic and genetic heterogeneity of neurometabolic disorders. This approach proved highly effective for novel disease-gene discovery as well. We suggest this approach for resource-limited setting with a similar population structure.

## PgmNr 1317: Novel *C19orf12* pathogenic insertion variant in a Taiwanese family with autosomal dominant mitochondrial membrane protein-associated neurodegeneration (MPAN).

### Authors:

H.Y. Lin <sup>1</sup>; J.S. Hsu <sup>2</sup>; P.L. Chen <sup>3</sup>; C.H. Lin <sup>4</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Genetic Counseling Program, Institute of Molecular Medicine, College of Medicine, National Taiwan University, Taipei, Taiwan; 2) Institute of Molecular and Genomic Medicine, National Health Research Institute, Taipei, Taiwan; 3) Graduate Institute of Medical Genomics and Proteomics, College of Medicine, National Taiwan University, Taipei, Taiwan; 4) Department of Neurology, National Taiwan University Hospital, Taipei, Taiwan

---

**Background/Purpose:** Mitochondrial membrane protein-associated neurodegeneration (MPAN) is a rare form of neurodegeneration with brain iron accumulation (NBIA) caused by biallelic pathogenic variants in the *C19orf12* gene. Autosomal dominant inheritance by different heterozygous pathogenic variants has recently been demonstrated in a few families. We report a first Taiwanese autosomal-dominant MPAN family with a novel insertion variant in *C19orf12* and compare the inheritance pattern within different ethnicities.

**Methods:** Exome sequencing and segregation analysis were performed to identify the disease-causing variants of the index patient. The clinical and brain MRI characteristics of the patient were compared to those reported in previous studies of mitochondrial membrane protein-associated neurodegeneration (MPAN) from 2011 to 2019.

**Results:** A 30-year-old male presented with the progressive onset of ataxia, dystonia and parkinsonism since the age of 25. Brain MRI T2-weighted images displayed symmetrical hypointensities in bilateral globus pallidus (GP) and substantia nigra (SN). His 55-year-old mother also presented with progressive dystonia and cerebellar ataxia in her early thirties and now was wheelchair bounded. There was no consanguinity in his family. Exome sequencing revealed the heterozygous c.273\_274insA (p.P92Tfs\*9) insertion in *C19orf12* caused a novel frameshift and premature stop in the protein sequence, which was predicted to be pathogenic. This novel potential pathogenic variant co-segregated within his family among 4 members. Autosomal dominant MPAN was diagnosed according to the neuroradiologic and genetic findings. The novel c.273\_274insA (p.P92Tfs\*9) insertion variant was on the third exon of *C19orf12*, which many previously reported pathogenic heterozygous variants were located.

**Conclusion:** Our findings support recent observations that monoallelic *C19orf12* variants on the last exon may contribute to autosomal dominant MPAN. Variants occurred in final or penultimate exons typically escape from nonsense-mediated decay, suggesting haploinsufficiency might play a role in dominant disease-causing mechanism in MPAN.

## PgmNr 1318: Statistical profiling of clinical data in *GBA1* mutation carriers, an at-risk population for Parkinson disease.

The association of mutations in *GBA1*, the gene coding for the lysosomal enzyme glucocerebrosidase, and the development of Parkinson disease (PD) is well established, although only a subset of mutation carriers will develop PD. Several non-motor features of PD manifest years before motor manifestations become clinically apparent, but do not exclusively predict future development of parkinsonism. *GBA1* mutation carriers provide a risk-enriched population, ideal for longitudinal assessment of non-motor and motor features that could help identify individuals earlier in the disease process. Patients with homozygous and heterozygous *GBA1* mutations with and without Parkinson disease (n=128) were evaluated longitudinally at the NHGRI Genetics Clinic over a period of 12 years. Evaluations included complete physical and neurological examinations, validated mood scales (Geriatric Depression Scale, Fatigue Severity Scale, Epworth Sleepiness Scale) and motor evaluations (9-hole peg), olfactory testing (University of Pennsylvania Smell Identification Test), transcranial sonography, and neuropsychiatric testing. Between-group comparisons were used to assess clinical variation within the cohort. Differences in olfaction, cognitive function, and areas of echogenicity on transcranial sonography were found between the PD and non-PD groups. Hidden Markov models were explored as a hypothesis-blind method to identify latent states with unique clinical profiles that might identify patients on a neurodegenerative trajectory. Mixed effects logistic regressions were then employed to identify additional variables associated with state assignment. Longitudinal evaluation of patients at risk for Parkinson disease may help identify important clinical features and potential biomarkers associated with disease development. They may also elucidate pathways associated with neuroprotection.

## PgmNr 1319: Modulating phosphorylation of ATXN1's serine 776 residue: A potential therapeutic approach for spinocerebellar ataxia type 1.

Spinocerebellar Ataxia Type 1 (SCA1) is a fatal adult-onset neurodegenerative disorder characterized by motor incoordination and early lethality. It is caused by an expansion of CAG repeats encoding a polyglutamine (polyQ) tract in ATAXIN-1 (ATXN1). The polyQ expansion stabilizes ATXN1 leading to its toxic accumulation primarily in cerebellar and brainstem neurons. Thus far, no treatment options are available to prevent ATXN1's accumulation and the subsequent neuronal degeneration.

Previous studies identified several serine residues on ATXN1 that are phosphorylated. Phosphorylation of one of these sites, Serine 776 (S776), was shown to enable binding to 14-3-3, which in turn stabilizes ATXN1. Given the importance of ATXN1 levels in SCA1, we hypothesized that disrupting S776 phosphorylation would decrease ATXN1 levels in affected brain regions and potentially rescue SCA1 phenotypes. To test this, we modified an existing SCA1 knock-in mouse model (Atxn1<sup>154Q/2Q</sup>), which, similar to SCA1 patients, carries a CAG repeat expanded Atxn1 allele and recapitulates all major features of SCA1. Using CRISPR/Cas9, we replaced S776 with an alanine (S776A) generating S776 phosphorylation-deficient SCA1 mouse models. We found that the disruption of S776 phosphorylation does indeed disrupt 14-3-3 binding and leads to a ~20% decrease in ATXN1 levels throughout the entire brain. Furthermore, using molecular and behavioral assays, we demonstrate that disruption of S776 phosphorylation ameliorates the molecular changes in the cerebellum, reduces cerebellar Purkinje cell degeneration, and rescues the motor incoordination. More importantly, abolishing S776 phosphorylation also delays neuromuscular respiratory failure, an end-stage feature of SCA1 that contributes to premature death, and increases the lifespan of SCA1 animals by six weeks thus far.

This study highlights the importance of phosphorylation at S776 on ATXN1 stability and emphasizes the potential for targeting this phosphorylation site as a treatment option for SCA1. As S776 can be phosphorylated via multiple kinases, future studies are required to elucidate the predominant kinases to target in each brain region.

## PgmNr 1320: Molecular analysis of *PANK2* gene in Korean patient with suspected pantothenate kinase associated neurodegeneration.

### Authors:

D. Yang <sup>1</sup>; H. Gu <sup>2</sup>; M.J. Kim <sup>3</sup>; S.I. Cho <sup>3</sup>; M. Seong <sup>3,4</sup>; S.S. Park <sup>3,4</sup>

---

**Background :** Neurodegeneration with brain iron accumulation (NBIA) describes a group of rare heterogeneous progressive neurodegenerative disorder characterized by excessive iron accumulation in the basal ganglia region. Pantothenate kinase associated neurodegeneration (PKAN) is a major form of this disease, which is caused by mutation of *PANK2* located on chromosome 20p13. Although the exact pathology of PKAN has not been established, it is assumed that defective *PANK2* enable to sufficiently convert pantothenate to 4'-phosphopantothenate, leading mitochondrial cysteine accumulation. In this study, we analyzed the *PANK2* gene in 26 Koreans among suspected PKAN patients.

**Method:** From August 2009 to February 2018, 26 unrelated Korean patients with suspicious PKAN were referred to the SNUH. Genomic DNA was extracted from the patient's EDTA peripheral blood. PCR was performed using the in-house primer. MLPA was performed using SALSA P120-B2 *PANK2* / *PLA2G6* Kits. Deletion breakpoint was re-evaluated using the in-house primers. To predict the mechanism of large deletion, RepeatMasker, and Clustal W were used.

**Result:** We identified nine variants in seven patients with Sanger sequencing. Seven of the nine identified variants were previously reported. 2 novel variants c.1210\_1214dupAATTA and c.1676C>G were respectively considered as likely pathogenic according to 2015 AGMG guidelines. As a result of MLPA, heterozygous exon 3-4 deletion was confirmed and in order to find the exact deletion breakpoint, a pair of in-house primers for sequencing was constructed. Sequence analysis revealed that exon 3-4 deletion was 5,016 bp deletion. The sequence of the breakpoint was found to be AluSx3 and AluSz6, and the sequence homology was about 97.3%.

**Conclusion:** In this study, we analyzed the *PANK2* gene in 26 Koreans among suspected PKAN patients. Exonic deletion of *PANK2* found in PKAN were mediated through *Alu*-mediated nonhomologous recombination.

## PgmNr 1321: *NEFH* founder mutation in Japanese autosomal dominant Charcot-Marie-Tooth disease and spinal muscular atrophy families.

### Authors:

M. Ando; Y. Okamoto; A. Yoshimura; Y. Higuchi; Y. Sakiyama; A. Hashiguchi; H. Takashima

[View Session](#) [Add to Schedule](#)

**Affiliation:** neurology and geriatrics, Kagosima university, Kagoshima, Kagoshima, Japan

### [Objective]

Mutations in neurofilaments genes are associated several neuromuscular disorders. Neurofilament heavy (*NEFH*) gene was known as a risk gene of sporadic ALS. In 2016, it was identified as the causative gene of Charcot-Marie-Tooth disease type 2. And mechanism was suggested toxic gain of function, which was caused by translation and aggregation of cryptic amyloidogenic element (CAE) in the 3' untranslated region (UTR) of *NEFH* gene. But the clinical and genetic spectrum of *NEFH* mutation is still unclear in Japan.

### [Method]

We analyzed whole exome sequencing data from the 891 patients in part of our genetic studies in neuromuscular disorders, included CMT, Spinal Muscular Atrophy (SMA). And we evaluated the identified *NEFH* variant according to the American College of Medical Genetics and Genomics (ACMG) standards and guidelines.

### [Result]

In this study, we identified novel *NEFH*c.3017dup p.Pro1007Alafs\*56 variant in three Japanese autosomal dominant CMT families and one Spinal Muscular Atrophy (SMA) family. And haplotype analysis of all four patients suggested founder event. This frameshift variant was absent in global, Japanese, and in-house control databases. In the segregation study, this frameshift variant was confirmed in other affected family members.

### [Conclusion]

Our study is the first report that referred to the spinal muscular atrophy (SMA) phenotype and the founder mutation in *NEFH*. The clinical diversity in our study, included CMT, CMT with pyramidal sign, and SMA, suggested that the causative lesions are peripheral nerve or spinal cord neuron or both. And it is important for future clinical and genetic analysis of *NEFH* mutation.

## PgmNr 1322: Analysis of the *TMEM230* gene in familial Parkinson's disease from south Italy.

### Authors:

G. Annesi <sup>1</sup>; R. Procopio <sup>1,2</sup>; M. Gagliardi <sup>1</sup>; G. Nicoletti <sup>1</sup>; M. Morelli <sup>2</sup>; A. Quattrone <sup>1,3</sup>

### Affiliations:

1) Institute of Molecular Bioimaging and Physiology, National Research Council, Section of Germaneto, Catanzaro, Italy; 2) Institute of Neurology, Department of Medical and Surgical Sciences, University Magna Graecia, Catanzaro, Italy; 3) Neuroscience Research Center, Department of Medical and Surgical Sciences, University Magna Graecia, Catanzaro, Italy

To date, more than 20 genes have been reported as involved in familial Parkinson's disease (PD). Recently, mutations in *TMEM230* exon 5 have been associated to PD in a large family from North America and in seven small Chinese families by *Deng et al.*

*TMEM230* encodes transmembrane protein 230, which belongs to the TMEM134/TMEM230 family, and it is involved in endocytosis and trafficking secretory/recycling vesicles. It is located on chromosome 20p13-p12.3 and contains five exons. Disease-linked mutations impair normal synaptic vesicle trafficking and the presence of TMEM230 protein in alpha-synuclein-positive Lewy bodies and Lewy neurites in midbrain and neocortex sections from sporadic PD cases gave supporting evidence for a role of this gene in PD pathology. However, in 15 studies published only approximately 0.28% PD patients were found to harbor potential PD-related variants with full detection information of coding regions of the *TMEM230* gene.

In order to clarify the relationship between *TMEM230* and southern Italy PD population, we performed a mutational screening of this gene in 168 autosomal dominant familial PD patients, defined by the presence of PD in at least other first degree, second degree, and third degree relative, and a control group consisting of 500 subjects from the same geographical area. After obtaining informed consent, genomic DNA was extracted from peripheral blood by standard method. All the 5 exons of *TMEM230* and intron-exon boundaries region were sequenced using an ABI 3500 Genetic Analyzed (Life Technologies, Carlsbad, CA, USA).

The screening highlighted the presence of four synonymous variants (rs186628284, rs6116651, rs763383477, rs6107576) with the same frequency in both population (PD cohort and control subjects) and the p.Ile125Met (c.375A>G, rs148033002) missense variant in a 64-years old woman. The patient (AAO: 39 years) who carries this variant in heterozygous state presented bradykinesia, rigidity and postural instability with a good response to levodopa treatment. Family history was positive with her mother and her two sisters with a diagnosis of PD. The genetic testing was extended to three sisters of the proband and their mother, and it confirmed the segregation of the c.375A>G variant in the affected members of the family.

Further studies are needed to evaluate the role of *TMEM230* in the pathogenesis of Parkinson's disease.

## PgmNr 1323: Exploring the molecular basis of hereditary spinocerebellar degeneration in a large Sudanese family.

---

**Background:** Spinocerebellar neurodegenerative disorders (SCD) are known for their complex phenotypic and genetic heterogeneity forming a heterogeneous spectrum of disorders with hereditary spastic paraplegias (HSP) on one end and hereditary ataxias (HA) on the other. In clinical practice, limb spastic weakness and cerebellar ataxia are frequently found together and present the hallmark of SCD. The genetics of SCD has been a target for extensive researches in many parts of the world, yet little is known about the genetics of SCD in Sub-Saharan African population.

**Methods:** In this study, we recruited a large consanguineous Sudanese family with five affected siblings. Genomic DNA was extracted and screened for genetic variations using whole exome sequencing (WES). Analysis was done to identify the culprit variations using bioinformatics tools and in-silico prediction of variants pathogenicity.

**Results:** Clinical results showed a complex phenotype of progressive spastic-ataxia complicated with deafness. Microcephaly was detected in the two eldest patients. Analysis of WES data and variant prioritization suggested two homozygous missense variants in two candidate genes (*MYO15A* and *SEMA5D*) that were not reported to be linked to similar disease before. The first variant in *MYO15A* gene (NM\_016239.3: c.1634C>T) was reported to cause autosomal recessive hearing loss but was not reported to similar neurological disease. The second variant (NM\_006378.3:c.1588G>A) was in *SEMA4D* gene which involved in brain development but not reported to be associated with inherited neurological conditions before. Both variants were extremely rare and highly conserved. They were predicted to be highly pathogenic using bioinformatics tools.

**Conclusion:** The scarcity of genetic data in the highly consanguineous Sudanese population makes whole exome sequencing a powerful and cost effective strategy to identify both known and new pathogenic variations and genes. Sanger sequencing and further functional studies are recommended to prove the association of *MYO15A* gene and *SEMA4D* gene with the complex clinical phenotype of deafness, spasticity and ataxia.

**Introduction:** Autosomal recessive cerebellar ataxia (ARCA) is a group of rare heterogeneous neurodegenerative disorders characterized by the involvement of both central and peripheral nervous system often associated with non-neurological signs such as pes cavus, diabetes, and ophthalmological features. They are complex diseases with an onset before the age of 30, worsening progressively and causing a major handicap. Very few studies have been reported in Sub-Saharan-Africa, and none in Mali.

**Objectives:** We aim to characterize clinically patients with ARCA, and to determine the underlying genetic defect.

**Methods:** Patients with ARCA phenotype were seen in our Neurogenetics Clinic and by ophthalmologist, cardiologist and ENT specialists. DNA was collected for genetic analysis. Brain and spinal cord imaging, electromyography and blood chemistries were performed to exclude other causes.

**Results:** We have enrolled six families totaling twelve patients, and the age of onset ranged from 1 to 21 years old. Alpha fetoprotein levels were normal in all patients. Brain MRI showed cerebellar atrophy in some patients while other had hearing impairment. *FXN* gene was sequenced in three patients (from three families) with Friedreich's ataxia-like clinical presentation, and only one patient was tested positive (999 and 766 repetition of GAA in the respective alleles of the gene). Subsequently, whole exome sequencing was performed in two families, and identified six homozygous variants in three genes in one family. Three variants were located in the *ATM* gene causing ataxia telangiectasia, two in *ANO10* causing autosomal recessive cerebellar ataxia type 3, and one in *SIL1* causing Marinesco-Sjögren syndrome that also manifests as recessive ataxia. All these variants segregated with the disease in the sequenced family members (patient, father, maternal aunt, brother). Analysis of the remaining families is underway.

**Conclusion:** We have diagnosed a rare Friedreich's ataxia case in sub-Saharan Africa. In addition, there is potential to expand the clinical presentation and genetic epidemiology of ARCA. Our future studies may indicate which of the three genes causes the disease in the family.

**Key words:** ARCA, genetic testing, variants, Mali.

---

**Background:** Segawa disease is a very rare inherited disease characterized by dopa-responsive dystonia with diurnal fluctuation. Partial defects of GTP cyclohydrolase (GTPCH I), which is the rate-limiting enzyme of bipterin synthesis is the cause of this disease. In Segawa disease patients, the amount of dopamine in their central nervous system (CNS) is diminished because shortage of bipterin decrease tyrosine hydroxylase (TH) activity and it suppress production of L-dopa from tyrosine. Some other pediatric neurotransmitter diseases such as sepiapterin reductase (SR) deficiency and TH deficiency also show dopa-responsive dystonic symptom.

**Method:** We examined 137 patients with dystonia and/ or some other involuntary movements from January 2012 to December 2016. We measured bipterin and neopterin concentration in their blood and cerebrospinal fluids. Genetic analysis of *GCH1* gene which was coding GTPCH I was performed in 50 patients, respectively. Some patients who wanted to diagnose SP deficiency or TH deficiency, we also performed genetic analysis of *SPR* and *TH* genes, which are coding genes of SR and TH enzymes.

**Results:** We detected 22 Segawa disease patients with mutations in *GCH1* gene. Segawa disease patients comprised 18 females and 4 males. The average age of patients who underwent genetic analysis was 19.35 years (Range: 7 to 62). Most of the patients who were diagnosed as adults showed dystonic symptoms from a very young age. No common mutation was observed in Segawa disease patients. In this study, Among the rest of the patients, two patients of SR deficiency and one patient of TH deficiency were also detected. In this study, we examined patients from 32 of the 47 prefectures in Japan (total population of these areas was 106,058,400 in 2016). The calculated incidence rate of Segawa disease was 4.1/100,000,000 per year in this study. The prevalence rate of Segawa disease was considered to be 1.6/1,000,000 when the average of duration of this disease was 40 years.

**Conclusion:** Over the course of five years, we genetically diagnosed patients with Segawa disease, SR deficiency and TH deficiency. No common mutation was observed. In Segawa disease the incidence rate was 4.1 per hundred million people per year and the prevalence rate was 1.6 per million people in Japan.

## PgmNr 1326: Mutational analysis of *SOST* in the first Italian family with sclerosteosis.

### Authors:

M. Gagliardi <sup>1</sup>; F. Bono <sup>2</sup>; R. Procopio <sup>1,2</sup>; A. Quattrone <sup>1,3</sup>; G. Annesi <sup>1</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Institute of Molecular Bioimaging and Physiology, National Research Council, Catanzaro, Italy Germaneto (CZ), Italy; 2) Institute of Neurology, Magna Graecia University of Catanzaro, Italy; 3) Neuroscience Research Center, Department of Medical and Surgical Sciences, Magna Graecia University of Catanzaro, Italy

Sclerosteosis is a rare autosomal recessive condition characterized by progressive bone thickening due to increased bone formation. Mutations in *SOST* gene coding for sclerostin are linked to sclerosteosis. There are the clinical and radiographic similarities between sclerosteosis and van Buchem disease, another autosomal recessive bone dysplasia. Sclerosteosis and van Buchem disease are linked to chromosome 17q12-q21, more just van Buchem disease is associated with a 52 kb deletion at downstream of the *SOST* gene, sclerosteosis is caused by loss-of-function mutation of sclerostin. This protein is the *SOST* gene product, it secreted by osteocytes and transported to the bone surface where it inhibits osteoblastic bone formation by antagonizing Wnt signalling. Very few sporadic cases have been described around the world mainly in Africa and South America. Here we described for the first time a South Italy patient with a mutation sclerosteosis.

Informed consent was obtained from the patients. The diagnosis of sclerosteosis was based on a history of chronic headache and nocturnal snoring documented by neurological and audiometric examination, Brain MRI, MR venography, polysomnography and 1-hour lumbar CSF pressure monitoring. Genomic DNA was extracted from peripheral blood by standard methods. The *SOST* purified PCR products were analyzed on 3500 Genetec Analyzer.

The two brothers of 45 and 36 years old presented macrocephaly and an enlarged mandible, they complained unilateral visual acuity loss and unilateral deafness since adolescence. Moreover the youngest one had a bilateral facial nerve palsy since childhood. The first brother was not interest to continue the neurological and genetic investigations. A nocturnal polysomnography showed a condition of Obstructive Sleep Apnea Syndrome (OSAS) of moderate entity. We detected a nonsense mutation, p.Gln24X (c.70C>T), in homozygous in our patient and also in heterozygous state in his parents, two brothers, one sister, two sons and one nephew. This nonsense mutation is predicted to exert a deleterious effect by Mutation Taster Server, and lead to premature termination of the protein. The bioinformatics analysis using amino acidic alignment attested that the Glutamine at position 24 is evolutionary conserved in Vertebrates. The clinical features of this patient show the presence of OSAS causing intracranial hypertension in Sclerosteosis, these symptoms enlarge the clinical spectrum of Sclerosteosis.

## PgmNr 1327: Recurrent *de novo* MAPK8IP3 variants cause neurological phenotypes.

Kinesin superfamily proteins play a fundamental role in intracellular transport such as axonal transport. Disturbed axonal transport has been associated with various human neurodegenerative diseases. JIP3, encoded by *MAPK8IP3*, is an adaptor protein of the kinesin-1 complex and essential for axonal transport in neurons. However, an association between *MAPK8IP3* variants and human disease has not been established. We identified two recurrent *de novo* *MAPK8IP3* variants in all five patients from four unrelated families. A *de novo* variant, c.1732C>T(p.Arg578Cys), was found in three individuals, including two siblings. The other variant, c.3436C>T(p.Arg1146Cys), was found in two individuals. The core phenotype includes spastic diplegia, intellectual disability, cerebral atrophy, and corpus callosum hypoplasia.

The two variants, p.Arg578Cys and p.Arg1146Cys, are absent in ExAC, gnomAD, Human Genetic Variation Database (HGVD), and ToMMo 3.5KJPNv2. Both missense variants also affect evolutionarily conserved residues and are predicted to be pathogenic by different *in silico* prediction tools (SIFT, Polyphen-2, MutationTaster, and CADD).

To test the pathogenicity of the two variants, we utilized a zebrafish model. The pLL nerve emerging from the ganglion beside the otocyst results in long axons along the mid-body line toward the tail of the zebrafish. We examined if the expression of JIP3 variants affects developing pLL axons because an abnormality of the lateral line

reportedly occurs in JIP3<sup>-/-</sup> zebrafish. A smooth long axon was observed when wild-type human JIP3 tagged with mCherry was transiently expressed in a single pLL neuron. When the variant JIP3<sup>R578C</sup> or

JIP3<sup>R1146C</sup> was expressed in a pLL neuron, abnormal varicosities were exhibited in the axon. These findings support the pathogenicity of the variants.  
Thus, we propose that *MAPK8IP3* missense variants cause a human neurodevelopmental disease.

## PgmNr 1328: Cerebral microbleeds and the risk of intracranial hemorrhage in Taiwanese patients with CADASIL.

### Authors:

Y. Liao <sup>1,2</sup>; Y. Hu <sup>1,2</sup>; F. Chang <sup>3</sup>; Y. Lee <sup>1,2</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Neurology department, Taipei Veterans General Hosp, Taipei, Taiwan; 2) Department of Neurology, National Yang-Ming University School of Medicine, Taipei, Taiwan;; 3) Department of Radiology, Taipei Veterans General Hospital, Taipei, Taiwan;

### Background

Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) is the most common monogenic cerebral small vessel disease worldwide. Intracerebral hemorrhage (ICH) was rare in Caucasian patients with CADASIL; however, 12-25% of CADASIL patients in East Asian populations suffered from ICH. The present study aims at investigating the frequency and predictors of ICH in CADASIL patients.

### Method

One hundred and nine genetically confirmed CADASIL patients from 86 families were included. All of them had underwent brain MRI with T2 star weighted (T2\*) or susceptibility-weighted angiography (SWAN) images. Neuroradiological features, including cerebral microbleeds (CMBs), lacunar infarcts, white matter hyperintensity and dilated perivascular space, were analyzed by visual inspection. Multivariate logistic regression was conducted to identify factors predicting the occurrence of ICH in CADASIL.

### Results

Twenty four of the 109 CADASIL patients (22.0%) had ICH on T2\* or SWAN images. A total of 33 ICH lesions were identified, including 15 symptomatic lesions with corresponding neurological deficits and 18 asymptomatic ICH. Ten of the 18 asymptomatic lesions and three of the 15 symptomatic lesions were lobar hemorrhage (55.6% vs. 20.0%,  $p = 0.04$ ), suggesting lobar hemorrhage more likely to be clinically unnoticed. CADASIL patients with ICH more frequently had a history of hypertension, lacunes in basal ganglia, thalami and infratentorial regions, and CMBs in all brain regions than those without ICH. Up to 83.3% of the CADASIL patients with ICH and 42.2% of patients without ICH had the number of CMBs higher than 10 ( $p = 4.2 \times 10^{-4}$ ). In the multi-variate regression analysis, presence of CMBs in the brainstem and age at examination were the strongest predictors for the occurrence of ICH in CADASIL patients.

### Conclusion

In contrast with as a rare phenomenon in Caucasian, ICH occurred in one fifth of the CADASIL patients in Taiwan. There was no significant difference in the clinical features between CADASIL patients with symptomatic ICH lesions and those with asymptomatic lesions, except for a higher percentage of lobar hemorrhage in asymptomatic ones. Age and presence of CMBs in the brainstem were significant predictors for the occurrence of ICH in CADASIL patients. Clinical vigilance, strict controls of hypertension, and cautious use of antithrombotic agents/anticoagulants are warranted in CADASIL

patients with high ICH risks.

## PgmNr 1329: Biallelic pathogenic variants in *TUBGCP2* cause microcephaly and lissencephaly spectrum disorders in humans.

---

The recent progress in DNA sequencing and brain imaging technologies has facilitated the discovery of a number of causative genes for malformations of cortical development (MCDs). Lissencephaly is a subtype of MCDs that can manifest over a range of clinical severity, including agyria, pachygyria and subcortical band heterotopia; each representing anatomical malformations of brain cortical development caused by neuronal migration defects. Genetic causes of neuronal migration anomalies are highly enriched for genes encoding microtubules and microtubule-associated proteins, which highlight the essential functions of the cytoskeleton in the developing human brain. Using exome sequencing and family-based rare variant analyses, we identified a homozygous variant c.997C>T; p.(Arg333Cys) in the gene for tubulin-gamma complex-associated protein 2, *TUBGCP2*, in two individuals from a consanguineous family presenting with microcephaly and developmental delay. *TUBGCP2* encodes GCP2 which forms the multiprotein g-tubulin ring complex (g-TuRC) together with g-tubulin and GCP3-6 to template the microtubule formation. Moreover, we have observed intrafamilial clinical variability in these individuals. Our detailed molecular studies revealed dual molecular diagnoses in the more severely affected sibling due to *TUBGCP2*-associated disease and a *de novo* 2q23.1 duplication. We found three additional families with rare biallelic variation in *TUBGCP2* and similarly affected phenotypes by querying the clinical exome sequencing database at Baylor

Genetics and through GeneMatcher. These include one homozygous variant c.1843G>C; p.(Ala615Pro) in two families and compound heterozygous variants consisting of one missense variant c.889C>T; p.(Arg297Cys) and one splice variant c.2025-2A>G in one family. Affected individuals displayed the clinical spectrum, ranging from pachygyria with mild learning disability to fatal microlissencephaly. Our data establish *TUBGCP2* as a novel disease gene for an autosomal recessive neurodevelopmental trait consisting of a neuronal migration disorder and implicate GCP2 as a core component of g-TuRC involved in both neuronal progenitor and migrating cells in humans.

## PgmNr 1330: Frontotemporal dementia: A novel *TUBA4A* variant identified in a Dutch family with TDP-43 pathology.

### Authors:

---

Frontotemporal dementia (FTD) is the second most common type of presenile dementia, encompassing a spectrum of clinical disorders including behavioral and language impairment. FTD shares pathophysiology and genetic etiology with amyotrophic lateral sclerosis (ALS). Approximately 40% of FTD is familial. Autosomal dominant mutations in several main genes (*C9orf72*, *GRN*, and *MAPT*) have been identified, though a substantial proportion (~45%) of familial cases remains unsolved.

Here we describe a Dutch pedigree consisting of five affected and one elderly unaffected individual. Patients presented with dementia without motor neuron disease, of which three received a definite diagnosis of behavioral FTD. Autopsy of the proband revealed frontotemporal lobar degeneration with TDP-43 pathology, not neatly fitting in a specific subtype. Genetic testing excluded mutations in *C9orf72*, *GRN*, and *MAPT*. Through whole exome sequencing (WES) on all six relatives, we identified a heterozygous c.313C>T (p.R105C) missense variant in *TUBA4A*.

This gene encodes for the Tubulin Alpha 4A protein, a major structural component of the microtubules. Mutations in *TUBA4A* have been previously implicated in familial ALS. The pathogenicity of our mutation is supported by segregation with the disease, absence in ExAc/GnomAD, and a CADD score of 33 (24 variants also passed these filters). Immunohistochemistry with *TUBA4A* antibodies revealed abundant extracellular deposits and a few cytoplasmic inclusions. Exposing cells with or without the mutation to low doses of nocodazole did not demonstrate a difference in the stability of the microtubules, which we did observe for the ALS-causing *TUBA4A* mutation (R320C). Follow-up with additional analyses, e.g. Western blotting, will be performed in order to proof the pathogenicity of the variant.

In conclusion, we describe a Dutch FTD family with predominantly behavioral symptoms and TDP-pathology possibly caused by a mutation in *TUBA4A*. The mechanism of pathogenicity is not clear and still under investigation.

## PgmNr 1331: Rare syndromes with X-linked cerebellar hypoplasia revealed by whole-exome sequencing.

---

X-linked cerebellar hypoplasia (XLCH) is a heterogeneous nonprogressive genetic disorder characterized by intellectual disability (ID) and delay in motor development. The well-known causes of XLCH include oligophrenin-1 syndrome,<sup>?</sup>and MICPCH/CASK syndrome (Mental retardation and microcephaly with pontine and cerebellar hypoplasia, calcium/calmodulin-dependent serine protein kinase. We studied four pedigrees with ID by WES and identified pathogenic variants in X-linked genes including *ABCB7*, *ATP2B3*, *HNRNPH2*, and *ZNF41*.

Patient 1 and 2 are brothers with ID and cerebellar ataxia. Brain MRI revealed atrophic cerebellar vermis. A missense variant was identified in *ABCB7*?(c.1256A>T:p.Q419L). *ABCB7* variants were reported in patients with sideroblastic anemia and ataxia. Protasova et al. [2016] found a missense mutation in the *ABCB7* in a pedigree with XLCH with neurodevelopmental phenotype. The pedigree did not show sideroblastic anemia. Patient 3 is a 5-year-old male proband with *ATP2B3* variant (c.982G>T: p.A328S). Variants in the *ATP2B3* gene, calcium-transporting ATPase predominantly expressed in the brain, are associated with X-linked spinocerebellar ataxia-1. Patient 4 had a *de novo* missense variant in *HNRNPH2* (c.89T>G: p.F30C).The *HNRNPH2* gene belongs to a member of the heterogeneous nuclear ribonucleoprotein family and is located on Xq22.1. Bain et al. [2016] reported six unrelated females with new neurogenetic syndrome with pathogenic *HNRNPH2* variants. This is the first male patient with a *HNRNPH2* mutation. Patient 5 is a 5-year old boy with cerebellar atrophy and ID. He had a mutation in *ZNF41* (c.2279C>G: p.S760W). This gene is associated with X-linked ID [Shoichet et al. 2003]. Association of *ZNF41* variants and cerebellar hypoplasia has not been reported. These genetic syndromes should be included in the differential diagnosis of XLCH.

## PgmNr 1332: Phenotypic similarities in one case with a microdeletion and two cases with single nucleotide variants in *BCL11A*: Cerebellar expressions of motor speech disorders.

*BCL11A* not only suppresses fetal hemoglobin in newborns but also influences neurogenesis via axon outgrowth. Deletions of *BCL11A* and its two closest neighbors have implicated the cerebellum, a brain region crucial for motor control and also spoken and written language. Several studies mention speech and language deficits where *BCL11A* was heterozygously deleted or altered, but only two studies provide a detailed description of these deficits, specifying childhood apraxia of speech (CAS), a severe speech disorder with cerebellar signs. Here, we describe two new cases with intragenic point mutations and one with a microdeletion.

Case 1 is a 9-year-old female with a p.Ala182Thr:c.544G>A missense mutation in exon 4 of *BCL11A*. This variant results in a non-conservative amino acid substitution, not described previously in actual cases but predicted to be highly deleterious. The patient has dysmorphic facial features, fine and gross motor delays, balance difficulties, generalized dyspraxia and dystonia, intellectual disability, ADHD, difficulties understanding and formulating sentences, and CAS. The CAS diagnosis was made at age 3 due to highly unintelligible speech and problems with oral motor tasks, chew-swallow sequences, and drooling. At age 9, she still has low intelligibility and difficulties with several consonants.

Case 2 is a 5-year-old female with a heterozygous 156 kb deletion harboring exons 1 and 2 of *BCL11A*. She was diagnosed with intellectual disability, ADHD, fine and gross motor discoordination, limited expressive language, and severe CAS. Her speech is highly unintelligible, and she is working on simple syllables and words consisting of one consonant and one vowel.

Case 3 is a 6-year-old male who carries a heterozygous *de novo* p.E611.X:c.1831 G>T variant. ClinVar lists this variant in a single case classified as pathogenic. The patient has severe fine and gross motor delays and while his expressive language is in the typical range, his speech, chewing, and swallowing are characterized by motor planning deficits.

In sum, all three cases show evidence of cerebellar dysfunction despite the different types of gene disruption. Furthermore, they share similarities including motor speech traits with a case with complete absence of one copy of only *BCL11A* described previously by us. These similarities are likely due to abnormal prenatal and early postnatal expression of *BCL11A* in brain regions crucial for motor, speech, and cognitive development.

## PgmNr 1333: Genetic mutation analysis of the COQ2 gene in Italian patients with MSA.

### Authors:

1) Institute of Molecular Bioimaging and Physiology, National Research Council, Section of Germaneto, Catanzaro, Italy; 2) Institute of Neurology, Department of Medical and Surgical Sciences, University Magna Graecia, Catanzaro, Italy; 3) Department of Neurology, Milan Center for Neuroscience, San Gerardo Hospital, University of Milano-Bicocca, Monza, Italy; 4) Neuroscience Research Center, Department of Medical and Surgical Sciences, University Magna Graecia, Catanzaro, Italy

Multiple system atrophy (MSA) is an adult-onset neurodegenerative disease of unknown etiology characterized by dysautonomia accompanied by parkinsonism, cerebellar ataxia, and pyramidal signs. The neuropathologic hallmark of MSA is the presence of  $\alpha$ -synuclein-positive glial cytoplasmic inclusion. MSA is classified into two main subtypes: MSA-P, in which parkinsonism is the characteristic motor symptom; and MSA-C, in which the predominant motor presentation is cerebellar ataxia. Although considered a sporadic disorder, rare familial MSA cases have been described, supporting the presence of genetic factors in the etiology of this disease. Recently, a homozygous variant p.V393A and compound heterozygous variants in the *COQ2* gene have been described in two multiplex Japanese MSA-C families.

To extend the knowledges about the role of *COQ2* in MSA in Caucasian ethnicities, we performed genetic analysis of *COQ2* in a cohort of 100 MSA patients from Italy.

The cohort consisted of 58 patients with MSA-P and 42 with MSA-C, diagnosed by movement disorders specialists. All participants provided written informed consent and genomic DNA was collected from peripheral blood by standard protocols. All exons and intron-exon boundaries of *COQ2* were amplified and sequenced using an ABI 3500 Genetic Analyzer (Life Technologies, Carlsbad, CA, USA).

No pathogenic *COQ2* variants were detected. We identified only one missense variant (rs6818847) and two synonymous variants (rs6535454 and rs1129617), with high frequency in the population.

*COQ2* encodes para-hydroxybenzoate-polyprenyl transferase, essential for the biosynthesis of coenzyme Q10, involved in the mitochondrial respiratory chain and his deficiency results in several types of neurological disorders, ataxia and cerebellar atrophy similar to MSA.

The more common form of MSA in Asia is MSA-C (67-84%), while MSA-P is the more common manifestation in Europe and North America (58/82%). Several studies of East Asian cohorts confirmed a significant association of p.V393A with MSA-C, while studies in non-Asian ethnic cohorts were unable to replicate this finding.

We did not detect pathogenic variant in *COQ2* in our Italian MSA cohort. Therefore, our results confirmed that *COQ2* did not associate with the development of MSA in Caucasian population, supporting the hypothesis that *COQ2* tended to play a pathologic role population and subtype-specific in MSA.

## PgmNr 1334: *BPTF* mutation in siblings diagnosed with a radiation sensitivity disorder.

### Authors:

S. Teraoka <sup>1</sup>; X. Liu <sup>1</sup>; M. Gupta <sup>2</sup>; J. Wright <sup>1</sup>; A. Quinlan <sup>2</sup>; R. Gatti <sup>3</sup>; P. Concannon <sup>1</sup>

---

A panel of 78 individuals who displayed radiation sensitivity, cancer susceptibility, immunodeficiency, neurological abnormalities and DNA double strand breaks were studied by whole exome (N=50) or whole genome (N=28) sequencing. These individuals had been previously referred for clinical testing for Ataxia-telangiectasia (A-T) or Nijmegen Breakage Syndrome (NBS) but no mutations in the causative genes *ATM* or *NBN* were identified. Whole exome sequencing uncovered a novel truncating mutation in bromodomain PHD finger transcription factor, *BPTF*, (c.2521C>T, p.Arg841\*), in a pair of siblings among 50 otherwise unrelated individuals. Although the initial expectation for the mode of inheritance for candidate genes was autosomal recessive based on A-T and NBS, autosomal dominant mutations in *BPTF* have been reported to cause a disorder with overlapping features, Neurodevelopmental Disorder with Dysmorphic Facies and Distal Limb Anomalies (NEDDFL). The siblings in our study had microcephaly, facial dysmorphology and short stature, consistent with the clinical features of NEDDFL. However, sensitivity to ionizing radiation has not been previously reported as a feature of NEDDFL nor has the *BPTF* gene been implicated in cellular responses to ionizing radiation or DNA damage. To explore the potential role of *BPTF*, cells in which siRNA had been used to knockdown *BPTF* were treated with a range of doses of ionizing radiation. A significant decrease in colony survival following treatment with ionizing radiation was observed in knockdown cells relative to controls. DNA from 28 additional radiation sensitive individuals was screened by whole genome sequencing. A second unrelated individual was identified with a 3.6Mb deletion including *BPTF*, providing a second example of a heterozygous loss of function mutation in *BPTF* associated with radiation sensitivity. Our results implicate microdeletions at 17q24.2, generally, and the *BPTF* gene, specifically, in cellular responses to ionizing radiation and highlight the utility of combining whole exome or genome sequencing with functional screens to facilitate novel gene discovery.

# PgmNr 1335: Comprehensive genetic analysis and genetic features of 1323 patients with Charcot-Marie-Tooth disease in Japan.

## Authors:

## Background and Objective

Charcot-Marie-Tooth disease (CMT) is a group of Inherited peripheral neuropathies (IPNs) primarily affecting the peripheral motor and sensory nerves. Clear classification of CMT is difficult because of its clinical complexity and genetic diversity. In this study, we aim to describe the genetic features of CMT patients in Japan.

## Methods

In the period from May 2012 to December 2017, we collected 1323 cases with suspected CMT throughout Japan, whereas *PMP22* duplication/deletion were excluded in advance for demyelinating CMT cases. We performed targeted resequencing for encompassing 60 or 72 IPNs-related genes using Illumina MiSeq or Ion Proton, respectively. All suspected variants were validated using Sanger sequencing and interpreted according to the American College of Medical Genetics and Genomics standards and guidelines. We analyzed the gene-specific onset age and genetic features of these cases.

## Results

We identified pathogenic or likely pathogenic variants in 402 cases (30.4%). The most common causative genes were *GJB1* (n = 88, 21.9%), *MFN2* (n = 84, 20.9%), and *MPZ* (n = 66, 16.4%), followed by *HSPB1*, *PMP22* (point mutation), *GDAP1*, *NEFL*, *MME*. In demyelinating CMT, variants were detected in 44.6% cases, and the most common causative gene were *GJB1* and *MPZ*, and these were occupying for 66.4% in demyelinating type. Axonal CMT yielded a relatively lower detection rate (24.1%), and the most common causative gene was *MFN2* (33.8%). The most common disease onset period was first decade of life, and early-onset CMT cases were most likely to receive a molecular diagnosis.

## Conclusions

Our results updated the genetic profile within a large-scale of Japanese CMT cases. Subsequent analyses regarding onset age and geographical distribution advanced our understanding of CMT, which would be beneficial for clinicians.

## PgmNr 1336: Genotype-phenotype correlation of transthyretin-related familial amyloid polyneuropathy in Chinese population.

---

**Objective:** Peripheral neuropathy can be caused by pathogenic TTR variants – a treatable rare neurodegenerative condition. To report the *TTR* pathogenic variants and clinical features in a cohort of 388 Chinese IPN families, and to summarize the genotypic and phenotypic spectrums in all reported Chinese TTR-FAP patients.

**Methods:** IPN families were recruited and analyzed with MLPA, gene panels and Sanger sequencing to detect *TTR* sequence variants. The published literature about TTR-FAP patients were reviewed and the phenotype-genotype spectrums were summarized.

**Results:** We detected five pathogenic *TTR* variants in five FAP families (p.Arg54Thr, p.Lys55Asn, p.Gly67Glu, homozygous and heterozygous p.Ala117Ser), including the first observation of coexistence of homozygous and heterozygous p.Ala117Ser alleles in one FAP family. The key clinical features were axonal motor and sensory neuropathies with prominent autonomic dysfunctions and organ involvements, and high inter-familial and intra-familial clinical heterogeneity. There are 88 reported TTR-FAP families (210 patients) of Chinese origin. Variants p.Ala117Ser, p.Gly103Arg, p.Val50Met and p.Val50Ala were relatively frequent. The age at onset ranged from 17 years to 80 years, with early-onset (age at onset < 50 years) accounting for 70.06% and late-onset (age at onset ≥ 50 years) accounting for 29.94%.

The autonomic symptoms alleviated after oral diflunisal treatment for 7 and 9 months in three patients, treated in the 2<sup>nd</sup> to 4<sup>th</sup> year after disease onset.

**Conclusions:** TTR-FAP accounted for 1.3% of all patients in our IPN cohort, which suggests a routine *TTR* screening is required in IPN patients. Due to the good efficacy we observed, as well as its economics and accessibility, diflunisal might be an ideal drug for Chinese FAP patients and large-scale clinic trial of oral diflunisal treatment should be carried out further.

# PgmNr 1337: NKX2-1 gene mutation: Unraveling brain-lung-thyroid syndrome in a Brazilian patient responsive to methylphenidate treatment.

## INTRODUCTION

Defects in *NKX2-1* on chromosome 14q13, which encodes thyroid transcription factor 1, produce a concurrent clinical manifestation of chorea, respiratory distress, and hypothyroidism known as “brain-lung-thyroid syndrome.”

## CASE REPORT

Male patient, 4 years, born to non consanguineous parents, after an uncomplicated pregnancy was referred for evaluation of hypotonia. He was under treatment of subclinical hypothyroidism with low doses of levothyroxin. His parents noted hypotonia and delayed motor development in first 2 years of life. Language and social development were normal. No report of respiratory problems at birth was reported. His investigation for causes of hypotonia (both central and neuromuscular hypotonia), including CK, lactate, acylcarnitine profile, organic acids chromatography and muscle biopsy turned out to be normal. Progressively, patient got better of his hypotonia, but developed irregular trunk and limb movements later recognized as chorea. The combination of extrapyramidal movement disorder and hypothyroidism pointed out to *NKX2-1* gene as cause of patient’s phenotype which was later confirmed by molecular analysis. He was started on methylphenidate showing dramatic improvement in his movement disorder.

## DISCUSSION

*NKX2-1*-related disorders range from benign hereditary chorea (BHC) to choreoathetosis, congenital hypothyroidism, and neonatal respiratory distress (also known as brain-lung-thyroid syndrome). Childhood-onset chorea, the hallmark of *NKX2-1*-related disorders, may or may not be associated with respiratory distress syndrome or congenital hypothyroidism. Chorea generally begins in early infancy or about age one year (most commonly) or in late childhood or adolescence, and progresses into the second decade after which it remains static or (rarely) remits.

## CONCLUSION

Neurological phenotype is prominent in this condition and that many patients with *NKX2-1* mutations may show hypotonia as main presentation and never fully develop the classic triad of brain-lung-thyroid syndrome

## PgmNr 1338: Brain region specific contribution of the ATXN1/CIC interaction to spinocerebellar ataxia type 1.

---

Spinocerebellar ataxia type 1 (SCA1) is a fatal adult onset neurodegenerative disease, characterized by loss of balance, slight cognitive impairment, breathing dysfunction and early lethality. This is due to selective neurodegeneration of cerebellar Purkinje cells (PCs) as well as hippocampal and brainstem neurons. The disease is caused by the expansion of CAG repeats, encoding the polyglutamine (polyQ) tract in ATAXIN-1 (ATXN1), a protein that is broadly expressed in the brain. Using biochemical and genetic studies, we discovered that the polyQ expansion stabilizes ATXN1 and mediates cerebellar degeneration through enhanced function with the transcriptional repressor Capicua (CIC). Disruption of the ATXN1/CIC interaction exclusively in cerebellar PCs rescues the motor deficits seen in a transgenic SCA1 animal model. However, the mechanisms of disease in the remainder of the cerebellum, hippocampus, and brainstem have not yet been elucidated. To investigate these unknowns, we modified the existing *Atn1*<sup>154Q/2Q</sup> knock-in SCA1 mouse model, that expresses one modified *Atn1* allele in which 154 CAG repeats replaced the endogenous 2 CAGs, and that recapitulates all known features of human SCA1. Using the CRISPR/Cas9 system we edited the 154Q allele to contain two amino acid changes (V591A and S602D), eliminating ATXN1<sup>154Q</sup>'s binding to CIC throughout the entire body. Using this mouse model, we will determine the contributions of the ATXN1/CIC complex to various SCA1 phenotypes by conducting behavioral and histopathological assays, as well as transcriptomic studies to assess levels of potential rescue. With these data, we will learn if the ATXN1-CIC complex is driving SCA1 disease pathology in regions other than Purkinje cells and can work towards discovering the mechanism of disease in these regions. This will be informative for other neurodegenerative disorders in which a broadly expressed protein is only selectively toxic, such as Alzheimer's and Parkinson's disease.

## PgmNr 1339: Somatic instability is a major determinant of clinical onset of Huntington disease.

---

Huntington disease (HD) is a neurodegenerative disorder that is caused by an expanded polyglutamine tract in the huntingtin (*HTT*) gene. The length of this repeat is inversely correlated with age of onset. Conventional analyses have assumed that polyglutamine length, not glutamine codon usage on the DNA level, is the most relevant variable to consider for predicting age of clinical onset in HD. This region is predominantly encoded by CAG trinucleotides, although the penultimate glutamine codon in this region is specified by CAA in the majority of HD patients [i.e. *HTT* reference: (CAG)<sub>n</sub>-CAA-CAG]. Recently, using patient samples collected over 25 years, we have shown that genetic variants that alter glutamine codon usage in this region significantly influence age of clinical onset in HD in an autosomal dominant manner. Two distinct modifiers of age of onset have been identified in this regard: (i) a variant that causes complete loss of interrupting (LOI) sequence [i.e. (CAG)<sub>n</sub>-CAG-CAG], that hastens age of onset by 13-29 years on average and (ii) a variant characterized by a gain of a CAA interruption [i.e. (CAG)<sub>n</sub>-(CAA-CAG)<sub>2</sub>], that delays age of onset by 4.2 years on average. Our previous work showed that the LOI variant is associated with increased CAG expansion ratios in whole blood, implicating increased somatic instability as a potential causal mechanism for hastening age of onset. In the current study, we assessed whether HD patients that are carriers of gain of interruption (CAA-CAG)<sub>2</sub> variant ( $n=10$ ) display differences in CAG expansion ratios in whole blood, compared to individuals with canonical repeat sequence ( $n=60$ ). These analyses revealed that somatic CAG expansion ratios were significantly reduced in (CAA-CAG)<sub>2</sub> carriers compared to individuals with only one CAA codon in this region ( $P=3.13 \times 10^{-3}$ ). For the first time, we show that reduced somatic instability may be the biological mechanism underlying the later age of onset observed in HD patients that are carriers of the (CAA-CAG)<sub>2</sub> variant. To further delineate these observations, we are currently obtaining access to brain tissue to assess the influence of the two variants on somatic instability in the tissues most relevant for the disease. The results of the current *cis*-modifier investigation help explain why certain individuals with identical polyglutamine lengths can present with HD at vastly different ages, implicating somatic instability as a chief determinant of age of onset.

## PgmNr 1340: Biallelic variants in *EXOSC5* cause phenotypic features found in exosomopathies.

The RNA exosome complex is an essential ribonuclease complex involved in processing and surveillance of coding and non-coding RNAs and RNA degradation. The exosome comprises 10 core subunits in a barrel-like configuration with a cap of 3 proteins encoded by EXOSC1-3 that rests on a ring of 6 proteins encoded by EXOSC4-9. We present two patients with biallelic variants in EXOSC5, a novel human disease gene. The first child had motor delays and ataxia from 11 months and had cone rod dystrophy at 3 years. An MRI of the brain showed cerebellar hypoplasia and delayed myelination. At 11 years, she used a walker for ambulation. WES showed compound heterozygosity for a deletion involving exons 5-6 of EXOSC5 and a missense variant, p.Thr114Ile, affecting the RNase PH-like domain that was predicted to result in the loss of a hydrogen bond. The second patient, a male who died at 11 months, had hypotonia, esotropia and ophthalmoplegia, craniosynostosis, pectus carinatum and micrognathia. He required a tracheostomy. A muscle biopsy showed neurogenic and myopathic changes, with fiber size variation comprising hypertrophic and atrophic/hypotrophic fibers. A brain MRI showed reduced size of the brainstem and pons and slight enlargement of the 4th ventricle. He was homozygous for p.Leu206His in EXOSC5. We generated the missense variants in yeast - rrp46-Q86I, corresponding to EXOSC5-T114I, and rrp46-L191H, corresponding to EXOSC5-L206H. The rrp46-Q86I mutant shows growth similar to wildtype cells, whereas the rrp46-L191H mutant shows a moderate growth defect at 30°C that is exacerbated at 37°C compared to wildtype. Biallelic mutations have been described in four genes encoding exosome subunits. EXOSC3 mutations cause pontocerebellar hypoplasia (PCH1b) and spinal motor neuron disease, whereas EXOSC8 variants cause a different form of PCH. Missense variants in EXOSC2 cause intellectual disability, retinitis pigmentosa, hearing loss, short stature and facial anomalies, while variants in EXOSC9 cause cerebellar atrophy and an SMA-like motor neuronopathy. The two patients described here show clinical findings that overlap with other exosomopathies. Deleterious variants in the RNA exosome subunit genes could result in tissue-specific defects through a variety of mechanisms. Our findings suggest that normal function of the exosome subunit encoded by EXOSC5 is essential for CNS development and illustrate the mechanism of RNA dysregulation in motor and cerebellar degeneration.

## PgmNr 1341: The *C9orf72* repeat expansion, associated with ALS/FTD, is a rare folate-sensitive fragile site.

Expansion of the *C9orf72* repeat, (GGGGCC)<sub>n</sub>, is the cause of a plethora of disease symptoms, including being the most common cause of Amyotrophic Lateral Sclerosis, Frontotemporal Dementia, Parkinsonism, Huntington's disease phenocopies, multiple sclerosis, Alzheimer's, as well as clinical overlaps of these. How the *C9orf72* expansion mutation leads to the wide spectrum of clinical syndromes remains unknown. Here we revealed that the *C9orf72* expansion is a cytogenetic rare folate-sensitive chromosomal fragile site (RFSFS), similar to the ten RFSFS mapped to (CGG)<sub>n</sub> expansions, including FRAXA, the cause of fragile X syndrome (FXS), autism, fragile X associated tremor ataxia and premature ovarian failure. In total, there are >250 fragile sites, ~225 common fragile sites, and ~25 RFSFS, where only the latter have been linked with inherited disease. Our report represents the first mapped RFSFS linked to neurodegenerative disease, with all 10 of the previously mapped RFSFS associated with neurodevelopmental diseases. Like other RFSFS, *C9orf72* expansions present chromosome breaks, gaps, regions of elongated under-condensed chromatin, aberrant CpG methylation and unusual DNA structures. These *C9orf72* expansion cells are prone to micronuclei, double-strand breaks, sister-chromatid exchanges, and are a "hot spot" of genetic instability. We observed chromosomes that have lost the telomeric 9p region from *C9orf72* onwards with its lost acentric fragment. One of our patient cell lines has incurred a large 9q duplication in every cell. Thus, as with other RFSFS like FRAXA, the expanded *C9orf72* shows genomic instability. As with the mutant FRAXA allele, the mutant *C9orf72* allele assumes a striking aberrant chromatin packaging, as evidenced by extreme nuclease inaccessibility exclusively on the expanded allele. Nuclease resistance sensitivity spans ~3.3kb upstream and ~3.7kb downstream of the expanded repeat, and resistance is exacerbated by aberrant methylation. That the *C9orf72* expansion is a cytogenetic fragile site – the most profound macro-scale epigenetic mark, now broadens the repeat sequences associated with RFSFS, and sheds light on the varied genetic alterations, variable symptoms and

multiple modes of pathogenesises that can arise at the *C9orf72* locus, as observed with FXS.

## PgmNr 1342: Repeat configurations of CGG repeats in the NBPF19, a causative gene for neuronal intranuclear inclusion disease, and correlation of expanded CGG repeat sizes with age of onset.

### Authors:

---

#### [Background and Aim]

Neuronal intranuclear inclusion Disease (NIID) is an autosomal dominant disease characterized clinically by various combinations of cognitive decline, parkinsonism, cerebellar ataxia and peripheral neuropathy, and neuropathologically by eosinophilic hyaline intranuclear inclusions in the central and peripheral nervous systems and other tissues. We have recently discovered expanded CGG repeats in 5'UTR of the NBPF19 gene as the causative mutations in NIID. Given the findings that there are five paralogs including NBPF19 that have sequences with enormously high identities (>99%), we first determined the detailed repeat configurations of NBPF19 in the controls, and then investigated correlations of the sizes of expanded CGG repeats with the ages at onset of patients with NIID.

#### [Methods]

PCR primers were designed to specifically amplify genomic regions containing the CGG repeat of NBPF19. The PCR products obtained from 182 controls subjects were barcoded, and then subjected to circular consensus sequencing (CCS) employing a PacBio Sequel sequencer. To determine the size of expanded CGG repeats, genomic DNAs were extracted from 28 patients with NIID, and SacI-digested genomic DNAs were subjected to Southern blot hybridization analysis.

#### [Results]

The number of CGG repeats determined from CCS reads ranged 7–39 repeats in 182 control subjects, and there were considerable variations in the repeat configurations. In addition, three SNVs (rs1172135200, rs1258206224, and rs1436954367) were exclusively present in the allele with the repeat motif of (AGG)(CGG)9(AGG)3 in 14 control subjects. The repeat motif of (AGG)(CGG)*n*(AGG)2(CGG) was observed in the majority of the alleles and the CGG repeat lengths tended to be larger than those with the repeat motif of (AGG)(CGG)*n*(AGG)3. The onset age was available in 22 NIID patients, which ranged from 55 to 78 years (mean 64.5). The expanded CGG repeats of NBPF19 in the 28 patients with NIID ranged from 270 to 550 bp in length, based on the Southern blot analysis. The size of the expanded repeats, however, did not show significant correlation with the onset age ( $p = 0.656$ ).

#### [Conclusions]

There was no significant correlation between the size of expanded CGG repeats and the onset age in NIID patients, necessitating further investigations, including the size distribution of expanded CGG

repeats in brains, expression profiling of mutant alleles of NBPF19 in brains and involvement of methylation status of CGG repeats.

## PgmNr 1343: The phenotypic spectrum of the *LAS1L*-associated X-linked disorder in a patient cohort.

*LAS1L* is required for synthesis of the 60S ribosomal subunit and maturation of 28S rRNA. Additionally, it plays a role in transcriptional regulation by affecting sumoylation status and transactivation potential of the zinc-finger transcription factor Zbp-89 (ZNF148).

Pathogenic variants in *LAS1L* have previously been associated with Wilson-Turner Syndrome (WTS, MIM#: 309585) in males. WTS is an X-linked neurological disorder typically characterized by intellectual disability (ID), dysmorphic facial features, hypogonadism, short stature, and truncal obesity. A patient with congenital lethal motor neuron disease has also been reported. We describe the phenotypic and genotypic spectrum of eleven male probands from unrelated families including three previously reported families and eight additional individuals, 7 of whom have novel *LAS1L* variants. Probands exhibit variable phenotypes overlapping with WTS, and also express additional novel phenotypes such as hypotonia and respiratory distress.

Probands in our cohort all have missense variations in *LAS1L*, with 10 unique variants identified in 11 unrelated families. Affected individuals from five families have variants clustering in exon 10, three of which impact the same amino acid residue. Remaining variants occur in exons 1, 2, 6 and 11. The variants in exons 1 and 2 fall within a conserved *LAS1L* domain. Only one variant is present in gnomAD (1/157718) in a female. Probands display variable phenotypes, including hypotonia (7/11), ID (5/11), genital abnormalities (5/11), respiratory distress (4/11), speech delay (4/11), obesity (4/11), motor delay (3/11), and abnormal gait (2/11) without a clear genotype-phenotype correlation. Respiratory distress and hypotonia have not previously been described in WTS, but some affected individuals present with both the WTS- as well as the motor neuron-related phenotypes. We hypothesize that the phenotypic spectrum for pathogenic variants within *LAS1L* is broader than previously described, and accounts for the motor delays, hypotonia, and respiratory arrest occurring

in our cohort.

Here we describe a cohort of patients with *LAS1L* variants expressing a complex and variable phenotype overlapping with WTS and including respiratory distress and hypotonia. Larger cohort and functional studies are needed to further elucidate the complex genotype-phenotype associations observed in these individuals and the mechanisms underlying the phenotypic variability.

## PgmNr 1344: Catatonia is a clinical feature of the natural progression of NLGN2-related autism spectrum disorder.

Neurexins and neuroligins are families of transmembrane synaptic cell adhesion molecule (SCAM) proteins located at the synaptic membrane which function to induce synapse formation and maturation. SHANK family proteins indirectly tether these SCAM proteins to glutamate receptor proteins creating a functional complex necessary for optimal synaptic growth and signalling. Variants in genes coding proteins in these pathways have been linked to Autism Spectrum Disorder (ASD). Catatonia is a comorbidity of ASD, and has been described in patients with variants in genes coding SCAM proteins and SHANK proteins, though to date has not been described in patients with Neuroligin-2 (*NLGN2*) mutations. We present a case of a patient with ASD, language impairment, behavior problems, hyperphagia and anxiety who presented as a teenager for evaluation of developmental regression, staring spells, weight loss and anhedonia; felt to represent catatonia. After treatment with benzodiazepines, the patient regained some developmental milestones. Genetic testing revealed a de novo missense mutation in *NLGN2*. We hypothesize that patients with pathogenic mutations in *NLGN2* diagnosed with ASD are at risk for catatonia as a comorbidity. The *NLGN2* protein, along with proteins in the SCAM and SHANK synaptic complex are present in GABA-ergic interneurons, and it is theorized that imbalances in the excitatory-inhibitory synaptic pathways cause derangement in optimal GABA and glutamate signalling at the synapse, provoking the onset of catatonia symptoms. Practitioners caring for patients with ASD second to pathogenic variants in genes coding SCAM and SHANK proteins, and more specifically in patients with disease-causing variants in *NLGN2*, should consider catatonia in the differential diagnosis for late onset developmental regression.

## PgmNr 1345: A rare cause of juvenile Parkinsonism.

**Authors:**

K. Hadzsiev; A. Till; J. Zima; R. Ripszam; B. Melegh

[View Session](#) [Add to Schedule](#)

**Affiliation:** Department of Medical Genetics, Medical School, University of Pécs, Pécs, Hungary

---

**Introduction:** Juvenile Parkinsonism (JP) is a rare condition with onset prior to age affects patients below 21, the genetic background of the disease is very heterogeneous. The most common genetical causes includes the alterations of PARK2, PINK1 and PARK7 genes. Symptomatology also can be very variable including classic Parkinsonian symptoms like rigidity, bradykinesia and postural instability as well as additional symptoms like depression, sleep disturbances, memory loss, constipation and urinary problems.

**Materials and Methods:** We report a 21-year-old girl with the onset of symptoms at 15 years. Initially symptoms included involuntary laugh and progressive mental decline, later associated with Parkinsonian symptoms.

**Results:** An apparently homozygous ATP13A2:c.2479G>A variant was identified in exon 22 of the *ATP13A2* gene by Whole Exome Sequencing. The variant is a novel missense variant previously not described in other patients. It is classified as a variant with unknown significance although in silico predictions suggest pathogenicity.

**Conclusions:** The above mentioned homozygous mutation confirms the diagnosis of Kufor-Rakeb syndrome, which is a rare autosomal recessive juvenile Parkinsonism syndrome. Through our case presentation we would like to shortly review the symptomatology, diagnostics and therapy of juvenile Parkinsonism.

## **PgmNr 1346: Markedly higher burden of schizophrenia associated copy number variants in very early onset psychosis compared to an adult schizophrenia population.**

### **Authors:**

---

**Objectives:** Very early onset psychosis (VEOP) is defined as the onset of psychotic symptoms before 13 years of age and considered to be a more severe form of the more typical adolescent/adult onset psychosis. Therefore, we hypothesize that VEOP will have a higher rate of rare genetic mutations. The objective of this study is to compare the genetic burden of schizophrenia-related copy number variants (CNVs) in a clinically-referred VEOP cohort to that of schizophrenia variants that have been found in a Psychiatric Genomics Consortium adult onset psychosis cohort.

**Methods:** DNA and medical records were collected from VEOP probands and parents enrolled into the Manton Center for Orphan Disease Research protocol at Boston Children's Hospital (BCH).

Chromosomal Microarray (CMA) was performed on 106 probands and available parental/familial DNA samples. Probands were evaluated by clinicians in the Developmental Neuropsychiatry Program (DNP) at BCH and assigned diagnoses based on DSM-5 criteria. Diagnoses include unspecified schizophrenia spectrum disorder, schizophrenia, schizoaffective disorder, depression with psychotic features, bipolar disorder with psychotic features, and OCD with psychotic features.

**Results:** 9 probands from our cohort were found to have one of the 12 copy number variants (CNV) associated with schizophrenia with genome wide significance (Rees, 2016). These variants include 1q21.1 duplication (N=1), 15q11.2 deletion (N=1), 16p11.2 duplication (N=1), 16p13.11 duplication (N=4), and 22q11.2 deletion (N=2). Our rate of CNVs in the VEOP cohort was higher than the 0.6% rate in adult controls ( $p < 0.00001$ ) and the 1.9% rate in patients with schizophrenia ( $p < 0.0002$ ) that was reported in a recent case control study of over 20,000 patients with schizophrenia and over 20,000 controls (Bergen et al., 2018). Overall, 60% of patients in the VEOP cohort had a rare CNV.

**Conclusions:** This increased burden of rare CNVs associated with schizophrenia in our VEOP cohort supports the hypothesis that VEOP is associated with a higher rate of rare genetic mutations than adolescent/adult onset psychosis. The study of rare Mendelian forms of complex disease (such as VEOP) is an effective way to discover and confirm variants that impact more common forms of the disorder.

## PgmNr 1347: *GJB2* and *GJB6* mutations in non-syndromic childhood hearing impairment in Ghana.

---

Our study aimed to investigate *GJB2* (connexin 26) and *GJB6* (connexin 30) mutations associated with non-syndromic childhood hearing impairment (HI) as well as the environmental causes of HI in Ghana. Medical reports of 1104 students attending schools for the deaf were analyzed. Families segregating HI, as well as isolated cases of HI of putative genetic origin were recruited. DNA was extracted from peripheral blood followed by Sanger sequencing of the entire coding region of *GJB2*. Multiplex PCR and Sanger sequencing were used to analyze the prevalence of *GJB6*-D3S1830 deletion. Ninety-seven (97) families segregating HI were identified, with 235 affected individuals; and a total of 166 isolated cases of putative genetic causes, were sampled from 11 schools for the deaf in Ghana. The environmental factors, particularly meningitis, remain a major cause of HI impairment in Ghana. The male/female ratio was 1.49. Only 59.6% of the patients had their first comprehensive HI test between 6 to 11 years of age. Nearly all the participants had sensorineural HI (99.5%;  $n = 639$ ). The majority had pre-lingual HI (68.3%,  $n = 754$ ), of which 92.8% were congenital. Pedigree analysis suggested autosomal recessive inheritance in 96.9% of the familial cases. *GJB2*-R143W mutation, previously reported as founder a mutation in Ghana accounted for 25.9% (21/81) in the homozygous state in familial cases, and in 7.9% (11/140) of non-familial non-syndromic congenital HI cases, of putative genetic origin. In a control population without HI, we found a prevalent of *GJB2*-R143W carriers of 1.4% (2/145), in the heterozygous state. No *GJB6*-D3S1830 deletion was identified in any of the HI patients. *GJB2*-R143W mutation accounted for over a quarter of familial non-syndromic HI in Ghana and should be investigated in clinical practice. The large connexin 30 gene deletion (*GJB6*-D3S1830 deletion) may not account for of congenital non-syndromic HI in Ghana. We are currently employing Next Generation Sequencing approaches and functional genomics studies to identify the other genes involved in most families and isolated cases of HI in Ghana.

## **PgmNr 1348: Identification of *LOXHD1* as a deafness gene causing ski-slope hearing loss in Korean population: Genotyping of STR markers confirms strong founder effect of c.4212+1G>A in *LOXHD1*.**

### **Authors:**

B. Kim <sup>1</sup>; W. Jeon <sup>2</sup>; J. Han <sup>3</sup>; H. Park <sup>3</sup>; S. Lee <sup>3</sup>; D. Oh <sup>3</sup>; D. Kim <sup>2</sup>; B. Choi <sup>3</sup>

---

*LOXHD1* (lipoxygenase homology domains 1) was reported to be a causative gene of autosomal-recessive non-syndromic hearing loss (ARNSHL, DFNB77) and it is also known as the causative gene for Fuchs Corneal Dystrophy (FCD) in the field of ophthalmology. DFNB77 is rarely documented in the literature and thus genotype-phenotype correlation is not well characterized. Further, it has never been reported in Korean deaf population. Here, we report the first *LOXHD1*-related deafness in Korean population supported by protein modeling study and the strong founder effect of a splicing region variant: c.4212+1G>A in this population.

Six pedigrees with congenital or pediatric-onset, bilateral sensorineural hearing loss (SNHL) were recruited for molecular genetic diagnosis. Audiogram showed a ski-slope pattern, which seems to progress to profound SNHL. Accordingly, two of six probands already received cochlear implant in their teens and twenties. Ophthalmologic examination did not reveal any problems. Molecular genetic diagnosis using whole-exome sequencing (WES) identified 2 missense variants, 1 frameshift variant and 2 splice region variants. Among them, c.4212+1G>A was the most commonly identified variant, involving 5 of 6 probands. 3D protein modeling study was done to prove the pathogenic potential of identified novel missense variants (c.2641G>C: p.Gly881Arg), which seems to exert pathogenicity by affecting the stability of beta sheet in the PLAT domain which comprises the entire protein encoded by *LOXHD1*. Genotyping of six c.4212+1G>A-linked Short Tandem Repeat (STR) markers revealed the strong founder effect of this variant in Korean deaf population.

Our work provides the first description of *LOXHD1*-related deafness in Korean population, as an important deafness gene causing progressive, ski-slope SNHL. Revelation of representative phenotype of DFNB77 and founder effect of c.4212+1G>A in Korean population will facilitate the genetic diagnosis in such cases, enabling more informative genetic counseling.

## PgmNr 1349: Overexpression of *CNRIP1*'s mRNA due to a genomic duplication associated with postlingual progressive hearing loss in the *DFNA58* family.

---

In 2009, we reported the mapping of the *DFNA58* locus in a large Brazilian pedigree in which autosomal dominant postlingual progressive hearing loss was segregating. Here we report the identification of an undescribed ~200Kb genomic duplication segregating with hearing loss in the *DFNA58* family: all 20 affected subjects inherited the duplication and all the 20 unaffected subjects did not, resulting in highly significant Lod score of 9.9. This novel duplication includes two entire genes (*PLEK* and *CNRIP1*) and, partially, a third gene, *PPP3R1*. One duplication breakpoint lies inside *PPP3R1*'s intron 1 and the other in intergenic region between *PLEK* and *FBXO48*, both breakpoints immersed in rich repetitive elements' regions. Analyses of the mRNA (RT-qPCR) of the three candidate genes in blood samples of affected individuals revealed significant overexpression (27.8X) of the *CNRIP1* gene in all 13 duplication carriers analyzed, but normal levels in the eight unaffected family members, when compared to six control individuals. The other two candidate genes did not show altered expression, when all affected subjects were analyzed. In situ hybridization as well as immunofluorescence in the neonatal murine cochlea showed that *Cnrip1* mRNA and the corresponding protein are largely expressed in the spiral ganglia and in the tympanic borders cells, but in 4-week-old animals, other cell types within and close to the organ of Corti also show *Cnrip1* protein expression. Clinical data such as ABR records, otoacoustic emissions and tonal audiometry from the affected duplication carriers, with varying degrees of hearing loss, suggested that the primary functional impairment resides in the cochlea. *CNRIP1* (CB1 cannabinoid receptor-interacting protein 1) is majorly known as the CB1 cannabinoid receptor interaction protein, with important functions in the nervous system such as a presynaptic modulator of neurotransmitter release. The human *CNRIP1* gene encodes two protein isoforms CRIP1a and CRIP1b. CRIP1a suppresses CB1-mediated tonic inhibition of voltage-gated Ca<sup>2+</sup> channels. *CNRIP1* has also been suggested to act as a tumor suppressor gene, since it was observed that demethylation of the *CNRIP1* promoter or overexpression

of *CNRIP1* can reduce the proliferative and migration abilities of colon cancer cells. In conclusion, our data support the causative association between the overexpression of *CNRIP1*, due to the 200Kb duplication, and autosomal dominant postlingual hearing loss.

## PgmNr 1350: Heimler syndrome: Hypomorphic mutations in the peroxisome-biogenesis genes *PEX1* and *PEX6* are in cause.

---

Heimler syndrome (HS) is a rare recessive disorder characterized by sensorineural hearing loss (SNHL), amelogenesis imperfecta, nail abnormalities, and occasional or late-onset retinal pigmentation. We firstly ascertained eight families affected by HS and, by using a whole-exome sequencing approach, identified biallelic mutations in *PEX1* or *PEX6* in six of them. Loss-of-function mutations in both genes are known causes of a spectrum of autosomal-recessive peroxisome-biogenesis disorders (PBDs), including Zellweger syndrome. PBDs are characterized by leukodystrophy, hypotonia, SNHL, retinopathy, and skeletal, craniofacial, and liver abnormalities. We demonstrate that each HS-affected family has at least one hypomorphic allele that results in

extremely mild peroxisomal dysfunction. Although individuals with HS share some subtle clinical features found in PBDs, the diagnosis was not suggested by routine blood and skin fibroblast analyses used to detect PBDs. Our findings define HS as a mild PBD, expanding the pleiotropy of mutations in *PEX1* and *PEX6*.

In a second time, we investigated another Moroccan family with Heimler syndrome with early onset, severe visual impairment and important phenotypic overlap with Usher syndrome. The patient carried a novel homozygous missense variant c.3140T > C (p.Leu1047Pro) of *PEX1* gene. As standard biochemical screening of blood for evidence of a peroxisomal disorder did not provide a diagnosis in the individuals with HS, patients with SNHL and retinal pigmentation should have mutation analysis of *PEX1* and *PEX6* genes.

## PgmNr 1351: Novel mutation in *CTNNA1* causes autosomal dominant pattern dystrophy.

---

**Introduction:** Pattern retinal dystrophy (PD) is a rare autosomal dominant disease that affects the central retinal region. In PD, pigment or lipofuscin accumulate within the retinal pigment epithelium leading to its erosion. This disease process can result in bilateral impairment of a person's central vision.

**Purpose:** To determine the genetic etiology, underlying PD in a three generation European family.

**Methods:** The proband, a 25 year old female presented to us with PD. Negative results were seen when gene panel testing was conducted. More, family members were examined by an ophthalmologist and recruited (n = 6); three other members, having a best corrected visual acuity of 20/50 or better were diagnosed with the disease. Whole genome analysis was done for three affected family members. Shared and rare variants were flagged.

**Results:** A heterozygous single nucleotide polymorphism, likely pathogenic was observed in a strong candidate gene, *CTNNA1* (NM\_001903: exon 6:c.835G>C:p.A279P). A segregation analysis was performed on all 7 family members; all affected family members were heterozygous for the novel presumed disease causing missense variant. The variant had strong pathogenicity scores (SIFT: 0.041 and polyphen:0.974) and was not seen in GnomAD. However, a family member thought to be unaffected clinically, also carried this variant.

**Conclusion and future directions:** This would be the second report linking *CTNNA1* with PD. We hypothesize that incomplete penetrance or age of onset provides an explanation of why the seemingly unaffected is a carrier of this disease causing variant. Allele specific expression will be addressed by RT-PCR and mass spectrometry on cDNA of patient derived fibroblast and sanger sequencing, to provide further support for the *CTNNA1* variant's pathogenic role. This variant discovery adds to the current theory that *CTNNA1* is involved in PD. Finding the pathogenic variant can help diagnose other patients with similar phenotypes. Furthermore, it will help expand the knowledge on the disease mechanism in PD that could help shed light to a cure in the future.

## PgmNr 1352: Exploring genetic conservation in the mechanisms of hearing and deafness between *Drosophila* and mammals.

Over 150 genes that cause deafness when mutated have been identified through genetic screening in humans and mice, many of which have not been functionally characterized. Strikingly, over 90% of these genes identified have orthologs in the fruit fly, *Drosophila melanogaster*. Flies provide quick and efficient strategies to identify molecular mechanisms of disease which can be further explored in mammalian model systems. The auditory system of the fly, the Johnston's organ (JO), is located within the antenna and is comprised of ~200 stretch receptor units called scolopidia. These scolopidia contain mechanosensitive neurons that respond to gravity and sound from vibrations of the outermost antennal segment. Although the human and fly hearing organs are anatomically very different, several studies have identified functional conservation of some human deafness genes in the fruit fly.

We designed and performed a genetic screen to identify the degree of molecular and functional conservation between the fruit fly and mammals in the auditory system to provide valuable tools to help elucidate the function of deafness genes in mammals. We first used the DIOPT (DRSC Integrative Ortholog Prediction Tool) tool to generate a comprehensive list of fly genes that are orthologous to human and mouse deafness genes, and identified genetic tools to assess the expression pattern of these genes and proteins within JO. We then explored whether these genes were expressed in specific cell types within JO using T2A-GAL4 and UAS-GFP lines, and tested whether certain proteins are enriched in specific structures within the scolopidia in pupal JO using GFP or YFP protein trap lines. In addition to validating previous findings that *Myosin VIIa*, *Non-muscle myosin II*, and *Protocadherin-15* orthologs are expressed in JO, many other conserved deafness associated genes or proteins are also expressed. Interestingly, orthologs of Usher syndrome proteins Cadherin-23 and Whirlin were also expressed in JO and partially colocalize with the Myosin VIIa and Protocadherin-15 orthologs, suggesting a potential functional link. The finding that many Usher syndrome proteins are co-expressed within JO suggests a molecular conservation between the Usher complex in humans and flies. Our future work will determine the extent of this conservation and test whether loss of function of these genes in *Drosophila* is sufficient to cause deafness.

## PgmNr 1353: A novel mutation in *MERTK* for rod-cone dystrophy in a North Indian family.

**Objective:** To identify the underlying genetic defect of childhood-onset severe rod-cone dystrophy (RCD) in a consanguineous family from North India with autosomal recessive retinitis pigmentosa.

**Material and Methods:** A detailed family history, clinical data, and blood samples were collected from 11 members of the family, including 4 affected by an autosomal recessive rod-cone dystrophy (arRCD), and DNA was extracted. Whole-exome sequencing (WES) was performed on DNA samples of proband and her unaffected maternal uncle. Ion Reporter software (ver. 4.4) was used for the annotation of variants obtained by WES. The variants detected in proband were tested for validation in all other affected and unaffected family members using Sanger sequencing technique.

**Results:** We have identified a novel nonsense mutation—c.1647T>G (p.Tyr549Ter)—in the exon 11 of *MERTK* that co-segregated completely with the disease phenotype in all the 4 affected members and was not observed in the 7 unaffected members of the family. This mutation was also not detected in 120 ethnically matched controls (240 chromosomes), hence excluding it as a polymorphism.

**Conclusions:** *MERTK* has a role in retinal pigment epithelium as a regulator of rod outer segments' phagocytosis. Due to c.1647T > G substitution, the stop codon (p.Tyr549Ter) appears early in the transcript. It seems that either the altered transcript would degenerate through nonsense-mediated decay (NMD) or potentially form truncated protein lacking a functionally important domain (i.e., tyrosine kinase domain). These findings thus further expand the mutation spectrum in *MERTK* and substantiate its role in the pathogenesis of retinal dystrophy.

## PgmNr 1354: Expanding the clinical spectrum associated with *TUBB4B* mutations.

### Authors:

1) Laboratory of Genetics in Ophthalmology, Imagine and Paris Descartes University, Paris, France; 2) Department of Genetics, University of Alabama, Birmingham, USA

**Introduction.** Recently, we reported heterozygous mutations affecting Arg391 in the  $\beta$ -tubulin 4B isotype-encoding gene (*TUBB4B*) in four unrelated families with a distinctive neuro-sensorineural disorder consisting in early-onset and severe retinal dystrophy and sensorineural hearing loss. The mutations dampened the dynamics of microtubules (MT) lattice but ciliation and intraflagellar trafficking were unremarkable. Here, we report clinical expression and functional analysis of a novel *TUBB4B* mutation (p.Pro358Ser) identified *de novo* in a sporadic case displaying blindness, sensorineural hearing loss, short stature, chronic kidney disease and recurrent sinus and ear infections, a constellation of symptoms strongly reminiscent of ciliopathies.

**Material and methods.** Cilia from nasal brushing of the index case were analyzed by transmission electron microscopy (TEM). The dynamics of MT in normal conditions and under treatment with taxol and ciliation were analyzed by immunocytochemistry in cultured cells overexpressing FLAG-tagged wild-type or p.Pro358Ser *TUBB4B*.

**Results.** Cilia from nasal brushing of the index case revealed ultrastructural abnormalities with rare axonemes and disorganized basal bodies. Functional analysis in cultured cells overexpressing FLAG-tagged wild-type or mutant *TUBB4B* showed that the mutant *TUBB4B* have a drastic impact on microtubulation and ciliation as demonstrated by the absence of visible MT lattice and of primary cilia. Inspection of the  $\beta$ -tubulin atomic structure revealed that the Pro358 residue is located in a region that binds Taxol, an inhibitor of MT depolymerization. Interestingly, treatment of cells overexpressing the p.Pro358Ser *TUBB4B* with Taxol (25 nM) allowed the formation of a MT lattice and of primary cilia.

**Discussion and Conclusion.** The severe cilia alterations in nasal epithelial cells of the patient are consistent with a ciliopathy. Functional analysis showing that overexpression of the mutant *TUBB4B* recapitulate deciliation, strongly supports the role of the mutation in the patient phenotype.

Interestingly, the presence of MT and cilia upon treatment with Taxol, a well known chemotherapy drug, suggests that the p.Pro358Ser mutation increases the affinity for the drug, thereby reducing availability for the other  $\beta$ -tubulin isotypes that can assemble with  $\alpha$ - subunits to form the MT lattice. Whether Taxol should be used to recover ciliation in affected tissues of the patient certainly deserves consideration.

## PgmNr 1355: Inherited retinal dystrophies, a group of diseases with many faces: Mutation spectrum from a case series of Romanian patients with unexplained visual loss.

---

**Background:** Retinal dystrophies (RDs) are degenerative diseases of the retina which can lead to vision loss. Common presentations among these disorders include night or colour blindness, tunnel vision and subsequent progression to complete blindness. Cases may be progressive or stationary, syndromic or non-syndromic and may be familial with autosomal recessive, autosomal dominant or X-linked modes of inheritance described, with sporadic cases also observed. More than 260 genes have been identified for the isolated forms and for syndromes. **Methods:** We present the results of genetic testing performed on rare patients experiencing visual impairment referred to Genetics Department in the last two years. Whole Exome Sequencing was performed on each patient in an international laboratory. Only for one patient Whole Genome Sequencing was applied. Cases aged between 8 months and 54 years were unrelated and their mean age of symptom onset was with range from birth to age of 30 years, with heterogeneous clinical presentation over time. Ophthalmological evaluation showed a large range of visual activity, with color vision defects and wide range of electroretinographic abnormalities. **Results:** Disease-causing mutations were identified in all analyzed patients, distributed across 10 different genes: *VCAN*, *C2orf71*, *CACNA1F*, *ABCA4*, *NDP*, *PDE6C*, *RPGRIP1*, *PDE6B*, *TUBB4B*, *CEP250*. Some sequence changes were predicted to be possibly or probably damaging and novel variants were described at the time of diagnostic testing. Few patients were identified to have many variants linked to retinal genes, interpreted as modifiers which could alter phenotype by acting as risk factors or protection factors. In our cohort, the most prevalent dystrophies were *ABCA4* gene-related disorders (5 patients). Given the large number of variants reported in *ABCA4*, most of them being polymorphisms, the identification of true disease-causing mutations was challenging in the frame of low local genetic resources which limited carrier genetic testing of the families. **Conclusions:** The clinical description remains an important first step in focusing genetic testing. A medical geneticist can help to choose the best genetic test, based on current test methodology. Eyecare professionals have an active role in caring for patients with retinal dystrophies. Next generation sequencing technologies are among the most promising approaches to identify mutations in RDs and to decide appropriate multidisciplinary management.

## PgmNr 1356: Molecular genetic analysis of rare non-syndromic prelingual hearing disorders in a Romanian patient population.

---

**Introduction:** About 1-3 / 1000 newborns are affected by a profound hearing disorder at birth or in the first two years of life. About 60% of these cases are due to genetic causes. Inherited hearing disorders are divided into syndromic or non-syndromic, non-syndromic hearing disorders (NSHL) are isolated, while syndromic hearing disorders (SHL) are associated with additional organic disorders. Approximately 70% of cases of inherited hearing disorders are non-syndromic and predominantly due to sensorineural causes. Of these, approximately 80% of cases are autosomal recessive (DFNB) and 18% are autosomal dominant (DFNA), about 2% are X-chromosome (DFNX) or mitochondrial (MT) associated. To date, 185 gene loci and 128 genes have been identified for this type of hearing impairment. Genetic changes in the *DFNB1* gene locus, in which the genes *GJB2* gene (connexin-26) and *GJB6* (connexin-30) are localized represent the main cause (~45%) of prelingual non-syndromic hearing disorders. The aim of the project is to demonstrate, in a Romanian patient group, which rare genetic hearing disorders occur.

**Methods:** So far 120 patients have been included in our studies that have been diagnosed with severe to profound non-syndromic hearing impairment in their first two years of life and which have been shown to have no alteration in the *DFNB1* gene locus, in the genes *GJB2* and *GJB6*, respectively. Initially, targeted genes were analyzed, which in some few rare cases led to hearing impairment in various European populations. The detection of genetic alterations was carried out by bi-directional sequencing of the coding exons, as well as the intron transitions.

**Results:** First of all, the genes *GRXCR1* and *ESRRB* were analyzed in this patient group followed by genes *TMIE*, *GIPC* and *LHFPL5*. By DNA sequencing, 6 novel mutations, 12 unknown polymorphisms and 14 known alterations that are already cataloged in the databases of international sequencing projects have been detected so far.

**Conclusions:** In the investigated patients mutations and previously unknown polymorphisms were occasionally identified in the genes *GRXCR1*, *ESRRB* as well as *TMIE*, *GIPC* and *LHFPL5*, however, an accumulation of changes is not detectable. Therefore, further investigations are required for a better understanding of the etiology of prelingual hearing disorders.

## PgmNr 1357: High-throughput functional genomics of hearing and vestibular disorders in Zebrafish.

Approximately 360 million people worldwide (5% of the world's population) are affected by hearing loss. Indeed, one in every 500-1000 newborns is affected by sensorineural hearing loss, making it one of the most common birth defects. Hearing loss is associated with a substantially reduced quality of life and overall health. Low-cost genomic sequencing technologies continually identify new mutations associated with human hearing loss, but their functional validation is unacceptably slow. There is a need to fill this knowledge gap, which is required to develop new treatments that arrest or reverse hearing loss and improve patient outcomes. We found that 94% of human hearing loss genes have an orthologue in zebrafish, suggesting high functional conservation. Zebrafish are an ideal model organism to study hearing loss, given their external embryonic development, transparent body, accessible inner ear and the presence of lateral line neuromasts, which are functionally analogous to mechanoreceptors of the mammalian inner ear. In addition, zebrafish have been shown to effectively recapitulate disease phenotypes. Numerous publications have demonstrated the efficacy of gene targeting in zebrafish using CRISPR/Cas9 including a variety of tools and methods for guide RNA synthesis and mutant identification. While all the published techniques work, not all approaches are readily scalable to increase throughput. We recently described a CRISPR/Cas9 based high-throughput mutagenesis and phenotyping pipeline in zebrafish.

Using this pipeline, we generated loss of function alleles in 80 hearing loss genes selected from the [hereditaryhearingloss.org](http://hereditaryhearingloss.org) database. We will present the mutagenesis pipeline, and phenotyping data from a selected candidate genes showing various hearing and vestibular defects.

## PgmNr 1358: Pathogenic variants with significantly increased odds ratio for Mendelian traits are rare in real world data.

### Authors:

---

**Introduction:** In the practice of clinical genetic testing, the ACMG/AMP guideline was widely accepted guidance for the interpretation of sequence variants. Among listed evidence in the guideline, significantly increased prevalence of a variant in affected individuals than controls (PS4) is considered as a strong indicator of pathogenicity. However, given the ultra-low frequency of most pathogenic variants for Mendelian traits, e.g. hereditary hearing loss, the availability of PS4 is expectedly limited.

**Methods:** 10889 hearing loss cases and 3204 normal controls from 31 provinces of China were recruited by the China Deafness Genetics Consortium (CDGC). By screening 156 hearing loss causing genes, 1470 reported and 624 novel pathogenic variants were identified from 90539 rare variants that alter amino acid sequence or splicing sites. Fisher's exact test and logistic regression with population stratification adjustment were used to compare the variant frequencies in cases and controls. Relative risk (RR) and odds ratios (OR) were calculated and evaluated for the precision and recall rate.

**Results:** Fisher's exact test and logistic regression by PLINK respectively indicate only 28 and 10 pathogenic variants were enriched in the cases ( $P < 0.05$ ). Controversially, results also indicate 8138 and 6082 non-pathogenic variants false positively associated with the cases by three tests. ROC analysis for the P values of two tests, RR and OR suggest that OR had the best performance in differentiating pathogenic and benign variants with an AUC of 0.808. By grouping the variants based on MAF, results suggest that, of the PS4 labeled pathogenic variants, 1% had a relatively common  $MAF > 1.4\%$ .

**Summary:** Although PS4 strongly supports variant pathogenicity, it's only prevalent in ultra-small portion of the pathogenic variants for hearing loss. False positive association results also largely interfered the usage of PS4. Our real-world data suggest that the PS4 should be considered in the context of other genetic information instead of as a standalone term.

## PgmNr 1359: A study of hereditary non-syndromic sensorineural hearing loss in a Nigerian population.

This study examined the mode of inheritance of non-syndromic SNHL using three generations pedigree. Data on the age, sex, region of the country where the patient comes from, age at onset of hearing loss, number of affected ears and family history of the patients were obtained through a structured questionnaire. Individuals whose hearing loss was as a result of environmental influence were excluded from the study. The frequency and severity of hearing loss was obtained from the pure tone audiometry. Syndromic sensorineural hearing loss patients were screened out during physical examination by Medical Doctors. A total of 148 patients (98.7 %) had autosomal recessive mode of inheritance while only 2 patients (1.3 %) had autosomal dominant mode of inheritance. None had either maternal or sex-linked mode of inheritance. Among the 102 patients that did audiological evaluations, 43 patients (42.1 %) had moderately severe SNHL, 28 (27.4 %) had severe SNHL, 24 (23.5 %) had profound SNHL, 7 (6.8 %) had moderate SNHL while none had mild SNHL. Fifty four patients (53 %) had high frequency SNHL, 30 (29.4 %) had middle frequency SNHL while 18 (17.6 %) had low frequency SNHL. The results of the study demonstrate that autosomal recessive mode of inheritance is the commonest mode of inheritance of non syndromic SNHL in the studied population. A novel mutation, Leu 56 His which caused non-syndromic SNHL, was discovered from this study.

## PgmNr 1360: *RIMS2*, a novel gene responsible for syndromic congenital cone-rod synaptic disorder associated with neurodevelopmental and pancreatic involvement.

---

**Introduction:** Congenital cone-rod synaptic disorder (CRSD) is a non-progressive disorder of the congenital stationary night blindness spectrum. CRSD manifests at birth by congenital nystagmus, photophobia and normal or near-normal fundus appearance. This presentation is reminiscent of Leber congenital amaurosis (LCA), the earliest and most severe retinal dystrophy. Electroretinography is pivotal to make the differential diagnosis, characterized by near-normal to subnormal rod function, and delayed and/or decreased to non-recordable cone responses in CRSD versus no rod or cone response in LCA. This examination may be challenging however in young infants. To date, mutations in *CABP4* and *CACNA1F* encoding proteins of the photoreceptor synapse have been involved in CRSD. Here, we report the identification of a third gene further involving the photoreceptor synapse in three unrelated families, two of which were initially diagnosed with LCA. **Material and methods:** WES has been performed in trio from 1 sporadic case born to non-consanguineous parents and in index cases from 2 multiplex and consanguineous families. Patients (n = 6, 5 ≤ age ≤ 32 years) were re-examined for ocular, metabolic and neurologic manifestations. **Results:** Variant analysis identified homozygosity for nonsense variants and compound heterozygosity for a nonsense and a consensus splice-site variant in *RIMS2* (p.Trp1042\*, p.Arg1170\*, p.Arg962\*/c.4363+1G>A p.?). *RIMS2* encodes the RAB3A-interacting molecule 2 (RIM) also known as RIM2, a protein regulating synaptic membrane exocytosis in photoreceptors and brain, and insulin secretion by pancreatic islets. Ophthalmological re-examination showed ERG traces consistent with the diagnosis of congenital cone-rod synaptic disorder. Neurological examination revealed autism spectrum disorder or intellectual disability in 4/5 individuals and metabolic work-up (3/5 individuals) showed abnormal glucose homeostasis in the eldest patient (32 years). *RIMS2* immunostaining was shown in the outer plexiform layer, Purkinje cells and pancreatic islets. **Discussion:** The disease presentation associated with biallelic *RIMS2* loss-of-function variants is consistent with its expression in human retina, brain and pancreas where it plays an important role in the release of synaptic and secretory vesicles. CRSD is reminiscent of

*CABP4*- and *CACNA1F*-disease that is non-syndromic however. Here, we describe the first syndromic CRSD with neurodevelopmental or pancreatic involvement.

## PgmNr 1361: Notch ligand *JAG1* is a novel candidate gene for familial exudative vitreoretinopathy.

### Authors:

Zhu <sup>1</sup>; L. Zhang <sup>2</sup>; Z. Yang <sup>1</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Sichuan Provincial People's Hospital, Chengdu, China; 2) University of Electronic Science and Technology of China, Chengdu, China

---

### Purpose

Familial exudative vitreoretinopathy (FEVR) is a blindness causing retinal vascular disease characterized by incomplete vascularization of the peripheral retina and by the absence or abnormality of the second/tertiary capillary layers in the deep retina. Mutations in known FEVR disease genes can only explain about 50% of FEVR-affected cases. We aim to identify additional disease genes in patients with FEVR.

### Methods

We applied exome sequencing analysis in a cohort of 49 FEVR families without pathogenic variants in known FEVR genes. Functions of the affected proteins were evaluated by reporter assay. Knockout mouse models were generated by endothelial specific Cre line.

### Results

Three novel rare heterozygous variants in Notch ligand *JAG1* were identified in FEVR families: c.413C>T p. (A138V), c.1415G>A p. (R472H) and c.2884A>G p. (T962A) and verified by Sanger sequencing analysis. Notch reporter assay revealed that mutant *JAG1* proteins *JAG1*-A138V and *JAG1*-T962A almost lost all of their activities, and *JAG1*-R472H lost approximately 50% of its activity. Deletion of *Jag1* in mouse endothelial cells resulted in reduced tip cells at the angiogenic front and retarded vessel growth, reproducing FEVR-like phenotypes.

### Conclusions

Our data suggest that *JAG1* is a novel candidate gene for FEVR and pinpoints a potential target for therapeutical intervention.

## PgmNr 1362: Copy-number variation contributes 9% of pathogenicity in the inherited retinal degenerations.

---

**Purpose:** Over two million people worldwide are affected by inherited retinal degenerations (IRDs). However, despite substantial progress in sequencing, current strategies can genetically solve only about 55-60% of IRD cases. This can partially be attributed to elusive mutations in the known IRD genes, including copy number variations (CNVs), which we believe are a major contributor of the unsolved IRD cases.

**Methods:** Five hundred IRD patients were analyzed with targeted NGS to detect mutations in the known IRD genes. The NGS data was analyzed by two bioinformatic approaches (ExomeDepth and gCNV) to detect likely causal CNVs. The CNV detection rate by the NGS methods was compared to the SNP-Array in 144 patients using PennCNV software. Likely causal CNV predictions were validated by quantitative PCR on genomic DNA.

**Results:** Single nucleotide variants (SNVs) and small indels likely leading to disease were found in 55.6% of subjects, with mutations in *USH2A*(11.6%), *RPGR*(4%) and *EYS*(4%) as the most common causes of disease. Deletions and duplication likely leading to disease were found in additional 8.8% of patients and 1.4% of patients carried the *MAK-Alu* insertion. Of the three CNV detection methods gCNV showed the highest performance (positive predictive value of 85%). One third of the remaining 171 unsolved subjects had a single likely pathogenic mutation in a recessive IRD gene and there is a high chance they carry a second elusive mutation in the same gene.

**Conclusions:** CNV detection using NGS-based software is a reliable method, which increases the genetic diagnostic rate of IRDs from 55.6% to 64.4%, with highest performance seen for gCNV. Since each of the prediction tools gave false positive results, experimental validation of CNVs is an important step in determining the genetic diagnosis. The results presented in this study suggest that additional analyses of elusive variants in known IRD genes (e.g. *Alu* insertions, deep intronic variants, other structural variations) will have a major impact on improving the diagnostic rate of IRD patients.

## PgmNr 1363: Alterations in *GRHL2-OVOL2-ZEB1* axis and aberrant activation of Wnt signaling lead to altered gene transcription in posterior polymorphous corneal dystrophy.

### Authors:

**Affiliation:** Ophthalmology, Stein Eye Institute, UCLA, Los Angeles, California

---

Mutations associated with posterior polymorphous corneal dystrophy (PPCD) have been identified in three genes: *ZEB1* (zinc-finger E-box binding homeobox 1) associated with sub-type PPCD3; *OVOL2* (ovol-like zinc finger 2) associated with sub-type PPCD1; and *GRHL2* (grainyhead like transcription factor 2) associated with sub-type PPCD4. Each of these genes encodes a transcription factor that regulates cell-state transitions. While the discovery of these PPCD-associated genes has greatly expanded our knowledge of the genetic basis of PPCD, the molecular mechanisms via which mutations in these genes lead to indistinguishable disease phenotypes have yet to be elucidated. To characterize the gene expression profiles of the genetic sub-types of PPCD, RNA-seq was performed on corneal endothelium derived from an individual with PPCD1 who harbors a c.-307T>C *OVOL2* promoter mutation; an individual with PPCD3 associated with a *ZEB1* truncating mutation (c.1381delinsGACGAT); and an individual with genetically unresolved PPCD. Transcriptomic analysis revealed: *OVOL2* expression increased in PPCD1 (259 fold), unchanged in PPCD3 and slightly increased in genetically unresolved PPCD (from 0 TPM to 0.86 TPM, undefined fold change); *ZEB1* expression decreased in PPCD1 (-5.9 fold), PPCD3 (-3.95 fold) and genetically unresolved PPCD (-3.96 fold); and *GRHL2* expression increased in PPCD1 (333.5 fold), slightly increased (from 0 TPM to 0.67 TPM, undefined fold change) in PPCD3 and increased in genetically unresolved PPCD (1853 fold). As *ZEB1* can act as an activator or repressor of downstream target gene expression depending on Wnt signaling pathway activation or deactivation, we also sought to determine whether or not Wnt signaling is active in PPCD by performing immunohistochemistry in corneal tissue sections derived from an individual affected with PPCD3 and from an individual with genetically unresolved PPCD. Immunohistochemistry results demonstrated corneal endothelial nuclear accumulation of S552 phospho-β-catenin and cytosolic localization of S33/37/T42 non-phosphorylated β-catenin in PPCD, indicating aberrant activation of Wnt signaling, which was not observed in control corneal endothelium. These findings suggest that alterations in the *ZEB1-OVOL2-GRHL2* axis (caused by PPCD-associated mutations) lead to changes in corneal endothelial cell state and molecular pathways, including the aberrant activation of the Wnt signaling pathway.

## PgmNr 1364: Discovering novel rhesus macaque models of human disease through a combination of forward and reverse genetics: Examples from retinal disorders.

---

One of the major impediments to the development of efficacious therapies for human genetic disorders is the lack of animal models that closely resemble the human conditions. A prominent example is the difficulty of modeling human macular disease in animals such as rodents, as they lack maculae and thus do not provide translational validity. By contrast, the retinal architecture of nonhuman primates (NHP), particularly their cone-dominated central retina and macula, closely mimics the human retina. Therefore, well-defined NHP models that closely resemble the human condition are essential for developing and testing novel therapies. We have designed a combined forward and reverse genetics approach to take full advantage of the naturally occurring functional genetic variation in rhesus macaques (*Macaca mulatta*) to develop NHP primate models of inherited human retinal diseases (IRD). To date, we have sequenced 1485 rhesus macaques across multiple National Primate Research Centers with a custom enrichment panel targeting protein coding regions of about 264 known IRD associated genes. A large number of genetic variants have been identified in the rhesus population with over 4000 rhesus SNPs also present in human population. The majority of the overlapped SNPs belong to CG transitions, and the allele frequencies of these overlapped variants are largely discordant between rhesus and human. More importantly, about 20 LoF mutations and 14 reported human likely pathogenic mutations were identified in IRD genes in the rhesus monkeys. For example, we found predicted damaging mutations in *NPHP4*, *OPA1* and other genes known to cause IRD. The rhesus carriers of these mutations are potentially useful for establishing new human disease models. Phenotypic studies of the identified rhesus carriers are in progress. In parallel, through a forward genetics screen among individual rhesus macaques which show visual system defects, we identified a missense mutation in *PDE6C* that causes achromatopsia in macaque homozygotes (Moshiri et al. JCI 129: 863, 2019). Targeted sequencing of individuals with other phenotypes is also underway. Overall, this broad approach consisting of large-scale sequencing of uncharacterized monkeys to discover spontaneous candidate pathogenic variants and phenotyping of additional candidate animals with relevant traits or deficits will uncover numerous primate models of human genetic disease.

## PgmNr 1365: Hidden genetic variations in *PAX6*-associated aniridia revealed by whole genome sequencing and machine learning based functional annotation.

---

Aniridia (MIM #106210) is a rare, congenital anomaly with autosomal dominant inheritance. It is usually caused by genetic defects of the *PAX6*, a master control gene for eye organogenesis, located on chromosome 11p13. This study was conducted to find hidden pathogenic variants associated with aniridia who were negative for *PAX6* gene sequencing. Two patients with classic aniridia, who were regarded as unsolved after *PAX6* Sanger sequencing or targeted next-generation sequencing (NGS) accompanied with MLPA, were recruited in 2 university-based hospitals. Whole genome sequencing (WGS) was performed using HiSeq X. Variants were filtered and prioritized by Genomiser, CADD (combined annotation dependent depletion), Eigen-PC, DeepSea, FATHMM-MKL (Functional annotation through hidden Markov models-multiple kernel learning). All 2 patients had aniridia, infantile onset-nystagmus, and foveal hypoplasia. None of patients had mental retardation, ataxia and other neurological features. The 2 patients have family history of aniridia, which was consistent with autosomal dominant trait. No copy number variants and large structural variants were found using Delly, ERDS, and CNVnator. The 5' untranslated regions (5'-UTR) c.-133\_-132delTA and splice site c.-52+5G>A variants in non-coding exons were prioritized by Genomiser, CADD, Eigen-PC, DeepSea, FATHMM-MKL algorithms. These two variants were absent in gnomAD and Korean Reference Genome Database. The minigene splicing assay of c.-52+5G>A and luciferase assay of c.-133\_-132delTA confirmed defective splice and abnormal *PAX6* expression. These findings suggest that WGS with machine learning-based algorithm can effectively identify pathogenic non-coding regulatory variant and splice variant in 5' upstream non-coding regions in *PAX6* gene. It is important to find causative mutations in patients with aniridia because it will guide us whether to screen Wilm's tumor.

## PgmNr 1366: AON-mediated exon skipping to bypass protein truncation in retinal dystrophies due to the recurrent *CEP290* c.4723A > T mutation.

---

**Introduction and Purpose:** Mutations in *CEP290* encoding a centrosomal protein important to cilia formation and maintenance cause a spectrum of diseases, from retinal dystrophies to multivisceral ciliopathies. In recent years, splicing regulation involving variable mechanisms e.g. endogenous and selective non-canonical exon skipping have shown to contribute to *CEP290* pleiotropy. This observation led us to consider targeted exon skipping to bypass protein truncation resulting from a nonsense mutation in exon 36 (c.4723A > T, p.Lys1575\*) involved in 2% of isolated retinal ciliopathy cases.

**Results:** mRNA analysis in control human retina and fibroblasts revealed the presence of low levels of a *CEP290* isoform lacking exon 36, supporting endogenous basal skipping. This isoform was detected in fibroblasts from two unrelated individuals carrying the p.Lys1575\* mutation (P1 and P2) and affected with early-onset severe retinal dystrophy and congenital blindness, respectively. Although low, the abundance of the *CEP290* isoform lacking exon 36 was higher in patients compared to controls suggesting basal skipping and nonsense associated-altered splicing of mutant exon 36. Furthermore consistent with a more severe disease, fibroblasts from P2 contained less skipped mRNA and exhibited reduced ciliation compared to P1 cells displaying normally abundant cilia; both lines presented however significantly elongated cilia, suggesting altered axonemal trafficking. Antisense oligonucleotides (AONs)-mediated skipping of exon 36 increased the abundance of the premature termination codon (PTC)-free mRNA and protein, reduced axonemal length and improved cilia formation in P2 but not in P1 expressing higher levels of skipped mRNA.

**Discussion:** The present study shows that increasing moderately the quantity of the *CEP290* protein isoform lacking residues encoding exon 36 in mutant cells ameliorated cilia formation whereas high abundance compromised cilia formation. Whether this would occur in photoreceptor cells is an important question. AON-mediated skipping of exon 36 in iPSC-derived retinal organoids from individuals carrying the c.4723A > T mutation would certainly merit consideration to address this

burning question.

## PgmNr 1367: Genotypic profile and phenotype correlations of *ABCA4*-associated retinopathy in Koreans.

This study was conducted to analyze the clinical features associated with the pathogenic variants of *ABCA4* in Korean patients with inherited retinal dystrophies (IRDs). We enrolled patients with IRDs who visited a tertiary referral hospital and identified the pathogenic variants of *ABCA4* by targeted gene panel sequencing and whole exome sequencing. We analyzed the clinical characteristics and phenotypic spectrum according to genotypes. Eleven patients (from nine families) with IRDs and pathogenic variants in *ABCA4* were included. Eight patients (from seven families) with Stargardt disease, two (from one family) with cone-rod dystrophy, and one with early-onset retinitis pigmentosa (RP) were included. Two heterozygous mutations were identified in eight families and one variant was found in a patient with fundus flavimaculatus. Two variants p.Gln294Ter and p.Gln636Lys were associated with severe phenotypes such as early-onset RP and cone-rod dystrophy. Four novel pathogenic variants, p.Gln636Lys, p.Ile1114del, p.Thr1117Ala, and p.Asn1588Tyr, were identified. p.Gln294Ter, p.Leu1157Ter, and p.Lys2049ArgfsTer12 were repeatedly detected in Koreans with *ABCA4*-associated retinopathy. Various pathogenic variants of *ABCA4*, including four novel variants, were identified and *ABCA4*-associated retinopathies exhibited various phenotypes and disease severities in a Korean IRD cohort. These findings will be useful for understanding the clinical features of *ABCA4*-RD and ethnicity-specific variants in East Asians.

## PgmNr 1368: Characterization of genetic spectrum of Leber Congenital Amaurosis (LCA) in Vietnamese patients with blindness.

### Authors:

---

Leber's Congenital Amaurosis (LCA) is the most severe form of the retinal dystrophy causing blindness at birth or early onset during the first year of life. To date, 33 genes have been identified to be genetically associated with LCA disease. The mutations in the gene *GUCY2D*, *RPE65*, *CRB1*, *CEP290*, *AiPL1* and *IMPDH1* represent the most frequent in LCA patients worldwide. However, little is known regarding the prevalence and genetic profile of LCA disease in Vietnam.

In Vietnam, there are about 2.000 patients expected to be diagnosed with LCA, spreading across the country from rural and urban areas. Lack of knowledge in molecular basis of LCA disease will lead to misdiagnosis and inappropriate indicated treatment. Therefore, genetic profiling specific for Vietnamese population of LCA-associated genes is essentially needed.

We aim at identifying the genetic profile of previously diagnosed LCA patients at Nguyen Dinh Chieu special school, and Ophthalmology Hospital in Hanoi and other locations in the North area of Vietnam by conducting targeted sequencing on specific genes in combination with Multiplex Ligation-dependent Probe Amplification (MLPA) for copy number variation detection. Variant spectrum and genetic frequency of LCA associated genes will provide insights to conduct important research project in the future such as (1) initiating a potential project on gene therapy, given that *RPE65* gene is an important target for a gene therapy approved by FDA for LCA treatment and (2) establishing a prenatal test for patients with high genetic risk of the disease.

## PgmNr 1369: A study of inherited retinal disease candidate genes.

---

Inherited retinal degeneration (IRD) is a group of diseases that leads to incurable vision loss due to death or dysfunction of photoreceptor cells. Although over 200 genes have been implicated in IRDs, together, mutations in these genes account for about 70% of the patients, leaving about 30% of patients without molecular diagnoses. Using a combination of whole genome and whole exome sequencing data from human patients and multi-omics datasets, a list of candidate disease-related genes has been identified. To validate these candidate genes, knockout mouse models generated via the CRISPR/Cas9 gene editing method are used to evaluate the gene function in retina. Retina of the KO mice were characterized by evaluating the morphological and functional phenotype of the retina at various timepoints. To study the progression of functional retinal degeneration, electroretinograms were used to measure the response of photoreceptor cells to light stimulation. Dark-adapted and light-adapted conditions were used to distinguish rod and cone responses. Retinal morphology was analyzed by using hematoxylin-and-eosin-stained retinal sections to visualize photoreceptor cell death. Knockout mice exhibiting either histological or functional defects provide strong evidence of the association of the gene with human IRDs. Using this approach, several novel human IRD disease genes have been identified, including *CWC27*, *REEP6*, and recently *FAM57B*. Further characterization of these mouse models is currently underway, which will provide additional insights of the disease mechanisms and form the basis for developing novel therapies. Progress of evaluation of additional mouse models will also be reported.

## PgmNr 1370: Biases in arginine codon usage correlate with genetic disease risk.

---

Arginine substitutions underlie 20% of all 'Pathogenic' single nucleotide variants (SNVs) listed in ClinVar, thus making arginine the most commonly substituted amino acid. Arginine can be encoded by four codons containing CpG dinucleotides ('CGX': CGA, CGC, CGG, CGU) or two alternative codons ('AGR': AGA, AGG). The persistence of the four CGX codons in human genes, despite the hypermutability of CpG dinucleotides, suggests the possibility of negative selective pressure at these sites, and that arginine codon usage could be an indicator of disease genes. We hypothesized that genes rich in CGX codons are particularly intolerant to variation and thus result in a greater burden of human disease.

We analyzed arginine codons from all 'canonical' Ensembl protein coding gene transcripts (hg38). Although AGR codons made up 42.3% of all arginine codons, fewer than 20% of arginines were encoded by AGR codons among a subset (16.3%) of CGX-rich, 'hyper-mutable' genes. We found that the frequency of CGX codons among a gene's total arginine codon count was significantly higher in genes linked to syndromic autism spectrum disorder (ASD) compared to genes not associated with ASD ( $p=0.006$ , t-test); this was exemplified by *CHD8* (MIM#610528), which had a CGX frequency of 72% ( $n=165$  total arginines) and for which 8/12 ClinVar 'Pathogenic' SNVs involved CGX codons. Strikingly, a comparison of genes annotated as dominant or recessive in the OMIM database with control genes not matching either classification revealed a progressive increase in CGX frequency moving from control to recessive to dominant genes ( $p<2E-16$ , ANOVA). We also found that CGX frequency is positively correlated with a gene's probability of loss-of-function (pLI) score ( $r=0.099$ ,  $p<2.2E-16$ ) and negatively correlated with gnomAD's 'observed-over-expected' (o/e) ratios for both loss of function ( $r=-0.128$ ,  $p<2.2E-16$ ) and missense mutations ( $r=-0.163$ ,  $p<2.2E-16$ ). We speculated that more highly expressed genes in regions of high GC content might contribute more to these associations with CGX arginine codon frequency; indeed, we found that GC content and median Cerebellum gene expression were both positively correlated with CGX frequency ( $r=0.537$ ,  $p<2.2E-16$  and  $r=0.172$ ,  $p<2.2E-16$ , respectively).

Our findings indicate that genes utilizing CGX codons are more likely to underlie single gene disorders and thus constitute a robust set of candidate genes, particularly for the study of dominant disease, including ASD.

## PgmNr 1371: Mouse models of glycobiology-related diseases: Identification of understudied genes.

### Authors:

M. Tomczuk; C. Smith; C. Bult; the Mouse Genome Informatics Staff and Software Team

[View Session](#) [Add to Schedule](#)

---

Glycans function in a variety of structural and modulatory roles and in regulation of cell-cell and protein-protein interactions. While progress has been made in discovering causes of glycobiology-related diseases, the many roles attributed to glycans make it difficult to identify these disorders in patients who present with variable symptoms. Mice are a superb organism to model diseases: they are genetically and physiologically similar to humans, all life stages can be accessed, completely sequenced, well annotated reference genomes for multiple strains are available, and many genomic tools are available for comparative and experimental manipulation. Mice with mutations affecting glycosylation, glycan degradation and carbohydrate metabolism can aid in disease discovery and identifying patients affected by such changes.

Mouse Genome Informatics (MGI, [www.informatics.jax.org](http://www.informatics.jax.org)) is the authoritative resource for the laboratory mouse, integrating data from multiple sources to facilitate links between mouse phenotypes and human disease symptoms. We will show how users can utilize MGI to gain understanding of glycoprotein-related gene function by analyzing phenotypes of mouse mutants and how mouse models of these diseases can be found and used to gain insights into disease pathogenesis and treatment, such as the Hexb knock-out used to study enzyme replacement therapy for Sandhoff disease. The more extensively researched diseases include muscular dystrophies like muscular dystrophy-dystroglycanopathy for which 8 mouse models involving 5 genes (B4gat1, Fkrp, Fktn, Large1, Pomt1) are reported and cellular storage disorders such as Gaucher's and Tay-Sachs for which multiple models are available. In collaboration with GlyGen ([www.glygen.org](http://www.glygen.org)), a resource for assisting glycoscience research, MGI surveyed a list of 96 genes involved in glycobiology to determine where informational gaps exist. We find that mice with mutations in or knock-outs of these genes are understudied, with 81 of these genes having collectively 204 germline transmissible alleles but phenotypes reported for only 67 of the genes and only alleles in 15 of these genes reported as disease models. In addition, complete elimination of individual glycans or relevant genes, such as Pigo and Pomt1, often results in embryonic lethality, supporting their biological importance and the need to develop better models with disease symptoms such as allelic variants, hypomorphic and tissue-specific targeted alleles.

## PgmNr 1372: 49,XXXXY syndrome: Report of a Colombian patient.

### Authors:

S. Maradei; J. Acosta Guio; A. Muñoz

[View Session](#) [Add to Schedule](#)

**Affiliation:** Human Genetics, Biotecgen S.A., Bogota, Cundinamarca, Colombia

---

**Introduction:** 49,XXXXY Syndrome represents an aneuploid chromosomal aberration in which there are three extra X chromosomes in boys and men. It affects over 1/85.000 to 1/100.000 newborn males, and is a different clinical entity than Klinefelter Syndrome (KS). Here we present the case of an 11 year old Colombian patient who was diagnosed with this condition.

**Case Report:** A prepuberal boy with short stature, congenital cardiopathy, hypogonadism (micropenis, hypoplastic scrotum and cryptorchidism), bilateral radioulnar synostosis, and a personal history of developmental delay and behavioural alterations, was first evaluated by an endocrinologist who suspected KS. However, and given the co-appearance of multiple congenital anomalies, the possibility of another gonadal dysgenesis disorder or a chromosomal imbalance was on the table, so the treating physician referred the patient to the Medical Genetics consultation for further examination. A conventional Karyotype analysis was ordered, showing presence of an abnormal number of the sexual chromosomes: 49,XXXXY. Comparative Genomic Hybridization was also carried out, confirming the diagnosis and excluding other copy number variants as causative. The boy is now undergoing a series of medical evaluations in order to give him the appropriate treatment and to establish the prognosis. Also, genetic counseling for the family was offered.

**Comments:** 49,XXXXY syndrome is a rare chromosomal condition characterized by severe hypogonadism, variable low IQ levels and progressive cognitive impairment with age, growth retardation that can appear shortly after birth or even *in utero*, congenital defects of the heart, skeletal anomalies or deformities (radioulnar synostosis, epiphyseal dysplasia, coxa valga, kyphoscoliosis, joint hypermobility), other dysmorphic features that are usually mild (hypertelorism, epicanthal folds, broad flat nasal bridge or tip, folded pinna, short neck), and in some cases added compromise of other systems/organs (hypoplasia of the corpus callosum, renal hypoplasia, visual acuity disorders). As most cases appear sporadically, recurrence risk for the family is low. Patients suffering from this condition need a multi-disciplinary approach for monitoring every possible outcome, despite a relatively normal life expectancy.

## PgmNr 1373: Long-sized AOH regions reveal IBD haplotypes that drive Mendelian disease through mutational burden at a locus.

### Authors:

In classical human and medical genetics, we learn that population structure is relevant to disease because of individual pathogenic alleles confined and enriched within specific populations. However, the impact of population structure on rare – even private – variants, or combinations of alleles at a locus, to disease traits remains unexplored. We hypothesized that within small or consanguineous populations long-sized absence of heterozygosity (AOH) regions are more likely be formed on recently configured haplotypes that could be enriched for combinations of rare deleterious variants per locus because time would not be sufficient for recombination and selection to eliminate these haplotypes from the population. To test this hypothesis, we studied a large Turkish (TK) cohort with high levels of consanguinity and admixture. In this cohort, we investigated the genetic architecture of disease by exome sequencing (ES) and family based genomics in 556 individuals affected with diverse disease phenotypes. As anticipated, we observed a larger amount of genomic intervals with AOH in TK affected (162.1 Mb) and unaffected (78.8 Mb), compared to non-TK individuals (72 Mb). This difference was more striking in long-sized AOH regions enriched for rare homozygous deleterious variants in the individual genomes of TK affecteds compared to TK-unaffecteds and non-TK affecteds ( $P=5.4^{-10}$  and  $< 2.2e^{-16}$ ). A systematic analysis of genotype-phenotype correlations using the complete haplotype in long-sized ( $>1.606$  Mb), but not short-sized (40-515 Kb) or medium-sized (0.515-1.606 Mb) AOH, is the most explanatory for the observed disease traits by systematic analysis of HPO (Human Phenotype Ontology) terms and controlling for the number of genes or size of the block using a permutation approach. Unexpectedly, and an interesting genomic observation with relevance to transmission of genetic traits, not just an increased coefficient of consanguinity in a population but rather identity-by-descent (IBD) in clans enabled by long-sized AOH regions is associated with a

higher deleterious rare variant burden at a locus contributing to the disease traits. In summary, our results provide compelling evidence that IBD is correlated with a higher number of long-sized AOH blocks allowing an elevated mutational burden contributing to disease traits in the TK probands. Moreover, our findings further support the Clan Genomics hypothesis and also allow insights into the La Reunion Paradox in human genetics.

## PgmNr 1374: Extensive allelic and phenotypic heterogeneity revealed by point-of-care exome sequencing of Mendelian disorders in Qatar.

---

The effectiveness of next generation sequencing at solving genetic disease has motivated its rapid adoption into clinical practice. In this study, we use whole exome sequencing (WES) to assess 48 patients with Mendelian disease from 30 serial families collected at the point of care, as part of the Qatar Mendelian Disease Program – a coordinated multi-center effort to build capacity and clinical expertise in genetic medicine in Qatar. By enrolling whole families (parents plus all available siblings), we demonstrate significantly improved power to discriminate candidate disease variants *versus* only sequencing trios; this held true for both *de novo* and recessive inheritance patterns. For the same index cases, we further demonstrate that even in the absence of families, variant prioritization is improved up to 8-fold when a modest set of population-matched controls is used vs large public databases (1,346 Qatari controls vs >250,000 alleles in public datasets), stressing the very poor representation of Middle Eastern alleles in presently available databases. Altogether, our in-house best practices pipeline identified candidate disease variants in 27 of 30 families (90%), 23 of which (85%) harbor novel pathogenic variants, some of which affected known disease genes, pointing to significant allelic heterogeneity and founder mutations underlying Mendelian disease in the Middle East. For 6 of these families, the clinical presentation was only partially explained by the candidate gene, suggesting phenotypic expansion of known syndromes. Our pilot study therefore demonstrates the utility of WES for Middle Eastern populations, the dramatic improvement in variant prioritization conferred by enrolling population-matched controls and/or enrolling additional unaffected siblings at the point-of-care, and 25 novel disease-causing alleles, relevant to newborn and premarital screening panels in populations of Arab ancestry. Moreover, this study lays down the groundwork, pipeline and local capacity for future whole-genome sequencing programs targeting rare diseases in Qatar and the Middle East.

## PgmNr 1375: High percentage of novel pathogenic alleles and loci found in more than 1500 parent child trio exomes from India in combination with a large diagnostics Indian database.

---

**Background:** Familial disease has largely been studied in populations of European ancestry. India presents a very different context with its multitude of diverse population groups, many of which have high rates of homozygosity and higher incidence of consanguineous unions. There are many genetically differentiated population groups when compared to Europe with genetic variation specific to the region.

**Methods:** To date we have performed exome sequencing on 4914 samples (median depth 77x) from 1501 families with suspected mendelian disorders representing 14 broad disease areas. Of the probands diagnosed, 42% were of consanguineous unions, the average age at presentation was 7 years and 63% were male. In addition, we cross checked candidate segregated variants to a large diagnostics database in India (MedVarDB) composed of 31,736 samples where clinical exome sequencing had been performed and phenotypic information was available.

### Results:

To date we have identified 200 alleles not previously reported in OMIM/ClinVar/HGMD. The majority of these alleles (n=126) are not found in the ExAC, or 1000G databases with the remaining alleles having an average ExAC allele frequency of <0.00006. For many of these novel alleles (n=138) we were able to match genotypes to MedVarDB that could be used to estimate allele frequencies in the Indian sub-continent and confirm phenotypes. The majority of these impact diseases related to neurology, metabolic disorders, ENT, immunology and other rare diseases. One specific example is RAB27A where we found 3 novel alleles in 6 families (4 of consanguineous unions, all homozygous) linked to Griscelli syndrome. All have not previously been reported in public databases however 2 are present at low allele frequencies within the Indian population (up to 0.0002 % in MedVarDB). In addition, we found a novel gene associated with Hemophagocytic lymphohistiocytosis. Of those cases reported, consanguineous unions showed a higher degree of diagnosis rates compared to non-consanguineous unions (80% vs 59%) as well as a higher rate of homozygous reported variants (79% vs 32%). We found higher degrees of homozygosity within our dataset for both the consanguineous

and non-consanguineous unions than would be expected compared to Europeans.

**Conclusion:** Expanding the genetic diversity in large scale familial studies will improve diagnostics worldwide as well as link new biological insights and treatment of mendelian disorders.

## **PgmNr 1376: Outcomes of selective use of rapid clinical exome sequencing for critically ill patients in a tertiary care center.**

---

We describe our ongoing experience with the selective use of rapid clinical exome sequencing (rES) for critically ill patients at The Johns Hopkins Hospital. This involves review by a multidisciplinary committee that assesses the likelihood that this expensive testing will affect medical management.

We have evaluated 22 inpatients with rES since 2015, the majority of whom were in the neonatal and pediatric intensive care units. Eleven had prior genetic testing. The primary indication for rES was neurologic (e.g., hypotonia) in 12 cases, gastrointestinal or hepatobiliary (e.g., acute liver failure) in 5 cases, and allergic or immunologic (e.g., immunodeficiency) in 3 cases. rES yielded a positive result in 9 (41%) cases, a negative result in 4 cases, and a non-informative variant of uncertain significance (VUS) in 9 cases. There were no dual Mendelian diagnoses. Of the 9 positive results, 6 were from rES ordered for neurologic primary indications. Newly-established diagnoses included combined oxidative phosphorylation deficiency 23 (MIM 616198), infantile liver failure syndrome 1 (MIM 615438), and RAS-associated autoimmune leukoproliferative disorder (MIM 614470). As expected, all positive results affected medical management. For example, we initiated treatment for a neonate with glucose/galactose malabsorption (MIM 606824), resolving life-threatening diarrhea. When the newly-established diagnosis was untreatable, as was the case for an infant with TK2-related mitochondrial DNA depletion syndrome 2 (MIM 609560), the result helped clarify the goals of care and concluded the diagnostic odyssey. Non-diagnostic negative results and VUSs also helped clarify goals of care and streamline differential diagnoses, and thereby affected medical management. Specific changes include transitions to comfort care, tracheostomy and gastrostomy, and prioritization of functional testing (e.g., neurotransmitter metabolite testing, global metabolomics, cytokine profiling, flow cytometry). Three inpatients died prior to return of results.

Our ongoing experience demonstrates that rES can decisively influence medical management. Both diagnostic and non-diagnostic results facilitated decision-making and clarified the goals of care. This allowed medical teams and families to prioritize treatment plans over additional diagnostic studies with diminishing returns, and avoid prolongation of extreme life-sustaining measures in some cases.

## PgmNr 1377: Potential involvement of the novel gene *ArfGAP2* in inherited retinal degeneration.

**Purpose:** To identify the molecular basis of inherited retinal degeneration (IRD) in a large consanguineous pedigree with multiple affected members using linkage, haplotype, whole exome and whole genome analyses and functional evaluation of the impact of the potential causative variant segregating with disease.

**Methods:** A large consanguineous pedigree with autosomal recessive retinal degeneration underwent complete ophthalmic evaluation including funduscopy and electroretinography. Linkage and haplotype analyses were performed using microsatellite markers. Whole exome and whole genome analyses were carried out to identify potential disease causative variants. Mapping and variant calling was performed using BWA and GATK and structural variants were called using Genome STRiP and LUMPY. Variants were prioritized for further analysis using the pipeline we had developed. The effect of the potential mutation in the *ADP Ribosylation Factor GTPase activating protein 2* (*ArfGAP2*) gene was studied by evaluating transfected cells and mouse retinal tissue using qRT-PCR, immunostaining, electron microscopy (EM), immunoblotting and GTP activating protein (GAP) assay.

**Results:** Linkage and haplotype analysis mapped the disease locus to a 19.9Mb interval on chromosome-11. Whole exome and genome sequence analysis identified a variant, p.Arg255Cys in *ArfGAP2*, the only pathogenic and rare variant residing within the linkage interval, co-segregating with recessive IRD. A protein interaction network analysis of *ArfGAP2* showed significant association with IRD implicated genes. In the retina, *ArfGAP2* localized to the photoreceptors, inner-nuclear, and ganglion cells. Cells expressing the mutant-*ArfGAP2* demonstrated trimerization of the protein, fragmentation of Golgi, and high Arf1-activity, indicative of impaired GAP function. The mutant -255Cys was predicted to generate novel disulphide bonds enabling pathogenic trimerization of *ArfGAP2* on the Golgi membrane resulting in abnormal vesicular traffic.

**Conclusion:** A homozygous p.Arg255Cys variant in the *ArfGAP2* gene segregated with IRD. This mutation results in impaired GAP function leading to hyper-activation of Arf1 and abnormal vesicular traffic in cells expressing the mutant *ArfGAP2*.

## PgmNr 1378: *De novo* missense variants in the *LMBRD2* gene in five unrelated clinical cases suggest association with developmental delay, intellectual disability, and dysmorphic features.

---

LMBRD2 (LMBR1 domain-containing 2) is a poorly understood but widely expressed transmembrane protein with no known disease association. Intriguingly, however, both LMBR1 (limb development membrane protein 1) and LMBRD1 (LMBR1 domain-containing 1) are associated with polydactyly and methylmalonic aciduria and homocystinuria, respectively. In addition, recent reports have shown that LMBRD1 is essential for gastrulation. The functions of these paralogues suggest a possible role for LMBRD2 in fundamental developmental processes.

Here we describe five unrelated cases with novel *de novo* missense variants in *LMBRD2*, resulting from a GeneMatcher collaboration. Clinical or research-based whole exome sequencing (WES) or clinical whole genome sequencing (cWGS) revealed *c.577T>C* (*p.Trp193Arg*) and *c.976C>G* (*p.Gln326Glu*) variants in one case each, and a recurrent *c.1448G>A* (*p.Arg483His*) variant in the remaining three cases. All variants are absent from population allele frequency databases including the Genome Aggregation Database and are predicted to be damaging by multiple algorithms including PrimateAI, SIFT, and PolyPhen. No additional variants were identified in four of the five cases that could potentially explain the patient's clinical presentations.

The patients ranged in age from one year to 14 years of age. Phenotypic overlap was observed among cases, which included developmental delay in all patients, intellectual disability (three patients), thin corpus callosum (three patients), microcephaly (two patients), hypotonia (two patients), and dysmorphic features (two patients). Variability in clinical presentation was also noted, with additional phenotypes of spastic paraplegia, clonus, facial features characteristic of Kabuki syndrome, patent foramen ovale, hypomyelination of white matter, and seizures being observed once.

Taken together, these findings suggest that *de novo* variants in *LMBRD2* can lead to a pronounced neurological phenotype. This finding is broadly consistent with the observation that widely expressed and so-called house-keeping genes are associated with a wide range of central nervous system disorders, including primary white and gray matter diseases. Further functional studies of *LMBRD2* are

warranted to better understand its role in neurological development.

## PgmNr 1379: Biallelic *GALM* pathogenic variants cause type IV galactosemia.

### BACKGROUND:

Galactosemia is caused by metabolic disturbances of galactose; types I, II, and III galactosemia, which are attributed to congenital enzymatic deficiencies in the Leloir pathway, portosystemic shunts, cholestasis and other metabolic disorders. A typing of galactosemia is crucial for appropriate care. Nevertheless, the causes of galactosemia has not been identified in a subset of the patients.

### METHODS:

To explore the etiology, eight patients with unexplained congenital galactosemia were enrolled. Trio-based whole-exome sequencing was performed in two unrelated families. Additional Sanger sequencing was performed in other six patients.

### RESULTS:

We identified biallelic pathogenic variants in the *GALM* gene encoding aldose 1-epimerase which catalyzes epimerization between  $\beta$ - and  $\alpha$ -D-galactose in the first step of the Leloir pathway by the whole-exome sequencing. Biallelic *GALM* pathogenic variants (p.Trp82\*, p.Ile99Leufs\*46, p.Gly142Arg, p.Arg267Gly, and p.Trp311\*) were identified in all eight patients. Bilateral cataracts were observed in two patients. Another two patients had also transient portosystemic shunts. All eight patients did not have any other complications or sequelae. *GALM* enzyme activities were undetectable in lymphoblastoid cell lines from two patients. The immunoblot analysis showed the absence of the *GALM* protein in peripheral blood mononuclear cells from three patients. In vitro *GALM* expression and protein stability assays showed decreased stability of the mutant *GALM* proteins.

#### DISCUSSION:

In summary, biallelic *GALM* pathogenic variants cause “type IV” galactosemia. The phenotypic spectrum of *GALM* deficiency may be similar to *GALK* deficiency.

## PgmNr 1380: Evolution of the facial features in a patient with the rare Siderius type XLID syndrome caused by hemizygous loss of PHF8.

---

Most resource-limited countries are unable to offer medical genetic consultation and diagnosis; this is in sharp contrast to the standard of care that is expected in the developed countries of North America, the UK, and Western Europe. Collaboration with a US-based laboratory allowed us to identify an Afro-Caribbean person with Siderius type X-linked intellectual disability syndrome (*PHF8*; OMIM 300560). The family of this patient previously had limited access to genetic medicine. There are only 4 reports describing this ultra-rare disorder in the medical literature. It is caused by hemizygous loss of *PHF8*, which is a dual function histone methylation reader and lysine demethylase enzyme. Exome sequencing showed that our patient had a protein truncation variant, c.1996delG, that causes a frameshift and a stop codon 163 amino acids following the mutation. We present the evolution of the facial features of our patient including low-set and posteriorly rotated ears, hypertelorism with epicanthus, broad nose, prominent chin, and a narrow palate. Our patient carries a clinical diagnosis of autism and attention deficit hyperactivity disorder. Understanding the genetic cause of the disorder in this patient has ended his diagnostic odyssey. His parents report a positive impact on family life and the management of his condition, and they are grateful to have a medical reason to explain his condition. Our work has enabled us to provide recurrence risk counseling to the parents as we have identified that the mother and the sister of the proband are carriers. We are also helping to develop autism awareness in the community and to dispel myths about causation of genetic disorders.

## PgmNr 1381: Diagnostic success across 300 heterogeneous rare disease cases from the BBMRI-LPC call analysed using the RD-Connect Genome-Phenome Analysis Platform.

---

The BBMRI-LPC WES Call was a transnational collaboration between the Biobanking and BioMolecular Resources Research Infrastructure-Large Prospective Cohorts (<http://www.bbmri-lpc-biobanks.eu/>), RD-Connect (<https://rd-connect.eu/>) and EuroBioBank (<http://www.Eurobiobank.org/>). It offered free-of-charge exome sequencing to selected collaborative projects involving PIs from at least two different countries, focusing on distinct rare diseases. A requisite of the call was that a biological specimen from each case to be sequenced be deposited at a EuroBioBank network member, to be available to the wider rare disease research community. Furthermore, a deep phenotypic descriptions for each affected case was required, and collated using Human Phenotype Ontology (HPO), OMIM and Orpha codes to facilitate case resolution.

Seventeen projects were selected for sequencing. All samples were processed using the RD-Connect standard analysis pipeline (Laurie et al, Human Mutation, 2016), and variant filtration and prioritisation undertaken using the RD-Connect Genome-Phenome Analysis Platform (GPAP, <https://platform.rd-connect.eu>). Advanced GPAP features such as on-the-fly gene-lists based upon gene-HPO relationships, homozygosity mapping, pathway associations, and patient matching through Matchmaker Exchange (<https://www.matchmakerexchange.org/>) expedited the identification of causative variants. Analysis and interpretation of cases was undertaken in collaboration between a clinical genomics specialist and relevant disease-domain experts.

Here we report the outcome of the call to date, for which the molecular diagnostic rate is approximately 40% across the project, despite the heterogeneous nature of the different phenotypes under investigation, ranging from neuromuscular disorders, through inborn errors of metabolism, to albinism. This is in line with similar studies which have focussed on a more restricted range of phenotypes. Of note, ten novel gene-disease relationships are currently undergoing functional

validation. Some of the cases that remain unsolved are being taken forward in the SolveRD project (<http://solve-rd.eu/>), where they will be included in more advanced analyses, and we anticipate the resolution rate will increase further.

## PgmNr 1382: Association of $\alpha$ -thalassemia and glucose-6-phosphate dehydrogenase polymorphisms with high-risk transcranial doppler velocity and stroke in Nigerian children with sickle cell disease.

### Authors:

O.O. Ojewunmi <sup>1</sup>; A.I. Oyetunji <sup>1</sup>; Y. Benn <sup>1</sup>; M.G. Ekpo <sup>2</sup>; T.A. Adeyemo <sup>3</sup>

---

Stroke is a major devastating complication of sickle cell disease (SCD) and contributes significantly to morbidity and mortality of SCD. It can be predicted through abnormally high cerebral velocities using transcranial Doppler (TCD). Co-inheritance of  $\alpha^{3.7\text{kb}}$ -thalassemia deletion and glucose-6-phosphate dehydrogenase (*G6PD*) deficiency in SCD (*HBB*: c.20A>T) is associated with haemolysis but their role in the development of stroke in children with SCD has been controversial. This study aimed at investigating the influence of alpha-thalassemia and G6PD polymorphism (202 G>A and 376 A>G) on Nigerian children with clinical history of stroke or high-risk TCD velocities. Of 155 SCD children (2 – 16 years) presented in this study, 73 had normal TCD risk (time-averaged mean of the maximum velocity < 170 cm/s), 69 had abnormally high TCD risk (time-averaged mean of the maximum velocity > 200 cm/s) while 13 patients had stroke history. Presence of  $\alpha$ -thalassemia 3.7 deletion was found in 65 of 155 patients (41.9 %) and was associated with a decreased risk of abnormal TCD velocity [odds ratio (OR) 0.40, 95 % confidence interval (CI) 0.20 - 0.80,  $p = 0.009$ ]. The prevalence of *G6PD* A<sup>-</sup> variant was 9.03% and was not associated with abnormal TCD or stroke. Hence, our results show the modifying outcome of  $\alpha$ -thalassemia deletion in reducing the risk of abnormal TCD velocity in Nigerian SCD children.

## PgmNr 1383: A new global *Slc7a7* knockout mouse models human lysinuric protein intolerance.

Lysinuric protein intolerance (LPI) is an inborn error of metabolism, characterized by urea cycle dysfunction, growth failure, renal disease, immune dysfunction and osteoporosis. LPI is caused by biallelic pathogenic variants in *SLC7A7*, which encodes the light subunit of the y<sup>+</sup>L amino acid transporter 1 (y<sup>+</sup>LAT1) required for intestinal absorption and renal reabsorption of arginine, lysine and ornithine (cationic amino acids). Perinatal lethality of the only *Slc7a7*<sup>-/-</sup> mouse model has hindered *in vivo* studies investigating the etiology of LPI complications.

Our objective was to develop a new mouse model of LPI for mechanistic studies of LPI pathology. We developed a *Slc7a7*<sup>-/-</sup> mouse model using CRISPR/Cas9 technology (mixed 129/C57BL/6 F2 background), which has a deletion of exons 3 and 4 resulting in a frameshift mutation. Due to the reduced survival of male and female *Slc7a7*<sup>-/-</sup> mice compared to wild type (WT) littermates, tissues were harvested at 14-18 days of age. At this time point, *Slc7a7*<sup>-/-</sup> mice demonstrated growth failure (body weight (g), means±SD; WT, 13.0±1.2; *Slc7a7*<sup>-/-</sup>, 3.6±1.2; *p*<0.0001). In addition, assessment of plasma and urine amino acid concentrations showed that *Slc7a7*<sup>-/-</sup> mice had reduced plasma concentrations and increased urinary excretion of the cationic amino acids compared to WT mice, which is consistent with the biochemical phenotype of LPI. Furthermore, urine amino acid analysis revealed generalized aminoaciduria in *Slc7a7*<sup>-/-</sup> mice. This generalized aminoaciduria in combination with a loss of brush border and increased lipid vacuolation and secondary lysosomes in the proximal tubules, based on electron microscopy and hematoxylin and eosin (H&E) staining, suggests proximal tubular dysfunction in *Slc7a7*<sup>-/-</sup> mice. H&E stained spleen sections showed disorganization of splenic structures, including expansion of the red pulp, in *Slc7a7*<sup>-/-</sup> mice. Moreover, micro-CT analysis in the L<sub>4</sub> vertebrae showed a 36% reduction in bone mass (trabecular bone volume/total volume) in *Slc7a7*<sup>-/-</sup> versus WT mice.

In summary, the *Slc7a7*<sup>-/-</sup> mouse model had the biochemical phenotype of LPI and demonstrated other characteristic phenotypes, including growth failure, renal disease and osteoporosis. Although this mouse model of LPI facilitates investigation of disease mechanisms during development, an adult mouse model of LPI is needed for mechanistic studies in adulthood and investigations of potential therapies.

## PgmNr 1384: A *Drosophila* model for Coffin-Siris syndrome.

**Authors:**

---

Coffin-Siris syndrome is a rare genetic disorder which may include developmental delays, intellectual disability, hypotonia, facial dysmorphology and digit abnormalities. Several genes that have been associated with Coffin-Siris syndrome play a role in chromatin modification. The fruit fly *Drosophila melanogaster* presents a powerful genetic model system for investigating human genetic diseases that result from disruption of evolutionarily conserved processes. Through the use of mutants in *Drosophila* orthologues of human candidate disease genes and transgenic expression in flies of human disease associated alleles, we can identify co-regulated transcriptional networks associated with elements of chromatin modification that are relevant to Coffin-Siris syndrome. We model Coffin-Siris syndrome through targeted RNAi knockdown using the binary *GAL4-UAS* expression system in controlled genetic backgrounds. Subsequent whole fly RNA-sequencing on the Illumina Novaseq platform combined with chromatin accessibility analyses using ATAC-seq will provide new insights in the pathogenesis of Coffin-Siris Syndrome.

## PgmNr 1385: Validating patient-centered phenotyping tools for use in rare disease diagnostics.

The Human Phenotype Ontology (HPO) encodes phenotypes for rare disease diagnostics. Patients have a wealth of knowledge about their condition, including features not captured clinically. Our hypothesis is that patient self-phenotyping will provide an accurate source of HPO terms. Two approaches allow patients to generate HPO terms. The first is a traditional survey developed by GenomeConnect, the ClinGen patient registry. The second involves direct translation of the HPO terms into “layperson” terms. We developed an anatomy based-term selection application, Phenotypr, to allow patients to record the layperson HPO terms. Here, we report on synthetic validation and rare disease patient evaluation using the two self-phenotyping tools.

We generated synthetic profiles for 7,336 known rare diseases using each of the tools, permuted them with noise and omissions, and compared against gold standard annotations using the Monarch Initiative’s algorithms. We found that roughly half of the 7,701 layperson profiles performed exactly as well for diagnosis as their gold-standard counterparts, representing the theoretical maximum utility achievable by profiles created by the average patient. This number dropped to 448 when we omitted profile phenotypes that did not have a corresponding question in the GenomeConnect survey.

We then tested both tools in patients with known genetic diseases to determine which tool resulted in phenotype profiles that were more comprehensive and specific to determine diagnostic efficacy. About 250 adult participants diagnosed with, or who were the parent/guardian of a child diagnosed with, a known rare genetic disease enrolled and were randomly assigned to the GenomeConnect or Phenotypr tool; a subset completed both. Participants were from the Boston Children’s Hospital Genetics clinic, Down Syndrome program, or Manton Center for Orphan Disease Research; GenomeConnect; or a 16p13.11 research registry. We also conducted qualitative interviews of a subset of participants to determine which modality was preferable. Early results suggest that while patients preferred the GenomeConnect survey, better phenotype profiles were generated with Phenotypr. This suggests that a hybrid approach that provides familiar tooling but access to richer HPO terms may be warranted. We conclude that such tools could be used to improve and accelerate diagnostic pipelines and promote collaboration and patient engagement with clinical caregivers and diagnosticians.

The PhenX (**Ph**enotypes and **ex**posures) Toolkit <https://www.phenxtoolkit.org/> is a web-based catalog of recommended measurement protocols and associated bioinformatics tools to facilitate cross-study analyses. These protocols are recommended by domain experts using a consensus-based process which relies on community input. The PhenX Toolkit currently includes more than 700 measurement protocols from 25 research domains and 20 collections and has more than 2,600 registered users. An established resource that continues to expand content for investigators, the PhenX Toolkit includes a new pediatric development research domain and updates to protocols in the speech, language, and hearing domain. Depth was added in the areas of hemophilia inhibitors and social determinants of health. One Working Group was assembled to identify 15 priority measures to address Pediatric Development and to enhance existing PhenX measures with content for children. Speech, language, and hearing experts reviewed the measurement protocols and recommended additions or changes to 11 of the 22 protocols. Additions included tablet/phone applications for hearing and language assessment and new voice technologies. The Hemophilia Inhibitor Research Working Group recommended 17 measures and 38 protocols that determine levels of Factor VIII and Factor IX, quantify inhibitors to Factors VIII and IX, measure the biological response to therapeutics, and capture key outcomes. A Social Determinants of Health Working Group recommended measures to capture conditions of where people live, work, and play as they affect a wide range of health outcomes. Separately, as a pilot study, PhenX protocols and variables were analyzed for their cross-compatibility with other data dictionaries and the interoperability of data collected using PhenX protocols. New tutorials help investigators search, browse and manage their toolkits of chosen measures and the PhenX Toolkit's ontology-based search tools and browsing allows users to find related measures across domains and links to other ontologies such as Human Phenotype Ontology (HPO).

## PgmNr 1387: Severe hemophilia A and inhibitor development in Brazilian admixed patients.

---

Hemophilia A (HA) is an X-linked disorder due to deleterious mutations in the factor VIII (FVIII) gene (*F8*). A recurrent inversion, originated by a homologous recombination event within the *F8* intron 22 and its extragenic inversely oriented copies (Inv22-1 and Inv22-2), accounts for about 45% of severe HA worldwide. The inversion of intron 1 (Inv1) is the second recurrent *F8* disruption, with prevalence of 4.5% among severe patients. The most clinically relevant complication of hemophilia A is the development of neutralizing alloantibodies (inhibitors) against FVIII, occurring in up to 30% of the severe patients. Environmental and genetic components are known risk factors for inhibitor development, including the molecular architecture of *F8* (large deletions, inversions and nonsense variants), as well as ethnicity, family history of inhibitors and, maybe, the type of the infused FVIII concentrate.

To explore the molecular features related to inhibitor development, we performed a customized Illumina NGS for *F8* exome sequencing and genotyping of two *CTLA4* risk variants against FVIII alloantibodies (rs23177 and rs3087243) in an admixed Brazilian cohort of 116 patients with severe (FVIII:C < 1%) HA. Inv22 and Inv1 were detected with inverse shifting and allelic specific PCRs. Patients were participants from two different studies - the HEMFIL Study (n = 67) and the BrazIT Study (n = 49). Patients were sorted as inhibitor positive (Inh+) based on the detection of inhibitor (at least two inhibitor tests with titer >0.6 Bethesda Units [BU]/mL) and negative (Inh-) when inhibitor titers were <0.6 (BU)/mL after 75 exposure days (ED) to FVIII. Most patients (73/116; 62.9%) were Inh+. The *F8* exome sequencing revealed 52 deleterious mutations, including previously reported and new variants. As expected, there was an association between *F8* mutation and inhibitor status (p = 0.022), with missense and frameshift mutations increased in Inh- and Inh+ groups, respectively (p = 0.001). Conversely, allelic frequency analysis showed no difference of rs23177 and rs3087243 of between Inh+ (n=44) and Inh- (n=43) patients (p = 0.500 and 0.806, respectively). To our knowledge, this is most complete overview of *F8* mutation of unrelated HA patients in Latin American. Considering the multidimensional features of inhibitor development in HA, we highlight the relevance of studying diverse/admixed populations at genetic level and when predicting biological markers.

## PgmNr 1388: GWAS arrays as potential sources of secondary genomic findings: Implications for return of results.

In clinical sequencing, informing participants of secondary genomic findings (SGF) is the standard of care and the American College of Medical Genetics and Genomics (ACMG) has a list of 59 genes for return of SGF. There is less consensus regarding SGF in the research setting. In the context of large, epidemiological cohorts, GWAS is a widely used analysis tool, for which genome-wide genotyping array data are generally used. However, because modern GWAS arrays include exonic content, they may interrogate variants in the ACMG genes. Given the larger number of research participants that have undergone genotyping than sequencing, researchers using genotyping data may have access to a significant source of SGF. We evaluated variants included on the Illumina Multi-Ethnic Genotyping Array (MEGA) that may confer high risk for SGF-associated diseases. The manifest of the MEGA was intersected with the ACMG list of 59 genes returning 4,310 variants. Variants were annotated using Alamut Batch (Interactive Biosoftware) and filtered for MAF in gnomAD, coding effect, and pathogenicity classification in ClinVar. A total of 1,608 coding variants passed our frequency filters and were either assessed as pathogenic or likely pathogenic by at least one ClinVar submitter or were putative loss of function alleles in genes where loss of function is a known mechanism of disease. While, in the context of clinical sequencing, the low population frequency of these variants ( $\leq 0.005$  in all gnomAD populations) supports their potential pathogenicity, in the context of GWAS, for which the MEGA Array data is often used, these variants are likely to be filtered out over concerns of low power. Thus, evaluating the presence of these variants must use data before applying frequency filters. These data suggest that ACMG variants can be identified from array-based genotyping that could have significant health-care implications and potential benefit for research participants. Therefore, the widely held notion that GWAS SNP array results are irrelevant to SGF is no longer true, though positive predictive value must be evaluated. Researchers and IRBs should consider whether individuals participating in SNP array-based studies and found to be carrying such variants should be identified and what follow up steps (clinical validation, return of results, and/or referral) are indicated.

## PgmNr 1389: Optical mapping of the schizophrenia-associated 3q29 deletion reveals new features of genomic architecture.

### Authors:

---

**Introduction:** 3q29 deletion syndrome is a rare genomic disorder (~1 in 30,000) caused by a typically *de novo* deletion spanning ~1.6 Mb and 21 genes. It is associated with neurodevelopmental and neuropsychiatric phenotypes, including a 40-fold increase in risk for schizophrenia. The 3q29 locus contains three low-copy repeats (LCRs). Two flank the canonical 3q29 deletion, LCR B (centromeric side) and LCR C (telomeric side). The third, LCR A, is 140 kb centromeric to LCR B. The presence of these LCRs suggests the region undergoes non-allelic homologous recombination (NAHR) to form the 3q29 deletion and reciprocal 3q29 duplication. However, our understanding of the local architecture at the 3q29 locus is limited.

**Methods:** We performed Bionano<sup>®</sup> Saphyr<sup>™</sup> genome mapping on 12 3q29 deletion trios and 3 additional deletion probands. We evaluated the genomic architecture at the 3q29 locus of probands and parents, characterized the breakpoints of the deletion in probands, and identified additional structural variants in the region, including inversions, in all samples.

**Results:** Deletion sizes range between 1.68-1.7 Mb. In ~60% of probands, deletion breakpoints are within LCRs B and C. For the remaining 40%, breakpoints lie on the telomeric side of LCR C. The interval in 2 probands span into *RUBCN*, a gene not previously implicated in 3q29 deletion syndrome. In parental genomes, we observe expansions at LCRs A and B ranging between 60-130 kb in size: 57% of alleles at LCR A and 54% of alleles at LCR B have expansions compared to the hg38 reference genome. We have identified common inversions at the locus, particularly between LCR A and B, but these do not appear to be related to deletion formation.

**Conclusion:** This is the first fine scale mapping of the 3q29 deletion interval in multiple trios. The observation that the deletion includes *RUBCN* in some cases may impact the phenotypes of 3q29 individuals. Expansions in LCRs A and B indicate variation at the 3q29 locus not captured by human genome build 38. The expansions may be critical factors that underlie the formation of the 3q29 deletion.

**Implications:** Fine scale mapping of the genomic architecture and identifying risk factors contributing to structural instability in the 3q29 region can be extrapolated to other genomic disorder loci. Subtle variation in deletion size and deletion of genes outside the canonical interval are not captured by clinical microarrays and may explain heterogeneity of the 3q29 deletion phenotype.

## PgmNr 1390: Mondo Disease Ontology: Harmonizing disease concepts across the world.

HGVS nomenclature is the standard for reporting variants, but there is no comparable standard for reporting diseases. Existing sources of disease definitions and data models include HPO, OMIM, SNOMED CT, ICD, PhenoDB, MedDRA, MedGen, ORDO, DO, GARD etc; however, these sources partially overlap and sometimes conflict, making it difficult to know definitively how they relate to each other. This has resulted in a proliferation of mappings between disease entries in different resources; however mappings are problematic: collectively, they are expensive to create and maintain. Most importantly, the mappings lack completeness, accuracy, precision; as a result, mapping calls are often inconsistent between resources. The UMLS provides intermediate concepts through which other resources can be mapped, but these mappings suffer from the same challenges: they are not guaranteed to be one-to-one, especially in areas with evolving disease concepts such as rare disease.

In order to address the lack of a unified disease terminology that provides precise equivalences between disease concepts, we created the Mondo Disease Ontology that provides a logic-based structure for unifying multiple disease resources. Its development is coordinated with the Human Phenotype Ontology (HPO), which describes the individual phenotypic features that define a disease concept. Like the HPO, Mondo provides a hierarchical structure which can be used to annotate data at different levels of precision. Mondo provides mappings to other disease resources, but in contrast to other mapping sets, Mondo precisely annotates each mapping using strict semantics, so that we know when two diseases are precisely equivalent or merely closely related.

Incorporating Mondo into variant prioritization tools such as Exomiser could improve their efficiency and accuracy, by reducing redundancy and inconsistencies between the many disease terminologies in use.

Mondo is used to accommodate a global alignment of disease concepts - e.g., subsumption of classification and axioms by The Experimental Factor Ontology (EFO) to assist annotation of disease information where EFO is used elsewhere - e.g., EBI resources, Open Targets, and Euro-Bioimaging. In addition, Mondo is being utilized in diverse applications and resources such as ClinGen, and Gabriella Miller Kids First. We invite the community to contribute to Mondo; visit [github.com/monarch-initiative/mondo](https://github.com/monarch-initiative/mondo) for details.

## **PgmNr 1391: Implementing clinically validated automated genomic variant prioritisation for whole genomes, exomes and virtual panels, with diagnostic performance that equals human experts.**

---

**Background:** Analysis and interpretation of genomes (and exomes) are major challenges requiring bioinformatics and professional resources in limited supply. We have developed an automated variant prioritisation framework, whose performance equals genomic diagnosis using human experts.

**Methods:** Genome.One operates a NATA-accredited (ISO15189) whole genome diagnostic service in Sydney, Australia. A reference set of ~500 clinical referrals underwent bioinformatics using a precisionFDA Award-winning pipeline (Kinghorn Centre for Clinical Genomics). Tertiary bioinformatics used published tools (Seave), with every case analysed by Doctoral genetics professionals. Additionally, a team of genetics experts performed variant review of selected non-trivial cases. We evaluated two automated pipelines: *Moon* (diploid.com), *Eclipse* (derived from Seave), and a combination of the two. Reference set concordance was required for all ACMG Class 4 and 5 variants, and desirable (but not required) for Class 3 variants. Discordant results were adjudicated by the variant review expert team. Following initial validation, prospective parallel analyses was undertaken by both manual and automated protocols.

**Results:** For whole exome analysis performed by whole genome sequencing, automated pipelines performed nearly as well as human experts, identifying at least 88-98% of Class 4/5 and 60-75% of Class 3 variants. Applying both in combination equalled human experts, with 100% concordance for all Class 4/5 reportable variants and 75-81% concordance for Class 3 variants. The new approach resulted in order-of-magnitude reduction (median reduced from 225 to 6 variants for whole genomes) in interpretation time. We have now extended this approach to include virtual panel analysis.

**Conclusion:** An automated variant prioritisation protocol has been developed, whose performance equals that of credentialed genetic diagnostic professionals. The pipeline is accredited for clinical diagnosis, for both whole genome analysis as well as now for virtual panel analysis.

## PgmNr 1392: Pathogenic variants of *EPHB4* cause lymphatic anomalies through over-activation of mTOR.

---

Central conducting lymphatic anomaly (CCLA) is a rare and progressive disorder in which lymph is inadequately cleared as a result of dilated lymphatic channels, dysmotility, and/or distal lymphatic obstruction. We identified a number of pathogenic mutations in *EPHB4*, a gene encoding ephrin type-B receptor 4 and involved in vascular development, through whole exome sequencing of patients diagnosed with lymphatic anomalies, including two missense mutations (c.2288G>A:p.R763Q and c.2654A>G:p.K885R) and a splicing mutation that leads to the use of a cryptic splice donor and the retention of the intervening 12-bp intron sequence and an in-frame insertion of four amino acids (c.2334+1G>C:p.L778\_G779insLMLG). Functional characterization using an *in vitro* spheroid-sprouting assay in human lymphatic endothelial cells showed these mutations cause a loss of function of *EPHB4*, and lead to unregulated lymphangiogenic sprouting and development. The functional consequences of these mutations were confirmed in a zebrafish model. Injection of *ephb4a* morpholino into zebrafish resulted in lymphatic vessel misbranching and developmental deformities that mimicked the lymphatic presentation observed in the patients. Further analyses revealed that over-activation of mTOR, as a consequence of *EPHB4* loss-of-function, led to the observed phenotype. Importantly, the phenotype could be rescued in both the spheroid and zebrafish models upon treatment with rapamycin and the mTOR dual inhibitor OSI-027. These findings demonstrate that these loss-of-function variants of *EPHB4* are implicated in CCLA, and that mTOR inhibitors may have therapeutic benefits in patients with lymphatic anomalies and other vascular disorders resulting from mutations that induce mTOR pathway upregulation.

## PgmNr 1393: A genocentric, optimization-based approach to discovery of Mendelian disease genes.

### Affiliations:

1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, Texas.; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX 77030; 3) Department of Pediatrics, Baylor College of Medicine, Houston, TX 77030; 4) Texas Children's Hospital, Houston, TX 77030; 5) School of Public Health, UTHealth, Houston, TX 77030; 6) Center for Human Disease Modeling, Duke University Medical Center, Durham, NC 27701

The advent of inexpensive, clinical exome sequencing (ES) has led to the accumulation of genetic data from thousands of samples from individuals affected with a wide range of diseases, but for whom the underlying genetic and molecular etiology of their clinical phenotype remains unknown. In many cases, detailed phenotypes are unavailable or poorly recorded and there is little family history to guide study. To accelerate discovery, we integrated ES data from 18,696 individuals referred for suspected Mendelian disease, together with relatives, in an Apache Hadoop data lake and implemented a genocentric analysis which rapidly identified 154 candidate Mendelian disease genes.

The approach did not rely on case-specific phenotypic classifications, but iteratively queried the data with variable gene-level (i.e. pLI) and variant-level (i.e. REVEL) filtering criteria revealing genes where at least five cases harbor ultra-rare (MAF < 1/10k), potentially pathogenic variants absent from all controls. Optimal filtering values were identified which maximize the ratio of output genes with recently-reported Mendelian disease-gene associations. Past discovery within a given gene set was consistently shown to correlate with continued discovery, supporting this optimization-based strategy. In the months following our analysis, Mendelian disease associations for 19 of the 154 candidates were independently reported to OMIM (expected = 2.29;  $p < 0.00001$ ;  $n=100,000$  permutations): *ATP1A1*, *CACNA1E*, *CHD3*, *CLTC*, *DOCK3*, *FBXO11*, *IRF2BPL*, *KDM5B*, *KIAA1109*, *LINGO1*, *MACF1*, *MAST1*, *MYO9A*, *PDE1C*, *SCN3A*, *SET*, *TBX2*, *TCF20* and *VPS13D*.

We sought replication by intersecting the candidate disease genes with a set of genes harboring *de novo* mutations in an independent cohort of ES trios with a wide range of congenital anomalies. Six genes overlapped between the set of 154 candidate disease genes and the 216 genes harboring *de novo* nonsynonymous variants (expected = 1.68;  $p = 0.005$ ;  $n = 10,000$  permutations): *AATK*, *CELSR1*, *IRF2BPL*, *MYO5C*, *ROCK1*, and *UBC*. No candidates overlapped with the set of 93 genes harboring noncoding variants, supporting the model that *de novo* nonsynonymous variants are much more likely to be pathogenic than other *de novo* variants.

Thus, we demonstrate the utility of genocentric and optimization-based approaches toward

accelerating Mendelian discovery, and provide a high-quality set of novel candidate disease genes (and variants) for ongoing discovery efforts.

## PgmNr 1394: Extensive allelic, genetic, and phenotypic heterogeneity identified in exome study of primary lymphedema.

### Authors:

E.C. Lawrence <sup>1</sup>; E.E. Blue <sup>2</sup>; D.A. Nickerson <sup>3</sup>; M.J. Bamshad <sup>4</sup>; R.E. Ferrell <sup>1</sup>; D.N. Finegold <sup>1</sup>; The University of Washington Center for Mendelian Genomics

The Pittsburgh Lymphedema Family Study (PLFS) is a cohort of over 300 families with hereditary lymphedema phenotypes, including a subset of individuals diagnosed with lymphedema-distichiasis syndrome (LDS). Causal variants in *FOXC2* were previously identified in this subgroup, though not all LDS probands revealed a *FOXC2* mutation.

For 27 members of 20 multiplex families previously screened [using early whole exome sequencing (WES) technology without a molecular diagnosis], we performed WES using an updated exome capture kit, 75bp paired-end reads, high coverage (mean = 60 to 80X), and an expanded analytical pipeline. Rare variants were extracted with a maximum alternate allele frequency of 0.5% predicted to have moderate to high impact consistent with the mode of inheritance predicted by patient pedigree data. We prioritized conserved variants, those predicted to be pathogenic, and those in genes previously implicated in lymphedema in humans or related phenotypes in animal models. The observed phenotype in 2/20 LDS families could be explained by frameshift variants in *FOXC2* not detected in the original analysis. To identify novel genotype-phenotype relationships, we expanded our WES analysis to include 94 probands from PLFS families along with co-segregation studies within families by Sanger sequencing. Among 22/114 families (19%), the phenotype may be explained by variants in genes causing dominant forms of lymphedema: *CELSR1* (4/114), *FLT4* (12/114), *FOXC2* (4/114), *GATA2* (1/114), and *GJC2* (1/114). An additional 10 families may be explained by variants in genes previously associated with lymphedema in humans with strong functional or animal model support: *FN1* (1/114), *HGF* (3/114), *KDR* (2/114), *NRP2* (1/114), *SOX17* (3/114), and *VCAM1* (1/114). Including genes necessary for lymphangiogenesis or animal models exhibiting lymphedema, we identify potentially causal variants in an additional 18/114 (16%) of families: *CALCR* (1/114), *CLEC1B* (1/114), *EMILIN1* (4/114), *ITGA9* (1/114), *PLXNA3* (3/114), *PROX1* (1/114), *SPRED2* (1/114), *TIE1* (5/114), and *VEZFI* (1/114).

We expand the known genotype - phenotype relationship in several genes and add support for novel genes in primary lymphedema. Current next-generation sequencing technology applied to previously analyzed phenotypes yields a wealth of novel variation. Resequencing of older samples yields important relevant new variation. These results add to the extensive genetic and allelic heterogeneity in primary lymphedema.

## **PgmNr 1395: The NHGRI Centers for Mendelian Genomics: Accelerating novel discovery in Mendelian disease.**

### **Authors:**

[View Session](#) [Add to Schedule](#)

**Affiliation:** National Human Genome Research Institute, Bethesda, MD.

---

The National Human Genome Research Institute (NHGRI)'s Centers for Mendelian Genomics (CMG) aim to discover the genetic basis of as many Mendelian traits as possible. The CMGs accelerate discovery by dissemination of tools, and approaches for Mendelian genomic analysis, collaboration with disease-focused investigators, and providing a range of educational opportunities. This poster will highlight the Centers for Mendelian Genomics contributions to the field, describe how data and findings from the CMG are shared with the community, and discuss some of the gaps and challenges that remain to be addressed.

## PgmNr 1396: A pipeline for genome-wide genotyping, filtering, and prioritization of tandem repeats.

The application of clinical next generation sequencing (NGS) has resulted in dozens of successful diagnoses for a wide range of disorders. However, several cases of clinical NGS remain unsolved. One potential explanation is that many genetic disorders may be due to complex mutations such as repeats not captured by standard analysis pipelines. Tandem Repeats (TRs) are regions comprised of short motifs of 1-20bp repeated in tandem. TRs have been associated with dozens of Mendelian diseases, such as Huntington's disease and Fragile X Syndrome. Beyond these well-known loci, additional pathogenic TRs continue to be discovered. Despite their established role in disease, repeat variants are typically missing from clinical NGS pipelines due to technical challenges of analyzing TRs from short reads. We present an end-to-end pipeline for genome-wide identification of pathogenic TR expansions involved in Mendelian disease. Our pipeline leverages GangSTR, which incorporates multiple sources of information from paired-end reads into a joint likelihood model capable of genotyping both short and expanded TRs from short reads. Our pipeline consists of the following steps: (1) genome-wide TR genotyping (GangSTR); (2) quality control and filtering (dumpSTR); (3) prioritization of candidate TR expansions based on gene annotation and comparison to unaffected control populations and available unaffected family members (postmaSTR). We validated our pipeline by analyzing 30x PCR-free whole genome sequencing from individuals with known pathogenic repeat expansions at the Huntington's Disease locus. For 12/13 individuals, genome-wide analysis correctly identified the premutation or pathogenic CAG repeat expansion. We then applied our pipeline to 41 undiagnosed pediatric cases from the Undiagnosed Neurological Disease Program at Rady Children's Institute for Genomic Medicine. Our pipeline was completed in an average of 3 hours per sample running in a cloud environment using virtual machines with 8 cores each. We identified an average of 100 candidate TRs genome-wide and 10 candidate TRs in coding or UTR regions per family. The top candidate list for several families included variants in or near a gene previously implicated in a neuro-developmental disorder. Our pipeline for genome-wide genotyping, filtering, and prioritization of TRs is publicly available on Github or as a Docker container and can be easily deployed on cloud environments such as DNA Nexus or Amazon Web Services.

## PgmNr 1397: Large-scale replication and discovery of genetic associations for rare diseases with self-reported medical data.

---

Though nearly 7000 diseases affecting fewer than 0.05% of the population are known, a large number of rare diseases still remain unsolved. State-of-the-art approaches for discovering the genetic basis of rare diseases rely on sequencing cases or case families for a single disease, followed by automated and manual curation to discover likely causal variants. This severely limits the rate at which the genetics of rare disease can be studied and understood.

Here we demonstrate the use of SNP array data combined with self-reported phenotype data to study rare diseases at a large scale and identify genetic associations for rare diseases through genome-wide association studies (GWAS). Using web-based questionnaires, we gathered self-reported data on rare diseases from a cohort of over 3.6 million research-consented DTC-genotyped individuals. We ran GWAS on over 250 rare disease phenotypes with a minimum of 30 cases in individuals of European ancestry.

We replicate known associations at a genome-wide significance level ( $p\text{-value} < 5e-8$ ) with a diverse range of minor allele frequencies (minimum MAF=0.0012, maximum MAF=0.4989) and effect sizes (minimum OR=1.16, maximum OR=207.02). We find common variant associations for Hirschsprung's disease (*RET*), cleft palate (*GSDMC*), Fuch's corneal dystrophy (*TCF4*), hemochromatosis (*HFE*), craniosynostosis (*BMP2*), factor V deficiency (*F5*). In addition, we find rare variant associations for Huntington's disease (*HTT*), cystic fibrosis (*CFTR*), alpha-1 antitrypsin deficiency (*SERPINA1*). In some rare diseases, we find associations tagging known causal genes, for example, Lynch syndrome (2p16.3, tagging *MSH6*) and epidermolysis bullosa simplex (12q13.13, tagging *KRT5*). For polycythemia vera, we replicate known associations in the *JAK2*, *TET2*, and *TERT* genes. For Von Willebrand disease, we replicate known associations in the *VWF* and *ABO* genes. We also find a novel association for Von Willebrand disease in the *USP7* gene, which has been previously associated with platelet count.

Our results show that large-scale online collection of self-reported data is a viable method for large-scale discovery and replication of disease gene associations for rare diseases. Further analyses will enable the discovery of more novel genetic associations for increasingly rare diseases.

## PgmNr 1398: Aromatic amino acid decarboxylase deficiency in 17 Mainland China patients: Clinical phenotype, molecular spectrum and therapy overview.

### Authors:

D. Qian

[View Session](#) [Add to Schedule](#)

**Affiliation:** Pediatric Endocrinology and Genetic Metabolism, Shanghai Institute for Pediatric Research, Xinhua Hospital, School of Medicine, Shanghai Jiao Tong U, Shanghai, China, Weiqian, Dai, MS

---

**Objectives:** The prevalence of aromatic amino acid decarboxylase deficiency (AADCD) is relatively high in certain Asian populations, due to a founder effect. However, only three cases have been reported in Mainland China. The purpose of this study is to broaden the clinical, molecular and treatment spectrum of AADC deficiency. **Methods:** We recruited 14 previously undescribed patients, who received a diagnosis of AADC deficiency, together with three reportedly cases in Mainland China. Full clinical information was collected, and disease-causing mutations in the DDC gene were detected by High-throughput sequencing. **Results:** The common clinical manifestation of patients, including intermittent oculogyric crises, retarded movement development, and autonomic symptoms. A patient showed bone-density loss which have not been reported so far. There are twelve of the 14 patients who showed severe phenotype besides two mildly affected children. The majority of patients showed a poor response to drug therapy, but two mildly phenotype patients improved psychomotor function after being prescribed medication. The most common genotype of Mainland Chinese AADCD is the splice-site pathogenic variant (IVS6 + 4A > T; c.714 + 4A > T), which accounts for 58.8% of all DDC mutations, followed by c.1234C > T (p.R412W; 17.6%). Three novel compound heterozygous mutations, c.565G>T, c.170T>C, and c.1021+1G>A, was firstly reported. Besides, we discovered that patients may presented with mild or moderate if found to be compound heterozygote or homozygote for one of the following missense or nonsense mutations: c.478C>G, c.853C>T, c.1123C>T, c.387G>A, c.665T>C. **Discussion:** The clinical data of the cohort of 17 patients in Mainland China broaden the clinical, molecular and treatment spectrum of AADC deficiency.

## PgmNr 1399: Prediction of lethality and severity of osteogenesis imperfecta variants in the triple-helix regions of COL1A1 and COL1A2.

### Authors:

---

**Background:** Osteogenesis imperfecta (OI) is a group of connective tissue syndromes primarily characterized by a lifetime liability to fractures. The classical form of OI is typically caused by autosomal dominant mutations in type I collagen-coding genes (*COL1A1* and *COL1A2*), particularly the substitution of glycine residues in the triple helical (TH) domain. OI is phenotypically heterogeneous with four common types: mild (Type I), perinatally lethal (Type II), progressively deforming (Type III), and moderately deforming (Type IV). However, a straightforward link between variant characteristics and OI types has proven elusive, complicating the interpretation of novel variants. Here, we address the assignment of OI types to missense variants in the TH domain by developing machine learning models for two related tasks: lethality prediction (Type II vs. the rest) and severity prediction (Types II and III vs. the rest). **Methods:** We investigated whether existing pathogenicity and functional effect predictors could be repurposed for these tasks. We also evaluated the performance of two methods more suited to this application: an OI-specific lethality predictor and a gene/disease-independent severity predictor. We then trained multi-layer neural network models on 891 variants obtained from multiple data sources, using features related to the variants' sequence context and position. Predictive performance was assessed through cross-validation experiments using standard evaluation metrics. **Results:** Pathogenicity, functional effect and severity predictors yielded poor (near-random) performance for both tasks. While the existing OI-specific lethality predictor fared better, it was outperformed by our models. Interestingly, although the "lethality" and "severity" models were generally correlated with each other, the scores from the former correlated better with the severity of the four OI types, which is a task that it was not explicitly trained for. **Conclusions:** Despite the use of a basic set of features, our COL1A-specific model performed better than more sophisticated methods when predicting OI severity. Our comparison of the lethality and severity prediction tasks also has implications for the development of methods that go beyond simplistic notions of "pathogenic" or "benign" by demonstrating that consistent definitions of phenotype severity and problem formulations across different genes/diseases are important for the development of generalizable methods.

## PgmNr 1400: Clinically associated genomic mutations database for heritable epidermolysis bullosa disease.

---

Genetic variant classification is critical for an accurate genetic diagnosis. However, for rare inherited disorders, it poses a major challenge since post-genomic era the number of genetic variants and complexity associated with assigned clinical impact has been increased exponentially. To address this challenge in epidermolysis bullosa (EB), a clinically and genetically heterogeneous group of rare inherited skin fragility disorders, we developed the Database of Epidermolysis Bullosa (EBDB). This comprehensive resource integrates all genetic variants in 21 currently known EB-associated genes from multiple data sources, including 1000 Genome, Exome Sequencing Project, Exome Aggregation Consortium, ClinVar, dbSNP, GME, Iranome and GNOMAD. All the genetic variants are re-categorized into single classification according to ACMG guidelines first computationally (using a custom built variant categorization pipeline) and then validated using manual curation. EBDB clearly improves the knowledge of existing clinically associated variant classification in the EB disease. As an example, *COL7A1*- a gene associated with dystrophic EB has a total of 7704 coding variants, where ClinVar classifies only 3% of the variants into different categories of variant effect including Pathogenic (P), Likely Pathogenic (LP), Variant of Uncertain Significance (VUS), Likely Benign (LB), or Benign (B). The remaining 97% genetic variants are not classified in any category. Using our custom built variant categorization pipeline which utilizes minor allele frequency (MAF) and functional prediction algorithm scores to re-categorize the variants, we successfully re-classified the *COL7A1* variants into 0.9% - P, 0.1% - LP, 7% - LB, 29% - B, and 63% - VUS. This re-classification of each variant was confirmed using manual curation. Using this approach, EBDB is successfully resulting in an improved classification of more than 95% of coding variants where pathogenicity is driven by minor allele frequency thresholds, variant effect and protein domain. In conclusion, we have implemented a computational variant classification algorithm to develop a database encompassing genomic variants re-categorized according to the ACMG standards to facilitate the application of comprehensive genetic testing to the clinical care of EB patients.

## PgmNr 1401: Variation in alpha diversity of the oral microbiome based on periodontal disease status, NHANES 2009-2012.

### Authors:

---

The National Health and Nutrition Examination Survey (NHANES) is a multistage nationally representative probability sample of the multi-ethnic, civilian, non-institutionalized US population. NHANES assesses the health and nutritional status of adults and children annually through personal interview, standardized examinations, and laboratory analysis of collected biospecimens. The v4 region of the 16S rRNA gene was sequenced from oral rinse samples collected from NHANES participants ages 14-69 years in NHANES cycles 2009-2010 and 2011-2012 (n =10,466) to characterize the oral microbiome. The resulting sequence data was processed via two pipelines: closed reference operational taxonomic unit (OTU) clustering and DADA2 for sequence variant generation. Resulting data include the following: alpha-diversity metrics (i.e., richness and evenness of microbes), beta-diversity matrices, principal coordinates of the beta-diversity matrices, and relative/absolute abundance tables for each taxonomic level from phylum to genus for each pipeline. Alpha diversity was calculated for data rarefied to 10,000 reads using three metrics: observed OTUs, Faith's Phylogenetic Diversity, and the Shannon-Weiner index. Participants with data from the oral health periodontal (30 years and older) and oral microbiome components were utilized (n=5,519). Periodontal disease (PD) status (PD vs. no PD) was calculated using CDC/American Academy of Periodontology case definitions. We examined the association between PD status and alpha diversity data by sex, age group, poverty status, self-reported race/ethnicity, education, smoking status, and marital status. We used pairwise *t*-tests to compare alpha diversity estimates by PD status overall and within all subgroups. Participants with PD had significantly higher alpha diversity than those without PD (p-value < 2 x10<sup>-11</sup>). This was observed across all three metrics in each pipeline. For demographic characteristics all subgroups had statistically higher alpha diversity for those with PD vs those without PD, the greatest differences were in the following: age group 35-49 (p-value < 1 x10<sup>-12</sup>) and never smoker (p-value < 6 x10<sup>-10</sup>) across all metrics in each pipeline. Further analysis of beta diversity and the taxonomic abundances will allow characterization of the community and individual microbial differences based on PD status at the US population level.

## PgmNr 1402: Federating association analysis in type 2 diabetes to protect participants' privacy.

### Authors:

J. Spalding <sup>1</sup>; N. Burt <sup>2</sup>; M. Costanzo <sup>2</sup>; M. McCarthy <sup>3</sup>; T. Keane <sup>1</sup>; AMP-T2D Knowledge Base and Portal Team

---

By increasing the number of genomes from subjects with type 2 diabetes (T2D) for analysis, we can increase the number of detected T2D genetic associations, leading to the discovery of functional pathways and development of novel therapeutic targets. The Accelerating Medicines Partnership in T2D (AMP-T2D) is a multi-sector, pre-competitive partnership among government, industry, and nonprofit organizations. AMP-T2D has built an infrastructure consisting of nodes for data storage and analysis (knowledge base), and presentation (knowledge portal). Many countries are now developing personalised health programmes, resulting in an increasing number of genomes being made available for secondary research purposes. Personal health information is subject to national laws, and may not be available for analysis in a global context. By separating the knowledge base from the knowledge portal a network of knowledge bases can be developed, which allows analyses to be configured on the knowledge portal, and distributed to nodes located within the jurisdiction where the data was generated. Analyses can be run on the federated nodes, and return anonymised results to the knowledge portal for interrogation and display. The AMP-T2D Knowledge Portal (<http://www.type2diabetesgenetics.org>) is an open access resource allowing analysis of data federated between the USA and UK.

Data are stored in a Data Coordinating Center (DCC) at the Broad Institute and also at the European Bioinformatics Institute (EBI). As of June 2019 the EBI knowledge base (KB) was hosting 8 datasets, which can be queried directly from the knowledge portal along with the datasets hosted by the DCC. The knowledge portal supports custom online genetic association analysis with dynamic sample filtering and covariate specification. A genetic risk score module has been added allowing calculation of the genetic risk score for a range of phenotypes based on a set of variants with association to T2D, and interactive manhattan plots are available to display genetic associations across the genome. To facilitate federated analysis the analysis engine is run inside Docker containers, which are accessible via a REST API. Phenotypes and sample attributes are harmonized across the network by utilising a registry. Access to the REST API is restricted to authorised users, with the authentication and authorization procedure compatible with Global Alliance for Genomics and Health (GA4GH) standards to maximise interoperability.

## PgmNr 1403: Addressing the missing data issue in multi-phenotype genome-wide association studies.

---

Joint analysis of multiple phenotypes in genome-wide association studies (MP-GWAS) increases power for locus discovery but suffers from missingness in phenotype values. We investigated properties of missing data imputation methods within MP-GWAS, focussing on single and multiple-imputation (SI/MI) using Bayesian approach and expectation-maximisation bootstrapping (EMB), k-nearest neighbour (kNN), left-censored imputation method (QRILC) and random forest (RF). We simulated genetic data for 5,000/50,000/500,000 individuals using Hapgen2, and highly ( $r=0.64$ ) and moderately correlated ( $r=0.33$ ) phenotypes (3/9/30/120) for them. We randomly selected common, low-frequency and rare variants to be significantly ( $P < 5 \times 10^{-8}$ ) associated with the simulated phenotypes. We considered several proportions of missing data (1/5/20/50%) under missing completely at random (MCAR), missing at random (MAR), and missing not at random (MNAR). We used the Root Mean Squared Error (RMSE) for the evaluations with complete cases (CC) vs. full data RMSE as the reference level. RF and MI-EMB diverged the most from the reference under MCAR ( $P_{RF}=7.18 \times 10^{-4}$ ,  $P_{MI-EMB}=6.27 \times 10^{-4}$ ). RF also outperformed under MAR ( $P=6.22 \times 10^{-4}$ ), whereas QRILC outperformed under MNAR ( $P=7.45 \times 10^{-5}$ ). RF was applied to the Northern Finland Birth Cohorts (NFBC) 1966 and 1986 (4,955 and 2,687 individuals, respectively) for the imputation of anthropometric and glycaemic measurements and 149 serum metabolite levels. MP-GWAS of 31 amino acids showed a novel association at *ADAMTS* after imputation with RF ( $P=2.61 \times 10^{-11}$  vs.  $P=5.68 \times 10^{-7}$  in CC) and improved power at *FCGR3B* ( $P=1.86 \times 10^{-9}$  vs.  $P=1.72 \times 10^{-8}$ ). We propose improved solutions for phenotype imputation in high-dimensional omics data-analyses and have implemented these into a user-friendly and computationally efficient imputeSCOPA software tool.

## PgmNr 1404: In silico analysis of coding/non-coding SNPs of human *RETN* gene and characterization of their impact on resistin stability and structure.

---

Resistin (*RETN*) is a gene coding for pro-inflammatory adipokine called resistin secreted by macrophages in humans. Single nucleotide polymorphisms (SNP) in *RETN* are linked to obesity and insulin resistance in various populations.

Using dbSNP, 78 non synonymous SNPs (nsSNPs) were retrieved and tested on PredictSNP 1.0 megaserver. Among these, 15 nsSNPs were predicted as highly deleterious and thus subjected to further analyses, such as conservation, post-transcriptional modifications and stability.

The 3D structure of human resistin was generated by homology modeling using Swiss Model. Root Mean Square Deviation (RMSD), hydrogen bonds (h-bonds) and interactions were estimated.

Furthermore, UTRscan served to identify UTR functional SNPs.

Among the 15 most deleterious nsSNPs, 13 were predicted to be highly conserved including variants in post-translational modification sites. Stability analysis predicted 9 nsSNPs (I32S, C51Y, G58E, G58R, C78S, G79C, W98C, C103G and C104Y) which can decrease protein stability with at least three out of the four algorithms used in this study.

These nsSNPs were chosen for structural analysis. Both variants C51Y and C104Y showed the highest RMS deviations (1.137 Å and 1.308 Å respectively) which were confirmed by the important decrease in total h-bonds. The analysis of hydrophobic and hydrophilic interactions showed important differences between the native protein and the 9 mutants, particularly I32S, G79C and C104Y. Six SNPs in 3'UTR (rs920569876, rs74176247, rs1447199134, rs943234785, rs76346269 and rs78048640) were predicted to be implicated in polyadenylation signal.

This study revealed 9 highly deleterious SNPs located in human *RETN* gene coding region and 6 SNPs within 3'UTR that may alter the protein structure. Interestingly, these SNPs are worth to be analysed in functional studies to further elucidate their effect on metabolic phenotypes occurrence.

## PgmNr 1405: Data-driven analysis of omics and electronic health records from the Estonian Biobank identifies early changes associated with incident type 2 diabetes.

High-throughput data has been used extensively to study the differences between healthy and diseased individuals. However, it is even more important to understand the earliest changes preceding the development of a disease, paving the way for possible prevention. Genetic risk scores can be used to summarise the genetic component, but risk also depends on other factors, such as age, lifestyle and external exposures.

We use NMR metabolomics data from the Estonian Biobank, coupled with the analysis of electronic health records. From 152,000 biobank participants, 10,840 have <sup>1</sup>H-NMR metabolomics data available. From these, 328 had developed incident type 2 diabetes by the time of linking of health records. Machine learning identified 33 metabolic markers predictive of incident type 2 diabetes. We used systems biology for the interpretation of these predictive metabolites, specifically, we created a similarity network between all metabolites. Additionally, Olink proteomics data and genetic risk score for type 2 diabetes was integrated with the same network.

Network analysis shows that 67.6% of the first-neighbour proteins of the predictive metabolites have already been shown to be involved in type 2 diabetes or related phenotypes. Specifically, we find that the set of first neighbours is enriched in cytokine signalling. When using STRING to see whether these proteins have any interactions, we identify a highly connected network of 9 proteins, including 6 ligands for chemokine receptors. The genetic risk score for type 2 diabetes is directly connected with glucose levels in the network, and in close proximity of  $\beta$ -hydroxybutyrate, lactate and acetate. Our data-driven analysis has shown the potential to use omics data from a population-based biobank and electronic health records for gaining insight into a complex disease. More specifically, by using only data to inform the analysis, we have recovered information already known about some aspects of the early changes in the development of type 2 diabetes.

Our next steps will include the develop of a predictive model using age, gender, predictive metabolites and genetic risk score, and validation of the findings in an independent cohort.

## PgmNr 1406: Explanatory knowledge graph analysis of GWAS and MWAS associations with obesity reveals biological interpretations of statistical results.

GWAS analysis discovers statistical associations between genetic variation and phenotypes; these associations require interpretation to determine the mechanistic role of the identified variation. One approach to probing biological underpinnings is to simultaneously collect a broader spectrum of data, such as RNA expression, methylation, or metabolomics, and conduct data driven integrative analyses. A second approach is to integrate derived associations with prior knowledge including e.g. gene functions, pathways, and metabolic reactions. To address the paucity of methods in the field, we have developed a Knowledge Graph framework approach to uncover the mechanistic role of genetic variants that combines both data driven and known pathways.

The ROBOKOP Knowledge Graph (RKG), developed as part of the NCATS Data Translator program and hosted at <http://robokopkg.renci.org>, is a collection of half a million nodes representing entities such as diseases, phenotypes, genes, chemicals, and sequence variants. The over 12 million relationships between these entities represent the integration of many open knowledge sources and bio-ontologies. We have augmented RKG through the integration of the GWAS catalog, GTEx eQTLs, and calculated Linkage Disequilibrium (LD), to enhance its use as a source of information in an integrative analysis.

We tested our platform using genetic and metabolomic data from the Hispanic Community Health Study/Study of Latinos (HCHS/SOL), a multi-center epidemiologic study of the factors playing a protective or harmful role in the health of Hispanics/Latinos. Using GWAS- and MWAS-associations with phenotypes, we used RKG to identify associations and pathways relative to literature-based prior knowledge. Explanatory queries can be issued against this combined graph, such as “find all GWAS variants near genes that metabolize MWAS-significant blood metabolites”, which implicates genes such as *AHR*, *TAT*, and *CASP1*. These queries produce scientifically coherent sub-networks containing a combination of new results and prior knowledge, and potentially explaining the disparate statistical results.

This work was funded by UNC-Chapel Hill’s Obesity Creativity Hub and the National Center for Advancing Translational Sciences, National Institutes of Health, through the Biomedical Data Translator Program (award number OT2TR002514).

**INTRODUCTION:** Although obesity is a known cardiometabolic risk factor, little is known about how genetic variation influences human adipocyte size across adipose depots or how such variability may confer risk to obesity and other cardiometabolic outcomes.

**OBJECTIVE:** To establish a link between genetic variation and adipocyte cell size by performing the first large-scale study of automatic adipocyte phenotyping with a novel method using both histology and genetic data.

**METHOD:** We developed an ML method, the Adipocyte U-Net, to rapidly estimate adipocyte area estimates from histology. The Adipocyte U-net is a Convolutional Neural Network (CNN) based on the U-net architecture. Here, we use a combination of a fine-tuned InceptionV3 network to classify histology tiles and our Adipocyte U-net to perform counting and binary segmentation of adipocytes. We validate our method using three SOTA approaches (Adiposoft, CellProfiler and floating adipocytes), run blindly on 2 external cohorts. We observe strong concordance between our method and traditional approaches (Adipocyte U-net vs CellProfiler:  $R^2_{\text{visceral}}=0.94$ ,  $P<2.2\times10^{-16}$ ,  $R^2_{\text{subcutaneous}}=0.91$ ,  $P<2.2\times10^{-16}$ ), and tractable run times (10k images: 6mins vs 3.5hrs).

**RESULTS:** We applied our Adipocyte U-Net to 4 cohorts with histology, genetic, and phenotypic data (N=820). After meta-analysis, we find that adipocyte area positively correlated with Body Mass Index ( $P_{\text{subcutaneous}}=8.13\times10^{-69}$ ;  $P_{\text{visceral}}=2.5\times10^{-55}$ ; average  $R^2=0.49$ ) and recapitulate the finding that adipocytes in subcutaneous depots are larger than their visceral counterparts ( $P_{\text{meta}}=9.8\times10^{-7}$ ). A random effects meta-analysis demonstrated no significant association between adipocyte size and T2D, independent of BMI, age and sex ( $P_{\text{subcutaneous}}=0.11$ ,  $P_{\text{visceral}}=0.37$ ), suggesting BMI is the primary

modifier of adipocyte size. Next, we observe sexually-dimorphic adipocyte size between adipocyte depots, where female visceral adipocytes are smaller on average than male visceral adipocytes ( $P_{\text{meta}}=3\times 10^{-7}$ ). Lastly, we performed the first GWAS and subsequent meta-analysis of adipocyte area and intra-individual adipocyte variation.

**CONCLUSION:** Despite having 2× the number of samples than any similar study, we find no genome-wide significant associations. This suggests that both larger and more homogenous collections of adipose depots derived from the same anatomical location will be required to identify robust genetic associations that validate previous findings.

## PgmNr 1408: Computational software for peak alignment and quantification of comprehensive two-dimensional gas chromatography time-of-flight mass spectrometry metabolomics data.

High-dimensional metabolomics profiling is an informative approach to characterize the metabolic state of tissues and bodily fluids. Comprehensive two dimensional gas chromatography time-of-flight mass spectrometry (GC×GC-TOFMS) is a sophisticated and sensitive technology that is well suited for separating complex biological samples. Here we present new software for processing and aligning peaks from large GC×GC-TOFMS data sets from the LECO Pegasus 4D instrument. The pipeline: (1) calculates and applies retention time adjustments based on spiked-in internal standards for all deconvoluted peaks; (2) compares mass spectra between proximate peaks within a sliding retention time window by performing pairwise correlation analysis; (3) aligns peaks within and across samples using a chosen correlation coefficient threshold; and (4) characterizes aligned peaks by outputting total ion count areas, among other statistics. To evaluate the software, we conducted a total of 75 runs (3 vials, 25 runs each at two different concentrations) of standards from EPA Method 8270 and processed the resulting metabolomics data from ChromaTOF with our software. After alignment (at Pearson  $r > 0.9$ ), 268 peaks were identified across all runs, of which 66 were observed in more than 95% of the runs and 146 were singletons. Of the 76 compounds in the standard mix, 69 (91%) were detected among the 66 robustly observed peaks; missed compounds included semi-volatiles with reactive nitro groups and both small and large compounds that fell outside the data acquisition window (470 to 3540 s). After standardization against total peak areas and log transformation, the robust peaks showed an average coefficient of variation of 5% (range from 1% to 18%), with increased variability observed at low 1D retention times (<600 s). Pairwise correlations yielded high  $r$  values between runs (0.63 to 0.995), which was reflected by tight clustering in PCA results. REML modeling attributed the vast majority of the total variation to variation between aligned peaks (93%), with non-significant amounts attributed to differences arising from the independent runs and vial source (both <1%). Thus, our software appears well suited for processing complex GC×GC metabolomics data, exhibiting limited variation in aligned peak areas of known compounds across runs. The software is now being used in the analysis of metabolomics data generated on >1800 blood plasma samples for identifying diabetes and obesity biomarkers.

## PgmNr 1409: A taxonomy-aware method for background noise correction increases power to detect associations.

In recent years, several studies have demonstrated associations between the human microbiome and diseases, such as obesity and diabetes. Yet, due in part to small sample sizes, results from individual studies are often inconsistent and replication among studies is poor. Combining datasets from different studies can overcome the lack of power but is complicated by the introduction of technical variability, i.e. batch effects, between datasets due to differences in sequencing protocols, experimental design, time of collection, etc. Ignoring these effects can lead to both false positive associations as well as loss of power in downstream analyses. Quantile normalization is the current method specifically designed for batch correction in microbiome data even though this method has been shown in other omics fields, e.g. epigenomics and transcriptomics, to remove biological variation and reduce power to detect associations. We propose an empirical Bayes framework for adjusting microbiome data for batch effects which takes into account the count nature and taxonomic hierarchy present in microbiome data. Our method extends ComBat, a method for batch correction in microarray gene expression studies, by partitioning the method of moments estimators based on taxonomy and learning taxa-specific batch parameters. Using real 16S data from six microbiome studies of obesity, we establish that technical differences between datasets have varying effects on different phyla justifying the need for a taxonomy-aware method. We find that the observed abundance of individual taxa as a function of coverage increases faster for some studies than others, resulting in considerable bias. We show that our method adjusts for batch effects, outperforming existing batch correction methods as measured using the KBET score and by fitting a linear mixed model to estimate sources of variation due to study label compared to disease status. Interestingly, the study label or batch of samples explains up to 0.45 of the variance in the uncorrected data, and 0.01 in the data corrected by our method. The ratio of variance explained by disease status to variance explained by study label also increases after applying our method from 0.10 in the uncorrected data to 1.94. Lastly, we show that our improved batch correction finds stronger associations between obesity status and composition, based on both testing of the entire microbiome composition and testing of individual taxa.

# PgmNr 1410: A deep learning model for accurate variant calling in congenital adrenal hyperplasia.

## Introduction

Congenital adrenal hyperplasia (CAH) is an autosomal recessive disease that impairs steroidogenesis. Mutations in *CYP21A2* account for a large fraction of CAH cases. *CYP21A2* and a pseudogene *CYP21A1P* have high sequence identity. Variant calling in *CYP21A2* is technically challenging due to frequent and complex gene rearrangements with *CYP21A1P*. We developed an enhanced deep learning model ("deepCAH") which introduces additional features and class labels to improve CAH variant calling.

## Methods and Results

Our original model for *CYP21A2* variant calling utilized two sets of features: i) allele-balance measurements summarizing the fraction and count of genic and pseudogenic alleles of interest, and ii) copy-number measurements consisting of normalized sequencing depths at differentiable loci on *CYP21A2* and *CYP21A1P*. Allele balance for *CYP21A2* variants is the aggregate of benign and deleterious reads counts paired end-specific to *CYP21A2* and *CYP21A1P*. Due to frequent sequence rearrangement, the fidelity of read contribution is often assessed during manual call review by examining paired end-specific read contribution. To provide the model with all information available to human review, we extended the model to include novel features---namely, paired end-specific read contributions. In addition to 11 variants, the extended model included a new variant indicating a deleterious mutation (Q319X) is in cis with gene duplication. A cohort of >50,000 samples was split into training (80%) and validation sets (20%). To improve sensitivity on rare variants, additional positive samples were generated by data augmentation. We employed a multi-layer recurrent neural network comprised of long short-term memory (LSTM) cells and a weighted cross-entropy loss function. The model was implemented in TensorFlow and trained using the Adam optimizer. Considering the human-reviewed calls as ground truth, the extended LSTM showed a validation error rate of < 1 in 500.

## Conclusions

The enhanced deep learning model, deepCAH, achieved high accuracy (>99.9%) for technically challenging CAH variant calling. The deepCAH caller is expected to significantly reduce call review burden as it can substitute secondary confirmation by another call reviewer.

## PgmNr 1411: Multi-omic analysis of discordant and concordant sib-pairs with inflammatory bowel disease.

### Authors:

---

Inflammatory bowel disease (IBD) is an immune-mediated chronic intestinal disorder that is typically divided into two distinct types; ulcerative colitis (UC) and Crohn's disease (CD). Over 240 IBD susceptibility loci have been identified, however, much of the etiology remains unexplained and, even within families, the disease can have a heterogeneous clinical presentation. Here we present a study attempting to discern the cause of that heterogeneity in discordant and concordant sib-pairs by comparing whole exome sequencing, epigenetic differences using DNA methylation analysis, and gene expression using next generation RNA sequencing (RNAseq).

A total of 96 discordant and concordant sib-pairs were included in the study. Genomic DNA and RNA were extracted from peripheral blood mononuclear cells that were isolated using cell sorting from whole blood. DNA methylation values were measured using the Illumina EPIC array. Whole exome sequencing was performed using the Illumina TruSeq Exome kit, and RNAseq was performed using the Illumina RNA Kit v2. Of 5000 initial variants, five genes— Notch Receptor 1 (NOTCH1); Serine/Arginine Repetitive Matrix 2 (SRRM2); Zinc Finger Protein 276 (ZNF276); GATA Zinc Finger Domain Containing 2A (GATAD2A); and Diphthamide Biosynthesis 1 (DPH1)—remain after cross-matching preliminary exome and methylation analyses. RNAseq analysis is currently underway and results will be presented.

Combining data from multiple technologies is an important next step for interpreting the results of genome-wide association studies (GWAS) and there is currently no agreement on the best approach for integrating these data. Given the known genetic and clinical heterogeneity in IBD, using discordant and concordant sib-pairs attempts to leverage the expected sharing between the sibs as supporting information to inform future studies.

## PgmNr 1412: Machine learning-based urinary screening for lysosomal disease.

---

Fabry disease, one of the most frequently observed lysosomal diseases, is an inborn error of metabolism with severe symptoms. Enzyme replacement therapy and pharmacological chaperones can stabilize the progression in Fabry disease but cannot reverse organ damage. However, time delays in the diagnosis and treatment often occur, because non-specific symptoms including pain can be the early symptoms of Fabry diseases. Physicians can find low enzyme activities, high biomarker level and specific Fabry mutations to confirm the diagnosis, but the prior the those biochemical tests, they needs some clue for diagnosis. Recently, it has been reported that the prevalence of Fabry disease is considerably higher than believed.

For addressing the diagnostic delay problem, we collected urine sediment images from Fabry patients and non-Fabry patients as training data sets for machine learning. The developed our models successfully distinguished the Fabry urinary images from the other patients' images. The AUCs on the dataset were 0.994 (0.987–0.998) for the existence of mulberry cells in each segment, with high-sensitivity and high-specificity. We expect this screening tools for Fabry disease to contribute to early disease diagnosis and intervention, near future.

## PgmNr 1413: BD-CoCoLasso: Alternating block descent penalized regression adapted for the presence of a block of inaccurate features.

---

**Introduction:** Sparse regression has achieved great success when modelling phenotypes as a function of high-dimensional feature sets. Although the standard formulation of a prediction problem assumes clean data, real world data is often corrupted—either partially missing or measured with error. Datta and Zou (2017) developed the CoCoLasso algorithm, an adaptation of the LASSO approach capable of handling a general class of corrupted datasets and achieving better prediction performance. Here, we adapt CoCoLasso to a class of problems where there are both corrupted (e.g. exposure information) and uncorrupted covariates (e.g. SNP data). The motivation of our work is to reduce the computational needs of this new penalization method when only a small percentage of the features are corrupted.

**Methods:** CoCoLASSO requires a computationally demanding positive semi-definite projection of the covariance matrix for a high dimensional feature set. In our context when there are corrupted and uncorrupted covariates, we take advantage of the block descent minimization trick to develop a more efficient algorithm. In an alternating block minimization algorithm, the CoCoLasso corrections are used when updating corrupted coefficient vectors, and a simple LASSO is used for the uncorrupted coefficient vectors. Both subproblems are convex and hence a global solution can be obtained, even though adaption of the cross-validation step requires care in this setting where there are products of corrupted and uncorrupted matrices.

**Results:** In simulations, our method proved efficient both when we generated additive errors, and when we varied proportions of missing data. The algorithm was tested with either sample size (n) or feature set dimension (p) as large as 1e4, assuming only a small proportion of the features were corrupted. Our algorithm decreases the bias on the coefficient vector compared to a simple LASSO algorithm, while it limits the number of false positives. Computational times are reduced relative to full CoCoLasso.

**Discussion:** This work has promising applications. When trying to predict complex traits such as osteoporosis, it may be interesting to mix genetic features with lifestyle features. Although the former, after imputation, can be considered as almost without error, the latter often suffers from missing data. Applying this block alternating CoCoLasso algorithm to such data could allow improvements of explained variance and take advantage of missing and noisy data.

## **PgmNr 1414: Clinical surface measurements derived from 3D imaging on a mobile device: Semiautomated workflow and results suggest utility for high-throughput phenotyping.**

While dysmorphology plays an essential role in delineation and diagnosis of many human syndromes, the acceleration in use of molecular testing has outpaced capacity to perform comprehensive clinical evaluation. Recent approaches to capture facial geometry using 2D facial images have demonstrated promise for high-throughput phenotyping but are affected by artifacts related to projection distortion that affect measurement accuracy. Capturing 3D images can circumvent these limitations but current devices (3dMD, Atlanta GA) are less widely available due to cost or space limitations.

Infrared based sensors used for facial recognition in mobile phones can capture 3D images for use in clinical measurements. The portability and ubiquity of these sensors may overcome some barriers to the widespread use of 3D clinical surface imaging. Here, we describe and validate a methodology and workflow to obtain clinically relevant dysmorphology measurements in a semiautomated fashion employing a mobile application and custom software.

We developed software to facilitate a workflow that comprises 1) capture of 3D images using infrared sensors from the iPhone X (Apple Inc, Cupertino CA), 2) subsequent semiautomated image analysis to identify facial landmarks based on publicly available models for facial recognition 3) calculation of point-point distances including palpebral fissure length and inner/outer canthal distance. We apply this approach as well as a conventional 3D imaging platform (3dMD, Atlanta GA) and compare measurements for 10 individuals. Measurements were obtained in triplicate for both modalities. Across individuals average differences in linear measurements from 3dMD and the iPhoneX ranged from 0.09-3.3mm for inner canthal distance and 0.33-2.5mm for outer canthal distance. Validation data from a pediatric population will also be presented. Potential sources of error positioning of landmarks during image analysis. As mobile sensors and computing continue to improve they may represent an increasingly important method of capturing clinical phenotypes to facilitate the diagnosis and delineation of syndrome.

## PgmNr 1415: HLA allele imputation with deep convolutional neural network.

### Authors:

C. Chi; L.F. Barcellos

[View Session](#) [Add to Schedule](#)

**Affiliation:** UC Berkeley, Berkeley, California

---

Human leukocyte antigen (HLA) genes in the major histocompatibility complex encode antigen-presenting proteins within the host immune system. HLA alleles are highly polymorphic and many have large effect sizes in autoimmune and infectious diseases, but direct HLA typing is expensive. Existing methods such as SNP2HLA have been developed to perform HLA allele imputation from genotype data. However, while imputation performs well for common alleles, quality drops for less frequent alleles. We investigate whether deep convolutional neural networks (CNN) can improve imputation performance compared to existing methods.

Our dataset is comprised of 5,225 individuals of European ancestry from the Type 1 Diabetes Genetics Consortium (T1DGC), each with 5,698 SNPs genotyped with the Illumina 550K array. HLA alleles were directly typed for *HLA\*A*, *HLA\*B*, *HLA\*C*, *HLA\*DPA1*, *HLA\*DPB1*, *HLA\*DQA1*, *HLA\*DQB1*, and *HLA\*DRB1* at 2-field resolution, with a total of 296 unique HLA alleles. For each HLA locus, we use flanking SNPs within 250 kb to predict the HLA allele. SNPs are first transformed into 5-grams before input into the CNN. Our CNN model consists of an embedding layer to train a feature vector representation for each 5-gram, followed by two 1D convolution layers, a dense layer, and a final softmax output layer for prediction. Performance is evaluated with 5-fold cross validation accuracy, with bootstraps ( $B = 1,000$ ) on the hold-out dataset to establish approximate 90% quantile intervals on accuracy. Our method is compared against SNP2HLA, which is considered the state-of-the-art for HLA allele imputation.

We report evidence that CNN outperforms SNP2HLA. SNP2HLA achieved a 5-fold cross validation accuracy of 96.05%, while CNN achieved 97.20% (97.10%, 97.29%). For each HLA locus, the CNN imputes as least as accurately as SNP2HLA, and significantly more accurately for *HLA\*B*, *HLA\*DRB1*, *HLA\*A*, and *HLA\*DPA1*. An occlusion sensitivity analysis, which blocks out SNPs in the neighborhood of a tag SNP to see how much the probability of the true allele drops, shows evidence that the CNN is indeed predicting HLA alleles using tag SNPs. These results show our application of CNN improves upon existing imputation methodology for HLA alleles.

## PgmNr 1416: Accurate and rapid prediction of first-line tuberculosis drug resistance using machine learning method.

---

Antimicrobial resistant (AMR) infection is one of the main threats to human health. Accurate and rapid in silico AMR prediction approaches are essential for physicians to prescribe the correct antibiotic to patients in a timely and effective manner. Existing knowledge-based AMR prediction tools, such as Mykrobe and ARIBA, process genomic sequencing data of bacterial isolates and achieve varying results: high accuracy on some antibiotics but relatively low accuracy on others. Here we present a machine learning method that predicts AMR to first-line Mycobacterium tuberculosis drugs. This method uses microbial lineage and detected AMR-associated genes and single nucleotide polymorphisms from raw sequencing data as input and completes AMR prediction of a target mycobacterium isolate in 6 minutes requiring only the computational resources of a standard laptop. Using an independent validation data set, in terms of accuracy, we found that this method results in significant performance increase in drugs that previously had relatively poor prediction from the state-of-the-art

knowledge-based method Mykrobe (76.3 % to 89.3% for ethambutol, and 92.5 % to 94.5% for rifampicin), while it performs as well as Mykrobe for isoniazid (96.2%) and pyrazinamide (87.3%).

In addition, the same method we describe here can be directly applied to AMR prediction of different antibiotics for other bacteria, if sequencing data, drug resistance phenotype, and lineage data are available for a large number of strains that cover the existing diversity.

## PgmNr 1417: Evaluation of multi-omic methods applied to immunology.

Future breakthroughs in the field of human genetics will increasingly come from integration of high dimensional datasets. Datasets with sequencing, metabolomics, methylation arrays, and others are now routine; however, these only measure one component of a complex system. Common human diseases appear to be caused by an accumulation of many low-effect variants, many of which exist outside of current genome annotations. Thus, elucidating the causes and therapeutic approaches to common diseases will require a more integrated approach that studies traits at multiple levels of organization.

Traditionally, integrating multiple 'omic datasets has been a serial process where experimental signals from one 'omic assay (e.g., GWAS) are then fed into another 'omic assay for validation or characterization (e.g., RNAseq). This approach prevents the discovery of synergistic effects which may exist between the 'omic datasets. In addition, using the first 'omic dataset to inform analysis of the subsequent 'omics datasets can prevent discovery of novel findings hidden in the latter datasets.

We have compared recently published multi-omic integration methods which analyze datasets simultaneously, including DIABLO, MCIA, and LASSO. Each tool approaches biomarker discovery with related but distinct statistical methods. We have used publicly available data (ImmPort, NIAID) from two different multi-omics datasets, each using a different combination of 'omic datasets. Correlated molecular signals (or a network of them) from transcriptomic, methylation, and metabolomics for two datasets, an influenza vaccine response dataset (n=150) and a newborn development dataset from Gambia and Papua New Guinea (n=50), were discovered and compared between all methods.

## PgmNr 1418: Gene scoring algorithms for identifying disease candidate genes.

A major understanding of the underlying pathophysiology of autoimmune diseases has been evaluated in genome-wide association scans, which have identified a degree of genetic sharing among autoimmune diseases such as rheumatoid arthritis and multiple sclerosis, among others. Based on the potential commonality among immune genes, we design a graph-based gene scoring algorithm. It initially constructs a backbone network based on protein interactions. Then, patient gene expression networks are added into the network. In the add-on process, disease-specific networks were obtained from weighted gene co-expression network analysis (WGCNA) from patients with a specific immune disease. Any WGCNA network that passes the screening procedure can be added on. With the disease-specific network, it employs the semi-supervised learning for gene scoring. The proposed method was applied to 27 immune diseases. Based on the scoring results, gene scoring identified potential key genes in immune diseases. In terms of prediction performance, an average AUROC of 0.82 was achieved, lifted from Avg. 0.76. Highly ranked genes are evidenced through retrieval and review out of PubMed literatures.

## **PgmNr 1419: The investigation of cell separation-induced gene expression via a penalized deconvolution approach.**

Recently, there has been increasing interest in studying genomics and transcriptomics at the single cell level. One of the keys to single-cell study is the success of developing cell sorting technology that is used to separate cells according to their type. However, the process of cell isolation changes the cell microenvironment that affects the gene activity, and thus, the gene expression change induced by cell separation can bias the conclusion of the single-cell study. To address the perturbation of the gene expression caused by cell sorting, we proposed the statistical deconvolution approach, named PEACH, to decompose the cell type-specific expression from bulk tissue and at the same time identify the genes that are expressed differentially to the pure cell samples that were affected by the cell sorting procedure. In this study, PEACH uses cell type-specific samples as the reference to estimate the underlying cell proportions of bulk samples with immune-related diseases and to identify the genes changing in its expression. As a result, the genes we identified are related to biological functions such as stress-responsive transcription factors, cellular metabolism, ribosomal proteins, and human leukocyte antigen. Our study illustrates that genes sensitive to the cell sorting process are biological meaningfully and non-negligible, and it may provide new insight into single cell study for transcriptomic analysis.

## PgmNr 1420: Navigating the treacherous waters of HLA imputation with the SHLARC (SNP-HLA Reference Consortium).

### Authors:

N. Vince <sup>1,2</sup>; V. Douillard <sup>1,2</sup>; S. Limou <sup>1,2,3</sup>; P.A. Gourraud <sup>1,2</sup>

---

The HLA region plays a crucial role in numerous pathologies as it accounts for 25% of known associations from the GWAS catalog, especially with immune-related diseases. Although SNP association studies importantly expanded in the last decade, direct HLA allele association has been hindered by the complexity of typing. HLA imputation offers a statistical alternative to current HLA typing, cutting costs and time alike. Customized machine learning models using attribute bagging, available within the R package HIBAG, can be generated from individuals with known SNP+HLA data to allow prediction of HLA alleles from SNPs. The composition of these models (or reference panels) highly affects imputation accuracy as target populations differ in both SNP and HLA allele diversity and frequency. To assess parameters potentially impacting this accuracy, we used close to 2,000 individuals from the 1000 Genomes Project and an African-American population. Our results demonstrated the effect of: 1) sample size, with a 2x increase (average of 45% to 86%) in accuracy from 10 to 100 individuals; 2) SNP number, accuracy improved from 75% to 86% with 100 to 5,000 SNPs. Additionally, we showed that custom models (i.e. taking only matching SNPs between reference panels and individuals to impute: reducing 2-15x the number of SNPs) can significantly reduce computation time and limit the prior need for SNP imputation. Our results contribute to define gold standards on how to dive in the HLA imputation waters, and call for further collective expeditions to grasp the role of pre-modelling, with population matching and identification of essential SNPs. We have therefore launched an IHI workshop component named 'SHLARC' ([bit.ly/2WGw8hr](https://bit.ly/2WGw8hr)) to gather immunogeneticists on a unique platform 1) to build and share large public reference panels with anonymized data, or 2) to directly impute HLA from SNPs, using our on-demand computation power. Moreover, we started to assemble scientists with complementary expertise (immunology, bioinformatics, informatics, intensive computing, artificial intelligence, inflammation diseases, population genetics, genomics, kidney diseases, immunogenetics, transplantation) from 18 labs in 10 countries and 4 continents aiming to collect data but also to improve methods and facilitate access to HLA imputation models. Altogether, we believe sharing SNP+HLA data in a global consortium will be beneficial to all and place HLA association at the forefront of immunogenomics.

## PgmNr 1421: HLA-poll, surveying tools for multiple HLA-prediction computational programs from WES/WGS data.

**Background:** Human leukocyte antigen (HLA) typing is crucial for donor-recipient matching in solid organ and stem cell transplantation as well as for a selection of suitable subjects in certain immune therapy. The traditional HLA typing methods are generally time and labor consuming. As sequencing costs drop exponentially, whole exome or genome sequencing (WES/WGS) has become a widely acceptable method-of-choice for genetic diagnosis and precision medicine, which pushes the demand in silico HLA typing on WES/WGS data.

**Methods:** We performed WES and WGS for GIAB NA12878 trio DNA sample and compared to a truth set on three Class I and three Class II HLA genes. WES with 80x coverage was also performed for 16 samples of donor-recipient pairs from stem cell transplantation and we compared the result to the clinically certified HLA-typing result using PCR method with sequence-specific oligonucleotide (SSO) probes. We built a capsulated pipeline HLA-poll, which surveys the HLA typing result from six computational algorithms; HLA-HD, HLAMiner, HLAScan, HLA-VBseq, Kourami, and Polysolver and generate a combined calling report.

**Results:** For the GIAB trio WGS, HLA-HD, Kourami, and HLA-scan all have >95% positive predictive value (PPV) and <5% false discovery rate (FDR). For the GIAB trio WES, HLA-HD demonstrated the best performance in PPV and FDR in comparison to five other algorithms. For the 16 clinical samples, both HLA-HD and Kourami have >95% PPV and <5% FDR. Our HLA-poll passes the >95% PPV and <5% FDR thresholds in all three cohorts.

**Conclusion:** Although various algorithms are available for in silico HLA typing on WES/WGS data, each algorithm has strengths and weaknesses. Most of the algorithms performed better in WGS than in WES. Class I HLAs are generally typed with better accuracy in comparison to Class II HLAs. By combining six algorithms, our HLA-poll showed convincing performance across various examined HLA classes in tested WES and WGS samples. Our method can be also applied to several Class III genes which needed to be validated with a diagonal truth set data.

## PgmNr 1422: Machine learning feature selection integrated with co-expression and Bayesian network analyses further elucidates inflammatory bowel disease in a large multi-omics cohort.

In the Big Data era of biology, -Omics technologies provide a wealth of information, but obtaining useful knowledge from this abundance of data can pose a challenge for researchers. Machine learning classifiers are a useful tool for exploring large datasets, but their performance can be stunted in cases where relatively few features (e.g., genes) are important for prediction, and those features that are chosen to maximize prediction accuracy may not relate directly to biological processes. To improve this, we have utilized a machine learning feature selection and classification strategy which relies on iterative feature ranking that is robust to these limitations. Application of our approach to RNA sequencing data generated on intestinal biopsies isolated from an Inflammatory Bowel Disease (IBD) cohort comprised of Ulcerative Colitis (UC) and Crohn's Disease (CD) patients and controls, resulted in the identification of a focused, stable, and predictive classifier that could well distinguish IBD cases from controls based upon a set of predictive genes identified by our feature selection strategy. The predictive set of genes identified were enriched in highly interconnected modules derived from the RNA-sequencing data, indicating mechanistic links of the machine learning classifiers to the underlying biological processes and disease phenotypes. Bayesian networks were created from these machine learning features and co-expression modules to uncover how these genes interact with each other and how they differ within disease and non-disease states. The synergy of the classifiers, co-expression, and Bayesian networks are being used to further elucidate differences between not only IBD and healthy controls, but also differences between UC and CD in various intestinal biopsy tissues. This feature selection strategy effectively reduces the dimensionality of a large RNA-seq Inflammatory Bowel Disease dataset (~100 genes per classifier with Receiver Operator Curve Area Under Curves: 0.7 - 0.9) while reflecting a greater predictive biological context of disease as shown in the enriched co-expression modules. Key Driver Analysis performed on the Bayesian networks uncovered genes that potentially modulate disease state. Future direction will be leveraging the classifiers, co-expression, and Bayesian networks to form a multi-omics model that incorporates the other datatypes from the cohort in an effort to better predict phenotypic outcomes of treatment effects.

## PgmNr 1423: A novel algorithm for *KIR* copy number imputation by KIBAG and consolidation of population specific *HLA* & *KIR* references in HKimpNet (*HLA* & *KIR* imputation network).

---

Natural killer (NK) cells are essential in innate immunity as well as playing a role in antigen-specific responses. NK cell activity is genetically modulated by differential expression of inhibitory and activating killer cell immunoglobulin-like receptors (*KIR*) that recognize *HLA* class I ligands. The high level of both allelic and gene copy number polymorphism of *KIR* may have resulted from selection pressure driven by exposure to a wide variety of diseases, possibly in parallel with or causally related to selection pressure underlying *HLA* polymorphism. Indeed, coordinated *KIR*-*HLA* associations have been detected with HIV infection, hepatitis C infection, human papilloma virus (HPV) induced cervical cancer, psoriatic arthritis and type 1 diabetes. With the recent advancement of next generation sequencing (NGS) technology, *KIR* can now be characterized to high resolution including *KIR* gene copy number (CP), *KIR* haplotypes and *KIR* allele types. However, *KIR* gene detection is currently very limited when examining genome wide SNP data from GWAS studies using conventional computational methods, despite the high-density SNP coverage. Thus, we developed a new methodology named KIBAG (*KIR* Genotype Imputation with Attribute Bagging) which enables a rapid and inexpensive way to determine *KIR* typing from a GWAS dataset. *KIR* typing of 726 Japanese individuals and 2,383 individuals from a wide range of populations was performed using the Scisco Genetics *KIR* typing kit and the Illumina Miseq sequencing system. SNP information of these samples were determined by a combination of genotyping platform including Illumina Omni 2.5, Affymetrix Axiom Japonica V1 & V2 and Affymetrix 6.0. *KIR* reference types were generated by the attribute bagging method applied in KIBAG. Both internal validation and external validation of *KIR* CP imputation were performed and average accuracies of 97.9% and 95.7% were obtained respectively across 16 *KIR* genes. However, *KIR* with > 2 copies remain the most difficult to impute due to the insufficiency of individuals with 3 gene copy numbers of any given *KIR* gene in the reference panel. Re-examination of GWAS with *HLA* class I associations or with SNP peaks in the *KIR* region may reveal novel *HLA*-*KIR* associations. This work is part of the project of HKimpNet (*HLA* & *KIR* Imputation Network) with the aim of providing

population specific *HLA* & *KIR* imputation systems to the research community.

## PgmNr 1424: Towards HLA-VBSeq v3: An HLA calling package for HLA class I and II.

---

**Introduction:** The human leukocyte antigen (HLA) system, which is the most variable gene region in the entire genome, encodes the major histocompatibility complex (MHC) proteins in humans on chromosome six and has been reported to be associated with numerous immune-mediated diseases. Various HLA calling tools from whole genome sequencing data (WGS) have been developing. Our tool HLA-VBSeq v1 (Nariai *et al.* BMC Genomics 2015) is one of the tools to estimate the most probable combinations of HLA genotypes from the multi-mapped reads to the HLA reference sequence. From the limitation of this approach, the HLA calling accuracy partially depends on the haplotype coverage of HLA reference sequence. The largest international HLA sequence database IPD-IMGT/HLA still cannot fully cover especially population specific HLA haplotypes. The situation was not exceptional to the Japanese population.

### Materials and Methods:

To solve the problem, we have recently developed a new package HLA-VBSeq v2 (Wang *et al.* Human Genome Variation 2019) that integrate the novel HLA Class I sequences constructed from PacBio sequencer that cover the full gene body regions to the major haplotypes of HLA-A, HLA-B, and HLA-C in Japanese (Mimori *et al.* Pharmacogenomics J 2019). In addition, we have also extended the core implementation of HLA-VBSeq v2 to estimate accurate haplotype combinations especially for the recent high coverage sequencing data (more than 30x) from short-read sequencer towards the release of HLA-VBSeq v3,

**Results:** We evaluated the performance of HLA-VBSeq v3 by using 418 Japanese samples as testing data, in which HLA genotypes were determined with both Luminex technology and WGS HLA typing kit. All of the tests were implemented based on 4-digit resolution. As a result, the calling performance of both HLA class I and II in Japanese population is significantly increased compared to HLA-VBSeq v1.

**Conclusions:** HLA-VBSeq v3 is the better calling tool for the former package v1 and v2. The software will be available from (<http://nagasakilab.csml.org/hla/>) as HLA-VBSeq v3.

## PgmNr 1425: A novel workflow for identifying causal variants underlying multivariate GWAS results.

Multivariate analysis of correlated traits increases power compared to univariate analysis. To date, however, multivariate genome-wide association studies (GWAS) have had some evident shortcomings: they have lacked essential tools for follow-up readily available for univariate GWAS, such as fine-mapping. Here we introduce a novel fine-mapping workflow that integrates Canonical Correlation Analysis (CCA) of correlated traits to boost statistical power of identifying causal variants from multivariate GWAS summary statistics.

We performed multivariate GWAS for 12 highly correlated inflammatory markers in the population-based FINRISK study of 6,890 Finns using metaCCA, a software implementing CCA for univariate GWAS summary statistics. In multivariate GWAS, CCA aims to find the linear combination of the phenotypes that is most highly correlated with a particular variant. We further developed metaCCA to produce these linear combination phenotypes (LCP) at a single variant level allowing us to perform LCP-GWAS detecting 11 independent genome-wide significant loci, 3 of which were not detected by univariate method. We used FINEMAP, a software aiming to identify causal variants from summary statistics using the Shotgun Stochastic Search, to identify causal variants from LCP-GWAS summary statistics.

Overall our FINEMAP results were very much in line with both multivariate GWAS and stepwise conditional analysis. FINEMAP increased the number of variants of interest from 11 lead variants from multivariate GWAS to 18 putative causal variants. In the *PCSK6* loci the top configuration included 3 variants among which rs2955967 and rs6598475 showed disease associations ( $p < 1e-4$ ) in the large Finnish FinnGen study ( $N = 135,638$ ). We also detected a Finnish specific missense variant rs200532195 in the *F5* locus with a higher probability of being causal than the lead variant in the locus. These variants would have gone undetected without LCP-GWAS and fine-mapping.

Our results demonstrate that multivariate GWAS outperforms univariate GWAS and fine-mapping multivariate GWAS results further increases the number of interesting variants. In conclusion, we introduce a novel and simple workflow that enables fine-mapping of multivariate GWAS signals, an important follow-up analysis previously only available for univariate GWAS results.

## PgmNr 1426: Algorithm for gene regulatory network inference recovers biological insights from large-scale gene expression data.

Gene regulatory network (GRN) is a set of causal interactions between genes underlying observed gene expression levels changes in response to external stimuli. Such networks are widely used in network analysis tools where perceiving gene regulation mechanisms help unravel hidden causes behind experimentally observed data. Currently existing methods for inference of GRNs do not allow processing the data of the real experimental size in current human studies. We developed a probability-based GRN inference method with ability to process tens of thousands of genes in reasonable time with robust and reproducible performance. We present new method based on Monte-Carlo Markov Chain (MCMC) approach. To improve quality of resulting GRN we propose an approach of careful data discretization. However, this requires additional time in network likelihood estimation. To resolve this issue and overall high complexity of the problem we provide an efficient way of storing computed probabilities along with advanced computational approach in running MCMC. We evaluated our method on simulated data to confirm its superior properties both in solution quality and resource usage compared to the known methods. Further, we used Brain Span developing brain expression data to construct regulatory networks that change significantly between pre-natal and post-natal conditions. Relating the observed gene regulation patterns we investigated relevance of gene expression regulatory genes in our network to known intellectual disability and autistic spectrum disorders. **In summary**, we present the first to date method allowing processing of the full-size human gene expression data to reconstruct regulatory interactions pattern.

## PgmNr 1427: *slivar*: Flexible filtering and annotation of genetic variants with simple expressions.

### Authors:

B.S. Pedersen; A.R. Quinlan

[View Session](#) [Add to Schedule](#)

**Affiliation:** Human Genetics, Salt Lake City, Utah.

---

*slivar* is a suite of command-line tools that facilitate rare disease research. It operates directly on data in variant call format (VCF) using a simple expression language that allows users to apply customizable filters. For example a filter to find *de novo* variants could be:

```
variant.FILTER == "PASS" && INFO.gnomad_popmax_af < 0.005
&& kid.het && mom.hom_ref && dad.hom_ref
&& kid.DP > 7 && mom.DP > 7 && dad.DP > 7
```

This example query enforces the expected genotype pattern for a *de novo* mutation and requires a sequencing depth of more than 7 in all three samples. In addition, it requires that candidate mutations are also rare in gnomAD, according to an annotation in the INFO field. Finally, to ensure high quality candidates, it requires that the FILTER field of the variant would be 'PASS'. This expression would be **applied to each variant, for each trio** discovered from the VCF and a pedigree file that indicates the relationships among samples.

Because of the utility of the (gnomAD) population allele frequency in rare disease research, we have created a special format and annotator within *slivar* that reduces, for example, the whole genome gnomAD VCF from 450 gigabytes down to about 2 gigabytes for selected annotations. This reduced file allows *slivar* to annotate more than 20 thousand variants per second.

We show that combining *slivar*'s fast expression language with population allele frequency filtering reduces the number of candidate variants to about 15 for a typical rare-disease trio in a matter of seconds. This number can be further reduced by filtering on the functional status (missense/stop-gained/synonymous) of each variant. This includes variants meeting *de novo*, X-linked recessive, X-linked *de novo*, compound heterozygous and single-site autosomal recessive inheritance patterns. We have encapsulated these analyses into a simple, best-practices workflow for rare-disease trios.

*slivar* is available under the MIT license at: <https://github.com/brentp/slivar> with the rare-disease commands at: [http://bit.ly/slivar\\_rare\\_disease](http://bit.ly/slivar_rare_disease)

## PgmNr 1428: Game theoretic centrality supports link between autism spectrum disorder and the HLA complex.

---

Complex genetic diseases with etiological heterogeneity like Autism Spectrum Disorder (ASD) often pose a challenge for traditional genome-wide association study approaches in defining a clear genotype to phenotype model. We propose applying a new method based on coalitional game theory that can capture the combinatorial interaction of mutations that manifests into a disease.

Coalitional game theory is used to model interactions among players--in our case genes--when they form coalitions. This approach has been previously employed to identify candidate genes in gene expression and whole genome sequence data. We applied a game theoretic centrality measure based on *Shapley value* to rank genes by their relevance--the individual gene's synergistic influence--in a protein-protein interaction network. Shapley values measure the average marginal contribution of a player across all possible coalitions. *Game centrality* extends the notion of Shapley value to the evaluation of a gene's contribution to the overall connectivity of its corresponding node in a biological network. Each of the nodes can also be assigned a weight based on *a priori* importance of the genes. Compared to other commonly used centrality measures such as degree centrality and betweenness centrality, game centrality takes into account not only the contribution of a single gene to the network, but also the interaction with all possible groups of genes.

We implemented and applied this method to rank genes using game centrality on whole genomes from 756 multiplex autism families. Likely gene disrupting mutations in coding regions were encoded into case (ASD) and control (unaffected) binary matrices. Genes harboring these mutations were used to generate a protein-protein interaction graph with STRING. We computed game centrality on this graph both with and without *a priori* knowledge--corresponding Shapley values computed from the binary matrices. The top five percent genes with the highest game centrality in both approaches were enriched for pathways of the immune system. In particular, three of the 19 selected genes--HLA-B, HLA-G, and HLA-DRB5--are part of the human leukocyte antigen (HLA) complex, which has been previously associated with ASD. These results suggest that game centrality can identify influential, disease-associated genes within biological networks, thereby decoding the polygenic underpinnings of complex diseases like autism.

## PgmNr 1429: Transcript mediation analysis of multi-trait associations.

**Authors:**

B. Wu

[View Session](#) [Add to Schedule](#)**Affiliation:** Division of Biostatistics, University of Minnesota, Minneapolis, Minnesota.

---

Recent research has suggested that the transcript expression plays an important role in the genetic architecture of most complex human traits: they can act as a direct or indirect mediator for the genetic effects on most clinical phenotypes. Utilizing the publicly available GWAS summary data and the large-scale gene expression and genetic data from GTEx project, and further capitalizing on the widespread pleiotropy association across multiple traits, we set out to develop novel methods and tools for studying the transcript mediated multi-trait associations. Our methods can quantify the contribution of mediated association and the residual association, which on the other hand can help boost our power to better detect those genetic variants that are significantly associated with multiple correlated phenotypes.

We will demonstrate the utility of our proposed methods through rigorous numerical studies and analysis of GWAS summary data for multiple lipids traits. Our approach identified many novel loci that were not detected by the existing methods, and also provided novel insights into the underlying genetic architecture of lipids traits.

---

Modern high-throughput technologies provide highly informative multivariate profiles of an exposure or an intervention, often manifested as quantitative changes in the affected traits. Finding similarities between such profiles of an intervention and genetic variants can pinpoint to important targets at the genetic level. Here, we aim to develop a statistical method to rank “candidate profiles” according to their similarities to a given “target profile”.

In our test case, we define a target profile as changes in 53 circulating metabolites associated with starting statin therapy, measured by a nuclear magnetic resonance platform, and we define the candidate profiles as effect sizes of different genetic variants on the same traits, estimated by genome-wide association studies (GWAS). Our goal is to identify the variants that lead to similar changes in the circulating metabolites as the statin therapy.

Conventional solution is to rank the variants by their correlation to the target profile. However, this approach does not account for uncertainty of the estimated effect sizes or the correlations among traits. Therefore, we adopt a Bayesian approach that incorporates these additional sources of information into the posterior distribution of the profiles. We then rank genetic variants by the Wasserstein distance between the posterior distributions of the genetic variant and the target profile. Our simulation results indicate that the ranking based on the Wasserstein distance of the posteriors (WDP) outperforms the correlation-based ranking (COR), especially when the number of traits included in the profiles is small.

We observe a similar behavior when we use GWAS data from Finnish samples (n=10,753) at 156 lipid-associated SNPs to search for genetic variants which have similar metabolic profile to starting statin

therapy. When all 53 traits are available, the top five variants selected by both methods are near the genes *LDLR*, *SORT1*, *APOC1*, *HMGCR* and *APOB*, which is consistent with known function of statins. If we use only the three standard measurements of LDL-C, HDL-C and TG, the ranks assigned to these genes become 1, 2, 3, 5, 11 with WDP and 17, 14, 31, 35, 42 with COR. To sum up, WDP seems to be a more reliable approach for ranking similarities between multivariate profiles than COR, as it is more robust to the number of traits available. Hence, we expect that WDP proves useful to identify new genetic targets that resemble profiles of successful interventions.

## PgmNr 1431: Precision genotyping of APOE from whole genome sequencing.

As APOE e4 is the strongest risk allele for Alzheimer's disease (AD), the accurate genotyping of APOE is important for both AD research and precision medicine. The genotype is based on two non-synonymous variants (rs429358 and rs7412) within 138 bp of each other. AD researchers have typically called these two variants with RFLP analysis or more recently, TaqMan SNP genotyping. GC-rich genes such as APOE have been difficult regions for whole genome sequencing for calling both SNPs using PCR+ libraries. With the availability of PCR Free (PCR-) sequencing, the GC-rich APOE region should result in better genotype quality and a higher call rate for the 2 APOE variants.

We evaluated our APOE genotyping pipeline on 4789 Alzheimer Disease Sequencing Project WGS samples with both PCR+(N=479) and PCR-(N=4310) libraries with 30x coverage aligned to GRCh38. The APOE WGS pipeline achieves greater than 99.9% accuracy for joint-genotyped whole genome sequencing samples in both PCR+ and PCR- WGS using a "gold standard" based on RFLP and TaqMan genotypes.

To achieve this accuracy, the pipeline uses GATK HaplotypeCaller (4.1.1) with a filter for bacterial reads. We had found reads from bacterial contamination had aligned near rs429358 and interfered with the HaplotypeCaller genotyping. The poor genotype quality (GQ<20) occurred in approximately 2% of the APOE genotype calls for SNP rs429358. Without the bacterial reads, the GQ scores passed (GQ ≥20). To fill-in missing SNP calls (3%) due to low coverage in the PCR+ samples, the VCF was phased with Eagle 2 and then genotyped with the APOE-Genotyper tool.

The WGS APOE calls had a concordance of 99% with the original "gold standard". We selected 18 of the 56 samples that were discordant for retesting and found 17 of 18 samples agreed with the WGS APOE calls. The single WGS ApoE call that was incorrect was due to a low level of human DNA contamination found in that sample (3%). Such human DNA contamination will be taken into account in a future version of the pipeline.

We found that highly accurate APOE genotyping can be achieved in PCR- and PCR+ WGS with the developed pipeline. With the updated "gold standard", we demonstrate that genotypes based on WGS achieved higher precision than lab-based approaches. The APOE pipeline should be useful for high

throughput precision genotyping of APOE calls in large scale sequencing projects such as TopMed and UK Biobank where readily available lab-based calls are not available.

## PgmNr 1432: Circadian phase inference in single-cell RNA-seq.

---

Disruption of the circadian clock and transcriptional timing are common features of aging and age-related disease such as Alzheimer's disease (AD). Characterizing changes in transcriptional timing will be important for understanding the biological consequence of these changes, identifying their cause, and understanding how to prevent/reverse their deleterious effects. Previous bulk RNA-seq time courses have reported age-related damping of circadian rhythms. However, such approaches may be confounded by circadian phase heterogeneity across cells from different types, suggesting the need for single-cell transcriptional measurements, such as single-cell RNA-seq (scRNA-seq). Using scRNA-seq data to study transcriptional timing requires methods to assign internal biological times to cells, such as placement in the circadian cycle. While computational phase inference methods have been developed for bulk RNA-seq samples, no approaches have been developed for scRNA-seq. To fill this gap, we develop a neural network autoencoder based approach for single-cell circadian phase inference. To capture circadian phase information, we introduce two circular nodes in the autoencoder latent space. By constraining their values to lie along the unit circle, these two nodes can capture angular information, and hence be used to infer circadian phase. We further include other latent variables to account for the contribution of other potential confounders, such as batch effect, to gene expression variation. Although autoencoders are ideally suited to model circadian phase, neural networks are an inherently challenging tool due to their non-convex optimization. To improve parameter search for neural networks, we propose an approach that improves both autoencoder training times and reconstruction errors using existing scRNA-seq datasets and simulated data. This method will also be applied to an ongoing scRNA-seq study on AD, which includes 146,473 cells generated across 15 human brains. Disruption in circadian rhythms are common symptoms of AD. By applying our method to this phenotypically well characterized dataset, we expect to find altered patterns of gene expression timing that are associated with AD. With the growing popularity of scRNA-seq in biomedical research, we believe our method offers the community a robust tool that enables the inference of circadian phase with single-cell resolution.

## **PgmNr 1433: MSeqDR mitochondrial disease data interpretation platform: Quick-mitome, registry, genome, and literature mining.**

---

MSeqDR (<https://mseqdr.org>) is a centralized genomic bioinformatics Web resource that supports genetic analyses and variant interpretation for people working in mitochondrial biology and disease. MSeqDR is a central data resource hub for the mitochondrial disease community, including MitoMap, HmtDB, LeighMap, ClinVar, ClinGen, PhenoTips, and GENOMIT resources, facilitating data sharing, cross-referencing, and active collaboration.

MSeqDR Content and Tool Update: Genome and phenotype data has been enhanced by assembling a large meta-population reference dataset for mitochondrial DNA (mtDNA) allele population frequencies, compiling ~90K mtDNA genomes from MitoMap, GeneDx, publications and sequencing initiatives, with substantial amount of data from Asian populations. MSeqDR-LSDB is a curated database of pathogenic variants for mitochondrial diseases, genes, and variants generated by data mining and systematic curation of public genomic resources and literature. It hosts 12,000+ variants from 1,607 genes related to mitochondrial function, including over 350 known disease genes with pathogenicity assessments for over 8,000 variants. We also developed a suite of bioinformatics tools to annotate and analyze mtDNA genome variants (MSeqDR-mvTool and Phy-Mer) and centralized access to a suite of tools hosted in or linked to MSeqDR, such as MToolBox from HmtDB, MitoMaster from MitoMap, MitoTIP, and LeighMap.

The mitochondrial disease data interpretation platform is built upon the above rich data content and tools to assess variant pathogenicity. Quick-Mitome automates online Exomiser analysis of whole exome/genome datasets. Then the candidate variants are deeply annotated with disease and mtDNA data. The unified report summarizes the Exomiser ranking and all relevant MSeqDR data. The literature mining tools process mitochondrial disease, variants, genes entries from Pubmed services including pubtator, and reconstruct the variant to disease associations. MSeqDR “pseudo” case registry for rare Leigh disease mines publications to compile the anonymous case level data from over 800 cases.

Overall, MSeqDR now provides extensive sets of genomic data, diverse bioinformatics tools that support mtDNA variant annotation, and haplogroup determination, exome data analysis guided by clinical feature. MSeqDR is now recognized world-wide as the genomic and data collaborative hub

supporting the mitochondrial biology and disease diagnostic research community.

## PgmNr 1434: Computational pipeline for RNA-seq based genetic diagnosis.

RNA sequencing has become a useful companion to DNA sequencing to diagnose patients with genetic disorders [1,2]. Specifically, three patterns (aberrant expression, aberrant splicing and mono allelic expression) can be detected from RNA-Seq data and used to prioritize candidate variants and genes. Although statistical methods for detecting each of these three patterns have been developed, a pipeline that integrates them and automatizes the generation of results from raw files is lacking and very much needed to analyse cohorts of hundreds of patients. Here, we present such an end-to-end pipeline that not only reports gene candidates from RNA-Seq data, but also summarizes and annotates variants called from DNA sequencing. The pipeline is based on the workflow management tool Snakemake [3] and wBuild [4]. It is built in R in a modularized fashion, so that the user can select which of these three patterns to use. The Snakemake framework makes it possible to interrupt the pipeline and resume it at any point without having to rerun previous steps that do not need to be updated. It also offers a parallelized backend, which allows to execute same processes on different samples at the same time and make effective use of compute clusters. Moreover, the wBuild functionality renders the scripts in HTML format for convenient visualization. This pipeline makes such analyses more stable and simple for larger sample sizes. We have successfully used it to analyze more than 200 patients with rare mitochondrial disorders. Overall, we foresee that the pipeline can be easily deployed on different environments and extended to include other multi omics modules.

---

Glucose-6-phosphate dehydrogenase (G6PD) deficiency is one of the most common human enzymopathies in the world and is inherited in an X-linked recessive manner. Defects in the G6PD enzyme results in the destruction of premature red blood cells leading to hemolytic anemia, which is usually triggered by the presence of oxidative agents. To date, more than 200 genetic variants of *G6PD* have been identified globally, however, none were reported in the Qatari population, although the disease incidence is around 5%.

In this study, we aim to investigate the genetic basis of G6PD deficiency in Qatar using the Qatar Genome Project (QGP) data, which consists of whole genome sequencing data (WGS) of 6,000 Qatari nationals and long-term residents of Qatar generated using the Illumina HiSeq X Ten1 platform. After processing the WGS data, we identified 21 high impact, 17 moderate impact, 19 low impact, and 320 modifier impact variants, based on SnpEff annotation, that are located within or near the *G6PD* gene. We focused on moderate and high impact variants and used various variant databases and computational analysis tools to investigate their pathogenicity. Among those variants, p.S188F (*G6PD Mediterranean*), p.N126D (*G6PD Ilesha*), p.V68M (*G6PD Asahi/A-*), and p.A335T (*G6PD Chatham*) were the most common known G6PD disease-causing variants seen in Qatar. In addition, we revealed 10 novel variants in the *G6PD* gene (5 high impact and 5 missense variants). We performed molecular visualization analysis of the G6PD variants using PyMol to assess the impact of three novel missense variants and seven reported variants on the protein structure. The novel variants seem to affect G6PD structure and they merit further validation and functional investigations in order to establish genotype-phenotype correlation. This study is the first to address the genetic basis of G6PD deficiency in Qatar and it highlights the importance of investigating such understudied populations in providing novel insights about the disease's pathogenesis.

## PgmNr 1436: Mitochondrial heteroplasmy: A review of current bioinformatic assessment tools.

**Authors:**

S.S. Chill; A. Baranova

[View Session](#) [Add to Schedule](#)

**Affiliation:** Department of Systems Biology, George Mason University, Fairfax, Virginia

---

Current advancements in next generation sequencing (NGS) technology has increased the resolution of mitochondrial DNA (mtDNA) generate data, allowing for the investigation of features such as heteroplasmy, with greater precision. Heteroplasmy has been identified through several recent studies, although because comprehensive bioinformatic tools have been scarce, data analysis required significant manual manipulation. As associations with complex disease patterns are becoming more evident, particularly as it relates to telomers and aging, tools to automate and standardize processing are in high demand. Four current bioinformatic methods (mtDNA-Server, MitoSeek, MitoSuite, and MToolBox) were assessed, to determine their overall functionality for heteroplasmy discovery, accuracy and consistency with calling features, and availability of quality control metrics. Publicly available data was analysed using each platform, with standard parameters and inputs. While congruency was found between samples (blood and skin) in each platform, the number of heteroplasmic calls, number of congruent pairs between samples, and congruency between heteroplasmic calls on each platform varied. Each platform allowed for automation of many of the steps required to make heteroplasmic calls, however, most still required varying amounts of user manipulation required to obtain heteroplasmy results. Additionally, users were required to curate the final results in terms of heteroplasmic matches among sample types and across platforms, in addition to integrate pathogenic variant information to the heteroplasmic findings on most platforms. Overall, while tools have advanced to allow for more automated calling, differences in platforms calls, in QC metrics, and in input type, demonstrate some of the current bioinformatic needs in the field.

## PgmNr 1437: Assessing and improving mitochondrial haplogroup assignments with low-coverage, genotype data.

Many loci within the mitochondrial DNA are polymorphic in the general population allowing over 5400 haplogroups to be defined by these variations. This makes choosing a set of SNPs for efficient haplogrouping of mtDNA a challenge.

We employed the 1000 Genome sequence data to develop a method to assess the accuracy, precision and efficiency of individual haplogroup prediction based on SNPs typed by the UKBiobank (UKB).

Our protocol involves; (1) Haplogroup assignment (using haplogrep) of individuals in the 1000 genome dataset, (2) Extraction of variation from this dataset based only on loci typed in the UKB dataset, (3) Haplogroup assignment of individuals based on this subset of variation, (4) Comparison of the two assignments. (5) Assessment of success rate by sample and haplogroup, (6) Reduction of precision, by haplogroup, until every group member is perfectly accurately defined.

When samples assigned to haplogroups on the UKB loci variations alone were compared with the gold standard results from the full data, we saw a collapse of 1137 subgroups down to 260 but only H and M contained samples from other letter branches. For example, 687 samples were correctly assigned to L but fell into just 40 of 224 possible, gold-standard subgroups. We had to reduce subgroup specificity of 11 of the 40 to ensure every subgroup member was assigned accurately. In 9 of these 11 adjustments, we were reducing precision for a small minority of samples (N<9) to guarantee group accuracy.

Beyond our specific use, this work flow allowed us to develop a more general tool for the investigation of a batch of SNPs before committing them to a microarray chip and also determine accuracy in other datasets.

The needs of a project will vary according to their target populations and their accuracy threshold. The success of their SNP combination can be visualised on a dendrogram and we can also predict groups obscured by a lack of defining SNPs, and where they will appear in the tree.

Our work has explored the SNP choices made for the microarray chip used by UKBiobank , with a long view to extend inferences and effectively 'impute' the variation in their individuals. This will greatly improve exploration of the effects of mito-nuclear interaction on human health, looking into the

complexities introduced by mito-nuclear ecology potentially throughout the gamut of phenotypes collected by UKB.

## PgmNr 1438: The added value of RNA sequencing over WES for variant interpretation and diagnosis of patients with rare genetic disorders.

---

RNA sequencing (RNA-Seq) is a promising technology to complement Whole Exome Sequencing (WES) for pinpointing the genetic cause of Mendelian diseases [1,2]. However, with improved and ever-growing databases of WES and Whole Genome Sequencing, and better variant effect predictors, the relative advantage of RNA-Seq may be questioned. Moreover, the relevance of RNA-Seq performed on non-affected tissues, which are typically more accessible for transcriptome profiling, has been debated. To address these questions, we investigated expression patterns in healthy donors from the GTEx project and performed WES and RNA-Seq of fibroblast samples for a cohort of 196 individuals affected with a rare mitochondrial disease, yielding the largest RNA-Seq compendium for rare disease diagnostics. Disease-associated genes are enriched among the genes expressed in the respective affected tissues. Nonetheless, the majority of OMIM genes are expressed in blood or skin. In particular, over 90% of mitochondrial disease genes and over 80% of OMIM diseases genes are expressed in skin, showing that RNA-seq of accessible, yet not affected, tissues is valuable. We considered three patterns used to prioritize genes: Aberrant expression [3], aberrant splicing, and mono allelic expression and developed a computational pipeline to integrate their results. Underexpression outliers were highly enriched (29% vs 0.1% in non-outliers) for rare (MAF <0.001) and likely expression-disrupting variants (stop, frameshift and splice). Similarly, we found a strong enrichment of rare splicing, intronic and missense variants in splicing outliers (18% of outliers with rare splicing variants vs 3% in non-splicing outliers). Also, monoallelic expressed genes were enriched for imprinted genes and for rare heterozygous stop and missense variants. Altogether, this analysis led to increase our diagnosis rate by 13% by (i) validating or (ii) invalidating the impact of WES variants on RNAs, and by (iii) revealing aberrant expression patterns that could not be predicted from WES data alone. Overall, our study and the computational pipeline we offer will help the rare disease research community by providing insights and tools to efficiently use RNA-Seq data for diagnostics.

---

Studying spatial chromosome structure has increased our knowledge of the underlying biological function of regulatory regions in the human genome. Hi-C data provide population averaged estimates of three-dimension (3D) chromatin contacts in the human genome across different cell types in heterogeneous bulk samples. To effectively leverage insights from the analysis of Hi-C data for clinical application, we must control for the almost inevitable confounding factor of differential cell-type proportions across these heterogeneous bulk samples. Deconvolution methods have been successfully applied to similar problems in the gene expression literature because of the availability of single-cell gene expression data, but such data had not existed in the Hi-C context until recently. To take advantage of these recent improvements, we propose a nonnegative matrix factorization (NMF) based Two-step Hi-c UNSupervised DEconvolution appRoach (THUNDER), to infer cell type proportions from bulk Hi-C data. The first step of our approach selects distinguishing features for every cell type if possible, and the second step leverages these features to estimate cell type proportions. We conducted extensive real, single-cell Hi-C-data based simulations to test our method. We explored both inter- and intra-chromosomal contacts to learn how different Hi-C readouts affect profiling. THUNDER proves robust to the level of Hi-C measurement used. In addition, THUNDER, being unsupervised, allows us to estimate cell-type signatures of 3D contacts under the realistic scenario where the number of contributing cell types are known. This feature of THUNDER is significant given that purified cell-type signatures of Hi-C contacts are not yet available in practice. Our results show that with less information THUNDER outperforms alternatives, including supervised methods such as CIBERSORT. For example, when analyzing interchromosomal contacts, THUNDER achieves a 61.38% reduction in mean absolute deviation (MAD) when applied to Hela-HAP1 mixtures and a 66.52% reduction in MAD when analyzing Patski- mouse embryonic fibroblast mixtures. We believe that our method, which can accurately identify cell type proportions in bulk Hi-C data, will be a useful tool to facilitate appropriate adjustments in subsequent analyses such as exploring differential 3D chromatin organization or investigating the genetics governing chromatin contacts.

## **PgmNr 1440: Development and implementation of a computational workflow for the molecular diagnosis of constitutional syndromes using genome-wide DNA methylation analysis.**

**Authors:**

E. Aref-Eshghi; B. Sadikovic

[View Session](#) [Add to Schedule](#)

**Affiliation:** Pathology and Laboratory Medicine, London Health Science Centre, London, Ontario, Canada

---

Constitutional syndromes frequently present with overlapping clinical features and uncertain molecular findings that result in significant challenges in obtaining a diagnosis. Many such disorders exhibit specific patterns in the epigenome (epi-signatures), utilizing which can assist their clinical diagnosis. We describe the computational workflow for mapping and clinical utilization of DNA methylation epi-signatures in ~30 different syndromes, involving feature selection, unsupervised clustering, and training and validation of supervised classification models. We illustrate the level of overlap and dissimilarities across different syndromes and highlight unusual situations when one syndrome presents with more than one epi-signature, two syndromes with contrasting DNA methylation patterns, and others with overlapping profiles. We discuss the analytical challenges posed by these instances and demonstrate the necessity of the concurrent modeling of multiple epi-signatures for disease classifications. Using a multi-class support vector machine classifier trained on ~1,500 informative CpG sites, we show that one can confidently use DNA methylation data for simultaneous classification of all of the syndromes discussed. We demonstrate the utility of this tool in resolving ambiguous clinical cases and disease screening among unresolved cohorts. Finally, we present the procedure used for the implementation of DNA methylation analysis in the clinical setting including the validation workflow, reporting framework, and early diagnostic yield of our computational tool as a clinical test across multiple clinical laboratories in Europe, Canada, and the US.

## PgmNr 1441: AMELIE 3.0: Continuous automatic reanalysis of undiagnosed patients with suspected Mendelian disease.

### Authors:

G. Bejerano <sup>1,2,3,5</sup>; J. Birgmeier <sup>1</sup>; E. Steinberg <sup>1</sup>; E. Bodle <sup>2</sup>; C.A. Deisseroth <sup>1</sup>; K.A. Jagadeesh <sup>1</sup>; P.D. Stenson <sup>4</sup>; D.N. Cooper <sup>4</sup>; J.A. Bernstein <sup>2</sup>; UDN

---

**Background:** An ever growing number of patients with a suspected Mendelian disease are sent to exome or genome sequencing every year, but only 30% receive a definitive diagnosis. This is partly due to our incomplete knowledge about Mendelian-disease-causing genes. Because a novel Mendelian gene-disease association is published, on average, every other day, thousands of undiagnosed patient cases could receive a diagnosis each year if the genomes were regularly compared to the latest literature. With millions of genomes expected to be sequenced for rare disease analysis by 2025, and over 25,000 peer reviewed papers appearing in PubMed every week, manually reanalyzing undiagnosed patients is not sustainable.

**Methods:** We describe an automatic reanalysis framework for patients with suspected, but undiagnosed, Mendelian disorders. The presented framework automatically parses newly published primary literature about Mendelian diseases. If an article possibly contains a new diagnosis, the system sends a notification to a clinician. We test the accuracy of the system using a “turn back the clock” experiment: we train our system on data available up to 2011 and then test its performance on a large cohort of both singleton patients (where no sequencing data of relatives is available) and trios (where sequencing data of unaffected parents is available) who gradually became diagnosable between January 2012 and the present.

**Results:** Our system is capable of alerting clinicians of newly published, likely diagnostic, articles for a large fraction of undiagnosed Mendelian patients at a practicably low false positive rate. For example given trio data matching current reality, where only ~10% of cases in the undiagnosed patients database become diagnosable per year, a full 1/3 of our alerts offer timely diagnoses, for a yield of over 3/4 of cases.

**Conclusion:** We show that continuous automatic reanalysis of patients with suspected Mendelian disease is feasible in practice and has the potential to expedite the diagnosis rate of patients with suspected Mendelian disease. The new system will be launched at <https://amelie.stanford.edu/>

## PgmNr 1442: Prediction of four novel SNPs V17M, R11H, A66T, and F57S in the SBDS gene possibly associated with formation of Shwachman-Diamond syndrome, using an in silico approach.

### Authors:

---

Shwachman-Diamond syndrome SDS (MIM 260400) is an autosomal recessive disorder. Characterized by exocrine insufficiency of the pancreas, bone marrow hypoplasia resulting in cytopenias, especially neutropenia, variable degree of skeletal abnormalities, failure to thrive, and increasing risk of developing myelodysplasia or transformation to leukemia. SDS is mainly caused by Shwachman Bodian Diamond Syndrome gene (MIM ID 607444). *SBDS* gene is 14899 bp in length, located in chromosome seven in the eleventh region of the long arm, and is composed of five exons. It's a ribosomal maturation factor which encodes a highly conservative protein that has widely unknown functions despite of its abundance in the nucleolus. A total number of 53 SNPs of homo sapiens *SBDS* gene were obtained from the national center for biotechnology information (NCBI) analyzed using translational tools, 7 of which were deleterious according to **SIFT** server and were further analyzed using several software's (**Polyhen-2, SNPs&Go, I-Mutant 2.0, Mutpred2, structural analysis software's and multiple sequence alignment software**). Four SNPs (rs11557408 (V17M), rs11557409 (R11H), rs367842164 (A66T), and rs376960114 (F57S)) were predicted to be disease causing, localized at highly conservative regions of the *SBDS* protein and were not reported in any previous study. In addition, the study predicts new functions of the *SBDS* protein DNA related, and suggests explanations for Patients developing cytopenias and failure to thrive through genetic coexpression and physical interaction with *RBF1* and *EXOSC3*, genes respectively.

## PgmNr 1443: Will variant matching improve the novel disease gene discovery rate?

---

Regardless of the sequencing strategy, the endgame for novel disease gene discovery comes down to identifying multiple affected individuals with similar phenotype and candidate variants in the same gene. For that end, the Baylor-Hopkins Center for Mendelian Genomics (BHCMG) has created GeneMatcher ([www.genematcher.org](http://www.genematcher.org)), a freely accessible website that allows investigators to post genes of interest automatically sending reciprocal emails to investigators who post the same gene. Subsequent follow-up is at the discretion of the submitters. There is also an option to match, based upon OMIM® number, genomic location, and on phenotypic features. The matches in GeneMatcher have supported more than 207 publications on novel disease genes and novel Mendelian diseases. More recently, we have created another data sharing tool, VariantMatcher ([variantmatcher.org](http://variantmatcher.org)), intended to share the data from the sequencing performed at the BHCMG with the public at the variant level. To comply with strict patient privacy and safety codes users of the site must register and be approved by site administrators. Users upload up to 10 genomic coordinates per day to the site and are notified if there is a match or not. The query format is “chr: coordinate refAllele>AltAllele” and is available for genomic builds hg18, hg19, or hg38. Phenotypic features can also be added to the query. When there is a match, both parties will be notified by a simultaneous email that contains the email address of both parties so they can exchange further information about their cases. If a match is not made the queried coordinates can be stored for future matching. The full dataset is not searchable. VariantMatcher contains the rare (MAF <1%), coding (synonymous not included), single nucleotide variants identified in 5,797 VCF files of affected and unaffected individuals sequenced by the BHCMG. As of June 6th 2019, VariantMatcher had 34 users from 13 countries and 4 variants had been matched. Future updates to VariantMatcher will include the capability to query databases such as CaféVariome, RD-Connect, and Illumina CaseLog through the Matchmaker Exchange API that we are developing now. With VariantMatcher we expect to increase our discovery rate by increasing the specificity of our matches, but, nevertheless, incomplete penetrance, variable expressivity of the phenotype, age of onset, and zygosity are some of the factors that should be considered when the phenotypes under investigation are being compared.

## PgmNr 1444: A computational approach for prioritizing potentially syndromic patterns of birth defects involving cleft lip and/or palate.

**Background and Objectives:** Orofacial clefts are among the most common birth defects, and they can occur as part of a variety of syndromes and birth defect associations. However, the prevalence and type of co-occurring birth defects vary between studies, and it is likely that there are additional cleft syndromes that have not yet been described. The goal of this study was to investigate patterns of birth defects that co-occur with cleft lip and/or cleft palate, using an approach capable of assessing high order combinations based on data from a population-based registry. Since other studies have focused on pairwise birth defect combinations and clinical populations, our findings could contribute towards identifying new syndromes and elucidating the genetic etiologies of these birth defects.

**Methods:** We analyzed data from the Texas Birth Defect Registry on 10,011 infants with cleft lip and/or cleft palate delivered between 1999 and 2014 and excluded cases with syndrome diagnoses. We used our new software platform, Co-Occurring Defect Analysis (CODA), to assess all possible 2-, 3-, 4-, and 5-way combinations of major birth defects among these cases by calculating an adjusted observed:expected ratio for each defect combination.

**Results:** We excluded 929 (27%) cases with cleft palate (CP) and 937 (14%) cases with cleft lip with or without cleft palate (CL/P) with syndrome diagnoses. The prevalences of non-syndromic CP and CL/P were estimated as 4.0 and 9.2 cases per 10,000 births, respectively. Approximately 29% of

infants with CP and 24% of infants with CL/P had at least one additional congenital anomaly, while 7% of cases with CP and 5% of those with CL/P had five or more birth defects. For both CP and CL/P, the co-occurring birth defects with the highest observed:expected ratios were in the central nervous and ocular systems. CP was also associated more often than expected with cardiovascular defects, such as VSD.

**Conclusion:** Our study identified patterns of multiple birth defects that co-occur with CP and CL/P more often than expected. An analysis of these high order combinations may lead to the recognition of new syndromic patterns, and a better understanding of the genetic etiologies and developmental mechanisms that underlie the respective birth defects.

## PgmNr 1445: CODA: A platform for assessing patterns of multiple congenital anomalies.

**Introduction:** About 3% of liveborn infants in the United States are affected by a birth defect, and up to one-third of those infants will have multiple defects. Identification of syndromes, sequences, and associations has previously relied on clinicians and researchers recognizing patterns occurring across patients. We present an alternative approach that is based on statistical analysis of large-scale data from birth defect registries.

**Methods:** Our approach involves assessing combinations of birth defects that occur more frequently than expected, using adjusted observed-to-expected ratios for all possible combinations of birth defect categories. To facilitate these analyses, we developed an open source R-based platform, Co-Occurring Defect Analysis (CODA), to systematically evaluate 2-, 3-, 4-, and 5-way combinations of defects observed in a dataset. CODA calculates an adjusted observed-to-expected ratio for a combination of birth defects that accounts for nonspecific co-occurrence of anomalies. To demonstrate feasibility, we analyzed data from the Texas Birth Defects Registry (1999-2014) using a Dell OptiPlex 7040 x64-based PC (Intel Core i7-6700 CPU, 3.40 GHz, 4 core, 16 GB RAM) running Windows 10.

**Results:** Using CODA to analyze Texas Birth Defect Registry data (175 birth defects in 206,784 cases), adjusted observed-to-expected ratios were calculated for 8,455 2-way combinations, 105,412 3-way combinations, 528,287 4-way combinations, and 1,473,775 5-way combinations. CODA ran efficiently, outputting results for 5-way combinations in 18.2 hours.

**Conclusion:** CODA can facilitate large-scale analyses of co-occurrence patterns in birth defects registries. Recognition of novel patterns of multiple anomalies may indicate a shared genetic basis

that should be further investigated.

## **PgmNr 1446: CAGI SickKids challenges: Assessment of bioinformatic strategies for predicting patients' phenotypes and identifying potential pathogenic variants and disease genes from their genomes.**

---

Most patients who undergo whole genome sequencing (WGS) lack a molecular diagnosis, largely due to the large number of undiscovered disease genes and inability to assess the pathogenicity of most genomic variants. The CAGI SickKids challenges were public competitions designed to address this knowledge gap by assessing state-of-the-art methods for predicting clinical phenotypes from genomes.

CAGI4 and CAGI5 participants were provided with WGS data and clinical descriptions for 25 and 24 patients respectively who had undergone WGS but remained undiagnosed after evaluation by the SickKids Genome Clinic project (NPJ Genom Med 2016 13:12016 and Genet Med 20:435 2018). Predictors were asked to identify primary and secondary causal variants. Additionally, for CAGI5, groups attempted to match each genome to one of three classes of disease (neurologic, ophthalmologic and connective), and separately to each patient. A team of clinical and molecular geneticists assessed group submissions.

The four groups participating in CAGI4 proposed 191 diagnostic variants for 25 patients. Most variants were nominated by only one group and did not fully explain the patient's phenotype. However, two of the ten variants proposed by two groups were deemed to be diagnostic.

The CAGI5 challenge was more difficult, as genomes were not linked to patients' clinical descriptions. The eight groups participating in CAGI5 all prioritized how well a candidate gene explained a phenotype over the pathogenicity of its variants. They did no better than chance in matching genomes to the three disease categories but two groups performed significantly better than chance in matching genomes to specific patients. Importantly, patients with ophthalmologic disorders were the most likely to be matched to their genomes and had the strongest correlation between the informational content of the clinical description and their chance of matching. Despite partial success in matching genomes to patients, no candidate variants in CAGI5 were nominated by more than one

group and none were deemed to be clinically diagnostic. However, several nominated variants of unknown significance are candidates for phenotype expansion.

Despite their clinical naïveté, the bioinformaticians solved two cases and identified multiple plausible causal variants in candidate disease genes that bear further evaluation. We will discuss implications for improving *in silico* assessment of genomic variants and identifying new disease genes.

## PgmNr 1447: WebSTR: An online database of tandem repeat variants in human populations.

**Authors:**

R. Yanicky; M. Gymrek

[View Session](#) [Add to Schedule](#)

**Affiliation:** University of California, La Jolla, CA.

---

Tandem repeats (TRs) consist of repeated motifs of 1 or more base pairs and comprise more than 2 million loci in the human genome. Due to their rapid mutation rates, TRs represent one of the largest sources of genetic variation. TRs have been shown to contribute to a variety of human diseases, including Mendelian disorders such as Huntington's Disease or Fragile X Syndrome, as well as more complex traits such as schizophrenia or cancer risk. We and others have generated population-wide catalogs of TR genotypes at more than 1.5 million loci across more than 5,000 individuals from diverse ancestry groups. We have additionally mapped associations between TR repeat number and a variety of traits including gene expression, height, and schizophrenia.

To maximize the use of these datasets, we have developed WebSTR, an online database of tandem repeat variants in human populations. WebSTR is built as a flask application that leverages an underlying sqlite database and provides interactive visualizations using the plot.ly library. It incorporates genome-wide TR genotypes from multiple cohorts, including individuals from the 1000 Genomes Project and Genotype-Tissue Expression Project. Users may browse for TRs by gene or genomic region. For each TR, WebSTR displays population-specific allele frequencies as well as summary information about phenotype associations, imputation quality, and estimated mutation rates. In future work, we are adding more cohorts and incorporating additional modules for interactively exploring TR association summary statistics.

The WebSTR platform can be expanded to include any number of cohorts and integrate results from diverse areas of genetics. This will allow researchers across many disciplines to be able to easily access and re-analyze existing data.

WebSTR can be accessed at [webstr.gymreklab.com](http://webstr.gymreklab.com)

## **PgmNr 1448: Detecting phenotype descriptors in clinical notes with ClinPhen: An assessment of sensitivity in a PhenoDB patient cohort.**

### **Authors:**

[View Session](#) [Add to Schedule](#)

**Affiliation:** Johns Hopkins University

---

The precise clinical and genomic diagnosis of a patient depends on the complete and accurate description of his/her features. Currently physicians assemble the patients' phenotypic features through the clinical and family history, the physical examination, laboratory and imaging results and through manual curation of prior clinical notes. The manual curation of prior notes can be a time-consuming process that is subject to inaccuracies and omissions. At the Genetics clinic of Johns Hopkins Hospital (JHH), we use PhenoDB, a secure Web-based portal, to enter and analyze the phenotypic and genomic information of our patients. In PhenoDB, the physicians described the phenotypic features of their patients using the PhenoDB terminology that includes 3,666 terms mapped to Human Phenotype Ontology (HPO), Elements of Morphology, and International Consortium of Human Phenotype Terminologies (ICHPT) terms. Based on the phenotype descriptor terms entered for each patient, PhenoDB generates a list of the 20 most likely diagnoses through an OMIM search, alerts the physicians if a gene known to cause any of these 20 possible diagnoses is found mutated in the patient's genomic data, and allows the search of other patients with similar phenotype descriptors in the database. The work here explored the use of PhenoDB to assess the sensitivity of ClinPhen to annotate the clinical notes of patients diagnosed with genetic disorders at our Genetics clinic. ClinPhen (<http://bejerano.stanford.edu/clinphen/>) is a concept recognition software that annotates free-text documents with phenotype descriptor terms from HPO. The number of notes per patient ranged from one to 119, with 32 notes on average (SD = 42). The number of unique HPO terms annotated by ClinPhen per patient ranged from 17 to 140, with 60 terms on average (SD = 40). One patient did not have any HPO terms recorded in PhenoDB and was excluded from the analysis of sensitivity. We found an average sensitivity of 71% (SD=38%) for ClinPhen to detect the HPO terms that were captured manually in PhenoDB. Our findings indicated a large variability in the per patient number of notes, number of HPO terms annotated, and sensitivity of ClinPhen to capture HPO terms for patients in PhenoDB. Further work is needed to determine the range and types of notes and patients that are optimal to enable computational phenotype extraction for diagnostic purposes.

## **PgmNr 1449: Validation of a clinical germline exome sequencing assay and bioinformatics pipeline at UPMC Genome Center.**

---

The University of Pittsburgh Medical Center (UPMC) Genome Center is a CLIA Certified CAP Accredited high-throughput industrial scale sequencing center providing high quality, clinical grade next-generation sequencing services to internal stakeholders and external clients. Exome sequencing for rare-disease, Mendelian disorders and other germ-line traits is experiencing increased clinical acceptance and adoption, due to faster turn-around times, and advances in cloud-based bioinformatics pipelines. Furthermore, whole-exome sequencing provides a cost-effective alternative to whole-genome sequencing when economies of scale and throughput is taken into consideration. Recently, the UPMC Genome Center, has validated an exome sequencing assay and bioinformatics pipeline to be used in newborn screening and for various Mendelian disorder panels. Here we present data from our extensive validation sets for whole exome germline sequencing assay and bioinformatics pipeline.

## **PgmNr 1450: Retrospective analysis of 634 rare and undiagnosed genetic disease cases tested by clinical whole genome sequencing identifies steps to reduce number of manually triaged variants.**

---

Clinical whole genome sequencing (cWGS) detects a greater range of variation than targeted panels or whole exome sequencing. As the turn-around time of sequencing and secondary analysis continues to shorten, interpretation remains a significant burden. Reducing the number of variants for manual review by a clinical laboratory case analyst is one area of focus to streamline cWGS analysis.

Here we performed a retrospective data analysis of variant triage decisions of 634 rare and undiagnosed disease cWGS cases analyzed over a two-year period at the Illumina Clinical Services Laboratory. Across the 634 cWGS cases, a total of 108,315 variants were triaged. Family structures included proband-only (n=67), duo (n=107), trio (n=436), quad (n=22), and quint (n=2). Pertinent annotations as well as variant-level and gene-level comments supporting triage decisions reflecting phenotype overlap, gene-disease association, allele frequency among others were aggregated and analyzed. We found that only 2.8% (n = 2,969, average 4.6 variants per case) were selected for follow-up and reviewed by the clinical team, while the remaining (163 variants per case) were excluded based on at least one of four major categories: variants in genes without gene-disease association (no-gda), pipeline artifact variants which escaped population-based filtering (artifacts), variants in recessive genes lacking a second allele (AR no 2nd hit), and variants in genes which did not overlap with patient phenotypes. We show that phenotype-based filtering is a powerful triage technique and allows the analyst to prioritize variants for review, however with limitations. The remaining triage decision categories (no-gda, AR no 2nd hit and artifacts) accounted for 50% of triage decisions and represent candidates for full triage automation.

Tracking case analyst input allowed us to optimize the analysis where manual triage work may be significantly reduced.

## PgmNr 1451: Phen2Gene: Rapid phenotype-driven gene prioritization for rare diseases using human phenotype ontology terms.

---

**Background:** Incorporation of clinical phenotypes can greatly facilitate interpretation of whole genome or exome sequencing data to prioritize candidate genes for individuals with Mendelian diseases. Human Phenotype Ontology (HPO) terms are increasingly used in diagnostic settings to characterize the clinical phenotypes of patients, so methods that leverage HPO terms can improve diagnostic sequence interpretation. Although existing HPO annotations map each phenotype term to multiple candidate genes, they do not provide a means to weight/rank the genes or combine multiple phenotype terms for each patient. To address these challenges, here we first compile a knowledgebase (HPO2Gene-KB) that associates each HPO term with a list of prioritized genes, each with a weight indicating the strength of the relationships. We next present Phen2Gene, a rapid computational approach that searches and prioritizes candidate genes from a list of HPO terms.

**Methods:** Existing HPO annotations, five disease-gene relationship databases, and four gene-gene relationship databases were incorporated to compile HPO2Gene-KB. Given an individual with suspected Mendelian diseases, Phen2Gene takes a list of HPO terms as input, pre-processes the HPO terms based on ontology-based information content, and uses a weighted approach to identify and rank candidate genes for the patient.

**Results:** HPO2Gene-KB stores much more phenotype-gene relationships than existing HPO annotations, and it provides weights representing the strength of phenotype-gene relationships. We tested the performance of Phen2Gene using five cohorts of clinical cases totaling 281 individuals with a known genetic diagnosis, and compared the rankings of causal genes to existing gene prioritization tools such as Phenolyzer. Among the 281 individuals, Phen2Gene ranked causal genes within top 100 in 60 individuals, while Phenolyzer did it in 37 individuals. In summary, Phen2Gene has comparable performance to Phenolyzer, but it is ~100X faster and can generate results instantly.

**Conclusion:** HPO2Gene-KB fills a void in the community in linking standardized phenotype terms to

genes with weighted scores, and it may facilitate the development of novel computational tools that link HPO to disease genes. As a special use case of HPO2Gene-KB, Phen2Gene serves as a real-time phenotype driven gene prioritization tool to aid clinical diagnosis of rare diseases.

## PgmNr 1452: Context matters: An approachable web tool for inspecting variants in genetic disorders.

### Authors:

Prioritizing variants in suspected genetic disorders involves taking into account several important factors. Here we show *gene.iobio*, a web tool for variant inspection that can quickly and easily provide important context and insight during variant prioritization.

During a typical variant prioritization workflow, an analyst will consider a number of criteria for a variant, including population frequency, inheritance mode and allele segregation, variant pathogenicity assertions, and known gene-disease associations. Our *gene.iobio* tool annotates variants in real-time, allowing an analyst to consider these important criteria. Often, for well described genetic disorders these criteria are sufficient to reach a confident genetic diagnosis and *gene.iobio* can return that genetic diagnosis in seconds.

However, sometimes after these considerations have been made, a genetic diagnosis is still lacking. Here an analyst will typically explore variants of uncertain significance and inspect data quality for potential insufficiencies. Our *gene.iobio* tool allows the analyst to continue their exploration into variants of uncertain significance by providing them with additional variant information such as gene burden, amino acid conversation, additional disease/molecular associations and exons where previously reported pathogenic variants reside. Our tool also provides an analyst with interactive and intuitive visualizations to explore data quality and give important context to each variant. Using gene coverage tracks and read pileup views, an analyst can spot regions of insufficient coverage or regions of poor alignment and account for these regions when considering modes of inheritance. For instance, an analyst would likely dismiss a variant reported as de novo, where neither parent has coverage at that region. Additionally, alternate/reference read counts are often not clear 0/100, 50/50 or 100/0 splits. *Gene.iobio* provides the analyst with read count information, allowing for more accurate assessment of inheritance mode. For instance, an analyst would likely be suspicious of a recessive variant if one parent had < 10% alternate reads observed. All of these features make *gene.iobio* a powerful web tool for rapidly reaching a diagnosis for well described genetic disorders, but also provides an avenue of continued inquiry when such an obvious answer is not reached.

## PgmNr 1453: A scalable framework for collaborative rare disease diagnosis and gene discovery.

---

Rapid advances in exome and whole-genome sequencing make it possible to identify the full spectrum of genetic variation in rare disease patients and family members. However, powerful filtering and decision support tools are needed in order to discover the causal variants amidst the noise of benign genetic variation. To address this challenge we developed seqr - an open source, interactive web-based platform that allows researchers to collaboratively search and annotate variant callsets from exome and whole genome studies involving families of rare disease patients. In our framework, variants are annotated with allele frequencies from population databases including 1000 Genomes Project, TOPMed, and gnomAD, transcript consequence predictions, clinically interpreted variant databases including ClinVar, and in silico predictor scores. Variants are filtered with these criteria as well as family-specific inheritance mode, and individual readviz data is available in the browser for all variants. Gene-level annotations and resource links such as OMIM, GTEx and UCSC genome browser provide researchers with a flexible framework for efficiently exploring the evidence for causality for candidate variants and genes. seqr is the core analysis platform for the Broad Institute's Center for Mendelian Genomics, having already been used by over 500 researchers to study potential causal variants across over 10,000 families affected by rare disease and facilitating over 1,000 diagnoses, many of them in novel disease genes.

Here, we will describe the framework underlying seqr with a focus on the design choices made to scale the system to tens of thousands of exome and genome samples. Additionally, we will describe how interactive visualization of read-level data, detailed phenotype data, external reference data, and other relevant data types were brought together in a single user-friendly interface. The ability to interactively search across terabytes of genomic sequencing data requires custom solutions and thoughtful design trade-offs, and we will present the details of how seqr dealt with these challenges.

## PgmNr 1454: Accounting for splicing effects in known missense variants improves *in silico* prediction of deleterious effect.

### Authors:

---

To characterize missense variation across the human genome, various *in silico* predictors exist for assessing deleterious effects from a combination of sequence, structural and evolutionary features. We previously showed that an ensemble *in silico* variant prediction (IVP) score from a Bayesian logistic regression model had high degree of prediction accuracy. In this study, an ensemble score is first estimated in a subset of 15 *in silico* predictors (including SIFT, PolyPhen2, PhyloP, PROVEAN and others), and then combined with a splicing impact prediction to form a joint score. The splicing impact prediction score was obtained from a previously developed tool, SpliceScan II, which combines *ab initio* splicing prediction with evolutionary conservation in the context of known gene structures to assess variant impact on splicing. We derived an ensemble score without accounting for potential splicing (IVPns; IVP with no splicing predictor), and the score accounting for potential splicing (IVPws; IVP with splicing predictor). We then compared the IVPws and IVPns scores in known (likely) pathogenic and (likely) benign missense variants with ClinVar classifications, defined as the most supported category among six submitters providing assertion criteria. For evaluating and reporting prediction performance, we separated the missense variants in 338 genes into two variant sets based on SpliceScan II at a cutoff 0.05 determined by the distribution of classified variants: 1) 9,761 variants with SpliceScan II  $\leq 0.05$  for no splicing impact; 2) 424 variants with SpliceScan II  $> 0.05$  for potential splicing impact. The prediction performance of IVPws and IVPns scores were compared within each of the two variant sets by area under the curve (AUC) statistic using direct cross validation. For variants in 1) with no predicted splicing impact, the AUCs of IVPws and IVPns were equivalent (0.9761 and 0.9756;  $p = 0.58$ ), showing that including splicing score in IVP model didn't impair the prediction performance. For variants in 2) with potential splicing impact, the AUC of IVPws was 4.8% higher than that of IVPns (0.971 vs. 0.927;  $p = 0.01$ ). To conclude, for missense variants with potential splicing impact, ensemble scores that incorporate splicing information improve *in silico* prediction of deleterious effects.

## PgmNr 1455: Full-length RNA-seq of Alzheimer brain sample on the PacBio Sequel II platform.

---

Alzheimer's disease (AD) is a devastating neurodegenerative disease that affects ~44 million people worldwide, making it the most common form of dementia. It has been shown that changes in gene expression due to alternative splicing likely contribute to the initiation and progression of AD. Most transcriptome studies conducted to date have used RNA-seq short read data, which provides quantification at the gene level, but cannot resolve complex isoform structures. The PacBio Iso-Seq method provides full-length, highly accurate transcripts of 10kb or longer with no assembly required, allowing unambiguous characterization of alternative splicing events, TSS usage, and allele-specific, isoform-specific phasing information. We sequenced the whole brain of a single male with AD on the PacBio Sequel II platform. Using a single SMRT cell, we obtained 4,277,293 full-length reads, which was processed using the Iso-Seq bioinformatics pipeline followed by a quality filtering tools SQANTI2 that removes cDNA library artifacts, resulting in a final set of 160,837 unique polyadenylated isoforms covering 17,546 genes ranging from 100bp-15kb (mean: 3.4kb). Compared with Gencode v29, 67% of the isoforms detected are novel, however the majority of the novelty comes from novel combinations of known donor-acceptor sites. The majority of novel isoforms that use at least one novel donor-acceptor site, however, all still have coding potential and are likely to be bonafide novel transcripts. As such, we show that the transcriptional landscape of AD is more complex than previously appreciated, and that the PacBio Sequel II system is a cost-effective solution for sequencing whole transcriptome in human disease research.

## PgmNr 1456: Prioritizing rare variants in non-coding WGS: Experience with the ADSP family sample.

---

Complex genetic traits such as late-onset Alzheimer's disease (AD) are highly genetically heterogeneous. Although both family studies and GWAS have implicated multiple loci, the underlying causal variants are largely unknown. Availability of whole-genome-sequence (WGS) now allows evaluation of virtually all DNA in a region of interest, including both common and rare variants. Causal common variants can be implicated by GWAS, but rare variants may be more effectively studied through family designs. We carried out linkage analysis in 110 individual families in the AD sequencing project (ADSP), followed by family-specific association analysis and bioinformatic filtering in the regions of interest (ROIs) implicated by  $\text{lod} > 1.9$ . These variants were further filtered based on population  $\text{MAF} < 0.01$  and family-specific p-value thresholds from family-based association, resulting in 17,765 variants across 1,312 genes.

A major challenge was that most variants implicated fell in the non-coding DNA. To further prioritize variants, we developed a Comparative Tissue-Specific Expression Annotator (CTEA) to use outside databases and estimate the relative importance of a gene tagged to a variant, based on the specificity of gene expression across all tissues available and compared to all genes in a specific tissue. For our purposes, we used the NCBI Gene Expression Omnibus (GEO) and the Genotype-Tissue Expression (GTEx) datasets in order to estimate these measures, although similar measures may be developed for other datasets.

From the filtered association results, we took the top 20% for the NCBI importance in brain and the GTEx importance for three AD-relevant brain regions. We isolated genes that passed all of these filters and were also identified by TReNA, a machine learning algorithm for identifying transcriptional regulatory networks. Following this, we applied a filter to the variants using functional inference (FIRE) scores ( $\geq 0.8$ ) based on a random forest classification relating to regulatory expression. Of the 9,152 variants across 65 genes identified through in these previous filters, 45 genes have 788 variants that pass the FIRE filter. We are in the process of adding a final filter based on recently released single-cell transcriptomic results in conjunction with AD progression. These results show that there may be statistically-driven approaches to prioritize non-coding variants that make use of outside bioinformatic data.

## PgmNr 1457: Structural characterization of rare missense variants within known neurodegenerative disease proteins.

---

Alzheimer's disease (AD) is the 6<sup>th</sup> leading cause of death in the US and currently remains untreatable. Recent work suggests unexplained heritability of AD may involve rare variants in genes implicated in other neurodegenerative disorders. However, existing gene-based tests have insufficient power to detect true associations when neutral variants are included. Therefore, it is critical to identify and prioritize variants with high impact to protein function before attempting gene-based statistical assessments. To that end, we employed the Phenotype Consensus ANalysis package (PCAN) in R to identify genes with Mendelian associations to neurodegenerative disorders. We examined the location of missense variants from the Alzheimer's Disease Sequencing Project (ADSP) in 3D protein structures. We compared to the locations of known variants curated from ClinVar (pathogenic variants) and ExAC (presumed benign variants) using the PathProx algorithm. Additionally, we computationally predicted the impact of each missense variant on protein folding (vs. canonical wildtype amino acid) via Rosetta's change in free energy (ΔG) algorithm. We structurally assessed protein products of the top 1% of ranked genes from PCAN (n=31). We excluded genes lacking ADSP variants (n=3) or classified as lncRNAs (n=2). The remaining genes (n=26) are presently being assessed, with preliminary findings including results from >50% of them. The number of ADSP variants per gene varied (mean 59.1, min=8, max=190). From the completed analyses, the mean number of variants per gene with PathProx scores suggestive of functional consequence was 13.6 (min=0, max=37). The mean number of variants per gene with a ΔG suggestive of a stabilizing function was 2.3 (min=0, max=16). The mean number of variants per gene with ΔGs suggestive of a destabilizing function was 10.7 (min=0, max=40). We have identified subsets of missense variants likely to impact the function of proteins associated with neurodegenerative diseases in the ADSP. These annotations can be used in multiple ways, such as producing variant sets for use in gene-based testing. Additionally, Functional characterization of rare variants using PathProx and ΔG could aid in heterogeneity testing of multifactorial diseases like AD. Finally, our methodology is phenotype-centric and applicable to other diseases with overlapping phenotypes to identify candidate genes in a variety of complex disorders.

## PgmNr 1458: Integration of interactome perturbation and cell-type-specific transcriptome implicates novel autism risk genes and cell types where they are expressed.

While large-scale sequencing has led to the discovery of more than 100 risk genes for autism spectrum disorder (ASD), fundamental questions remain. For example, regarding these risk genes, when and in what cell types are their gene products expressed? The answer would provide clues to how mutation of these genes alters typical neurodevelopment and neurophysiology. In addition, do these genes lend insight into what other genes are likely involved in development of ASD? Utilizing genomic data from a recent whole-exome sequencing study from the Autism Sequencing Consortium, we investigate the functional relevance of missense mutations through integrated interactomic and transcriptomic analyses. We use three resources for these analyses: a human interactome network compiled from eight widely used interaction databases; the BrainSpan transcriptome resource for the developing brain; and estimated cell-type-specific (CTS) expression from analysis of BrainSpan using the MIND algorithm. Interactome interface mapping reveals significantly higher interaction-disruption rate in ASD probands than in unaffected siblings (1.8-fold), and interaction disruptions in probands tend to target known ASD genes (35-fold). Using pairs of genes whose interaction is found to be disrupted in ASD subjects, we construct a PPI network. In this “disrupted network”, we find strong enrichment of ASD genes as hubs; genes closely connected to these hubs are more likely to be ASD genes themselves using the guilt-by-association principle; and the missense mutations that disrupt hub interactions are more likely to be meaningful for ASD than the larger set of non-disruptive missense mutations. Our CTS transcriptomic analysis identifies key cell types for ASD risk based on when and where genes are expressed and co-expressed. Finally, incorporating genome, transcriptome, and interactome information into a unified statistical framework implicates hundreds of genes as candidate ASD risk genes. These genes are highly intolerant to loss of function variation and ASD subjects harboring mutations of these genes exhibit more severe phenotypes. Taken together, our study facilitates translating the wealth of genomic data into biological and etiological understanding for ASD.

## PgmNr 1459: *Straglr*: Short tandem repeat genotyping using long-reads.

Short tandem repeats (STR) are tandem arrays of 1 to 6 base pair (bp) repeat motifs. STR expansions are known to underlie the molecular pathogenesis of over 40 diseases, most of which involve the nervous system. Southern blot (SB) analysis, the gold standard molecular diagnostic test for detecting STR hyperexpansions, is labor- and time-intensive. Alternatively, short reads from next-generation sequencing (NGS) technologies with analysis by recently-developed algorithms can successfully detect expansions of some known disease STRs. However, large STR expansions that exceed sequencing read (~125-150 bp) or fragment (~350-500 bp) lengths still pose challenges for methods that use NGS data. Furthermore, GC-bias inherent in short reads presents a hurdle in genotyping GC-rich STRs, such as the *FMR1* CGG-repeat expansion mutation, which causes fragile X syndrome. Third-generation sequencing technologies, such as those from Nanopore and PacBio, are appealing alternatives due to their longer read lengths and lack of significant sequencing bias. A number of long-read STR analysis algorithms such as RepeatHMM and tandem-genotypes have demonstrated reasonable accuracy in genotyping long repeat expansion alleles in spite of the generally inferior single base accuracy of long reads relative to NGS data. However, existing tools have room for improvement in robust genotyping of STRs with different repeat motifs or lengths and in scaling for genome-wide scans for novel STR expansions.

Here we present *straglr*, a versatile software package that can be used for both identifying novel STR expansions and genotyping known disease loci. *Straglr* captures novel STR expansions by detection of sizeable insertions from minimap2 alignments of long reads and uses Tandem Repeats Finder for identification of STRs in genotyping either detected or pre-defined loci. We use Genome in a Bottle datasets to demonstrate the utility of *straglr* in performing genome-wide scans to reliably detect polymorphic expanded alleles at STR loci with a wide spectrum of repeat lengths and motifs. We also use long-read data of targeted disease loci to show *straglr* can estimate the size of expanded alleles at known STR disease loci with accuracy comparable to that of PCR or SB analysis.

## PgmNr 1460: Comparison of the gene expression between microglia and monocytes in epilepsy patients and their association with clinical variables.

**Background/Objectives:** Recent studies have implicated the role of the immune system in epilepsy, but understanding the diversity of human microglial cells (the main resident immune cell in the brain) and their association to clinical/phenotypical variables has been limited. In particular, transcriptional changes in microglia and peripheral monocytes and their association with different clinical variables such as sex, age, GTC and seizure frequency in epilepsy is not yet well understood. Here, we compared the gene expression profiles of region-specific microglia and monocytes in surgically resected brain tissue from epilepsy patients, and investigated their association with clinical and phenotypical variables.

**Methods/Overview:** We conducted bulk RNA-Seq analysis on microglia isolated from temporal cortex and amygdala/hippocampus regions of the brain and monocytes from blood to determine expression pattern alterations in 12 epilepsy patients. We fit a linear mixed model on gene expression to investigate the association of genes attributed to multiple clinical and phenotypical factors like sex, source, age of onset, GTC history and frequency etc. We included all the categorical variables as random effects in the model, whereas continuous variables like age were modeled as a fixed effect. For each gene, we were able to scrutinize the fraction of variation attributable to each factor included in the model. Using Canonical Correlation Analysis between all pairs of clinical variables, we also studied each variable's association with respect to each other.

**Results:** Our findings on 12 epilepsy patients provide insight into disease phenotypes that may be attributable to differential expression of specific genes. The largest proportion of variance was accounted for by the cell type (microglia versus monocytes) and the second strongest contributor to variance in gene expression was with age of onset of the disease. We also found a subset of genes such as SLC2A1 and BRD2 associated specifically with GTC seizure frequency and age of onset respectively. Some of these genes have previously been associated with epilepsy, but we also identified a set of less well-characterized genes that may be involved in immune-specific contributions to epilepsy subtypes.

**Conclusions:** Even with a relatively small sample size (n=12), our study recapitulates genes with known associations with epilepsy, and also identifies new candidates worth pursuing further.

## PgmNr 1461: Systematic approach for drug repositioning of anti-epileptic drugs.

Epilepsy is the most common neurological disorder with heterogeneous causes, affecting 1-2% of the population. The majority of patients with Epilepsy can be effectively treated, given an accurate diagnosis and appropriate treatment. Thus, it is very important to determine the accurate type of epilepsy in order to select appropriate drug therapy. Most of existing therapies for epilepsy patients have focused on the symptomatic treatment with such drugs and there are general sorted antiepileptic drug lists which have been known to use for a specific type of epilepsies. In spite of improved efficacy of new AED drugs and novel therapy, there still approximately 20~ 30% of patients, who have either intractable or uncontrolled seizures.

Recent improvement in cost and accuracy of whole-exome sequencing (WES) has enabled the accurate diagnosis of genetic diseases and it allows for identification of the causative variants of diseases. Especially, for patients with refractory epilepsy, WES is popularly used to find accurate causative genes through the trio analysis, which would be very helpful to provide the accurate diagnosis for individual epilepsy patient with unknown origin. The understanding of biological mechanisms of existing AEDs and pathology of epilepsies leads to the dramatic advance of AED development. Thus, it is feasible strategy to predict the appropriate drug based on the causative genes or perturbed biological pathways of refractory epilepsy patients, which leads to the real potential of precise medicine.

In this study, we constructed the epilepsy drug-target network (EDT) and successfully demonstrated the characteristics and effectiveness of popularly used AEDs and the pathological mechanisms of existing AEDs. Especially, we discovered that the causative genes of most of intractable patients were not the targets of existing AEDs as well as they are very far from the etiological mechanisms of existing AEDs in the functional networks. Finally, we showed the existence of new drugs which is targeting the causative genes of intractable epilepsy patients, which will be a new candidate for refractory epilepsy patients. Our systematic approach demonstrated the new possibility for the drug repositioning through combination of the drug-target network and functional network.

## PgmNr 1462: Global alteration of circRNA landscape in Alzheimer's disease.

Circular RNAs (circRNAs) are a class of endogenous RNAs with a unique circularized structure derived from back-splicing of exons in precursor mRNAs, and have recently emerged as one of the pivotal regulatory RNAs in higher eukaryotes. Many circRNAs are enriched in mammalian brains and dynamically regulated during neurodevelopment. CircRNAs are relatively stable and resistant to exonuclease due to their covalently circularized structure, thus they could accumulate in the brain during aging and have been linked to age-related neurodegenerative disorders, such as Alzheimer's disease (AD). However, the molecular functions of circRNAs in AD pathogenesis remain elusive. While numerous computational tools have been developed to predict circRNA production using junction reads from RNA-seq data, algorithms to identify critical genomic features regulating circRNA biogenesis, such as repetitive elements in the introns flanking circularized exons, are still lacking. Furthermore, rigorous statistical methods to perform differential expression analysis of circRNAs remain under-developed. In this work, we first developed circMeta, a unified computational framework for genomic feature annotation and differential expression analysis of circRNAs. Second, we utilize circMeta to identify genome-wide alteration of circRNA landscape in prefrontal cortex of control and AD human postmortem brains, as well as in the well-established 5XFAD mouse model. As a result, we discovered 2,484 and 1,948 differentially expressed circRNAs associated with AD in human and mouse brains, respectively, with 516 circRNAs conserved between species. Interestingly, many circRNAs were produced from host genes that have been well-established in AD pathology, such as circAPP, circRIMS2 and circNRXN1. Mechanistically, a significant portion of differentially expressed circRNAs were produced from loci displaying aberrant alternative splicing associated with neuropathology and clinical manifestation, implying the potential contribution of circRNA biogenesis in AD-related aberrant alternative splicing. In addition, many of these circRNAs could serve as AD-related miRNA sponges to affect key miRNA-mRNA networks. One circular RNA, circKTN1, is predicted to sequester miR-516b, a key miRNA that regulates neuron differentiation and aging. Taking together, our study reveals global alteration of the circRNA landscape associated with AD and offers potential mechanistic insights of circRNA-related AD pathogenesis.

## PgmNr 1463: NeuroSeq: A platform for investigating the genetics behind neurological conditions.

The development of personalized medicine has far-reaching implications for clinical care, with the opportunity to assist with diagnosis, inform treatment, and give insight into clinical course. As genetic sequencing becomes more prevalent, medical associations are recommending sequencing as front-line care for an increasing number of diseases and disorders.

We are developing a comprehensive, searchable repository of genotype/phenotype correlations in neurological conditions for use by clinicians, genetic counselors and laboratory directors in their mission to provide the best available care. The repository securely holds all variant data added to it so as to protect patient privacy, while also acting as a public resource for health care, research, and education. Aggregate data is available to any user, but only appropriately educated/trained users qualify for accounts that grant additional rights: adding new genotype/phenotype data, accessing subject symptom/diagnosis details, and using analytical tools for both individuals and pedigrees.

The NeuroSeq database (<http://www.neuroseq.ca>) is available for ethically approved users: they may upload data, search for correlations, and communicate with other users about results.

## PgmNr 1464: Integrated SNV/structural variation analysis on the genome research platform GENESIS.

The diagnostic gap for many rare diseases, especially in the neurodegenerative field, still exceeds 30-50%. These patients do not receive a diagnosis and will not be able to benefit from the upcoming genetic therapy developments. We have created the GEM.app/GENESIS genomic analysis platform to facilitate research diagnosis, gene identification, and data sharing (Gonzalez, 2013, 2015). To date, more than 9,000 exomes, genomes and panels from rare disease patients have been analyzed in GENESIS and are available for gene matching. This has contributed to the identification of 65 Mendelian genes in the past 8 years. Recently, structural variant (SV) analysis of whole genomes has been added for easy querying through a user-friendly web interface. This allows for a fully integrated analysis of SNV, indels, and SV without prior bioinformatics expertise required. SVs have historically been under-studied due to the difficulty of their detection in short-read whole genome sequencing (WGS) data. We are applying the Parliament2 software (Zarate et al., 2018) annotated with population frequency and predicted loss of function data on over 400,000 SVs from gnomAD-SV along with labels of neighboring and overlapping genes and gene regulatory elements as identified by ENCODE. As we reanalyze several hundred WGS samples with this pipeline, we fully expect to diagnose unresolved patients and identify novel genes to be reported in this study in the next 6 months.

## PgmNr 1465: *In silico* characterization of repeat expansion variation in 1,116 genomes.

**Authors:**

S. Fazal; M.C. Danzi; S. Zuchner

[View Session](#) [Add to Schedule](#)

**Affiliation:** Department of Human Genetics, University of Miami, Miami, Florida.

---

Rare monogenic disorders are largely caused by pathogenic variation in protein coding regions of the genome. Yet, the phenotypes of 30-50% of patients remain unexplained. Thus, we and others have speculated about non-coding sequence contribution to the pathogenic variant spectrum. One such unorthodox mechanism is the expansion of short tandem repeats (STRs) into long repetitive stretches of the wild-type or mutated motif. Only 30 such loci have been linked to diseases thus far. In the past, these repeat expansions have been found primarily through linkage analysis of families. Direct identification from short-read whole genome sequencing data has proven difficult due to the inefficiency of alignment algorithms to correctly match reads to the reference genome. However, with the advance of new tools such as ExpansionHunter, many of these challenges can be overcome. Another challenge has been the lack of an extensive structural variation database focused on repeat sequences in the general population. Here we report a thorough analysis of STR expansions in 1,116 genomes. We find that on average, each genome contains 260 large, repetitive loci; with each new genome containing 3-10 new expansions not seen in our previous analysis. Only 2% of all loci identified are shared amongst all the samples, while more than half are observed only in 1-2 samples. Certain regions in the genome show evidence of expansions in a large number of samples, which could indicate that the reference genome underestimates the number of repeats in these areas. The majority of expansions we identified are intergenic, about 28% are intronic, and less than 1% are exonic. Large expansions were overrepresented near Alu elements, appearing proximal to AluS or AluJ sites over 6 times more often than expected by random chance. We will use this data to identify pathogenic repeat expansions in rare neurological disorders such as axonal neuropathies, motor neuron diseases, and undiagnosed ataxia cases. Because of the considerable diagnostic gap in rare diseases it is likely that repeat expansions as a mutational mechanism play a larger role than currently estimated.

## PgmNr 1466: Leveraging machine learning to accelerate gene discovery in developmental brain disorders.

---

Developmental brain disorders (DBDs) including microcephaly (MIC), megalencephaly (MEG) and cortical malformations are complex neurodevelopmental phenotypes with multiple co-morbidities. A majority of these disorders are genetic in origin caused by ultra-rare, largely *de novo*, variants. We performed exome sequencing on an ethnically diverse cohort of 154 individuals diagnosed with various types of DBDs. Using a comprehensive approach including expert review of clinical and neuroimaging features, as well as an in-house bioinformatics pipeline, we identified pathogenic variants in (44/154) 28.6% and candidate variants in (40/154) 26% of individuals. This approach, however, relies on manual curation of candidate variants and/or genes and knowledge regarding genes-variants associated with DBDs. We sought to develop a more systematic computational approach for DBDs to increase the gene discovery rate for these disorders. To address this, we developed a machine learning approach that identifies pathogenic variants in DBDs. We trained this model with clearly pathogenic variants from our cohort and annotated pathogenic variants from the Human Gene Mutation Database (HGMD), the Leiden Open Variation Database (LOVD), and ClinVar, expression profiles, supplemented by pathway analysis including KEGG, Ingenuity Pathway Analysis. This new systematic approach improved the diagnostic yield in our cohort. We believe this approach offers a valuable tool for the analysis of exome data for families with DBDs, enabling faster diagnoses and ultimately more targeted medical management.

## PgmNr 1467: Non-synonymous co-variation is crucial for SUDEP in *SCN1A* driven epilepsy.

### Authors:

P. Vandeventer; A. Ghazi; E. Chen; A. Goldman; C. Shaw

[View Session](#) [Add to Schedule](#)

**Affiliation:** Baylor College of Medicine, Houston, Texas

---

Sudden Unexpected Death in Epilepsy Patients (SUDEP) is a rare disorder that affects some individuals with *SCN1A* driven epilepsy as well as epilepsy patients with different genetic etiology. The prevailing hypothesis for *SCN1A* SUDEP risk has been that co-variation on the other homologue of *SCN1A* from the haplotype bearing the disease variant is a necessary and sufficient condition for SUDEP outcomes. We have developed an alternative genetic modifier model of *SCN1A* SUDEP. Under this model, concomitant variation – or genetic load – outside of *SCN1A* but in genes related to the SUDEP pathophysiology drive SUDEP outcome risk. Individuals with increased loads or specific patterns of co-variation in these SUDEP risk genes have higher risk, while individuals that lack such variants are at lower risk.

To pursue this hypothesis we created a data set and computational approach to evaluate this model. We identified individuals who underwent exome sequencing that have pathologic or potentially pathologic *SCN1A* variation from the Baylor Genetics laboratory who were also patients at Texas Childrens hospital. We also utilize exome data from SUDEP individuals with *SCN1A* driven epilepsy. Taken together, these data provide a set of positive control *SCN1A* SUDEP cases as well as a collection of test individuals that we can evaluate genomically and by chart review.

The computational procedure considers the rate of pathogenic or potentially pathogenic variation in genes related to the pathophysiology of SUDEP. The gene set used for load analysis was independently identified by prior expert review of the literature and publications of genetic models of SUDEP. The pathways and processes implicated include cardiac arrhythmia, respiration and spreading depression associated genes. Our preliminary results indicate significant evidence for increased load of Variants of Uncertain Significance (VUS) and potentially pathologic alleles in the candidate gene set among the SUDEP cases.

This suggests we can identify specific patterns of co-variations segregating within the pathophysiological molecular SUDEP pathways that will allow us to discriminate between high risk *SCN1A*+ SUDEP cases vs low risk for SUDEP among *SCN1A*+ live epilepsy patients.

## PgmNr 1468: Rapid genome wide tissue specific filtering in rare variant aggregation based modeling.

**Authors:**

**Affiliation:** Case Western Reserve University, Cleveland, Ohio.

---

Rare variant analyses often group variants together into units that reflect a biological function, such as gene regions, to combine their small individual effects and improve statistical power. The standard practice for these aggregation based tests is to include every variant within a gene, often filtering by most damaging variant consequence, with no regard to transcript activity or tissue-specific isoform expression. This creates the possibility for variants with important effects under specific biological conditions (such as within a particular tissue) to be obscured by variants which are irrelevant to the context of interest (i.e. variants whose transcripts are actually silent within a tissue of primary interest). Resources such as the genotype-tissue expression (GTEx) project contain data describing the tissue specific activity levels of transcripts, which in turn describes the tissue specificity of the variants within them. By annotating variants with their tissue specific activity, biologically irrelevant variants can be ignored during rare variant aggregation based analyses, which may reveal biologically relevant rare variants that would otherwise be undetectable at existing sample sizes.

We conducted gene region-based rare variant analyses, using the seqMeta R package implemented on a Hadoop cluster, with tissue specific variant filtering for 53 tissues across 29,000 genes. We developed and applied a generalized framework for aggregation based analyses with variant annotations derived from the GTEx dataset, and evaluated the impact of tissue specific filtering on SKAT tests including all gene-based variants for different strata of significance cut-offs. For the most significant alpha values ( $p < 10e-6$ ), tissue specific filtering removed 1 to 3 genes from significance. At more moderate alpha values ( $10e-4 < p < 10e-6$ ), newly significant genes appear within analyses of some tissues, and in general as the significance cutoff decreases, the set of significant genes becomes more differentiated across tissues. These findings indicate that for SKAT analyses including all genic variants (without functional filtering), accounting for tissue specific expression in the analysis does not cause major shifts in p-values. We anticipate that analyses restricted to putatively functional variants (i.e. missense) may induce greater tissue-specific differences in statistical results.

## PgmNr 1469: Characterization of medically actionable variants in 2,500 publicly-available, high-depth genomes of diverse ancestry.

---

The creation of powerful annotation databases such as gnomAD has been enabled by the availability of population-scale whole genome sequencing (WGS). This has greatly improved clinical interpretation of simple SNVs and indels. Yet, many medically important regions and variants such as triplet repeats and homologs require specialized informatics methods and are not included in these current WGS-based databases. To this effect, population-level characterization of known clinical variants is needed to maximize the impact of population sequencing experiments. The recent availability of public sequence data such as the high depth (>30x) WGS data from >2,500 samples from the 1000 Genomes Project (1kGP) will allow scientists to develop new methods and release results for public scrutiny. As a demonstration of this concept, we have developed several tools that address difficult medical variants/regions and annotated these variants in the 1kGP samples.

For this demonstration, we identified three clinical variants that are not reported in standard secondary analysis pipelines: 1) spinal muscular atrophy (SMA) detection and carrier screening, 2) *CYP2D6* genotyping for pharmacogenomics applications and 3) detection of triplet repeat expansions. The SMA and *CYP2D6* loci pose difficulties because the regions include segmental duplications, i.e. *SMN1-SMN2* and *CYP2D6-CYP2D7* paralogs, resulting in ambiguous read alignments and unreliable variant calls. We have developed a general method that overcomes the challenges with segmental duplications. Repeat loci are challenging because they occur in low complexity regions prone to elevated error rates and are detected using ExpansionHunter. Because these are complicated regions, we confirmed our locus-specific methods by extensively validating the calls against those made by orthogonal technologies. We then applied our methods to call the *SMN1* and *SMN2* copy number, *CYP2D6* star alleles and repeat expansions in the 1kGP population and quantified differences between subpopulations. The software tools used to make these variant calls are freely available to the community under an open-source license, and the per-sample variant calls on the 1kGP samples will be made public and linked to the WGS sequence data for use as a community resource. We will present the allele frequency distributions by sub-population and ongoing perpendicular validation of these methods as validation data are generated from high-quality long reads.

# PgmNr 1470: A new machine-learning based method to accurately assess copy number variants from whole genome sequencing data and its application on the analysis of the Hirschsprung disease genome.

**C**opy **N**umber **V**ariants (CNVs) are defined as DNA segments larger than 50 base-pairs with copy number changes. CNVs discovery is essential for uncovering genes/risk factors for a wide range of diseases, including Hirschsprung disease(HSCR; colon aganglionosis). Incidentally, gross deletions encompassing *RET* or *EDNRB* lead to the discovery of these two main HSCR genes. Importantly, our previous CNV analysis of HSCR patients identified the association of CNVs encompassing *NRG3* with HSCR, therefore vindicating a role for CNVs in HSCR.

As CNV calling is still a challenge, we have devised and developed a new machine-learning based method CNV-JACG to accurately assess CNVs. Initially, in order to get the most comprehensive CNVs, we used four complementary CNV discovery methods namely CNVnator, Delly, Lumpy and Seeksv to call CNVs. We used 9 in-house trios to produce training dataset, 11 pairs of in-house duplicated samples for validation, and 2 trios from 1000 Genomes Project for evaluation. For deletions, after CNV-JACG assessment, the concordance between each pair of 11 duplicated samples increases from 63% to 88%, and the Mendelian inconsistent rate of the 2 trios decreases from 25% to 6%. In the benchmark sample NA12878, 84.7% of CNV-JACG predicted CNVs are consistent with previously published result.

CNV-JACG has been used for the CNV analysis of whole genome sequencing data (pair-end 150bp, ~30X) generated from 443 HSCR patients and 493 matched controls. Here we will present the performance of our new program together with the genome-wide association results.

---

Dementia with Lewy bodies (DLB) is the second most common subtype of neurodegenerative dementia in humans following Alzheimer's disease (AD). Present clinical diagnosis of DLB has high specificity and low sensitivity, and finding potential biomarkers of prodromal DLB is still challenging. MicroRNAs (miRNAs) have recently received a lot of attention as a source of novel biomarkers. Here, using serum miRNA expression of 478 Japanese individuals, we investigated potential miRNA biomarkers and constructed an optimal risk prediction model based on several machine learning methods: penalized regression, random forest, support vector machine, and gradient boosting decision tree. The final risk prediction model, constructed via a gradient boosting decision tree using 180 miRNAs and two clinical features, achieved an accuracy of 0.829 on an independent test set. We further predicted candidate target genes from the miRNAs. Gene set enrichment analysis of the miRNA target genes revealed 6 functional genes, including the DHA signaling pathway associated with DLB pathology. Two of them were further supported by gene-based association studies using large numbers of single nucleotide polymorphism markers (*BCL2L1*:  $P=0.012$ , *PIK3R2*:  $P=0.021$ ). Our study provides an effective tool for DLB classification, and with further improvement, such as integrative analyses of genomic and/or transcriptomic data, has the potential to contribute to practical clinical application in DLB.

## PgmNr 1472: Comprehensive identification of somatic single nucleotide variation using a multi-institute analysis of a common brain tissue sample.

### Authors:

Y. Wang; on behalf of the Brain Somatic Mosaicism Network

[View Session](#) [Add to Schedule](#)

**Affiliation:** Department of Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, Michigan.

---

Somatic mutations are genetic differences among cells within an individual that arise from unrepaired DNA damage that occurs during DNA replication and other cellular processes. Somatic variation has been established as a causal feature in various cancers. However, while tumor cells undergo clonal expansions that often increase the frequency and subsequent detection rate of somatic mutations, it is difficult to discover somatic single nucleotide variants (SNVs) from non-tumor tissues because they are present in a low number of cells and can occur early in development, leading to their presence in both sample and control tissues. Here, we sequenced a single human brain to develop, optimize, and evaluate the performance of methods for somatic variant discovery as part of the Brain Somatic Mosaicism Network (BSMN), a multi-institutional initiative that seeks to gain a comprehensive understanding of somatic mosaicism in the human brain. We first simulated mosaic variants at various allele frequencies by mixing and sequencing DNA from four unrelated individuals. Using these data, we evaluated the performance of commonly used tools for somatic variant discovery. This experiment revealed that the naive application of common tools used for germline variant discovery from a single sample or somatic variant calling from paired samples (as typically done in cancer studies) is neither precise nor sensitive enough to confidently detect low frequency mosaicism (*i.e.*, variants present in <10% of the cells in an individual). Next, different BSMN labs produced four replicates of whole-genome sequencing and two replicates of whole-exome sequencing from bulk dorsolateral prefrontal cortex tissue and dural fibroblasts from a reference healthy human brain. We developed and applied several analytical approaches for calling and filtering somatic SNVs from these data to arrive at a set of 1298 putative SNV calls. We conducted extensive validation on a subset of 400 variants comprising both high confidence and randomly selected low confidence events, leading to the identification of 44 *bona fide* somatic variants. As part of this process, we derived a series of bioinformatics filters and consensus best practices for somatic variant discovery. This analytical resource and best practices implementation will be made available to the scientific community and provide a guide for the assessment of the role of somatic single nucleotide variation in human neuropsychiatric disease.

---

Alzheimer's disease (AD) is an age-dependent illness with increased environmental contributions at older ages of onset. Thus, understanding epigenomic changes in AD are likely to shed new light on AD disease risk. Among the most widely studied epigenomic change is DNA methylation. Multiple Epigenome-Wide Association Studies (EWASs) on AD show 100s of differentially methylated sites in different brain regions. However, current array-based technologies that these studies utilized profile only about 2% of all CpGs which is inadequate. In this study, we developed EWASplus, a novel computational method that is capable of predicting whether a CpG site is likely to be associated with a disease or trait. Build upon the results from EWAS studies conducted using array-based technologies, and using genome-wide profiling (such as ChIP-seq, DNase-seq and ATAC-seq) data as features, EWASplus uses a supervised learning strategy to train a model that can distinguish CpGs associated with the disease or not, and then apply the trained model genome-wide to predict whether an arbitrary CpG site in the genome is associated with a disease or not. Cross validation studies conducted on an existing EWAS study on seven AD-related clinical and neuropathologic outcomes show promising results (AUC of ROC curves range from 0.792 to 0.960; for CERAD and neurofibrillary tangle density, respectively). When applying EWASplus genome-wide, we identify hundreds of CpGs that are not on the array but are highly likely to be associated with AD, some of which were further validated by targeted bisulfite sequencing. The development of EWASplus will enable to identify additional epigenetic loci that could be involved in AD pathogenesis.

## **PgmNr 1474: Scalable ensemble learning frameworks on single cell transcriptome from fresh human brains accurately identify rare cell states contributing to the development of Alzheimer's disease.**

---

Better understanding of regulatory architectures and underlying disease etiology substantially enhance our ability to target effective risk variants or biological processes in complex diseases including Alzheimer's Disease (AD). Recently, one study analyzed 8,000 single cells from matched healthy and AD-transgenic mice, identified a novel microglial cell type, and further proposed generalizable but hypothetical models likely restricting the progression of neurological diseases. Transferring the insightful models into applicable therapeutics in human neurodegeneration is much more challenging, as single-cell experiments with human samples are difficult to be controlled for various covariates and their heterogeneity is presumably more complex. In this study, we used fluorescence activated cell sorting (FACS) to isolate immune cells from both biopsies and postmortem human brain tissues in 30 healthy and neurodegenerative patients including AD and Parkinson Disease and generated scRNA-seq libraries of 120,000 cells via 10x protocols. To accurately identify distinct cell-states of several but unknown immune cell-types especially in disease contexts, we also developed scalable and robust computational frameworks. The incorporation of complementary approaches from parametric generative models and nonparametric statistical analyses into iterative optimization more efficiently leverage the unwanted effects of inevitable stochastic noise, sparsity of reads, and various batch effects. With rigorous analyses of these largescale single cell assays, we observed a comparable number of immune cell populations in human to those found in mice and additionally identified distinct microglial states selectively enriched in aged controls and distinctive classes of neurodegeneration. Systematic investigation of the identified subpopulations with GWAS neuropsychiatric traits revealed that a particular subset of cell-states showed large differential regulations of genes adjacent to trait-relevant loci. Regulatory network and state transition analysis on the cell populations also corroborated the differential regulatory interplay among particular microglial states for AD developments via transcriptional binding of elective transcription factors. We hope that our scalable machine learning approach and novel biological findings assist in the identification of immunological therapies, targeting the regulatory mechanisms observed across multiple neurodegenerative diseases.

## PgmNr 1475: INFERNO2: Scalable Spark-based framework for inferring dysregulated enhancer and noncoding RNAs for WGS and GWAS data.

---

Noncoding variants and structural variants can substantially alter gene expression and are enriched at regulatory elements, highlighting the importance of noncoding variants in disease pathology. However, interpretation of these variants remains challenging in part because current tools mostly focus on protein coding genes or previously reported variants, and largely ignore potentially causal noncoding variants observed in whole-genome sequencing (WGS) and GWAS. Here we introduce INFERNO2, the first Spark-based annotation and analysis pipeline for large-scale WGS and GWAS studies. INFERNO2 expands upon our INFERNO method by introducing a distributed Spark-based implementation of genomic analyses and WGS-based analyses, coupled with a curated, harmonized functional genomic database (GADB).

INFERNO2 provides a systematic approach to harmonize information from diverse data sources using a cell-type categorization system to prioritize causal noncoding variants and identify the affected regulatory mechanisms, tissues, and target genes. By converting the WGS/GWAS data into Spark Resilient Distributed Datasets (RDDs) and using distributed Spark transformations to efficiently identify loci, users can rapidly query a million of variants approximately a minute in a distributed manner against >60,000 GADB tracks (>20 billion genomic intervals) in parallel. INFERNO2 currently integrates >30 data types from 12 consortia including Roadmap and FANTOM5 enhancers, GTEx eQTLs, DASHR ncRNAs, etc.

We applied INFERNO2 to characterize the landscape of rare noncoding single nucleotide variants using the largest and most diverse late-onset Alzheimer's Disease (LOAD) WGS data from 3,709 case-control subjects across three populations from the Alzheimer's Disease Sequencing Project and Alzheimer's Disease Neuroimaging Initiative. In the LOAD group, we identified approximately 29M, 32M, and 35M variants in Caucasian, Hispanic, and African American populations, respectively, of which 73.4%, 62.6%, and 62.2% were rare variants. Overall, of the 189M analyzed variants across populations, 65% were rare variants, with 1.1% of coding, 31.8% of intronic, 7.7% of UTR, 0.8% of promoter, and 58.6% of intergenic regions, on average. FANTOM5 and Roadmap enhancers overlapped 2.7% and 49.0% of rare variants. These analyses support the utility of INFERNO2 (<https://bitbucket.org/wanglab-upenn/INFERNO2/>) for inferring the molecular mechanisms underlying

noncoding WGS signals in a common complex disease.

---

Tandem repeats (TRs) are a major contributor to human genetic variation. Estimates based on the latest high-quality structural variant (SV) truth sets indicate that over half of human SVs correspond to expansions and contractions of TRs. TRs are linked to a variety of Mendelian diseases (e.g. amyotrophic lateral sclerosis, myotonic dystrophy, Friedreich ataxia) and cancer (e.g. microsatellite instability and Lynch syndrome). Subtle changes in the repeat motif and flanking regions have also been shown to have an impact on disease onset and progression. Despite the abundance and clinical importance of TRs, they remain a challenge for standard short read-based computational pipelines. Although specialized methods for TR analysis have been recently developed, the application of these tools genome-wide requires accurate and comprehensive TR catalogs. Existing TR catalogs do not resolve repeat locus structure sufficiently well to be used with this new class of variant callers and, because they are biased to the reference, do not include many TRs that are polymorphic in the population.

To address this problem, we have created a novel method to annotate TRs. This method automatically determines repeat composition and identifies common variants in and around the repeat sequence. The method works by (a) locating approximate positions of TRs by performing a simultaneous scan of read alignments across many whole-genome sequencing (WGS) samples, (b) creating assembly scaffolds for these loci using PacBio CCS long-read samples, and (c) realigning WGS data to the scaffolds to annotate precise boundaries of polymorphic regions and their sequence composition. We have applied this method to high-depth sequencing data for 2,504 WGS samples from the 1000 Genomes Project and four PacBio CCS samples. We are releasing a pilot version of the resulting catalog that includes over 200,000 highly polymorphic TR loci together with their genotypes across all 2,504 samples, including about 5,000 loci containing two or more adjacent repeats. The list of polymorphic repeats identified by our method includes 22 out of 24 known pathogenic short tandem repeats suggesting that polymorphic TRs are not only useful for resolving common structural variation but also an appropriate target for studies aimed at the discovery of novel pathogenic TRs.

# PgmNr 1477: A deep learning framework for interpreting repetitive DNA sequence in heritable disease.

---

**Introduction:**

Pathogenic short tandem repeats (STRs), such as those associated with amyotrophic lateral sclerosis (ALS), fragile X syndrome, and Huntington's disease, elude interpretation by NGS due to their length (often hundreds of nucleotides) and low sequence complexity. Advances in PCR/capillary electrophoresis (CE) chemistry and instrumentation have enabled the analysis of STR DNA fragment size through electropherograms with visually identifiable peaks that are translatable into corresponding genotypes. Existing approaches for PCR/CE peak discernment either require manual inspection or heuristic algorithms tailored to the signal idiosyncrasies of a specific assay or instrument. To circumvent these limitations, we reframed the task of PCR/CE analysis as a computer-vision image classification problem and developed a convolutional neural network (CNN) to robustly detect and interpret STR alleles.

**Methods:**

Biological specimens from the Coriell catalog with known  $G_4C_2$  repeat lengths in *C9orf72*, an ALS-associated gene, were collected and analyzed with the AmpliX<sup>®</sup> PCR/CE *C9orf72* Kit (Asuragen). The resulting PCR/CE traces were portioned into training and testing cohorts for model development and evaluation. Potential genotypic peaks were automatically selected and classified as predicted peaks or background noise with multiple convolutional layers and pooling operations using Keras and TensorFlow. The trained CNN was evaluated and compared to a rule-based algorithm on the Coriell test set and an independent clinical cohort.

**Results:**

The CNN was trained on fewer than 600 PCR/CE traces and evaluated on  $\geq 150$  independent validation samples. The model achieved sensitivity and PPV of  $\geq 99\%$  at the genotype level and  $\geq 99\%$  accuracy at the sample category level (i.e., normal, intermediate, and expanded) in both independent datasets, outperforming a heuristic method. The limit of detection for expanded mosaic peaks in the background of normal *C9orf72* alleles was 20%. The final pipeline was deployed as an analysis plugin with swift ( $< 3$  min per 100 samples) push-button reporting, automated QC checks, and a user-friendly interface for external assessment.

**Conclusion:**

CNNs can greatly improve the accuracy and expedience of PCR/CE-based genotyping for *C9orf72* STR mutations. This is the first deep-learning platform for the automated analysis of PCR/CE data and can be leveraged to accelerate research and diagnostic applications in STR disorders and other PCR/CE applications.

## PgmNr 1478: A new pipeline designed for reliable and accurate short tandem repeat realignment.

---

Short tandem repeats (STRs) are DNA sequences composed of tandemly repeated 1-6 base pair units. STRs comprise ~3% and are widely distributed throughout the human genome. These repetitive sequences have very high mutation rates that lead to both sequence and length variants. STR variants have been associated with a number of severe neurological diseases including Fragile X syndrome, amyotrophic lateral sclerosis, and Huntington's disease. Despite the likely important role of these genetic variants in human disease, accurate calling of STR variants from short-read next-generation sequence data has been extremely challenging due to the high complexity of the DNA sequence that leads to higher rates of sequencing errors and lower mapping efficiency of sequence reads that include repeated sequence. Here, we developed a new pipeline focusing on stable and accurate realignment of sequencing reads containing tandemly repeated sequences. Our pipeline highlights the following three features that distinguishes it from existing STR realignment softwares: (1) simplifying the information required for local realignment of the target STRs provided by user to diminish the impact of any imperfect input and allow easier user customized target lists, including unbiased compilations of STRs in any user interested reference sequence; (2) providing a convenient tool to locally realign the short next generation sequencing reads to the target STR and flanking regions; (3) combining both mapping based flank-guiding method and k-mer based repeat-guiding method to ensure both the accuracy and the sensitivity of STR sequence realignments. Our pipeline successfully realigned >99.9% of simulated STR sequencing reads incorporating a sequencing error rate of 0.5% from individuals with extension or truncation variants of varying sizes at the amyotrophic lateral sclerosis associated *C9ORF72* STR locus. Our pipeline also succeeded in identifying a pathogenic STR expansion variant from an amyotrophic lateral sclerosis patient with a clinically-confirmed and quantitatively assessed pathogenic variant by applying a subsequent calling analysis to the realignment result. In summary, our new pipeline provides a user-friendly choice for genomewide target STR realignments, with reliable and accurate realignment results highly adaptable for subsequent variation calling and analysis.

## PgmNr 1479: Artificial intelligence approach to genomics-image analysis of Alzheimer's disease.

Deep learning demonstrates great potential for diagnosis and prediction power in complex diseases. Despite its great progresses in computer vision, diagnosis and early detection of complex diseases, it is well known that deep learning is 'black boxes' due to their low interpretability to humans. The lack of transparency of deep learning compromises its application to the prediction and mechanism investigation in complex diseases. Overcoming these limitations remains a great challenge. In this report, we develop a novel general framework that integrates deep learning and causal inference for genomic-image analysis. It consists of two stages: (1) develop convolutional neural networks (CNN) to classify AD status and use occlusion map to find image regions that are most distinctive for disease status and (2) the state-of-the-art causal inference tools to determine if the selected image regions are causal for AD and identify genetic variants that cause image variation. The CNN model VGG was chosen for image classification and prediction. Prediction difference analysis for visualizing the response of CNN to a specific input was used to select features for DTI image classification. Wasserstein conditional generative adversarial networks (WCGAN) will be used to discover causal relationships between the brain neuroimaging region and AD, and causal relationships between the brain neuroimaging region and gene as well. A novel statistic for testing causation and its asymptotical distribution are developed. The proposed algorithm is applied to the Alzheimer's Disease Neuroimaging Initiative dataset with diffusion tensor imaging (DTI) in 151 subjects (51 AD and 100 non-AD) that were measured at 4 time points of baseline, 6, 12 and 24 months, and 1,589,061 SNPs. The algorithm achieved prediction accuracies of more than 92% at all four time points. The algorithm also identified brain regions underlying AD consisting of the temporal lobes (including the hippocampus) and the ventricular system. To uncover genetic architecture of brain regions, we conducted genetic imaging causal analysis for these two brain regions. We identified that 43 genes had causal relationships with the frontal, left temporal lobe and 46 genes that showed causation with the right temporal lobe region such as CD33, APP, FGF4, FRMD6, Dock9, H3F3B, SCYL1, PIGC and AKAP5 that were confirmed causations with some diseases in literature.

## PgmNr 1480: Bioinformatics approach to propose autism spectrum disorders priority genes in Mali.

### Authors:

---

**Introduction:** Autism Spectrum Disorder (ASD) is a developmental disorder affecting social interaction, communication and repetitive movements of restrictive interests. ASD is familial in 10% of cases.

**Aim:** This work was aimed to propose a panel of ASD priority genes for the genetic study of ASD in Mali.

**Methods:** The literature review and the use of bioinformatics tools have made it possible to identify ASD genes. Priority criteria were used to determine the frequent mutations in the hot regions of the identified genes and to identify regions recognized by restriction enzymes.

**Results:** The priority genes *Tcf4*, *Tsc2*, *Chd8*, *Nlgn3*, *Nme1*, *Mef2c*, *Shank3*, *Dhcr7*, *Tsc1*, *Comt*, *Pten*, *Snta1*, *Akt1*, and *Prodh* were obtained with high priority scores. In the following five genes *Mef2c*, *Pten*, *Prodh*, *Nme1*, and *Dhcr7*, mutations were found at endonuclease restriction sites *BseRI*, *Nspl*, *PfrJS2IV*, *BspGI*, *BsaBI*, and *SpoDI*.

**Discussion:** The list of these priority genes could be used as a starting point for the determination of a panel of ASD genes in Mali. *Chd8*, *Pten*, and *Shank3*, *Mecp2* and *NLGN3* are listed as priority genes by the Simmons Foundation for Autism Research Initiative, too. Restriction by endonuclease may reduce the cost of sequencing eligible genes.

**Conclusion:** Determining the frequency of mutations of these genes in subjects living with ASD and in the general population in Mali will further clarify their relevance in Mali.

## PgmNr 1481: A maximum flow formulation for dimensionality reduction and identification of high-confidence noncoding variants associated with autism spectrum disorder.

---

The effect of noncoding variants on the phenotypes of complex genetic disorders remains unclear. Machine learning approaches for predicting putative genetic variants from whole genome sequence (WGS) data have been proposed to elucidate the relationship between genotype and phenotype; however, the predictive power of these methods is severely limited by the presence of high-dimensional variant feature spaces, which lead to model instability and lack of generalizability. Here, we design a novel maximum flow formulation based on linkage disequilibrium (LD) to address this issue and extract a set of stable, high-confidence noncoding variants that are likely to be associated with Autism Spectrum Disorder (ASD).

We analyze 232,193 variants in simple repeat sequences (SRS), collected from 30x coverage WGS of 2182 children with ASD and 379 unrelated control patients with a distinct late-onset disease. We perform 5-fold cross-validation with an  $L_1$ -regularized logistic regression classifier and extract the list of variants assigned non-zero coefficient scores from each validation fold. A model with stable features will be resistant to slight perturbations in the underlying data; to obtain a list of stable variants, we use maximum flow to identify a maximum variant matching across folds based on the presence of LD. The five sets of variants are assembled in a flow network, in which each node  $n$  is defined by a variant and the fold in which it occurs, represented as  $n=(v,f)$ . A directed edge is drawn between a pair of nodes  $n_1$  and  $n_2$  if the following criteria are satisfied: (1)  $n_1$  and  $n_2$  are present in neighboring folds such that  $f_2=f_1+1$  and (2)  $v_1$  and  $v_2$  are in LD as indicated by the  $R^2$  value exceeding 0.8. This maximum flow formulation identified 50 regions (representing 55 SRS variants) that remain stable across all five folds.

To determine if this set of 55 SNPs can serve as a viable biomarker for ASD, we train a logistic regression classifier on this reduced feature set, which we found to perform well on the test set (AUC-ROC=0.812) as well as on an independent dataset consisting of unique ASD samples and non-ASD controls (AUC-ROC=0.922). The classifier also significantly outperforms a bootstrapped analysis with randomly-selected variants ( $p<0.05$ ). Thus, we determine a set of stable SRS variants that are likely to be associated with the ASD phenotype and show that this method can effectively identify

predictive variants from a high-dimensional feature space.

## PgmNr 1482: Shared genetic etiology underlying LOAD and MDD.

### Authors:

Patients with late-onset Alzheimer's Disease (LOAD) frequently manifest comorbid neuropsychiatric symptoms (NPS), with depression and anxiety being most frequent. Furthermore, depression has been found to be associated with increased risk to develop LOAD. Major depressive disorder (MDD) is a neuropsychiatric condition that patients have an increased prevalence of LOAD. These evidences suggest the possibility of shared etiologies and intersecting pathways between LOAD and MDD. As the first logical step towards understanding their overlapping etiologies, we focused on genetic risk and investigated genetic pleiotropy between LOAD and MDD. We performed analyses for the identification of shared genetic signatures based on comparisons between associated-single nucleotide polymorphisms (SNPs) of the two diseases. Specifically, we assessed genetic pleiotropy by conditional false discovery rates (FDR), fold-enrichment plots and conditional quantile-quantile (q-q) plots using LOAD and MDD genome-wide-association studies (GWAS). GWAS datasets for LOAD were obtained from the International Genomics of Alzheimer's Project and for MDD from the Psychiatric Genomics Consortium (PGC). We found an enrichment of 4-8-fold for LOAD across increasingly stringent levels of significance with the MDD GWAS association (LOAD|MDD), including and excluding the *APOE* region, respectively. Conditional FDR analysis supported known LOAD-risk loci including *SPI1*, *MS4A2/MS4A6A*, *SORL1*, *CR1* and several novel risk-loci including *MADD* and *MFSD2A* as pleiotropic for LOAD and MDD. *MFSD2A*, is particularly interesting as it's required for blood-brain-barrier formation and function, probably by mediating lipid transport. Noteworthy, SNPs in *SPI1*, previously identified as eQTLs, showed FDR significant association with LOAD and MDD. The reverse conditional association (MDD|LOAD) showed moderate enrichment of approximately 7 fold. Overall, our results showed a moderate level of polygenic overlap between LOAD and MDD. Identifying the common genetic signatures for LOAD and MDD will advance our understanding of the shared genetic etiologies and impaired pathways between these two conditions. Our data suggest that *SPI1* (PU.1) may play a role in both MDD and LOAD, implicating common pathways involved in myeloid cell function. This knowledge will provide insights regarding actionable targets for novel therapies to treat depression preceding dementia in an effort to delay or ultimately prevent the onset of LOAD.

## PgmNr 1483: ParseCNV2: Optimized for fast easy curation and CNV disease association.

Copy number variation (CNV) detection has remained an area of heavy emphasis for algorithm development; however, both CNV curation and disease association remains in its infancy. The current candidate CNV era, where researchers study specific CNVs they believe to be pathological while discarding others, misses the full spectrum of CNVs in a hypothesis free GWAS. We present a next-generation approach to CNV association by natively supporting the popular VCF specification for sequencing derived variants as well as SNP array PennCNV format. While many VCF parsers exist, few if any support the variety of VCF presentations and interpretations of CNV genotypes. Therefore, we implemented a flexible VCF to rawcnv/bed format conversion tool. Key challenges include the variety of ways to represent the end genomic position and the alternative alleles. The end position may have any combination of "LENGTH=" or "END=" in the info field or may need to be inferred by the string length difference between ref and alt alleles. The allele coding for the genotypes can use any combination and order of alternative allele copy number states. ParseCNV2 is a combination of Perl, R, Bash, and C programming. The required inputs are a CNV call file (VCF or rawcnv format) and the case sample definition. ParseCNV2 starts with a comprehensive quality control (QC) pipeline of both samples and individual CNV calls. The pre and post association CNV curation is rigorously supported and emphasized to yield reliable results of highest quality. Chr, start (base pair position based on the genome build), end, p-value, odds ratio (OR), cases (count), controls (count), and filter are statistical association fields in the output. Direction, type, cases, controls, caseIDs, controlIDs are annotated to track the kind of association signals produced. Segmental duplications (SegDups), Database of Genomic Variants (DGV), Guanine/Cytosine base content (GC), cytoband, recurrent events, exon impact, gene(s) impacted and telomere/centromere involvement are provided as genomic feature annotations. Collectively, this provides high confidence and high quality association results. Significant CNVRs are then QC reviewed for further curation and bias screening and either kept or dropped based on predetermined significance criteria. ParseCNV2 allows fast and easy curation and association of CNVs in both population and family-based disease settings. The software is available at <https://github.com/CAG-CNV/ParseCNV2>.

## PgmNr 1484: Introducing privacy preserving machine learning in pharmacogenomics research.

**Motivation:** In the era of large genomic data sets and machine learning (ML), secure data management is one of the key challenges when developing biomedical software, handling personal, clinical and genomic patient information. Particularly in psychiatric and pharmacogenomic research, where state-of-the-art ML approaches are slowly gaining attention, data confidentiality is a continuous concern. Therefore, privacy-preserving technologies will play a crucial role to pave the way for the application of modern ML in medical diagnostics and treatment optimization of psychiatric disorders.

**Methodology:** In this presentation, we will highlight the pitfalls of traditional ML approaches with respect to data privacy and leakage, as well as the availability and distribution of biomedical and genomic data sets. Subsequently, we will introduce possible solutions utilizing the power of distributed systems, such as federated learning, and the integration of different ensemble learning techniques. The aim is to implement a high-quality centralized model while patient data remains at a potentially large number of secure host locations. In summary, it uses the concepts of distributed computing to (1) train local models on the host devices, (2) build a central aggregated model, and (3) re-distribute the updated model to the hosts.

**Application:** Finally, we will demonstrate potential applications of privacy-preserving ML on large cohorts with extensive clinical and genomic data of patients diagnosed with major depressive disorder and schizophrenia. Thereby, we will outline the importance and performance of federated ML within the scope of personalized psychiatric diagnostics and pharmacogenomic research for treatment optimization.

# PgmNr 1485: Prediction of deleterious effect of noncoding variants mediated by RNA-binding proteins in developmental disorders.

Previous studies identified significant contribution of *de novo* coding variants to developmental disorders such as autism spectrum disorder (ASD), but the impact of *de novo* noncoding variants is not well understood. Most research in noncoding variants has focused on transcriptional regulation through transcription factors and chromatin modifications, while post-transcriptional regulation has been relatively under-studied. We aim to address this gap and improve the understanding of the role of noncoding mutations by investigating disruption of RNA binding protein (RBP) binding sites. In this study, we developed a deep convolutional neural network (CNN) model to learn different RBP binding sites from genomic sequence, and to predict when mutation can cause significant disruption of these sites and disturb normal post-transcriptional regulation. We trained the model using eCLIP binding sequence data with a balanced negative set of sequences randomly sampled from the human genome, controlled for GC content. The eCLIP data was obtained from ENCODE and consists of binding sites of 112 unique RBP types in two cell lines (K562, HepG2). Similar to deep learning methods for identification of transcription factor motifs, both canonical and novel RBP binding motifs were captured within the convolution layers and visualized with techniques like Grad-CAM for validation. Strong binding prediction performance was achieved for the 160 RBPs with a median AUC of 0.890 (10-fold CV). HepG2.HNRNPC (AUC=0.97), K562.TARDBP (AUC=0.96), and HepG2.RBFOX2 (AUC=0.94) performed the best. We applied our method to analyze *de novo* noncoding variants from a whole genome sequencing study of ASD (An et al 2018). We predicted variants as highly loss-of-function (LOF) or gain-of-function (GOF) by maximal likelihood score delta derived from the difference in binding prediction between the alternate and reference sequences across all RBPs that are constrained (ExAC pLI $\geq$ 0.5). We observed significantly more noncoding *de novo* mutations predicted LOF in cases than in controls, suggesting a substantial role of post-transcriptional regulatory noncoding *de novo* variants in ASD. In summary, we developed a deep learning method to predict disruption of RBP binding by noncoding mutations using sequence information not captured by other genetic and epigenetic annotations, and utilized it to prioritize candidate pathogenic variants that potentially disrupt binding of key RBPs.

## PgmNr 1486: Bioinformatics approach to support genetic research in Autism in Mali.

### Authors:

M. Kouyate <sup>1</sup>; M. Sangare <sup>2</sup>; S. Samake <sup>1</sup>; S. Keita <sup>1</sup>; H.G. Kim <sup>3</sup>; D.H. Geschwind <sup>4</sup>

### Affiliations:

1) ACE, USTTB, Bamako, Mali; 2) FMOS, USTTB, Bamako Mali; 3) Neurological Disorder Center, Qatar Biomedical Research Institute (QBRI), Doha, Qatar; 4) Center for Autism Research and Treatment (CART), UCLA, Los Angeles, USA

---

**Introduction:** Autism is a complex condition resulting from the interaction between genetic predisposition and environmental factors. Bioinformatics can shed light on the genetics of autism. In addition, human genetic studies can be expensive even unaffordable in developing countries in which genetics and mental health are not the health priorities.

**Aim:** To pilot the use of bio-informatics tools to guide scientifically valid, locally relevant and economically sound autism genetic research in Mali.

**Methods:** We used databases NCBI, Assembl, HGMD, LSDB, and DBSNP to identify point mutations and associated endonucleases. Criteria (phenotype, transmission pattern, theoretical expression in the brain, impact of the mutation on the 3D structure of the protein) were used to assign priority to the selected autism genes. We used the protein database (PDB), Modeller (protein 3D structure modeling), Web logo (design the motif of functional domain of the protein) and clustal W (alignment of sequences to find similarities).

**Results:** We found hot point mutations in these high priority autism genes *Mef2c* (Gly27Ala/Leu38Gln), *Pten* (Thr131Ile), *Prodh* (Leu289Met), *Nme1* (Ser120Gly), and *Dhcr7* (Pro227Thr/Glu224Lys) (**Tableau 4**) were respectively associated with restriction restriction enzymes *BseRI*, *NspI*, *PfrjS2IV*, *BspGI*, *BsaBI*, and *SpoDI*. Gly27Ala/Leu38Gln mutations impacted on the 3D structure of the Mef2c protein (**Figure 1**). Alignment of Mef2c protein sequences from different organisms showed high percentage of similarity with highly conserved MADS domain (**Figure 2**).

**Discussion:** The determination of the *Mef2c*, *Pten*, *Prodh*, *Nme1*, and *Dhcr 7* gene mutation frequencies in the Malian population will be interesting in many ways. First, the association of restriction enzymes to the hot spot point mutations will allow us to use PCR + restriction enzyme digestion for mutation screening. Sanger sequencing will be used for confirmation only, which represents an importance saving on the *Sanger sequencing cost*. Second, any discrepancies between the restriction enzyme digestion and sequencing results will lead further discussion and investigation. The knowledge of the 3D structure and potential impact of the mutations on Mef2c protein informed on the protein family and altered function (ex. Leu38Gln).

**Conclusion:** Bio-informatics tools allowed to generate new genetic information on African-led autism research in Mali. Our approach can be applied to other neuropsychiatric disorders.

# PgmNr 1487: Predicting psychiatric phenotypes: Developing and evaluating a standardized, machine learning workflow for genome-wide and clinical data.

## Authors:

V. Marshe<sup>1,2</sup>; A. Hauschild<sup>1,3</sup>; M. Maciukiewicz<sup>1</sup>; J. Reimand<sup>4,5</sup>; D. Müller<sup>1,2,6,7</sup>

[View Session](#) [Add to Schedule](#)

---

**Introduction:** While state-of-the-art machine learning (ML) approaches are only slowly gaining attention in psychiatric research, ML is already widely applied and shows exceptional diagnostic and prognostic performance in oncology and radiology. Here, we present a standardized ML workflow for psychiatric phenotype prediction using large scale genome-wide data, as well as the evaluation of varying parameters on model performance.

**Methods:** Our sample included 748 individuals from the Alzheimer's Disease Neuroimaging Initiative (ADNI) with genetic (Illumina Omni2.5) and clinical data after standard quality control. We investigated various modelling parameters including phenotype definition, genetic pruning threshold, genetic coding (genotypic vs. allelic SNP coding), sample balance (unbalanced vs. upsampled), feature prioritization feature selection and classifier selection within a nested, 5-fold cross-validation framework. After splitting the sample into independent training (70%) and holdout test (30%) sets, we explored Alzheimer's disease status, beta-amyloid levels, and cognitive performance. Features were prioritization using either functional-based (CADD PHRED scores) or univariate association-based filtering. Subsequently, features were selected using either LASSO or random forest with recursive feature elimination. Lastly, we optimized several classifiers including tree-based, boosting, linear, and kernel-based algorithms. Model performance was assessed using AUC, sensitivity, and specificity.

**Results:** In total, we fit 896 unique parameter combinations. While internally there appeared to be no impact of the coding scheme, externally, additive coding showed better performance (AUC =  $0.53 \pm 0.03$ ) than 'boosted' allelic coding (AUC =  $0.51 \pm 0.04$ ,  $p = 0.006$ ). Sample balancing did not have a significant impact on performance in genome-wide genotyping data (FDR > 0.05). Internally there were significant differences in performance among classifiers, however, these were not reflected in external performance ( $p > 0.05$ ). In addition, features from our best-performing model revealed interesting biological insights showing a potential association of angiogenic pathways with beta-amyloid levels.

**Conclusion:** Our prototype workflow and preliminary results represent a proof of concept showing

the feasibility of such an ML workflow for genome-wide, psychiatric studies and potential for the systematic evaluation of methodological decisions on the modelling process.

The NIMH Center for Collaborative Genomic Studies on Mental Disorders, now known as the NIMH Repository and Genomics Resource (NRGR), maintains biomaterials, demographic, and phenotypic data from over 200,000 well-characterized individuals with a range of psychiatric illnesses, their family members, and unaffected controls. NRGR receives these data from principal investigators of NIMH-funded studies. The center is then responsible for curating the clinical data submitted and creating collections of well-characterized, high-quality patient and control data and biosamples that are widely used for psychiatric research.

Previously, the curation effort was largely manual with ad-hoc harmonization procedures in place that led to inconsistencies and variance across studies and disorders. To streamline and formalize this process we developed a web-based automated quality control system (AutoQC) for phenotypic data submissions (<https://nimhgenetics.org/submit-your-data/overview>). AutoQC curates submissions and ensures stringent data quality requirements. At the heart of the system is a custom, flexible data dictionary format that enables the system to automatically enforce standard syntactic checks and also allows users to self-describe their phenotypic file format, which the system then enforces. Users upload a zip file comprised of comma- or tab-separated files containing data for NRGR and user-defined dictionaries. AutoQC verifies that users' data submissions satisfy the requirements defined in the corresponding data dictionaries, and performs a variety of additional checks (e.g., individuals identified as fathers are males). In addition, AutoQC implements advanced curation steps that verify users' data against the center's database, ensuring that clinical data is correctly linked to an individual's biosamples, that individuals' diagnosis codes conform to DSM standards, referential integrity constraints across multiple files, and other checks. AutoQC generates a web-based report in real-time for investigators to review. Error-free data submissions are forwarded to experts for final manual curation, for checks which haven't yet, or cannot be completely automated.

Each user submission is implemented as a distributed workflow managed by Pegasus WMS. This facilitates the addition of new curation checks into the framework. If new checks are later added, we can easily re-submit the existing, accepted distributions, resulting in improved quality of the overall datasets.

## PgmNr 1489: Interpretable neural networks for schizophrenia risk prediction based on whole exome sequencing data.

---

**Objective:** Schizophrenia is a highly heritable mental disorder with a complex etiology. Recent studies have associated more than 100 different loci with schizophrenia, demonstrating the complex polygenic nature of this psychiatric disorder. Modern methods, such as neural networks, allow exploration of complex data with higher-level dependency. Applying such an approach might yield novel insights into the etiology and genetic risk of schizophrenia.

**Methods:** The prediction model was built by training a neural network using a Swedish case control study with 4969 cases and 6245 controls, involving ~1,2 million exome variants. Variant data was reduced to 21,390 genes using a special network layer developed for omics data analysis.

**Results:** The model reached an area under the curve of 0.65 and an accuracy of ~60% in the test set, with a theoretical maximum ~74% upper limit of performance calculated on the basis of the prevalence of schizophrenia and the concordance rate in monozygotic twins. The interpretability of the network allowed us to identify the genes most crucial for network prediction of schizophrenia versus control. The five most discriminant genes were: *HLA-C*, *TTN*, *TRY2P*, *HLA-A* and *LINC00226*.

**Conclusion:** We developed an interpretable neural network architecture for exome data, which incorporates prior biological knowledge (i.e., gene annotations), and can be easily extended to include genomic, tissue, cell type, or other functional annotations. Given that every node in the network is interpretable, we anticipate this approach as having the potential for uncovering novel insights into the genetic architecture of complex diseases, such as schizophrenia.

## **PgmNr 1490: Accurate imputation of summary statistics for non-additive models can assist in the discovery of new, and fine-mapping of existing, GWAS signals.**

Methods for direct imputation of summary statistics, e.g. our group's DISTMIX tool, were shown to be practically as accurate as genotype imputation method, while incurring orders of magnitude lower computational burden when it was paired with a heavily processed reference panel. However, due to the large linkage disequilibrium (LD) between additive summary statistics of neighboring variants, such tools are of limited use in fine-mapping signal regions. As signals for non-additive models (e.g. recessive) decays faster than the typically used additive statistics, imputing summary statistics for non-additive models might assist in fine-mapping of signals. Thus, there is a great need i) for much larger and diverse panels (that can also facilitate imputation of non-additive models, e.g. recessive) in processed form and ii), for accurate LD estimation between variants, to automatically estimate the ethnic composition of the cohort. Thus, for exhaustive analysis of even cosmopolitan cohorts, we propose DISTMIX2 method/software. When compared to DISTMIX and its competitors, the proposed method adds a i) much larger and diverse reference panel, ii) imputation of summary statistics for non-additive models (recessive and dominant) and iii) novel estimation for weights of ethnic mixture based solely on Z-scores (when allele frequencies are not available). To build a larger and more diverse reference panel, we heavily processed the publicly and privately available data to obtain a 33K subject panel which includes ~11K Han Chinese. The non-additive summary statistics are imputed assuming Hardy-Weinberg Equilibrium (HWE) between variants, which is quite reasonable given the HWE testing of variants in GWAS. We apply DISTMIX2 to the GWAS summary statistics from the Psychiatric Genetic Consortium (PGC). Our method uncovered signals in numerous new regions, with most of these findings coming from the rarer variants. For instance, while there were only three (rather marginal signals) in PGC2 PTSD, our method uncovered four large signals (three of them associated with rare variants). Even more, the largest signal (p-value<1e-42 in PKN2 gene) suggests a recessive mode of inheritance for this locus.

## PgmNr 1491: Can machine learning aid in discovery of disease genes? The case of autism spectrum disorder.

---

Machine learning (ML) algorithms utilizing gene networks have been proposed as an approach for disease gene discovery. For example, for autism spectrum disorder (ASD) ML has been positioned as a supplement to traditional genetic association-based approaches to predict risk genes. However, work in our lab has raised questions about the general utility of ML methods for such tasks due to biases in gene networks and poor real-world performance. Here we report a computational evaluation of eleven published ASD gene prioritization methods, including four “pure” ML algorithms (incorporating gene network information but no genetic association data), four that rely solely on genetic association (as a control), and two “hybrid” ML-genetic methods. For evaluation we took advantage of a set of novel high-confidence ASD genes ( $n=40$ ) recently reported by Satterstrom et al. (2018) and Ruzzo et al. (2018) and not used for training the ML algorithms. We also examined a set of 86 previously reported high-confidence genes, many of which had been used to train the ML methods. We hypothesized that if the ML methods are effective, they should recover both the “known” and “novel” genes with high precision. Instead we found that, compared to genetic association methods, the pure ML methods perform relatively poorly both at recovering previously identified ASD genes (maximum precision at 20% recall [P@20R] 5% compared to 100% for genetics) as well as novel genes (1% vs 7% for genetics). In agreement with our previous reports, most of the ML methods also exhibit bias towards highly-studied and/or highly-connected genes (e.g.  $r=0.44$ ), which implies they are learning generic features of gene networks, not specific to ASD. The hybrid methods perform at best slightly better than simply using genetic association (maximum P@20R known=94%; novel=6%). Importantly, a generic gene-level feature, the haploinsufficiency score (pLI) has comparable performance to sophisticated ML methods (P@20R known=7%; novel=1%). The poor performance and bias of the ML methods compared to this naïve approach suggests there is still a substantial challenge in providing useful ML-based prioritization above that provided by direct genetic analysis.

## PgmNr 1492: Study of brain cell types underlying schizophrenia through a machine learning approach.

### Authors:

---

The understanding of genetic architecture of schizophrenia (SCZ) has significantly improved in the past decade. The genetic risks of SCZ are mostly attributable to common variants. However, very little “actionable” knowledge has been established to guide subsequent experimental modeling. One important reason is that the molecular and cellular complexity underlying SCZ remains poorly understood. Understanding of genetic risks at cellular level is crucial, as it would make it possible to identify the cells that are fundamental to the genesis of the disease. The recent development of single-cell RNA sequencing (scRNA-seq) technologies provide us a unique opportunity to dissect the genetic risks of SCZ in a cell-type specific manner. However, mapping the genetic findings to the specific cell types that they best fit to is not an easy task. Few accurate SCZ genes are available for mapping due to the factor that the majority of SCZ-associated SNPs identified by GWAS lie in non-coding regions, making it is not straightforward to infer the exact genes potentially affected by the associated risks. To address this challenge, we proposed a machine learning approach to simultaneously identify disease genes and the cell types they are active in using a bi-clustering algorithm. The basic assumption of our approach is that different cell types contribute to the heterogeneity of disease pathology by affecting different groups of disease genes. The application of our approach to brain scRNA-seq and SCZ GWAS data identifies different disease gene modules and the relevant cell types. We found the majority of SCZ disease genes were highly expressed in neuron cells, confirming previous findings. In addition, we also identified disease gene modules that were active in oligodendrocytes and endothelial cells. Disrupted synaptic connectivity has often been observed in SCZ patients and emerging evidence suggests that this is a result of dysfunctional oligodendrocytes. Also, changed brain endothelial cell gene expression has been observed in SCZ patients. The disease genes associated with neuron cells did not overlap with that of oligodendrocytes and endothelial cells, suggesting that different cell types contribute distinctively to SCZ etiology. These results also show that our approach is a powerful tool to dissect genetic heterogeneity underlying disease pathology.

## PgmNr 1493: Markov affinity-based proteogenomic signal diffusion (MAPSD) reveals dynamics of multi-omics data integration in brain disorders.

---

Heterogeneous pathophysiology of brain disorders, such as schizophrenia (SCZ), autism spectrum disorders (ASD) and Alzheimer's disease (AD), necessitates taking a holistic perspective through extracting knowledge from diverse sources of data modalities. Extensive genome wide association studies (GWAS), genome/exome sequencing studies and transcriptomic studies have led to a large pile of biological knowledge on various brain disorders. Tissue or cell type specific epigenomics and proteomics data are also accumulating rapidly on brain disorders, through large-scale consortium efforts such as PsychENCODE and Human Protein Atlas. How to understand complex brain disorders in the contexts of multi-omics and multi-tissue data remains a challenge. To account for such a critical need, we propose Markov affinity Proteogenomic Signal Diffusion (MAPSD), a novel multi-omic systems biology model to identify and prioritize disease-associated proteins given existing biological evidences including: GWAS hits, rare variants association hits, *de novo* mutations, differentially expressed genes, differential open chromatin and differential methylation data in cell type specific manner. MAPSD superimposes the existing evidences on human protein interactome or any arbitrary protein-protein interaction (PPI) networks and diffuses the disease signals across the network using Laplacian characteristic of network adjacency matrices which acts as a low-pass filter, and is able to remove weak signals from distant proteins (nodes) arrived at un-annotated proteins. MAPSD signifies critical features governing protein function including subcellular localization and normal abundance of proteins in various microdomains. Using data from the Human Protein Atlas, we investigated three brain regions including cerebellum, cerebellar cortex and hippocampus as well as multiple different cell-types such as neuronal cells, glial cells, Purkinje cells, endothelial cells, and the cells in granular and molecular layers. We demonstrated that existing biological knowledge can facilitate multi-omics data integration and improve the understanding of proteome data, and highlight contributions from different brain regions or cell types in different brain disorders.

## PgmNr 1494: Dissecting phenotypic variation in PTSD using genetically-regulated transcriptional variation.

### Authors:

---

**Background:** PTSD occurs in some trauma-exposed individuals, but its molecular basis remains uncharacterized. Previously, we have associated genetically regulated gene expression (GReX) across tissues with PTSD revealing the importance of RNA splicing in the prefrontal cortex for PTSD biological mechanisms (Huckins et al. Under review 2019). We additionally, established that brain GReX is more closely associated with brain biomarkers (i.e., neuroimaging), while blood GReX is closer to blood biomarkers (i.e., observed blood gene expression and peripheral cytokines) (Chatzinakos et al. In Preparation 2019). Here, we study the relationship between genetically-regulated transcriptional variation, and phenotypic variation in PTSD, in a cohort of 9400 inner-city, low-socioeconomic-status, primarily-African-American patients of the Grady Memorial Hospital.

**Methods** Each individual was ascertained phenotypically using interview-based assessments, self-reports and lab tests. In addition, we imputed gene expression across 48 tissues using GTEx project's eQTL maps. To study the comorbidity patterns of transcriptomic and phenotypic information across individuals, we used MixEHR, a Bayesian unsupervised learning method (Li & Kellis, 2018). **Results** We identified 3 latent disease topics predictive of PTSD diagnosis (absolute LASSO coefficient > 5).

Based on symptom severity and trauma exposure, 2 of the topics were related to vulnerability (one with high childhood trauma and depression) and one related to resilience. We found enrichments for genes and tissues in the disease topics across multiple tissues.

Top brain tissues with the highest PTSD associations are dorsolateral prefrontal cortex and anterior cingulate cortex, which have been associated with cognition, emotion/stress regulation and PTSD. We also constructed a ranked list of PTSD genes across multiple disease topics. The top genes were: adipose and cardiovascular GXYLT1, a glucoside xylosyltransferase, blood SLC35A4, a glucose transporter, and brain genes related to post-transcriptional and post-translational modifications.

**Conclusions** By combining transcription imputation across the body with Bayesian machine learning in a trauma-exposed sample, we discovered tissue-types and genes that yield new biological insights into the genetic and phenotypic architecture of PTSD.

## PgmNr 1495: Deep-learning-based prediction of late age-related macular degeneration progression.

---

Age-related macular degeneration (AMD) is a leading cause of incurable blindness worldwide. Previous genetic studies have shown the progression time to late AMD could be affected by genetic variants and environmental factors. The Age-Related Eye Disease Study (AREDS), a clinical trial from the National Eye Institute, includes genome-wide genotyping data, longitudinal color fundus photographs, and disease severity assessment over a period of 12 years, providing an unprecedented opportunity to investigate prediction models for progression to late-stage AMD. In this report, we jointly used genotypes and fundus images to dynamically predict an eye as having progressed to late AMD (e.g., whether the time to progression to late AMD for the eye exceeds 2 years from the current visit) with a modified deep convolutional neural network (DCNN). In total, we used 31,262 color fundus images in field 2 (centered above the macula) from 1,351 subjects with corresponding genotypes and phenotypes available at baseline and follow-up visits. The first part of this model was derived from a CNN to extract features. After obtaining the output vector of the final convolutional layer, we imputed these extracted image features to a fully connected layer for classifying AMD severity. Thereafter, we incorporated this estimated severity along with reported genetic variants to another layer for predicting the probability of progression to late AMD. Our results showed that the color fundus photos coupled with genotypes could predict late AMD progression with an averaged area under the curve (AUC) value of 0.85 (95%CI: 0.83-0.86). The results using fundus images alone showed an AUC of 0.81(95%CI: 0.80-0.83). We have validated our results in an independent dataset of 200 Caucasians extracted from UK Biobank and the results showed an AUC of 0.9 (95%CI: 0.85-0.94) for predicting whether the eye progresses to late AMD exceeding the 3 years.

## PgmNr 1496: Using phenotypic heterogeneity to model the pathogenic contribution of individual *USH2A* alleles.

Phenotypic heterogeneity provides a significant challenge to the interpretation of genetic testing results. *USH2A* is both the most common cause of type 2 Usher syndrome and the most common cause of non-syndromic retinitis pigmentosa (RP), yet little is known about which combinations of alleles in this recessive gene will lead to which disease. We present a technique to model the pathogenic contribution of different alleles using only the genotypes and referring diagnoses of cases gathered from public sources. We employ this model to predict diagnosis based on genotype.

Genotypes and referring diagnosis (Usher or RP) were gathered from *USH2A*-positive cases from the Leiden Open Variation Database as well as 20 published cohorts. Individuals were excluded: 1) if they did not have exactly two reported alleles, 2) if any of their reported alleles was unique in the dataset, and/or, 3) if their referring diagnosis was unclear. This yielded 866 patients (71.7% Usher syndrome). From these patients, a system of inequalities was constructed with coefficients for each allele. This system of inequalities was based on the assumptions that the alleles act in an additive fashion and that Usher syndrome is more severe than non-syndromic RP. This system was solved using a linear programming solver. To evaluate the performance of the model, leave-one-out cross-validation was performed.

The model correctly predicted the phenotype of the patient 84.6% of the time. Additionally, the optimization divided alleles into three types: 1) alleles that always cause type 2 Usher Syndrome when opposite any disease-causing mutation; 2) alleles that cause Usher syndrome when in combination with a similar variant; and, 3) alleles that only cause Usher syndrome when opposite a strongly deleterious allele.

Knowledge of the pathogenic contribution of individual alleles in recessive disease will ultimately allow physicians to provide more accurate prognostic information and facilitate the identification of outliers caused by modifying factors.

## PgmNr 1497: Automated variant ranking: A valuable tool for Mendelian disease analysis.

---

### Purpose:

Inherited retinal diseases (IRDs) are highly heterogeneous, with over 250 genes known to cause photoreceptor degeneration, following all modes of Mendelian inheritance. High throughput panel sequencing has been increasingly used in the diagnosis of IRDs, with ~50% of cases being genetically solved by single nucleotide variants (SNV) or small insertions/deletions in the exons of known IRD genes. With the plethora of NGS data coupled with a high rate of straight-forward solutions, there is a need for bioinformatics tools to address the repetitive and time-consuming process of variant analysis. To this end, we have developed a Mendelian Analysis Toolkit (MATK), an automated variant ranking software with the purpose of predicting the most likely causal variants for a given patient.

### Methods:

MATK uses a primary input of annotated VCF files, aggregating information from sources such as HGMD, ClinVar, gnomAD, and CADD scores, and providing customizable weights to the information based on expert input. It produces a ranked list of potentially disease-causing variants based on the weighted score. The tool can also perform pedigree aware analysis as well as integrate CNV predictions into the ranking. To determine if MATK performed similarly to a human analyst, the tool was used to prioritize variants in >600 panel-sequenced IRD subjects, a subset of which was compared against expertly curated variants from samples analyzed individually.

### Results:

Considering only first ranked variants, MATK found that 15% of cases were predicted as solved by variants in *USH2A*, 6% by *EYS*, and 4% by *ABCA4*, which corresponds roughly to expected prevalence rates of these genes in IRD etiology. When comparing the tool's output to expert curation, MATK's first or second ranked variant matched human analysts' choices in >90% of cases. The tool was particularly good at identifying and ranking high likely disease-causing variants in cases of recessive inheritance due to loss of function variants.

### Conclusions:

Automated variant ranking is a valuable bioinformatics tool that can expedite the process of identifying likely solving variants in IRD subjects, as shown by a high concordance of MATK with expert curation of individual samples. The ability to programmatically rank variants in large cohorts helps to remove variability that comes from human error and researcher bias, and can be used to avoid tedious re-analysis in the event that variant annotations are added or updated.

## PgmNr 1498: An hybridized *in-silico* model for *Plasmodium falciparum* mRNA seq data analysis elucidates enriched function for several vital unclassified genes.

The era of genomics and microarray technology has ushered in a new dawn of tremendous amount of biologically useful data. This has led to various forms of research; there are various ways of analyzing such data, one of which is clustering. In this study a Hidden Markov Models, an aspect of clustering technique is presented. HMMs are useful for gene expression analysis for two reasons. The first is that the model has a very good theoretical and mathematical structure. Secondly, HMMs exhibits the Markov property, which allows time dependencies to be considered between elements; this makes it very effective for solving problems related with time series data.

In this work, HMM forward-backward algorithm and the Baum-Welch training algorithm was implemented. The *Plasmodium falciparum* RNA-seq expression data (Otto et al, 2010) was the time series data deployed on HMM. Baum-Welch algorithm was used to train the dataset to determine the maximum likelihood estimate of the Hidden Markov Model parameters. The left-to-right HMM with states varying from 2 to 10 and three observations was constructed. Cluster validation was conducted by performing a likelihood ratio test. This test makes it possible to compare the results of the simpler cluster to that of the complex cluster in order to know when to stop adding more paths and parameters. This method proved to be able to determine the optimal number of clusters in the dataset.

The fitted HMM identify three clusters from the dataset. Cluster one had 506 genes, cluster two had 488 genes and cluster three 701 genes. Sixteen functional enrichment genes were found in the cluster set. Cluster one had four GO functional annotations with percentage of genes ranging from 8.3 to 1.9%, cluster two had five GO functional annotations with percentage of genes ranging from 7.8 to 1.7% and cluster 3 had the highest GO annotation with seven functions and gene percentage ranging from 3.2 to 1.5%. The HMM clustering results was compared with the traditional k-means result and discovered that it performed more efficiently in the sense that the clustering results were more evenly distributed when compared to the K-means result. This research work has successfully cluster the *plasmodium falciparum* gene expression dataset using the Hidden Markov Models, it also obtained enriched functions for other unclassified genes from the cluster set.

## PgmNr 1499: Development and application of methods for resolving molecular diagnoses from patient sequence data.

**Authors:**

D. Alyousfi

[View Session](#) [Add to Schedule](#)**Affiliation:** Human Genetics, University of Southampton, southampton, United Kingdom

---

Identifying molecular causes of disease from sequenced genomes can be extremely challenging usually requiring tiered filtering with the possibility of missing the causal variant(s). This study is concerned with integrating predictors of gene essentiality to understand how gene-level approaches could improve filtering of clinical sequence data. We assessed relationships between essentiality measures in different gene groups including non-essential genes not involved in disease, Mendelian disease genes and genes classed as essential. By examining a range of well-studied and independent gene-level scores, our results suggest that individual methods are less effective than combined scores for predicting genes involved in Mendelian diseases. The results of principal component analysis show that our combined Essentiality Specific Pathogenicity Prioritization (ESPP) score is a more powerful predictor than individual scores. The ESPP score explains more than 40% of the variation across eight diverse scores. Interestingly, the *CHD3* gene was given a relatively high score  $\sim 4.77$  in the classifier, but has only very recently been recognised as having an associated Mendelian phenotype. Success of the classifier is constrained by incomplete understanding of which genes should be assigned to the different gene classes but as gene function is increasingly understood the utility of the classifier should increase. Ultimately, these findings reveal that our combined score better reflects the modularity of many genetic properties measured by each score separately and might help improve diagnostic rates.

## PgmNr 1500: New candidate *Alu* sequences in AK1 Korean reference genome.

### Authors:

K. Bahk; J. Kim; J. Sung

[View Session](#) [Add to Schedule](#)

**Affiliation:** Genome Epidemiology & Health Big Data, Department of Epidemiology, Graduate School of Public Health, Seoul National University, Seoul, Korea

**BACKGROUND:** The *Alu* element family is densely populated repetitive sequences, particularly abundant in primates and humans, characterized by *Alu* restriction endonuclease., with typical ~300bp length. With recent discoveries that *Alu* elements not only have roles in the phylogenetic and evolutionary implications but some functional significances, we attempted to search whether new types of *Alu* elements exist in the ethnic genome. The AK1 is one of the highest quality genome assemblies with haplotig N50 > 16Mb, based on one Korean. Our previous studies showed that 1.8% of total AK1 sequences do not exist in the GRCh38p12, including the alternative and random sequences. We did find about ~3,000 candidate regions with putative coding functions in this non-overlapping 1.8% segments of AK1, but it is elusive whether some unidentified repetitive elements such as *Alu* elements or SINEs/LINEs exist.

**METHODS:** We used the RepeatMasker program, that screens DNA sequences for interspersed repeats, with RMBlast search engine to find *Alu* candidates on these non-overlapping scaffolds. We applied BLASTN to the candidate *Alu* to identify the similarity of subfamily and sequence between the candidate *Alu* elements and the *Alu* in the nucleotide database. Further validation by Sanger sequencing is still ongoing for new types of candidate *Alu* sequences.

**RESULTS AND INTERPRETATIONS:** A total of 371 candidate *Alu* elements were found from the initial search using non-overlapping AK1 genome regions and met the criteria (e-value < 0.001) by the BLASTN comparisons. The *Alu* elements comprise ~3,300 Kbps, indicating that the average number of repeats were ~8.9K. Among 371 *Alu* candidates 343 *Alu* elements were classified into *AluY* (with 8 *AluJb* and 20 *AluSx*) suggesting that the most of the new candidate *Alu* elements are the results of recent evolutionary changes. We are verifying ~20 novel types of *Alu* elements by Sanger sequencing, and further searching the location in the whole genome in the AK1. We expect the identification of new *Alu* subfamilies would help understand the recent human evolutions and ethnic differences in the genetic susceptibilities to diseases.

## PgmNr 1501: Findings from the Critical Assessment of Genome Interpretation, a community experiment to evaluate phenotype prediction.

### Authors:

C. Bakolitsa <sup>1</sup>; G. Andreoletti <sup>2</sup>; R.A. Hoskins <sup>1</sup>; P. Radivojac <sup>3</sup>; J. Moulton <sup>4,5</sup>; S.E. Brenner <sup>1</sup>

---

Interpretation of genomic variation plays an essential role in the analysis of cancer and monogenic disease, and increasingly also in complex trait disease, with applications ranging from basic research to clinical decisions. Yet the field lacks a clear consensus on the appropriate level of confidence to place in variant impact and interpretation methods. The Critical Assessment of Genome Interpretation (CAGI, 'k?-j?') is a community experiment to objectively assess computational methods for predicting the phenotypic impacts of genomic variation. CAGI participants are provided genetic variants and make blind predictions of resulting phenotype. Independent assessors evaluate the predictions by comparing with experimental and clinical data.

CAGI has completed five editions with the goals of establishing the state of art in genome interpretation and of encouraging new methodological developments. Challenges have been predominantly based on human data, mirroring problems in clinical practice and much basic research. The focus has been on interpreting nonsynonymous variants, splicing variants, structural variation, whole-exomes and whole-genomes, with phenotypes ranging from molecular and cellular measurements to organismal phenotypes in inherited disease and cancer. Results from previous CAGI experiments have been described in two special issues of *Human Mutation*.

Each previous edition of CAGI has revealed new aspects of the methods, and there has been significant progress in several areas. Independent assessment has found that top missense prediction methods are highly statistically significant, but individual variant accuracy is limited. Missense methods tend to correlate better with each other than with experiment. Bespoke approaches often enhance performance. Interpretation of non-coding variants shows promise but is not at the level of missense.

In challenges using clinical data, such as the Johns Hopkins and SickKids challenges, predictors identified causal variants overlooked in the initial clinical analysis. Data from the CHEK2 challenge were recently presented to the ClinGen Sequence Variant Interpretation Working Group to explore stronger weighting when methods demonstrate sufficient reliability for clinical use. CAGI results suggest that running multiple uncalibrated methods and considering their consensus may result in undue confidence, so we advise against this.

Detailed information about CAGI may be found at <https://genomeinterpretation.org>.

## PgmNr 1502: Target interval builder: A tool to obtain and annotate clinically-significant intervals.

### Authors:

---

**Background:** Hybrid capture-based target enrichment uses custom-designed oligonucleotide probes to capture specific genomic regions for NGS. Target Interval Builder (TIB) implements all computational steps required to specify target regions for a list of HGNC gene IDs. TIB creates versioned BED files with annotations for known/potential disease-causing variants from HGMD/ClinVar and NCBI RefSeq transcripts (exons, introns, CDS, UTR). These versioned BED files are used to design NGS capture library probes and to mask clinically excluded genes/regions during data analysis.

**Methods/Results:** TIB is implemented using AWS Batch/EC2/EBS/S3, Broad Institute WDL/Cromwell, bedtools, BCftools, Docker, biomaRt, Nginx, Django, and custom-developed Python and Bash scripts. Six Docker images, stored in AWS ECR, encapsulate TIB functionality.

Users provide a text file of HGNC gene IDs and optionally BED files of regions to include or exclude via an AWS-hosted web form. TIB can generate a new reference BED file or use a specified BED file. The software builds the reference BED file based on data from UCSC Genome Browser, HGNC (genenames.org), Ensembl, ClinVar, and HGMD. TIB uses a previously downloaded snapshot stored on AWS S3 if it cannot access a source database. It versions all files using a clear naming convention.

When designing a set of new capture targets, TIB searches the reference BED file for genomic features using the HGNC gene IDs provided at runtime. It filters out non-protein-coding transcripts, if protein-coding transcripts are available, and splits the resulting BED file to generate BED files with and without UTRs and introns. Moreover, metrics are gathered, over the chosen intervals, for parameters that impact NGS performance, e.g., segmental duplications, repeats, and read alignment uniqueness. TIB deposits output files in AWS S3.

TIB annotates intervals with the HGNC approved gene symbol, HGNC ID, and source. Optional annotations include RefSeq transcript, exon number, HGMD accession, Ensembl transcript ID, database timestamp, HGVS variant, ClinVar ID, and type (intron, CDS, etc.).

**Conclusion:** TIB annotates genomic intervals to facilitate design and filtering of targeted NGS capture libraries. Standardized annotation retains interval provenance throughout library design. Poorly performing intervals are intersected with genes, variants, and regions. NGS data can be subset at runtime by filtering annotated intervals against a custom list of HGNC IDs.

## PgmNr 1503: Variant reclassification in a routine diagnostic setting on a highly heterogeneous patient population.

### Authors:

The 2015 guidelines by the American College of Medical Genetics probably represent the most widely accepted framework for classification of genomic variants. The contained categories are: pathogenic (P), likely pathogenic (LP), variant of uncertain significance (VUS), likely benign (LB) and benign (B). With additional relevant information becoming available over time, variants may need to be reclassified.

Along our routine diagnostic workflow, variants that need re-consideration are automatically flagged. Triggers include (i) findings in additional family members, (ii) identification in an unrelated patient, (iii) a change in internal population frequencies, and (iv) availability of biochemical/metabolic data. Subsequent semi-automated review of all ACMG-relevant information may or may not result in eventual reclassification.

We will present a re-classification data set that is based on a 5-months period, covers 248 variants, and has a highly heterogeneous background as regards the ethnic, phenotypic and mutational spectra. 47 reclassifications did not immediately impact on the diagnostic interpretation (i.e. L↔LP and B↔LB); 43 of these (91%) were upgrades from LP to P. Of the remaining 201 reclassifications, n=99 (49%) and n=44 (22%) were VUS to LP/P and VUS to LB/B, respectively. Substantial additional traffic was observed from LP/P to VUS (n=34; 17%), while reclassifications from LP/P to LB/B (n=17; 8%), LP/P to VUS (n=4; 2%) and LB/B to LP/P (n=3; 1%) were much rarer. The reclassifications affected a total of 840 patients (median=2; range 1 to 99). With the exception of LN↔N (2 variants vs. 100 patients), the proportion of specific reclassifications were highly similar between variants and patients.

Our data suggest that the major net effect of re-classification is a reduction of the VUS category. Also within LP/P and LB/B, most classifications become more definite. Despite the heterogeneous background of our data set, these findings are consistent with observations of others focusing on certain diseases or populations. They also confirm that reclassification is an important part of a sustained diagnostic process.

## PgmNr 1504: Identification of elusive copy number variation by targeted coverage depth analysis.

### Authors:

---

Copy number variation is a major class of human structural variation which affects spontaneous and complex disease as well as human diversity. Advances in whole-genome sequencing have driven the development of computational tools to identify copy number variants (CNVs), and implicated CNVs in many rare and common disease phenotypes.

However, while common, CNVs created by non-allelic homologous recombination (NAHR) between high-identity repeats remain difficult to identify with current methods. This is not surprising since discordant and split-read alignments rarely exist for these CNVs due to the flanking repeats that drive copy number variation, and evidence from sequencing depth is often confounded by the low mappability of the flanking repeats. Worse still, depth-based CNV detection tools typically scan arbitrarily-sized windows across the entire genome, thereby decreasing the likelihood that any indicative change in coverage be captured in a given window, especially when the CNV is small.

Instead, our approach (NAHRly) utilizes the prior knowledge of the locations and compositions of human genomic repeats to focus analysis on NAHR-prone regions. Using annotations of segmental duplication, we have identified ~1000 regions of the human genome with the potential for NAHR-driven copy number variation. To demonstrate the power of this approach, we analyzed 603 whole-genome samples from 33 three-generation families in the CEPH Utah cohort. We developed a peak-identification algorithm that separates depth clusters within the cohort for CNV detection and genotyping. We reveal deletions and duplications in many of the regions predicted to be NAHR-prone and used inheritance and transmission tests to evaluate our findings and tune our method. We report variants identified with this focused method that are missed by both CNVnator and SVTYPER. Our results suggest that NAHRly complements existing CNV detection techniques for the identification of CNVs that were previously very difficult to detect

## PgmNr 1505: A comparison of variant effect prediction algorithms and their performance on specific disease phenotypes.

Popular variant prediction tools use functional, structural and/or conservation-based features to distinguish damaging variants from background variation. A tool's training variants for damaging behavior may derive from multiple diseases, including those with disparate pathogenetic mechanisms such as loss of function (LoF) or dominant negative effect. We hypothesized that prediction tools have intrinsic differences in performance based on genetic mechanism and disease type. To study this, we analyzed the performance of variant prediction tools by disease phenotypes available in ClinVar (1000+ phenotypes/traits; 100+ diseases; multiple biological systems). We selected ClinVar variants with evidence to assert consistent clinical interpretation (2 star or higher). For simplicity, we dichotomized the predictions by combining pathogenic with likely pathogenic calls and benign with likely benign calls. Variants were annotated through Variant Effect Predictor to gather predictions for the following tools: *Polyphen*, *SIFT*, *CADD*, *REVEL*, *M-Cap*, *MetaSVM*, *MetaLR*, *MutationTaster*, *MutationAssessor*, *FATHMM*, *FATHMM-MKL*, *PON-P2*, *CAROL*, *DANN*, *LRT*, *MTR*, *MPC*, *Condel*, *VEST3*, *PROVEAN*, *GenoCanyon*, *Eigen*, *Eigen-PC*, *GERP++*, *PhyloP*, and *SiPhy*. For each phenotype and all of its associated variants, we compared the ClinVar clinical significance of the variant to each tool's prediction. We computed sensitivity, specificity and F1-score (harmonic mean of precision and recall) per tool-phenotype combination. We also compiled common non-synonymous and LoF variants from 1000 Genomes (GnomAD MAF>0.01), which are assumed to be tolerated, and assessed each tool's performance similarly. The performance of these tools differs considerably by disease phenotype (mean F1-score: ~0.1-0.8). We observed that most of these tools had better sensitivity compared to specificity across disease phenotypes indicating that these tools are better at correctly predicting disease-causing variants compared to benign variants. Ensemble-based classifiers like MetaSVM and REVEL were among the top performing tools for complex diseases including several cardiovascular phenotypes, and limb girdle muscular dystrophy. CADD was a better performer among cancer phenotypes. Our results demonstrate that the ability of bioinformatic tools to predict clinical pathogenicity varies markedly by underlying phenotype. We speculate that explicitly considering underlying disease mechanisms may yield improved variant classification.

## PgmNr 1506: nanotatoR: An annotation tool for genomic structural variants.

### Authors:

S. Bhattacharya <sup>1</sup>; H. Barseghyan <sup>1,2</sup>; U. Boddeti <sup>3</sup>; E.C. Délot <sup>1,2</sup>; E. Vilain <sup>1,2</sup>

---

Whole genome sequencing (WGS) has been efficient in identification of single-nucleotide variants (SNVs) and small insertions and deletions (INDELs) but, due to utilization of short reads (~150 basepairs), not effective in identification of larger structural variants (SVs). Introduction of genomic Optical Mapping (OM), which utilizes long fluorescently labeled DNA molecules for *de novo* genome assembly and structural variant calling, substantially increased both sensitivity and specificity for identification of SVs. However, compared with short-read sequencing technologies, OM doesn't have many tools that annotate identified variants (population frequency, overlapping genes, etc.) for filtration and classification.

We developed an R-based annotation package that provides comprehensive information for SV filtration by integrating the patient's OM and expression data sets and reference databases information.

*nanotatoR* uses external databases DGV, gnomAD, 1000 genomes and DECIPHER, to estimate population frequency of the variants. Additionally, *nanotatoR* builds a database of SVs based on the samples provided by the user to estimate the variant's frequency within the user's cohort. User-provided BED files can be used to annotate which genes overlap or are near (upstream and downstream) the identified SV, as well as whether the SV affects specific exon/s or intron/s. Overlap percentages and distances for nearest genes are automatically calculated and can be used for filtration. A primary gene list is extracted from public databases (OMIM, DDD, dbVar, ClinVar, GTR) based on the patient's phenotype and compared with genes overlapping SVs, providing the analysts with an easy way to filter variants. *nanotatoR* also extracts from the GTEx database information about expression level in the sample tissue for the genes and non-coding RNAs overlapping an SV. If RNAseq expression data is available for the sample, it is also aligned to the SV map and displayed in a separate column. The output is given in an Excel file format, subdivided into multiple sheets based on SV type and inheritance pattern (INDELs, *de novo*, inversions, translocations, etc.).

The extensive annotation and the expression pattern of genes near/overlapping variants enables users to identify potential pathogenic SVs with precision with fast turnaround times (currently ~1hr for a human genome OM annotation)

## PgmNr 1507: Imputation after whole genome sequencing to get genotypes for SNPs from the GWAS Catalog.

**Authors:**

[View Session](#) [Add to Schedule](#)

**Affiliation:** Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai Hospital, New York, New York.

---

While genome-wide association studies (GWAS) have identified large number of trait-associated SNPs, their functional basis remains unclear. To begin to understand the functional basis for SNPs involved in prostate cancer and inflammatory bowel disease, we asked if they were eQTLs in data from the GTEx Consortium. Surprisingly, upon first examination we found that some SNPs were not present in the GTEx genotype data. Genotypes in GTEx were measured with whole genome sequencing (WGS), which theoretically probes the full spectrum of genetic variation including both common and rare variants. However, some regions of the genome are less amenable to sequencing and may not pass quality control measures. Genotype imputation from genome-wide SNP data has been a widely used approach to “fill in” missing common genetic markers that are not directly genotyped. We hypothesized that such imputation could be useful with whole genome sequencing data to enable us to obtain a measurement for every SNP of interest. We compared imputed genotypes from UK10K+1000Genomes (UK10K+1000G) and Haplotype Reference Consortium (HRC) Panels against WGS genotypes from the GTEx data. We used the Sanger Imputation Server to perform imputation. We found that 92%, 93% and 97% of variants from the GWAS Catalog could be readily found in the WGS, HRC and UK10K+1000G panels respectively. Based on these findings, we propose that imputation with the UK10K+1000G reference panel after WGS may be the best approach to find previously reported SNPs from the GWAS catalog in GTEx and other whole genome sequenced datasets.

## PgmNr 1508: GeneBytes: Interactive and intuitive tool for genome analysis.

Last years we have witnessed an economic and technological revolution in the clinical sphere. The evolution from the analysis based on genes panels to exomes, from exomes to the whole genome is due to the fact of the decrease of the sequencing cost and to the trend to include studies of personalized medicine as clinical routine, leading to a clinical Big Data, with a huge potential for scientific knowledge. Considering this large amount of information and the continuous time reduction demand on diagnostic, it's necessary to rely on tools able to properly manage and organize a massive volume of information.

With this aim arises GeneBytes, a tool for genomic data mining that has been designed and built by a multidisciplinary team of engineers and doctors. In a diagnostic context, GeneBytes allows the analysis of Structural Variants (balanced translocations and inversions), Copy Number Variants (CNVs) and point mutations, allowing also the possibility to design, save and automatically apply variant prioritization algorithms. This will drastically reduce the time around time per analysis. Moreover, this algorithms and the results obtained can also be exported, guaranteeing the traceability of the whole analysis process.

Filtering functions of the tool include more than 70 features related to variants, including information from to the last versions of reference databases such as HGMD Pro, Clinvar, 1000 genomes, GnomAD, ESP, information about in silico algorithms, clinical guidelands or information about inheritance patterns, giving versatility to the analysis. Among the viewing Features highlights the integration of IGV tool for the display of the sequence alignment, that will help to discriminate between true positive and false positive variants.

Finally, specific functions have been added for Structural Variants and CNV analysis, allowing, for example, to state if the alteration affects or not OMIM disease associated genes. Thus, GeneBytes allows the standardization of NGS genetic data analysis, helps with data interpretation and assures the traceability of the whole process.

## PgmNr 1509: Empirical performance of tree-based inference of phylogenetic networks.

**Authors:**

Z. Cao; J. Zhu; L. Nakhleh

[View Session](#) [Add to Schedule](#)

**Affiliation:** Computer Science, Rice University, Houston, Texas.

---

Phylogenetic networks extend the phylogenetic tree structure and allow for modeling vertical and horizontal evolution in a single framework. Statistical inference of phylogenetic networks is prohibitive and currently limited to small networks. An approach that could significantly improve phylogenetic network space exploration is based on first inferring an evolutionary tree of the species under consideration, and then augmenting the tree into a network by adding a set of 'horizontal' edges to better fit the data.

In this paper, we study the performance of such an approach on networks generated under a birth-hybridization model and explore its feasibility as an alternative to approaches that search the phylogenetic network space directly (without relying on a fixed underlying tree). We find that the concatenation method does poorly at obtaining a 'backbone' tree that could be augmented into the correct network, whereas the popular species tree inference method ASTRAL does significantly better at such a task. We then evaluated the tree-to-network augmentation phase under the minimizing deep coalescence and pseudo-likelihood criteria. We find that even though this is a much faster approach than the direct search of the network space, the accuracy is much poorer, even when the backbone tree is a good starting tree.

Our results show that tree-based inference of phylogenetic networks could yield very poor results. As exploration of the network space directly in search of maximum likelihood estimates or a representative sample of the posterior is very expensive, significant improvements to the computational complexity of phylogenetic network inference are imperative if analyses of large data sets are to be performed. We show that a recently developed divide-and-conquer approach significantly outperforms tree-based inference in terms of accuracy, albeit still at a higher computational cost.

## PgmNr 1510: Using Atlas-CNV to identify large and small deletions in clinical exomes.

Identifying Copy-Number Variants (CNVs) in exome sequencing is an important analytical step in the clinical pipeline to achieve a higher molecular diagnostic rate. The conventional exome analysis is well suited for detecting single nucleotide variants (SNVs) and small indels but not CNVs. Current CNV calling from exome data has limited power to detect small changes (e.g. single-exon deletions), and therefore needs further improvement. A recent method to identify CNVs (Atlas-CNV) at the single-exon level was reported for capture targeted gene-panels (eMERGESeq) using normalized coverage among batch samples and single-exon metrics to control false calls. Here, we extend those capabilities to capture-based exomes and evaluate its effectiveness in a retrospective blinded study of 34 clinical exomes (9 probands, 7 trios, 1 quad), which include six families with known disease-causing CNVs. Combining the 34 samples as a batch with default calling thresholds, an average of 2,146 deleted exons were called per sample with average quality metrics per exon of  $E_{\text{StdDev}}=0.26$  (standard deviation of  $\log_2$  scores at an exon) and **C-score**=-5 (Z-like score of  $\log_2$  divided by  $E_{\text{StdDev}}$ ). The data analysis focused on identifying potentially disease-causing CNVs that are related to patient phenotypes and correctly called all the six clinically significant deletions: three large deletions encompassing multiple genes; 2q24.3, 4.8 Mb; 22q11.21, 2.5 Mb; 15q11-13, 3.7 Mb, and three small intra-genic deletions: RPS6KA3 (exon 1, chrX), HPS1 (exon 15-16, chr10), NF1 (exon 27, chr17). These deletions were confirmed by orthogonal methods including SNP analyses (n=2), low-pass whole-genome sequencing (n=2), and junction read analysis (n=2). The average  $E_{\text{StdDev}}$  and **C-score** were 0.26 and -4.7 respectively for the large deletions, and 0.29 and -3.3 for the small deletions. Although additional refinements and larger datasets are needed to identify exons with high frequency spurious calls, we conclude that Atlas-CNV has clinical utility to screen both large (>2Mb) and small deletions (single-target exon) in exomes.

## PgmNr 1511: Kibio, a scalable tool to unify, explore and visualize life-sciences massive data.

Linking information between biological databases on the web is a challenging task for any researcher, which needs to manage very large databases and cross the information between them. In this context, we present Kibio (<http://kibio.science>), a new resource that integrates dozen of biological public repositories in the form of a web portal. It offers search, exploration and data linking through dynamic visualizations. Kibio also provides a userspace system, allowing private databases upload and linking to the existing network of databases in Kibio. This extensible environment, based on an advanced visual filtering system, can be used to explore multidimensional Omics data, allowing interactions search, validations of experimental protocols, simplified literature search, hypothesis discovery, characterization of biomarker signatures, identification of non-directly related biological functions and much more. Furthermore, a custom Extract-Transform-Load (ETL) software called Lucan, has been developed to deal with biological data heterogeneity, hence ensuring the consistency between original biological databases and the version imported in Kibio. As of June 2019, Kibio integrates about 40 databases, reaching 2.1TB of public data and 2.5 billions documents whose some contains hundreds of fields.

## PgmNr 1512: PseudoNet: A graph representation learning method for inferring pseudogene functions by borrowing information from coding genes.

Pseudogenes are ubiquitous and abundant in genomes. It has been recognized that some pseudogenes play essential roles in expression regulation of their parent genes, and might contribute to cancer development. Given the fact that experimental identification of pseudogene functions is time-consuming and expensive, it is important to develop computational methods to predict the functions of pseudogenes, and provide testable hypotheses for targeted experimental validation. Since the existing functional annotation of pseudogenes is limited, traditional supervised machine learning methods that require abundant training data are not suitable.

Here we propose PseudoNet, a graph representation learning model that can make use of multiple information and borrow information from coding genes to predict pseudogene function. Our graph-based method can consider both network structure (sequence similarity network) and gene attributes (expression profile) together to make predictions by organizing genes into an attributed network architecture. To be more specific, we first build sequence similarity networks of genes and pseudogenes by using BLAST. We then calculate the co-expression matrix using TCGA RNA expression profile (take BRCA for example), and run node2vec to obtain initial embeddings which are used as node attributes in our PseudoNet model. In summary, sequence information is used to construct network structure while expression profile information is used as node attributes in the networks, so that PseudoNet can consider both features. Then we utilize variational graph auto-encoder (VGAE), a deep learning-based network representation learning algorithm to learn ultimate informative representations for all genes and pseudogenes. The final step is to train a multi-label neural network classifier to predict pseudogene functions by training on coding genes using the learnt representations.

In our benchmark dataset, there are 1325 pseudogenes and 14565 coding genes, and we use Gene Ontology (GO) as the functional annotation. Our model could achieve higher than 0.75 in terms of AUC-ROC on all three ontologies, better than traditional machine learning methods such as SVM. What's more, the learnt informative representations can be used for various downstream analyses, such as performing clustering analysis for discovering inherent patterns, detecting association with drugs or diseases, and visualizing data using t-SNE and PCA.

## PgmNr 1513: Identifying novel regulatory elements using RELICS, a statistical framework for the analysis of CRISPR regulatory screens.

---

High-throughput CRISPR/Cas9 screens are a powerful new tool for the systematic discovery of regulatory elements in the human genome. In these regulatory screens, thousands of guide RNAs (gRNAs) are delivered to cells to target potential regulatory sequences for mutation, activation or inhibition. The cells are then sorted into high- and low-expression pools based on the expression of a target gene. While, these screens have the potential to perform unbiased discovery of regulatory elements, they generate noisy data and the performance of analysis methods has not been rigorously assessed. Here we describe RELICS, a statistical framework for **R**egulatory **E**lement **L**ocation **I**dentification in **C**RISPR **S**creens. RELICS models the observed guide counts in different expression pools with a generalized linear mixed model. This approach is very flexible, can jointly model multiple expression pools (beyond just high and low), incorporate variability across guides, and accommodate over-dispersion. To assess the performance of RELICS we have developed a simulation framework for generating CRISPR regulatory screen data and simulated 1000s of data sets under a wide variety of experimental and biological conditions. RELICS outperforms existing analysis methods on the simulated data and we have applied it to identify regulatory elements in several published datasets. In addition, we have applied RELICS to data from a paired-guide regulatory screen that we performed for *GATA3* in Jurkat T cells. We identify a total of 23 putative regulatory elements within the 2MB targeted region surrounding *GATA3*. Notably 16 of the identified elements lie within the same topological associating domain as *GATA3*, but only 3 overlap enhancers predicted by ChromHMM.

## PgmNr 1514: Secure storage and query of genomics data with blockchains.

**INTRODUCTION:** The genomic characterization of millions of individuals promises to be useful for medical research. Having a larger number of studied individuals is assured to boost statistical power; therefore, genomes from more individuals likely will be sequenced going forward. One of the main barriers to expanding sequencing is the ability to provide a secure platform for storage of this sensitive data. While cloud computing offer solutions to maintain and compute on large amounts of data, security, data integrity, and robustness vulnerabilities such as the consequences of single-point-of-failure have not yet been addressed. A potential approach to circumvent these challenges is blockchain technology due to its security, immutability, and decentralization properties.

**OBJECTIVES:** Required storage space and computational power of blockchains is greater than a centralized database application, due to each of the blocks needing to contain the information of the rest of the preceding blocks. Decentralized system creates a higher latency during retrieval of data. The goal is to develop time and space-efficient blockchain-based ledgering solutions for storage and retrieval of genomic data.

**METHODS:** MultiChain is a private blockchain platform that offers data streams embedded in the chain for storage. Using this platform, we first developed a secure storage and query mechanism for genomic access logs (e.g dbGap logs) to prevent potential data misuse such as genomic privacy attacks. Based on the same framework, we then developed a series of tools called SAMChain and SCTools that allow users to efficiently store genome sequencing data (BAM files) in a blockchain, and provide analysis functions such as querying, read streaming, depth analysis, pile-ups for variant calling, and re-creating BAM files. To allow for rapid access, SAMChain is based on turning data streams into hash tables, in which keys are important features of the reads such as their location on the reference genome. These hash tables also allow us to minimize the off-chain operations in the local memory.

**RESULTS:** We compared read streaming, depth analysis, and pile-ups results of SCTools with samtools and confirmed that our tools return accurate results.

**CONCLUSION:** We envision a real-world scenario that individuals create private blockchains to store their personal genomes to share with their healthcare providers. Our storage protocol allow query of data from personal genomes using blockchains.

## PgmNr 1515: Decoding regulatory structures and features from epigenomics profiles: A Roadmap-ENCODE Variational Auto-Encoder (RE-VAE) model.

### Authors:

R. Hu <sup>1</sup>; G. Pei <sup>1</sup>; P. Jia <sup>1</sup>; Z. Zhao <sup>1,2,3</sup>

---

The development of chromatin immunoprecipitation (ChIP) with massively parallel DNA sequencing (ChIP-seq) technologies has promoted generation of large-scale epigenomics data, providing us unprecedented opportunities to explore the landscape of epigenomic profiles at scales across both histone marks and tissue types. In addition to many tools directly for data analysis, advanced computational approaches, such as deep learning, have recently become promising to deeply mine the data structures and identify important regulators from complex functional genomics data. We implemented a neural network framework, a Variational Auto-Encoder (VAE) model, to explore the epigenomic data from the Roadmap Epigenomics Project and the Encyclopedia of DNA Elements (ENCODE) project. Our model is applied to 935 reference samples, covering 28 tissues and 12 histone marks. We used the enhancer and promoter regions as the annotation features and ChIP-seq signal values in these regions as the feature values. Through a parameter sweep process, we identified the suitable hyperparameter values and built a VAE model to represent the epigenomics data and to further explore the biological regulation. The resultant Roadmap-ENCODE VAE (RE-VAE) model contained data compression and feature representation. Using the compressed data in the latent space, we found that the majority of histone marks were well clustered but not for tissues or cell types. Tissue or cell specificity was observed only in some histone marks (e.g., H3K4me1 and H3K27ac) and could be characterized when the number of tissue samples is large (e.g., blood and brain). In blood, the contributive regions and genes identified by RE-VAE model were confirmed by tissue-specificity enrichment analysis with an independent tissue expression panel. Finally, we demonstrated that RE-VAE model could detect cancer cell lines with similar epigenomics profiles. In conclusion, we introduced and implemented a VAE model to represent large-scale epigenomics data. The model could be used to explore classifications of histone modifications and tissue/cell specificity and to classify new data with unknown sources.

## PgmNr 1516: Comparing haplotype assembly approaches.

**Authors:**

A. Johnson <sup>1</sup>; S. Sun <sup>2</sup>

[View Session](#) [Add to Schedule](#)

---

Haplotype information is important for further understanding genetic diseases. Therefore, it is crucial to obtain haplotypes for disease studies. With the development of next generation sequencing (NGS) technologies, it is now possible to obtain haplotypes using sequencing reads. The process of determining haplotypes based on sequencing reads is called haplotype assembly. It is challenging to conduct haplotype assembly because NGS datasets are very large and have complex genetic and technological features. Even though a large number of approaches or software packages have been developed, it is unclear how well these programs perform. Most of them are not well evaluated as they are only compared with a small number (e.g., 1 or 2) of other methods and validated based on different datasets. In this project, we will conduct a comprehensive analysis to compare currently available haplotype assembly approaches (software packages). We will compare these approaches based on their statistical or computational methods, algorithmic features, and evaluation features as well. We will show our comparison results based on both real data and simulated data. With our comparison results, we shall provide users with both detailed input on the performance of current methods and new perspectives on haplotype assembly, which will be helpful for developing more accurate and efficient algorithms.

## PgmNr 1517: Characterizing deleterious variation using sub-population allele frequency information.

As natural selection purges deleterious variation from the population, the allele frequency of a variant is a useful estimator of its functional effect. However, when a population goes through a bottleneck, a subset of deleterious variants will be boosted in allele frequency. Here, we describe the impact of multiple distinct population bottlenecks on the allele frequency distribution of deleterious variants, using exome sequence data from 125,748 individuals and genome sequence data from 15,708 individuals. In particular, we focus on the deleterious consequences on genetic variants, arising from the strong recent bottlenecks in Finnish and Ashkenazi Jewish individuals, as well as the serial Out-of-Africa population bottlenecks.

Consistent with an expectation that bottlenecks allow some extremely rare variants (with higher rates of deleteriousness) to jump dramatically in frequency, we demonstrate that these enriched variants are more likely to be in functionally-relevant coding categories, especially predicted loss-of-function variation. We thus propose a new metric: that the proportion of variants enriched through a bottleneck represents the deleteriousness of that category of variants. We show this metric correlates with previous metrics of variant deleteriousness as well as the severity of the bottleneck. We apply this metric to assess the deleteriousness of different categories of non-coding variation, identifying promoter regions in particular as those that are under the strongest negative selection.

Finally, we assess the influence of these bottlenecks on results from genome-wide association studies, and find that variants enriched by a bottleneck are more likely to be identified as significant hits than equally frequent but non-enriched variants. Using LD-score regression, we characterize the heritability explained in summary statistics from bottlenecked populations, as a function of allele frequency in cosmopolitan populations. These results indicate the power of bottlenecked populations for identifying deleterious classes of variation as well as discovery of genetic variants associated with disease.

---

Metabolites provide information on important biological processes. To fully understand these processes, it is important to link them to gene activity and expression. Epigenetic regulations via DNA methylation are known to reflect gene expression. Thus, we have aimed to analyse the associations between epigenome-wide DNA methylation measured at CpG sites and nuclear magnetic resonance (NMR) targeted metabolomics.

The most common way of analysing epigenome-wide DNA methylation data has been by univariate analysis, where each CpG site is tested for association with a univariate phenotype independently from the rest. In this study, we have investigated the associations through the angle of two-way multivariate association analysis, where the outcome is a matrix of multiple phenotypes and the predictor is the matrix of DNA methylation at CpG sites.

We utilised an integrative approach for two-way multivariate association analysis to investigate the relationships between DNA methylation and NMR metabolomics (both measured in blood samples) in Northern Finland Birth Cohort 1986 dataset (n=470). We used concentrations of 144 metabolites as the multivariate phenotype, and methylation levels at a subset of 27,688 CpG sites as the predictors. The method used is a canonical correlation analysis (CCA) approach modified from the one proposed by Seoane et al. (2014). The classical CCA finds linear combinations of outcomes and predictors with the highest correlations. The proposed method combines the classical CCA with a genetic algorithm optimization method, which is based on principles of evolution, with steps analogous to inheritance, mutation and crossover (Seoane et al. (2014)). This approach also performs variable selection for both predictors and outcomes.

Using the above method we found associations between VLDL and glucose-related metabolites with DNA methylation sites related to cellular metabolism and signalling genes. We also compare these results to the ones from univariate association analyses. Our results showcase the advantages of a two-way multivariate association analysis as it can aid in discovery of new findings, even with modest sample sizes, for multidimensional datasets.

## PgmNr 1519: GMASS: A novel measure for genome assembly structural similarity.

---

Thanks to the recent advancements in next-generation sequencing (NGS) technologies, large amount of genomic data, which are short DNA sequences known as reads, has been accumulating. Diverse assemblers have been developed to generate high quality *de novo* assemblies using the NGS reads, but their output is very different because of algorithmic differences. However, there are not properly structured measures to show the similarity or difference in assemblies.

We developed a new measure, called the GMASS score, for comparing two genome assemblies in terms of their structure. The GMASS score was developed based on the distribution pattern of the number and coverage of similar regions between a pair of assemblies. The new measure was able to show structural similarity between assemblies when evaluated by simulated assembly datasets. The application of the GMASS score to compare assemblies in recently published benchmark datasets showed the divergent performance of current assemblers as well as its ability to compare assemblies. The GMASS will contribute to the understanding of assembly output and developing *de novo* assemblers, and serve as a valuable measure for studying genomes of various species including human.

## PgmNr 1520: AtacWorks: A deep convolutional neural network to enhance ATAC-Seq data.

---

ATAC-Seq (Assay for Transposase-Accessible Chromatin using Sequencing) is a DNA sequencing technique used to measure genome-wide chromatin accessibility. Since its development in 2013, ATAC-Seq has been used to identify regulatory DNA elements, to localize epigenetic changes underlying development and disease, and to construct cellular regulatory networks. More recently, single-cell ATAC-Seq has enabled mapping of accessible chromatin in individual cells, leading to the identification of cell-type specific regulatory elements and networks.

The quality of the ATAC-Seq signal depends on the amount of input material for the experiment. ATAC-Seq derived from few cells can be so sparse that open chromatin regions fail to be identified. This leads to errors in characterizing rare cell types in a single-cell ATAC-Seq experiment.

We introduce AtacWorks, a deep convolutional neural network that takes as input a sparse, low coverage ATAC-Seq signal, and reconstructs a higher-quality signal. To predict chromatin accessibility at each position on the genome, our model uses information from a wide surrounding region, combining local features of the ATAC-Seq signal with large-scale features spanning several kilobases. We applied AtacWorks to both bulk ATAC-Seq (where it generates a high-quality signal from low sequencing coverage) and single-cell ATAC-Seq (where it generates a high-quality signal from a small number of cells).

We demonstrate that enhancing noisy ATAC-Seq data using our model increases the accuracy of open chromatin identification for downstream analysis. In an experiment using single-cell ATAC-Seq from 600 cells, our model doubles the number of true open chromatin sites that can be identified from the low-quality signal, from 40.0% of the true sites to 80.7%. We also show that an AtacWorks model trained on data from one cell type can accurately reconstruct data from other cell types. This suggests that our model identifies common patterns in ATAC-Seq data across diverse biological datasets.

## PgmNr 1521: BioTuring Browser: A modern data visualization and analytics platform for single-cell sequencing data.

---

Single-cell sequencing technologies provide unprecedented tissue resolution and quickly allow breakthroughs in a wide spectrum of biological research in both academic laboratories and pharmaceutical companies. On the other hand, the amount of information generated in a typical scRNA-Seq study grows exponentially and creates huge computational challenges in data processing, analytics, and visualization in both private and public single-cell data sets. To address these challenges, we introduce BioTuring Browser, a modern data visualization and analytics application to explore scRNA-Seq dataset in our curated database as well as combining with newly generated data. Our database consists of more than 3.4 million cells from 12 different tissues and 56 single-cell studies, all supported with state-of-the-art analytics and visualization packages for single cell transcriptome, and CITE-Seq data. The visualization and computation in BBrowser are optimized so that it can effectively analyze up to 1.3 million cells at a time on a standard laptop, and allow users to quickly export, reanalyze, or remove batch effects and merge data from different studies. BioTuring Browser addresses major computational challenges in single-cell analytics, fosters transparency in science, and helps scientists explore single-cell data more effectively.

# PgmNr 1522: Discovering SNVs and indels from RNA-Seq: Comparison of results of whole transcriptome sequencing to those of whole genome sequencing.

---

**Introduction:** Molecular test for genetic variations has been DNA sequencing, and RNA sequencing (RNA-Seq) has been mainly used for gene expression analysis. Recently, attempts have been made to detect genetic variants from RNA-Seq results, as splice-aware aligners' functionality has greatly improved and RNA-Seq utilization has increased. In this study, we compared the results of whole transcriptome sequencing (WTS) and those of whole genome sequencing (WGS) obtained from the same individual to find out the possibility of RNA-Seq as a tool for discovering genetic variants (SNVs and Indels).

**Methods:** RNA and DNA were extracted from peripheral blood of one healthy adult male. WTS was performed as 200 cycles using HiSeq2500 system (Illumina, USA). We aligned reads to the GRCh38 human genome assembly using STAR v2.7.0f. After sorting and deduplication using Picard v2.20.0, variants were called using freebayes v1.2.0. The variant calling was restricted to the coding DNA sequence (CDS) region of all protein-coding genes. WGS was performed 300 cycles using HiSeq X-10 system (Illumina). We aligned reads from the sequencer using bwa v0.7.17. After sorting and deduplication, variants were called using freebayes. The variant calling was also restricted to the CDS region. After merging vcf files of WTS and WGS using bcftools v1.9, we compared the results between two methods.

**Results:** A total of 9,376 variants (SNVs and Indels) were found from CDS regions of WTS data. On the other hand, a total of 8,591 variants were found in CDS regions of WGS. Among them, 8,248 variants were found in both methods, the concordance rate was 84.9%. Discrepancies between the results of WTS and those of WGS were not randomly distributed throughout the entire genes but were clustered in specific genes, mainly in the *HLA*, *IGH*, *IGK*, *IGL*, and *TRB* subgroups that make up the immune system. When these five subgroups were excluded, 8,140 variants were detected in WTS data and 8,311 variants in WGS data. Among them, 7,943 variants were identical, showing 94.3% as concordance rate.

**Conclusions:** In this study, we confirmed that germline variants on DNA could be reliably predicted from RNA-Seq results using splice-aware aligner and CDS region-specific variant calling. However, special attention should be paid to the prediction of variants in the genes related to the immune system.

## PgmNr 1523: Development of a whole genome sequencing-based assay for detecting copy number variations at a clinical grade level.

### Authors:

W.P. Lee <sup>1,2,3</sup>; Q. Zhu <sup>3</sup>; X. Yang <sup>2,3,4</sup>; S. Liu <sup>3</sup>; E. Cerveira <sup>3</sup>; M. Ryan <sup>3</sup>; A. Mil-Homens <sup>3</sup>; L. Bellfy <sup>3</sup>; C. Zhang <sup>1,3</sup>; C. Lee <sup>1,3,5</sup>

### Affiliations:

1) Precision Medicine Center, The First Affiliated Hospital of Xi'an Jiaotong University, Xi'an, China; 2) MOE Key Lab for Intelligent Networks & Networks Security, School of Electronics and Information Engineering, Xi'an Jiaotong University, Xi'an, China; 3) The Jackson Laboratory for Genomic Medicine, Farmington, CT; 4) Department of Computer Science and Technology, School of Electronic and Information Engineering, Xi'an Jiaotong University, Xi'an, China; 5) Department of Life Sciences, Ewha Womans University, Seoul, South Korea

Despite the growing use of next-generation sequencing (NGS)-based assays for the detection of SNPs and INDELs in clinical settings, it remains challenging to reliably detect copy number variants (CNVs) for clinical diagnostics. At the clinic, it lacks robust end-to-end tools or pipelines that will process raw sequencing datasets and detect CNVs. Although several whole genome sequencing (WGS) based CNV calling algorithms have been developed, none of them is widely accepted for pathogenic or high-risk CNV discrimination due to either high false positive or false negative rate. Building pipelines using a combination of existing calling algorithms can gain strength and preclude limitation of each tool. However, replicating those pipelines is not realistic without a full release of them, including versions and parameters. Moreover, using an ensemble of calling algorithms may improve accuracy, but it will add complications and thus take longer to make a diagnostic decision.

As a solution, we developed JAX-CNV, a multi-tiered computational algorithm for the detection of CNVs on WGS data. The performance of JAX-CNV was evaluated on 31 samples (coverage 30-45) from patients with constitutional disorders, which were examined in parallel by the clinically-validated chromosomal microarray analysis (CMA) assay in our CLIA-certified laboratory. As a result, JAX-CNV identified all 104 CNVs reported by the CMA assay including pathogenic CNVs in the 101Kb-94.2Mb size range. The result demonstrated 100% concordance between JAX-CNV and the clinical CMA assay. Moreover, JAX-CNV detected an additional 767 CNVs that were not captured by the CMA. To assess the false discovery rate of JAX-CNV, we randomly selected 16 novel discovered CNVs from two samples and successfully validated 14 by Droplet digital PCR (ddPCR). One deletion was not conclusive and the other one duplication was considered as false positive where it locates in segmental duplication and simple repeat regions. The robustness test of JAX-CNV is performed by downsampling to lower coverage sequencing data (30x, 20x, 15x, 10x, and 9x) and found 100% sensitivity for the detection of CNVs >300Kb (the current cutoff set by CAP for clinical CMAs) at as low as 9x sequencing coverage. This study demonstrates that WGS paired with JAX-CNV has the potential to replace CMAs for clinical diagnostics.

## PgmNr 1524: Quality control for full genome sequencing with Sequila.

The number of sequenced full genomes is growing steadily in recent years. It is done mainly in Illumina high-throughput technology and is becoming the basis of precision medicine. Every sequenced genome, sequenced in low coverage is resulting in a large dataset with sizes ranging in terabytes. Thus the analysis techniques once useful eg. for exomes, become too costly computationally.

A partial answer to the growth of the dataset size is the application of novel software, eg. based upon Apache Spark[1] that takes advantage of map-reduce scaling and memory optimization. Recent versions of Sequila[2] are providing fast coverage function, which may be used eg. for copy number analysis or for checking the coverage-based quality of a full genome, and to do this in not prohibitive time.

Calculating the genome-wide coverage function is the first step. Then a set of genomic regions with sub-standard coverage needs to be identified. There are specific thresholds below which variant calling becomes statistically not reliable[3,4]. The set of those sub-standard regions needs to be then compared with gene coordinates and low-mappability regions. It is important also to point out possible reasons for low coverage. The reasons may include mappability, large deletions, copy number issues or technical or algorithmic artefacts of a specific type of sequencing.

Our concept of quality control for full genomes includes the following:

- \* fast calculation of genome-wide read coverage function
- \* finding sub-standard genomic regions with low coverage (LCRs)
- \* finding the overlap of LCRs with low mappability regions
- \* finding the overlap of LCRs with genes and exons
- \* attempting to distinguish between various types of reasons for LCRs

Sequila includes now optimized features for finding coverage and overlapping large sets of genome coordinates, which can be used for the productive solutions of the functionalities above. We present the recent algorithmic approaches with implementation as well as tests on full genomes with different level of coverage. Important issues that still need to be solved technically are eg. scalability or memory tuning. Overall, the results in the poster show how efficiently the measures can be calculated and how to interpret them. This will be the basis for a dedicated software package for the full genome QC.

---

Current software used for gold-standard next generation sequencing (NGS) bioinformatic pipelines (BWA, PICARD, GATK, Samtools and variant annotation software) are all programmed to utilize conventional central processing units (CPU). Slow computational runtime remains a major hurdle in NGS bioinformatic pipelines despite the ability to multi-thread some of the pipeline's software. Currently running full pipelines for thousands of whole exome or whole genome sequencing (WES and WGS, respectively) samples, requires several months even on high-performance computing CPU clusters. Graphical processing units (GPU) have not yet been efficiently employed in NGS bioinformatic pipeline acceleration but have been demonstrated to accelerate computational runtime in computational chemistry, molecular dynamics and medical imaging. To address this problem, we have developed a Kubernetes GPU-accelerated bioinformatic pipeline where we adapted the code of the different NGS bioinformatic pipeline software to utilize GPU. We tested the applicability and performance of GPU frameworks to accelerate BWA, PICARD, GATK, Samtools and variant annotation software (ANNOVAR, SnpEff and VEP). We show through multiple experiments the extent of acceleration in each software with varying combinations of multithreaded CPUs and GPUs. Overall, we demonstrate that GPU is effective for enhancing the computational speed of NGS bioinformatic pipeline analyses. We also show that with further development the combination of CPU and GPU for these analyses will likely become the gold standard in the field.

## PgmNr 1526: Baited abrogation of contamination.

F. Mendez; R. Jiang; S. White; W. Lee

[View Session](#) [Add to Schedule](#)

**Affiliation:** Helix Opco LLC, San Carlos, California.

---

Whole exome and whole genome sequencing (WES and WGS, respectively) have proven valuable tools to hasten diagnosis of genetic disorders and enable discovery of heritable traits and disease. These approaches rely on next generation sequencing (NGS) technologies and have been scaling up due in part to the ease of sample collection with saliva, both in the clinic and at home. NGS methods are very sensitive, but also susceptible to the effects of contamination. Saliva-based collection methods require collection protocols (i.e. waiting 30 minutes) that attempt to minimize the impact of exogenous factors such as food on data quality. Nonetheless analytical tools are necessary to combat possible sample contamination that could lead to incorrect genotype calls, which impact ancestry estimates, estimates of relatedness, and clinical diagnosis. A number of statistical methods (like Freemix) enable the efficient detection of human cross-contamination; however, these methods were not designed for cross-species contamination. The effects of cross-species contamination on human genotype calls have not been carefully explored, possibly due to the lack of large saliva based collections that are subsequently sequenced on NGS technologies. Potential sources of contamination in saliva include oral microbiome and ingested food. Bacterial sequences are very divergent from those of humans, but some animal sequences may be mapped and incorrectly used in variant calling.

We have studied the effect of mapping sequences from nine farm and pet animals to the human reference genome and found that a considerable number of human genes in a contaminated human sample could be flagged as having pathogenic mutations. This includes more than a third of the genes included in the ACMG 59 list of genes with actionable mutations. We tested various levels of animal contamination and observed that amounts of foreign DNA that are not detected as contaminating by Freemix can still result in genotyping errors. We implemented a filtering method that greatly alleviates this problem, removing most incorrect calls without significantly affecting the coverage by reads of human origin. We then applied this method to human samples that were collected from saliva and exome sequenced. We show that our method significantly reduces the risk of incorrect genotype calls with potential healthcare consequences, thereby improving consumer confidence in genomic testing results.

## PgmNr 1527: AutoMap: High performance homozygosity mapping using sequencing data.

### Affiliations:

1) Département de Biologie Computationnelle, Université de Lausanne, Lausanne, Vaud, Switzerland; 2) Department of Genetics and Genome Biology, University of Leicester, Leicester, United Kingdom; 3) Division of Genetic Medicine, Lausanne University Hospital (CHUV), University of Lausanne, Lausanne, Switzerland; 4) Department of Medical Genetics, Faculty of Medicine, Mashhad University of Medical Sciences, Mashhad, Iran; 5) Division of Applied Medicine, Medical School, University of Aberdeen, Foresterhill, Aberdeen, UK; 6) Noncommunicable Diseases Research Center, Fasa University Of Sciences, Fasa, Iran; 7) Instituto de Oftalmologia Dr Gama Pinto, Lisbon, Portugal; 8) Institute of Molecular and Clinical Ophthalmology Basel (IOB), Basel, Switzerland; 9) University of Basel, Basel, Switzerland

**Purpose:** Through the identification of genomic runs of homozygosity (ROHs), homozygosity (autozygosity) is a powerful approach to find autosomal recessive mutations, especially in consanguineous families, via Most tools for ROH discovery rely on data from genotyping arrays, querying polymorphic variants at fixed positions. However, current investigation in medical genetics are mostly based on exome sequencing (ES), producing genotypes at variable locations of the coding genome with different allele frequencies. For this reason, existing tools were adapted or created for the use of ES data, but with limited performances. We have developed AutoMap (Autozygosity Mapper) to allow investigators to use directly ES data for the identification of ROH, without the need of performing additional genotyping tests.

**Methods:** AutoMap directly uses standard VCF files produced by various variant callers as primary source of data. A careful variant filtering step relying on coverage and alternative reads count is implemented, prior to the identification of ROHs, by a sliding-window approach and subsequent filtering. The tool was first trained on ES data from 26 samples from consanguineous families, and further validated in 26 additional samples with same ethnic background and degree of consanguinity. The performances of AutoMap were compared to other existing tools by using PLINK on genotyping array data as a reference.

**Results:** AutoMap displayed similar performance for both training and validation cohorts, with sensitivity of 90.3% and 91.6% and specificity of 81.1% and 83.2% respectively. Our method showed a significantly higher F-score with respect to 8 existing tools. When applied to unpublished ES data, AutoMap allowed the discovery of homozygous non-coding variants that in turn led to the identification of disease genes for two novel conditions including the Liberfarb syndrome.

**Conclusion:** AutoMap is a reliable tool that can predict, in less than a minute, ROHs with extremely high specificity and sensitivity. It can run efficiently by using a single VCF file derived from individual ES experiments. Our tool is available both via a web-based interface, for a quick analysis with default parameters, as well as a command-line package, allowing assessment of a large numbers of samples and the customization of many parameters. Finally, AutoMap can be used without adjustments also

on VCFs from whole-genome sequencing (WGS) experiments.

## PgmNr 1528: Constraint and phenotypic similarity characterization of drug targets and their paralogs to inform on drug side effect burden.

### Authors:

D. Rhodes; P. Cacheiro; D. Smedley; M.R. Barnes; M. Caulfield

[View Session](#) [Add to Schedule](#)

**Affiliation:** William Harvey Research Institute, Queen Mary University of London, London, London, United Kingdom

---

Side effects are a major concern in drug development due to their contribution to clinical trial failures or reducing patient compliance. A possible source of side effects include non-specific binding to paralogs - homologous genes resulting from prior gene duplication events. Here we describe efforts to systematically identify whether an association between the number of paralogs of a target protein and the number of side effects exists. There are multiple challenges associated to this analysis, among them: how to properly define relevant paralog groups and how to identify relevant side effects amongst the redundant or infrequent side effects reported.

First we curated 2,764 high confidence sets of paralogs (components) covering 11,882 unique proteins based on Ensembl 95 annotations and subsequent filtering using pairwise gene ontology semantic similarity, amino acid sequence similarity, and finally network based community detection algorithms. 519 proteins targeted by FDA approved drugs with known mechanism of action were labelled across 172 components. Drug targets were amongst the most constrained genes of the component as measured by their loss-of-function observed/expected upper bound fraction (LOEUF) score; with 62% of drug targets being more constrained than the mean constraint of their component. Components containing drug targets are on average double the size (mean 8.55 vs 4.5) and showed greater within-component phenotypic similarity (mean score 71.3 vs 64.8) than non-drug target containing components. Phenotypic similarity scores were computed using mouse orthologue phenotype data from the Mouse Genome Informatics resource.

We expanded our list of approved drug targets to include drugs with strong evidence of binding for downstream analysis. We then summarised SEs (from the Side Effect Resource (SIDER 4.1)) for drug-target containing components to per component measures of SEs using the intersection of SEs reported for any protein targeted by more than one drug. Initial findings suggest a positive correlations between side effect number and severity with component size. Further investigation will aim to further curate the component SE burden using SE frequency data.

A better understanding of the relationship between a drug target and its paralog group, will provide additional information on the appropriateness of new candidate targets and consequently may help prioritise targets with favourable SE profiles.

## **PgmNr 1529: Novel methods for structural variant detection using Linked-Reads: Analysis of 68 human whole genomes across 11 HapMap populations.**

### **Authors:**

Linked-Read technologies such as the 10x Chromium system promise a comprehensive structural variant (SV) screening of a large cohorts at a reasonable cost. In this work, we present two computational methods for SV calling using Linked-Read sequencing: (i) Novel-X, a method for detection and assembly of novel sequence insertions in a sequenced genome which is based on a local assembly of interconnecting barcodes, and (ii) VALOR2, a mapping based algorithm for characterizing complex large-scale SVs. Using these methods, we performed a search for large duplications, inverted duplications, insertions, inversions and novel sequence insertions of 68 whole human genome samples sequenced using 10X technology. This cohort consists of samples from different populations from the HapMap project that allowed us to study interracial dependencies of the obtained calls. For the novel sequence insertion we were able to find that number of insertions in Asian samples is higher than in the samples of African or European origins. This finding is consistent with Sherman et al. 2019. Moreover, we were able to find 16 insertions presented in  $\geq 50$  samples, some of them exceeding 1000 bp in length that proves that current human reference genome is far from being complete. In total we identified 676 inversions, 60 duplications, 13 inverted duplications, and 12 Mbp of novel insertion sequences across all samples. Interestingly, African genomes also represented the highest total number of inversions, duplications and inverted duplications among populations of similar sample sizes. Our work also shows a higher degree of conserved variants in Yoruba/Nigerian and USA/African genomes as no other population has more than 10 variants shared across  $>50\%$  of the genomes ( $N \geq 5$ ). This is consistent with Gurdasani et al. 2015, showing low differentiation within African populations.

## PgmNr 1530: Machine learning approach to literature mining for the genetics of complex diseases.

### Authors:

J. Schuster <sup>1,2</sup>; M. Superdock <sup>2</sup>; A. Agudelo <sup>1</sup>; P. Stey <sup>3,4</sup>; J. Padbury <sup>1,2,5</sup>; I.N. Sarkar <sup>2,4</sup>; A. Uzun <sup>1,2,5</sup>

---

To better understand the genetic mechanisms of complex disease, we hypothesized that it was necessary to identify relevant, phenotype-specific gene sets that combined the curation of public literature, review of experimental databases, and interpolation of pathway-associated genes for a given disease or phenotype. Using this strategy, we built publicly available databases for two complex reproductive disorders: The Database for Preterm birth (dbPTB) and The Database for Preeclampsia (dbPEC). The completeness and accuracy of these genetic databases is essential for our understanding of these complex disease phenotypes. Unfortunately, given the exponential increase in biomedical literature, it is becoming increasingly difficult to manually maintain these databases. We used these two previously developed, highly-curated databases of literature describing the genetic architecture for complex diseases as reference data sets to develop a machine learning-based approach to optimize article selection for manual curation. Our approach employed automated text-mining tools to extract rich features from titles and abstracts, supervised machine learning to predict article relevance, and human expertise to extract relevant genetic data. We used logistic regression, random forests, and neural networks to classify articles that were relevant to the diseases of interest that should be considered for further manual analysis. We examined features that we hypothesized would best classify articles with genetically relevant content. Various combinations of these features were used to classify articles and the performance of these feature sets were compared to the standard Bag of Words feature set. Several of the feature sets, which include the MESH terms, gene significance triplets (sentences in which there was a co-occurrence between the "GENE" semantic group and UMLS concepts related to statistical significance) and semtype features, outperformed Bag of Words in terms of workload savings (% reduction of required manual curation), F-score, and Fg-score at 95% gene sensitivity. Workload savings ranged from 0.814-0.846 for the dbPTB data set and 0.301-0.371 for the dbPEC data set. A rich database of metadata and annotations for each article is generated which allows for rapid query of individual features. Our results demonstrate that machine learning algorithms can identify articles of interest for creation of a database of gene sets for complex diseases.

## **PgmNr 1531: Truwl.com: A web platform to publish bioinformatics methods in a reusable, findable, understandable fashion.**

**Authors:**

K.B. Seby; T. Thompson

[View Session](#) [Add to Schedule](#)

**Affiliation:** xD Bio, Inc., Whitefish, Montana.

---

The lack of solutions to find, understand, and apply established bioinformatics methods has led to a lack of reproducibility, underuse of open source tools, continued dependence on outdated tools, and time-consuming reimplementations of established methods. Bioinformatics tools and workflows published on truwl.com (truwl) are exposed to crawlers through server-side rendering and provide context through tags, commenting, and voting making methods easily findable through search engine queries. The proper use of tools and workflows can be understood through collections of use cases that show examples of how tools and workflows have been used, including their input and output files and parameter settings. The ability to easily explore the relationships between tools, workflows, and their inputs and outputs is key to understanding how methods are applied and provides the necessary context to vet and adapt methods. Truwl makes exploring these relationships simple through a web interface: file inputs link to pages that describe them and link to any known locations where the files can be obtained; workflows are displayed as interactive graphs that can be navigated to the tools that they use and are similarly linked to sets of use cases that enable users to see how the workflows are used in practice. Behind the web interface, tools and workflows displayed on truwl are described by files written in the Common Workflow Language (CWL) and Workflow Description Language (WDL) that are standards to make methods executable by a variety of workflow management systems. Furthermore globally unique identifiers are assigned to each version of tool, workflow, and associated use cases allowing unambiguous citation not only to the method but to how the method was used. The combination of a user friendly web interface, focus on findability, platform agnostic executable descriptions, and community curation tools promises to allow users to share, find, and implement the most appropriate and up to date bioinformatics methods.

## PgmNr 1532: Automated reporting of germline variants using machine learning approaches.

Usage of NGS technologies has become an integral part of clinical settings for genetic screening, diagnostics, and clinical assessment. For better diagnosis and treatment of a disease like cancer, knowledge, and understanding of genomic variants is the key factor. In order to classify a variant as reportable or not, a user has to depend on multiple sources of information and form complex rules to reach a conclusion. Here, we used machine learning algorithms to combine information from the public data sources and our proprietary database of 10000 patients to classify the variant. This reduces the processing time (to about less than 5 min) and the workload of the clinician to validate the variants and generate a report for the patient.

We used Hereditary Breast and Ovarian Cancer germline panel and subsetting our database for variants of genes in this panel to create a classifier model of report generator using supervised learning algorithms. Initial data cleanup was done to exclude the outliers, missing results, and some exceptional cases. Finally, we arrived at a list of 3746 variants from 12 genes of the selected gene list and used it for classifier modeling. These variants were annotated with attributes like Gene name, Mutation type, Strand's ACMG label, Clinvar ACMG labels, Minor allele frequency from ExAC, EVS and 1000 Genomes, dbNSFP predictor scores, and Conservation scores.

We used the WEKA library's Logistic Regression, Naive Bayes, Random Forest, Random Tree, Support Vector Machine with various kernels to choose the algorithm that best suited our purpose of classifying the variant as reportable (yes) or not (no). From the input variants dataset, 80% of the variants were selected randomly for training purpose and the remaining 20% were used for testing. Based on the initial analysis, SVM with RBF kernel suited well for this one-vs-one classification and gave consistent results with an overall accuracy of 98.91%, precision, and recall of 0.989. For validation, about 81 variants that were not taken in for model creation were used. From these variants, 90% were predicted correctly (53 variants as yes and 20 as no). The 10% (8 variants) incorrectly predicted variants were all false positives and these can be quickly resolved by the variant scientist. From the above results, we were able to demonstrate our capability of modeling report generator and this generic approach can be applied to any gene(s) and variant(s) annotated with the required attributes.

## **PgmNr 1533: Machine learning approach to predicting important interacting proteins between human red blood cells and *Plasmodium falciparum* schizont.**

**Introduction:** The need to develop vaccines that targets the parasite erythrocytic invasion stage becomes imperative because the estimated reduction in malaria in Africa has not been commensurate with the much effort put in place by the world health organization. Identification of important interacting proteins between host and parasite at those crucial stages precedes vaccine development. Previous studies have predicted several interactions between host and parasite, however, the mechanism related to invasion is poorly understood. Again, invasion has been identified as a potential vaccine target, being one of the few stages when the parasite is directly exposed to the host immune system. **Aim:** Therefore, this study identified important interacting proteins (IIPs) that are responsible for merozoite invasion of the human Red Blood Cells (RBCs). **Methods:** RNA-Seq gene expression profiles of human RBCs and merozoite were obtained from experimental data with the differentially expressed genes obtained after statistically analysis in R. Correlation distance metric, K-nearest neighbour algorithm and Bipartite graph were implemented to make the final predictions. **Results and Future Direction:** The predicted results shows 63% IIPs that corroborate with predictions from previous studies and 37% novels. The IIPs predicted should be experimentally validated and then use as drug targets for vaccine development against the parasite invasion of the red blood cells

## PgmNr 1534: A pipeline for large-scale simulation of population-based linkage.

The advent of large-scale sequencing projects such as TOPMed and GSP allow for interrogation of rare, population specific variants. To test the limits of detection of modern genotyping arrays' power to discover rare variant associations compared to whole exome or whole genome sequencing experiments, we developed a pipeline simulating human evolutionary history that generates variants recapitulating global patterns of population structure and identity by descent (IBD). IBD, by detecting patterns of recent relatedness, is often proposed as an alternative strategy for interrogating recent variants that remain rare in the population when only array data is present. This pipeline generates realistic distributions of IBD segments by including evolutionary parameters simulating cryptic relatedness, population substructure and demography, along with a realistic array design model using a similar tag SNP selection strategy to the MEGA array. The pipeline may be run over a variety of parameters by investigations to determine how to optimize their study design based upon demographic history of the populations of interest, underlying genetic architecture of the trait of interest and recruitment sample sizes. Using a mix of python for user-friendliness and C++ for computational efficiency, the pipeline is containerized using Docker to allow for rapid deployment across disparate computational infrastructures. Using this pipeline, we describe the relationship between IBD segments and variants across the rare spectrum, and provide recommendations for investigators interested in rare variant detection and trait association studies. We plan to use this IBD generation pipeline to evaluate novel methods of scalable IBD tract detection (iLASH) and segment clustering (iCURL) to improve power of association testing over traditional GWAS methods because long IBD segments account for recent, rare variation and the pervasive cryptic relatedness present in modern biobank-sized datasets.

## PgmNr 1535: High-level optimizations over query engines ensemble: Accelerating distributed genomic data science.

---

**Background:** Nucleic acid sequencing is well adopted in performing molecular diagnosis and is the very core of large-scale research projects producing immense amount of data which are meaningless until further examined by algorithms. Presently computational analysis step is the major bottleneck in clinics as well as sequencing research projects however there is a handful of ideas for improving performance of bioinformatics pipelines. Although one of the possibilities, distributed computing is reasonable, available distributed software suffers from either limited functionality, or rather poor overall performance as it is usually being optimized for one of the two kinds of analyses (single sample analysis for clinical purposes vs. cohort/case control research studies).

**Methods:** In recognition of various access patterns instead of using single query engine we plan to construct and use an ensemble of data stores each optimized for specific conditions. We designed efficient primary model exposing different views of the data and helper structures with synchronization mechanisms. Our high-level optimizer, aware of these elements, is able to route the query to the suitable component which will most certainly be superior under encountered conditions.

**Benchmarking:** We have performed tests on 1000 Genomes Project data on our Hadoop-based cluster. We have confirmed that both efficient implementation of appropriate distributed algorithms and routing query to suitable query engine significantly reduces the computation time for painful bioinformatics operations.

**Conclusions:** We expect that optimized access to data will streamline tertiary analyses, resolve the challenge of manipulating heterogeneous genomic data sets and will lay down foundation to wider adoption of data-heavy machine learning methods bringing a new stimuli into the personalized medicine.

## PgmNr 1536: *TypeTE*: A tool for genotyping mobile element insertions in whole-genome sequencing data.

---

The proliferative activity of non-LTR retrotransposons (*Alu*, *LINE-1* and *SVA*) over the last 100 million years has generated thousands of copies, accounting for ~32% of the human genome. Many of those insertions are polymorphic, where individuals or populations share the presence or absence of a mobile element insertion (MEI). Such polymorphic MEIs, in addition to contributing to structural variation, can alter gene expression. Polymorphic MEIs are also used as markers of ancestry in population genetics to understand the structure and evolution of populations. These studies depend on accurate genotyping of MEIs for correct estimation of their allele frequencies, and for phasing these insertions with other variants that comprise the haplotype. In fact, we found that ~17% of the MEI genotype calls from 1000 genome project data (1KGP) are erroneous when compared to a validated set of genotypes (>200) generated by polymerase chain reaction (PCR). Accurate MEI genotyping using short-read alignments is inherently challenging due their repetitiveness, and dedicated tools are scarce. We thus have developed a computational pipeline, *TypeTE*, that aims to genotype both reference and non-reference MEIs (specifically *Alu* insertions) from whole-genome paired-end resequencing data aligned to the reference assembly. The pipeline performs an in-depth analysis of the *Alu* breakpoints detected by other tools. First, all mapped reads including discordant reads and mates are extracted from each locus. The consensus sequence of *Alu* at each locus is either generated through a local *de novo* assembly or extracted from the Repbase database. The pipeline then identifies the signatures of non-LTR retrotransposition (i.e. poly-A tail and target site duplications) and the strand orientation of the *Alu* insertion. The extracted reads are then mapped to two alleles (with and without the *Alu* insertion) separately, and the genotype likelihoods are calculated using established methods. To confirm the accuracy of prediction, we compared *TypeTE* predicted genotypes for both reference and non-reference loci to >200 PCR-based genotypes, which is considered the 'gold standard'. Altogether, *TypeTE* improved genotype accuracy from 83% to 92% in the 1KGP dataset. *TypeTE* is adaptable to other retrotransposon families and is a valuable addition to the toolbox for population genetics and genomics.

## PgmNr 1537: Skipping: A versatile genome assembler for read clouds technology.

The high-throughput barcoding technology, which tags reads that originate from a single DNA molecule with a unique barcode, has been the foundation for generating Synthetic Long Reads (SLR) and linked-reads. The accuracy of short-read data combined with the long-range information encoded in the read clouds formed by linked-reads make protocols like 10X GemCode and TELL-Seq the preferred solutions for haplotype genome phasing and structural variant calling. Linked-read technologies also bring new hope to completely solve the long-standing genome and metagenome assembly problems. Existing linked-read assemblers use linked-read data to scaffold contigs generated from traditional assemblers and significantly improve the assembly. However, this strategy does not utilize the assembly graph and limits its ability in resolving complex repeat structures. We have developed *Skipping*, a versatile genome assembler for read clouds (linked-read) data, to support *de novo* assembly for both small and large genomes, as well as complex metagenomes. *Skipping* assembler constructs the de Bruijn graph from raw sequencing data then leverages the barcode information to resolve complex regions in the graph caused by repeats in the genome. To increase the continuity of the draft assembly, we use k-mer mapping approach to link pairs of consecutive contigs that share a large number of barcodes. For *E. coli* DH10B dataset, *Skipping* assembler outputs one complete chromosome with highly contiguous quality (NA50: 4.5 Mb). In a mock metagenome dataset, *Skipping* assembler's result has the largest contig and the largest N50 compared to other SLR assemblers' results. We also use data from the Vertebrate Genomes Project to benchmark *Skipping* with other SLR assemblers to see the advantage of *Skipping* in terms of accuracy and speed for medium and large genomes. Although *Skipping* is originally an end-to-end assembler, it can also be incorporated into any existing assembly pipeline as a scaffolding module using linked-read data, which helps improve the quality of draft assemblies.

## PgmNr 1538: Proteinarium: Multi-sample protein-protein interaction analysis and visualization tool.

---

The generation of high throughput screening methods accelerated and improved building protein-protein interaction (PPI) networks. Large scale protein interaction maps show that genes involved in related phenotypes frequently interact physically at the level of proteins in model organisms as well as in humans. This is also true for complex diseases phenotypes. Proteins associated with similar disease phenotypes have a strong affinity to interact with each other. Therefore, identifying disease specific biological networks and subnetworks dynamically through the analysis of experimental data is a valuable application in order to understand the hidden layers of relationships between complex diseases and their associated phenotypes in individuals or patient groups. Hence, new analysis and visualization tools are needed to better identify the shared and individual network pathways within complex diseases or phenotypes. For that purpose, we developed Proteinarium to analyze and visualize the networks of complex diseases and their associated phenotypes in the context of clustered samples based on their network similarities. The feature of this program is that the user can input separate gene lists for each sample as a distinct input which are further examined through protein-protein interaction analyses. The input can be derived from transcriptome analysis or any high-throughput screening approach. For each sample; Proteinarium (1) converts the list of genes into proteins, (2) maps proteins onto the interactome where STRING database, v11 for humans is used, (3) applies Dijkstra's Algorithm to generate PPI networks. Then, Jaccard distance is used to identify the network similarities between samples. Next, samples are clustered according to their network similarities using UPGMA method and displayed as a dendrogram. Each branch of the dendrogram can be visualized to present layered graph of PPI networks. Proteinarium provides several outputs. For example, users can also analyze the network(s) on other platforms like Cytoscape or dendrograms can be visualized on other programs. Proteinarium, through the derivation of shared PPI networks, allows researchers to address important questions on high throughput data for a variety of disease phenotypes based on their PPI networks. Proteinarium is freely available at <https://github.com/Armanious/Proteinarium>.

## PgmNr 1539: An automated functional annotation pipeline rapidly prioritizes clinically relevant genes for neurodevelopmental disorders which may impact treatment.

---

There are hundreds of genetic risk variants for neurodevelopmental disorders (NDDs) and the list is continually growing. To understand how genetic data can be used to inform treatment, it is important to develop efficient ways to sort through association study and other related results and prioritize clinically relevant genes. We developed an automated translational bioinformatics pipeline using databases that incorporate evidence from multiple sources to identify: 1) genes associated with NDDs that are expressed in the brain with evidence for convergent biological function, 2) genes with evidence for functional consequences relevant to NDDs in mice, 3) genes with evidence of pathogenic genetic variants and/or predict potential genes via evidence for direct interactions with the protein products of known pathogenic genes, and 4) genes encoding proteins targeted by approved pharmaceutical compounds with evidence for pharmacogenomics effects influencing individual treatment response. We identified 916 unique NDD candidate genes which were annotated and compared with 1,000 random sets of  $n=916$  human protein coding genes defined in Ensembl v86. Compared to all of the random gene sets, more NDD candidate genes ( $p < 1.0 \times 10^{-3}$ ) were annotated in functional categories of interest. Specifically, more NDD genes were associated with phenotypes reflecting nervous system and/or behavior dysfunctions when knocked-out in mice (ProportionNDDSet=0.11,  $\mu$ ProportionRandomSets=0.08 $\pm$ 0.01). Proteins encoded by NDD genes showed more evidence for direct interactions with proteins encoded by American College of Medical Genetics-recommended clinically actionable genes (ProportionNDDSet=0.51,  $\mu$ ProportionRandomSets=0.33 $\pm$ 0.01) and were targets for FDA-approved drugs (ProportionNDDSet=0.14,  $\mu$ ProportionRandomSets=0.03 $\pm$ 0.01) or bioactive molecules with drug-like properties (ProportionNDDSet=0.15,  $\mu$ ProportionRandomSets=0.08 $\pm$ 0.01). In total, 22 NDD genes were prioritized based on functional evidence in all annotation categories, compared to an average of  $7 \pm 3$  genes from random sets. Our automated approach for functional annotation of NDD candidate genes may help to rapidly prioritize potentially actionable results from genetic studies, which may inform future work focused on supporting clinical decisions regarding the benefits of genetic testing for optimizing personalized approaches to treatment on a case-by-case basis.

## PgmNr 1540: Using long and linked reads to generate a new Genome in a Bottle small variant benchmark.

Mountain View, CA

---

The Genome in a Bottle (GIAB) consortium performs authoritative characterization of 7 human genomes. Here, we describe work towards generating a new GIAB small variant benchmark that incorporates long and linked read sequencing data. The GIAB collection includes 2 son-mother-father trios from the Personal Genome Project that are broadly-consented, including for commercial redistribution. The GIAB benchmarks are created by integrating variant calls from multiple sequencing technologies and analysis methods. This integration systematically evaluates and arbitrates amongst the technologies and methods to identify consensus calls, and regions containing those calls, that can be relied upon as benchmarks. The benchmark variants and genomic regions cover, for example, 87.8% of assembled bases in chromosomes 1-22 of GRCh37 for one genome (HG002). Because many clinically-relevant variants, such as those in *CYP21A2* lie outside the current GIAB benchmark regions, expanding these is important for medical applications. Short read variant callers perform poorly in segmental duplications and low-complexity repeat-rich regions as well as other regions with high homology. We utilize PacBio CCS long read data and 10x Genomics linked reads to expand the GIAB benchmark regions and reduce errors in current regions. Preliminary analyses suggest that long and linked reads might be able to add between 40,601 and 457,130 benchmark small variants along with expanding the coverage of GRCh37 by approximately 20 to 214 million base pairs. The draft benchmark covers substantially more challenging regions, such that the false negative rate for short read-based methods increases by a factor of about 7.6 to 17.2 relative to the current benchmark. Furthermore, initial inspections show a few thousand potential errors in the current benchmark in difficult-to-map regions, such as LINEs, where the current short read-based methods are inaccurate. We generated draft benchmark variant calls, worked with GIAB consortium members for evaluation, and are currently developing more robust calls in segmental duplications. We are developing a similar benchmark set for GRCh38 because it represents segmental duplications better than GRCh37. To confirm the accuracy of the draft benchmark, we performed long range PCR and Sanger sequencing to test variants including those in *CYP21A2* for which we confirmed 12 variants. This work will enable benchmarking in challenging genomic regions.

## PgmNr 1541: Physician-driven genomic analysis using IOBIO web tools.

### Authors:

A. Ward <sup>1,2</sup>; T. Di Sera <sup>1</sup>; M. Velinder <sup>1</sup>; A. Ekawade <sup>1</sup>; G. Marth <sup>1,2</sup>

1) University of Utah, Salt Lake City, MA; 2) Frameshift Genomics, Boston, MA

The diagnosis of inherited diseases, cancers and other genetic disorders are already benefiting from DNA sequencing and analysis. Given the difficulty of interpreting the genetic basis of these disorders, it is becoming increasingly important for subspecialty clinicians to carry out analysis in their own patients' genomic data. Existing genomic analysis software tools, however, require substantial bioinformatician involvement. We are developing a tool to guide physicians through all necessary steps of clinical diagnostic genomic analysis, from data quality review, candidate gene generation, variant interrogation and prioritization, to reporting of all findings, in a visual, compelling fashion. This clin.iobio tool is based on our popular IOBIO web apps, and performs analyses in real time, without requiring the help of bioinformaticians.

**Clin.iobio** provides a flexible analysis workflow, combining multiple IOBIO apps into a single platform. Following the lead of other medical procedures, a checklist of tasks promotes analysis consistency and repeatability. A user begins by building a candidate gene list using **genepanel.iobio** (<http://genepanel.iobio.io>). This app combines NCBI's genetic testing registry, the Phenolyzer tool, and the user's knowledge of likely genes to generate this gene list. These genes are then propagated to **gene.iobio** (<http://gene.iobio.io>) for real-time variant annotation and analysis. Variants are automatically prioritized by gene.iobio, and users are encouraged to assign a significance level and attach notes to variants to promote collaboration. Finally, variants drawn from the whole exome or genome, independent of the candidate gene list, and conforming to predetermined filters are presented for review. This ensures all potentially disease-causing variants in all genes are examined. The analysis findings are summarized in a final, interactive report. An important feature of **clin.iobio**, is that it facilitates dynamic analysis and re-analysis. If no candidate variants are discovered, the user can quickly create a more expansive gene list, bringing in additional variants for review. This dynamic and collaborative analysis platform will help move genomic analysis into the clinical practice of subspecialty clinicians.

## PgmNr 1542: Fast estimation of genome-wide and partitioned genetic correlation for complex traits.

### Authors:

Y. Wu<sup>1</sup>; D. Palmer<sup>3,4</sup>; A. Ganna<sup>3,4,5,6</sup>; S. Sankararaman<sup>1,2</sup>

[View Session](#) [Add to Schedule](#)

1) Computer Science, UCLA, Los Angeles, California.; 2) Department of Human Genetics, UCLA, Los Angeles, California; 3) Analytic and Translational Genetics Unit, Center for Genomic Medicine, Massachusetts General Hospital, Boston, MA, USA; 4) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA, USA; 5) Stanley Center for Psychiatric Research, Broad Institute of MIT and Harvard, Cambridge, MA, USA; 6) Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden.

---

Genetic correlation can provide insights into shared genetic pathways as well as providing a starting point to investigate causal relationships among traits. Further, partitioning of genetic correlation provides additional insights into identifying groups of genetic variants that contribute disproportionately to the genome-wide genetic correlation. While several methods for estimating genome-wide genetic correlation have been proposed, no existing method can partition genetic correlation on large-scale individual data. We propose a method based on bivariate linear Mixed models (LMMs) that can estimate genome-wide genetic correlation as well as partition genetic correlation.

The bivariate LMM jointly models the effect sizes of a given SNP on each of the pair of traits being analyzed. The parameters of the bivariate LMM, i.e., the variance components, are related to the heritability of each trait as well their genetic correlation. We further extend the bivariate LMM with additional information on grouping of SNPs. Specifically, we assume that the effect sizes of SNP from the same group for two traits are independent and follow a multivariate distribution with group-specific parameters. However, inference in bivariate LMMs, typically achieved by maximizing the likelihood, poses serious computational challenges that make it impractical to apply at scale

We propose, RGcor-mc, a scalable randomized Method-of-Moments (MoM) estimator of partitioned genetic correlations in bivariate LMMs. RGcor-mc leverages the structure of genotype data to obtain runtimes that scale sub-linearly with the number of individuals in the input dataset (assuming the number of SNPs is held constant). First, we perform extensive simulations to validate the accuracy of RGcor-mc to estimate genome-wide genetic correlation. We show RGcor-mc is as accurate as running GCTA on each group of SNPs separately. RGcor-mc is scalable and can compute the genetic correlations on the UK biobank dataset consisting of 430,000 individuals and 460,000 SNPs in 3 hours on a stand-alone compute machine, and partition the genetic correlation with no additional cost. We validate that the genome-wide and local genetic correlation are consistent with previous studies. We applied our method on UK biobank, and found novel significant genetic correlations. We document that rheumatoid arthritis (RA) and Crohn's diseases have negative genetic correlation ( $g=-0.22$ ,  $p=2.2e-13$ ).

## PgmNr 1543: ENmix: An efficient and comprehensive analysis tool set for Illumina HumanMethylation BeadChip.

**Authors:**

Z. Xu; J. Taylor

**Affiliation:** NIH/NIEHS, Research Triangle Park, North Carolina.

---

The Illumina Methylation BeadChip is being broadly utilized in large epigenome-wide association studies. Methylation differences between groups are often very small and proper preprocessing of array data are critical to maximizing signal and minimizing noise. We developed a comprehensive R package, ENmix, to facilitate the analysis by removing unwanted experimental noise and improve accuracy and reproducibility of methylation measures. This new-enhanced package provides a set of quality control and data pre-processing tools, including background correction, dye bias correction, probe-type bias adjustment, low quality sample and probe filters, a low quality data point filter and imputation of missing data. In addition, we implemented a set of complementary functions, including data import from idat files, data visualization, identification of probes with multimodal distributions due to SNPs or other factors, exploration of data variance structure using principal component regression analysis plots, control surrogate variable information, an efficient algorithm oxBS-MLE to estimate 5-methylcytosine and 5-hydroxymethylcytosine levels, cell type proportion estimators and methylation age calculators. This stand-alone software is specifically designed to support large-scale data analysis, provides multi-processor parallel computing options for all functions, includes pipeline defaults for new users and supports 27K 450K and EPIC arrays.

## PgmNr 1544: Applying AMELIE to the NIH Intramural Cohort of the Undiagnosed Diseases Network.

---

The NIH Undiagnosed Diseases Program (UDP) was started in 2008 to find diagnoses for individuals with severe medical conditions that remained undiagnosed despite extensive workup. The UDP joined with other medical centers across the country to form the Undiagnosed Diseases Network (UDN) in 2013. Genomic medicine approaches have formed an important role in finding diagnoses for UDN participants. A central challenge in this field is the identification of diagnostic and research worthy DNA variation in the patient genome or exome. AMELIE (Automatic Mendelian Literature Evaluation) developed in Stanford is a computer tool to rank candidate genes based on phenotypes by finding gene-phenotype associations mined from literature. It takes a list of gene symbols and term identifications of the Human Phenotype Ontology and returns a ranked list of genes. We applied this tool to a subset of diagnosed cases enrolled in UDP to assess its usefulness in identification of variants from genome or exome sequencing data for a diagnosis. In 62 out of 83 diagnosed cases (75%), the genes harboring the diagnosis-associated variants are among the ranked top five. AMELIE is useful in ranking variants for identification of known disease-gene associations. It allows a long list of candidate variants including those intragenic non-coding regions to be automatically examined for reported associations. Further work on a subset of UDP undiagnosed cases and a few example cases will be presented.

## PgmNr 1545: Predicting pathogenicity of missense variants using deep learning.

---

Accurate predictions of genetic effects of missense variants is critical to the interpretation of genome sequence. Previously published methods have been used to improve power in genetic studies and to identify pathogenic variants in clinical genetic testing. However, the performance of these methods is suboptimal, due to issues related to the complexity of the mechanisms of pathogenic variants and suboptimal usage of large training data sets. In addition, it is often hard to interpret predicted scores. Here we report on a new prediction method MVP2, aimed to improve prediction performance and interpretability. MVP2 uses a deep learning approach to learn protein-context-specific pathogenicity of amino acid changes from large number of curated pathogenic variants. MVP2 learns the latent representation of amino acid types using context-wise embedding technique and uses convolutional neural network to learn the patterns of context including evolutionary conservation, structural properties and subgenic coding constraints in general population. To assess the utility in clinical genetic diagnostic testing, we obtained high-throughput functional data of ~1600-1800 missense variants in PTEN, TP53, and BRCA1 from recent publications as ground truth. We tested the ability to identify pathogenic variants excluding all known pathogenic variants in ClinVar. The area under the precision-recall curve of MVP2 is 0.69, 0.77 and 0.71 in PTEN, TP53 and BRCA1, respectively, substantially better than the best of previously published methods (0.50, 0.60 and 0.68, respectively). We also showed that our model and the scores are interpretable. Amino acids with similar biophysical properties are clustered together based on embedding vectors learned during training. We also found that amino acids mutated to proline in BRCA1's helix regions are predicted to be highly pathogenic, even in positions not well conserved. This is consistent with the fact that proline rarely occur in the middle of alpha-helix. This showed that, without prior knowledge, MVP2 captures context-dependent impact to protein function from amino acid substitutions. In summary, we show that MVP2 improves predictions of pathogenicity of missense variants by capturing protein context-dependent information using deep learning, and it has the potential to significantly increase the power in genetic studies and enhance the utility of clinical genetic testing.

## PgmNr 1546: AgentBind: Profiling context-specific determinants of transcription factor binding affinity with deep learning techniques.

---

Binding of transcription factors (TFs) to DNA is one of the major transcriptional regulation mechanisms. Disruption of TF binding has been shown to affect a wide variety of phenotypes, including cancers and diabetes. Most TFs have intrinsic binding preferences for short DNA motifs of 5-20bp. Intriguingly, while millions of instances of a given TF motif may exist in the human genome, typically only a small fraction (less than 1%) of them are actually bound, suggesting sequence context around the motif also plays a significant role. To interpret the role of sequence context in TF-DNA recognition, we designed a novel deep learning framework, AgentBind. Our framework uses a convolutional neural network to classify bound vs. unbound TF motifs based on 1 kb of sequence context and make predictions of binding affinity for new samples (*binding scores*). It then applies Grad-CAM, a state-of-the-art model interpretation technique, to score the contribution of each nucleotide to the classification label (*context scores*). These scores can then be used to predict the impact of individual non-coding variants.

We evaluated AgentBind on 38 TFs profiled by ENCODE. Using only sequence information, AgentBind could accurately classify bound vs. unbound TF motifs (average AUC=0.945) and outperformed IMPACT, an alternative method which makes predictions based on dozens of epigenomics profiles. By interpreting the well-trained models, we were able to quantitatively annotate each nucleotide in the context and identified the k-mers enriched in the high-scored regions. This analysis identified many known co-factor pairs, such as SP1 and NFY.

We then tested the ability of AgentBind in predicting the impact of non-coding variants. We used LD-score regression to quantify the heritability explained by single-nucleotide polymorphisms (SNPs). Strikingly, SNPs in regions with high *binding scores* for TFs Gata3, Stat3, and Foxp3 were strongly enriched for explaining the heritability of rheumatoid arthritis (enrichment 20-80). We then analyzed SNPs from the 1000 Genomes Project and found that SNPs with high *context scores* (top 1%) were enriched for singleton variants compared to SNPs with low scores (p=0.0069), suggesting they are under increased selection. Taken together, these results suggest AgentBind scores accurately pinpoint genetic variants influencing binding of nearby TFs and can be used as a precise prioritization metric to identify disease-associated variants.

## PgmNr 1547: Evaluating nanopore sequencing data processing pipelines for structure variation identification.

---

### Background

Structural variations (SVs) account for about 1% of the differences between human genomes and play a significant role in phenotypic variation and disease susceptibility. Widely adopted next generation sequencing technologies have short read-length which limits their ability to identify SVs. The emerging nanopore sequencing technology applies real-time single-molecule sequencing and can generate long sequence reads. This technology can potentially provide better SV identification. However, the available tools for aligning long-read data and detecting SVs have not been thoroughly evaluated.

### Results

Using three human nanopore datasets, including both empirical data and simulated reads, we evaluated four alignment tools and three SV detection tools. We also evaluated the performance of the consensus calls from multiple SV callers and the impact of sequencing depth on SV detection. SV callers' performance varies depending on the SV types. For an initial assessment we recommend using aligner minimap2 in combination with the SV caller Sniffles because of their speed and relatively balanced performance. For users with specific requirements for SV types, precision or recall rates, other combinations or consensus call sets could provide better results.

### Conclusions

We established a workflow for evaluating aligners and SV callers for nanopore sequencing data. Our results indicate that optimizations are needed to improve SV detection accuracy and sensitivity. The nanopore technology keeps improving and the nanopore sequencing community is likely to grow accordingly. In turn, better benchmark call sets will be available to more accurately assess performance of available tools and facilitate further tool development.

## PgmNr 1548: A rare variants association test by weighting variants using sigmoid function.

Statistical tests of burden of rare variants in individual genes is one of the main approaches to identify new risk genes in genome or exome sequencing studies of human diseases. In many studies, it is necessary to use large-scale data generated outside of the study as controls. This strategy improves statistical power of detecting association of rare variants, but inevitably introduces technical batch effect between cases and controls. A practical method would be robust to such subtle technical batch effect. Additionally, missense variants are the most common type of genetic variation in protein-coding regions, but many missense variants are not deleterious, and including these in association tests would decrease signal to noise ratio and reduce power. Previous it was shown that pre-select deleterious missense variants based on in silico prediction can improve power (Zuk et al 2014); however, the optimal threshold of defining deleterious variants is likely different in different genes (Wilfert et al 2016). Furthermore, different risk variants from the same gene likely have different effect size.

We reason that relative risk of a missense variant in a true risk gene is correlated with in silico prediction scores, and the correlation can be modeled by a sigmoid function. In this work, we propose radTest, a burden test method using a logistic function to weight the variants by in silico prediction of deleteriousness. In each gene, we try a range of midpoint values to reach maximal significance in case-control comparison, and then permute the data to build background model of the test statistics to calibrate p-values. To benchmark performance, we obtained 193 rare variants in cases and controls from recent publications in BMP2 (Machado et al 2015), a major risk gene of pulmonary arterial hypertension. This data set allows us to simulate conditions without making unrealistic assumptions about dependency of effect size on predicted deleteriousness. We did observe a sigmoid shape in relative risk over predicted deleteriousness in the data. We then model a range of effect size by randomly switch case/control labels for a subset of rare variants, and showed that compared with current standard methods, radTest has superior power to detect association under realistic conditions with modest effect size. Finally, we show that radTest is robust to randomly injected small batch effect, making it applicable to genetic studies in which such batch effect is unavoidable.

## PgmNr 1549: Galaxy as an integrative environment for microbiome analysis and visualization.

### Authors:

D. Blankenberg; The Galaxy Team

[View Session](#) [Add to Schedule](#)

**Affiliation:** Genomic Medicine Institute, Cleveland Clinic, Lerner Research Institute, Cleveland, Ohio.

---

A microbiome is a prime example of a complex biological system, a tangled web of multi-layered interactions, of which we are only beginning to be able to explore, elucidate, and command. The accelerating expansion in the kind and availability of high-throughput assays and technologies coupled to the increasing accessibility, refinement, and accuracy of molecular techniques to probe microbiomes continues to push the capability boundaries of computational analysis and data visualization. These physical experimental efforts can result in a wide-range of disparate datatypes and datasets that span across multiple domains and breach the threshold into big data classifications.

As microbiome datasets increase in size, scope, and complexity, how can we ensure that researchers are empowered to make effective use of not only the data, but also analysis tools, pipelines, visualizations, and compute resources? Furthermore, how can we make certain that researchers are able to do so in a Findable, Accessible, Interoperable, and Reusable (FAIR) manner?

Here we discuss the current status of Galaxy as a FAIR-capable integrative environment for microbiome analysis and visualization, including recent developments and future directions. Galaxy provides an ideal foundation for our microbiome analysis and visualization environment.

Galaxy (homepage: <https://galaxyproject.org>, main public server: <https://usegalaxy.org>) is a web-based scientific analysis platform used by tens of thousands of scientists across the world to analyze large biomedical datasets such as those found in genomics, proteomics, metabolomics, and imaging. It is a widely used and deployed open source platform for data integration and analysis in the life sciences. It can be used via a web GUI or a programmatic API. It has been deployed on everything from laptops to servers, to public cloud providers and supercomputers. There are well over 125 publicly accessible Galaxy instances, plus many national and public cloud deployments, and published containers and VMs. Many additional private installations have also been deployed.

## PgmNr 1550: FIREcaller: An R package for detecting frequent interacting regions from Hi-C data.

### Affiliations:

1) Department of Genetics, University of North Carolina at Chapel Hill, Chapel Hill, NC.; 2) Ludwig Institute for Cancer Research San Diego Branch, San Diego, CA.; 3) Bioinformatics and Systems Biology Graduate Program, University of California San Diego, La Jolla, CA.; 4) Department of Cellular and Molecular Medicine, University of California San Diego, La Jolla, CA.; 5) Institute of Genomic Medicine and Moores Cancer Center, University of California San Diego, La Jolla, CA.; 6) Department of Quantitative Health Sciences, Lerner Research Institute, Cleveland Clinic Foundation, Cleveland, OH.; 7) Department of Biostatistics, University of North Carolina at Chapel Hill, NC.; 8) Department of Computer Science, University of North Carolina at Chapel Hill, NC.

High-throughput chromatin conformation capture (Hi-C) has been widely used to measure genome-wide chromatin spatial organization since first introduced in 2009. Analyzing Hi-C data has led to the discovery of structural readouts at a cascade of resolutions, including: A/B compartments, topologically associating domains (TADs), chromatin loops at Kb resolution, and significant chromatin interactions. Among these Hi-C readouts, TADs and chromatin loops are largely conserved across cell types, while A/B compartments and chromatin interactions exhibit rather moderate levels of cell type specificity.

To identify Hi-C readouts that are better indicative of cell type or tissue-specific chromatin spatial organizations, we previously reported thousands of frequently interacting regions (FIREs) by studying a compendium of Hi-C data across 14 human primary tissues and 7 cell types. We defined FIREs as 40Kb genomic regions, which have substantially more frequent interactions with their neighboring regions. FIREs are enriched for tissue-specific enhancers and nearby tissue-specifically expressed genes, suggesting their potential relevance to tissue-specific transcription regulatory programs. In our original study, we relied on an in-house pipeline to identify FIREs, limiting the general application of FIRE analysis and the full exploration of tissue-specific chromatin interaction features from Hi-C data. Here, we present FIREcaller, a stand-alone, user-friendly R package to detect FIREs from Hi-C data. FIREcaller takes Hi-C contact frequency matrix as input, performs within- and cross-sample normalization, and outputs continuous FIRE scores, dichotomous FIREs, and super-FIREs. To demonstrate the application of our FIREcaller, we used the human hippocampus Hi-C data from our previous study, as well as cortical tissue samples across two developmental epochs, fetal and adult. Among our results, we show that in the human hippocampus tissue, a super-FIRE overlaps with a schizophrenia-associated GWAS SNP rs9960767, leading to a hypothesis that the chromatin spatial organization may play a role in gene regulation in this region, which may ultimately affect the risk of schizophrenia. In addition, in the cortical tissue, we observe that FIREs dynamic across brain developmental stages are closely associated with developmental gene regulation. Overall, we believe that our FIREcaller will become a useful tool in studying tissue-specific chromatin spatial organization features.

## PgmNr 1551: *Mezcal*: Rapid and accurate local ancestry inference at scale using conditional random fields.

The genetic architecture of human health is shaped by our ancestry, with individuals' ancestral origins influencing linkage disequilibrium patterns and the presence of disease-associated mutations. Genome sequence or whole genome genotype data can be analyzed to infer patterns of local genetic ancestry, i.e. the ancestral source of specific chromosomal regions. With the increasing number of large-scale human genome sequencing projects and biobanks that sample from cosmopolitan populations, there is a growing need for rapid and accurate approaches to local ancestry inference (LAI). However, scalable tools for the reliable inference of local ancestry are currently not publicly available to the research community. We have developed the LAI implementation *Mezcal*, which uses a conditional random field (CRF), parameterized on random forest classifiers, to predict the local ancestry composition of human genome sequences drawn from diverse, admixed populations. Our CRF is distinguished by the use of variable transition probabilities, which are modeled on the local genomic context. Our LAI implementation allows users to save their custom random forest classifiers generated via the analysis of ancestral reference and admixed genomes for the rapid characterization of individual samples as they become available in the future, thereby overcoming the N+1 problem often faced by bioinformatics scientists. We tested the performance of *Mezcal* on simulated and real-world human genome sequence datasets, characterized by combinations of two and three distinct continental ancestry components. Our approach to local ancestry inference yields a 50x time performance improvement over the current state-of-the-art, with no appreciable loss of accuracy. We were able to achieve an average of 98% accuracy for the calculation of African, European, and Native American ancestry components from six admixed populations in the Americas.

## PgmNr 1552: Use of burden test to identify the association of rare functional variants to rare Mendelian phenotypes.

### Authors:

---

The identification of causative rare variants associated with rare Mendelian phenotypes is challenging but it can be facilitated by the increasing availability of genomic data. Here we present an analysis based on a burden test using a multisample VCF file containing whole exome sequencing (WES) data from 2662 samples sequenced as part of the Baylor-Hopkins Center for Mendelian Genomics (BHCMG) project. FASTQ files were aligned to the reference genome (GRCh37) with the Burrows-Wheeler Alignment (BWA 0.5.10) resulting in SAM/BAM output. GATK best practices were applied in order to obtain a multisample VCF file. Non-Single Nucleotide Variants (SNVs) were ruled out and the final multisample VCF was annotated with ANNOVAR. SNVs were filtered based on RefSeq, ExAC, gnomAD and Kaviar annotations to include functional (missense, nonsense, and splicing variants) rare (MAF  $\leq$  0.01) SNVs. 1635 unrelated samples were assigned as controls. For each phenotype investigated, the case group included all the affected probands. A contingency 2x2 table containing the sum of individuals presenting at least one functional rare SNV was built for each gene containing control and case groups data. Fisher's exact test was determined and  $p < 0.05$  was considered as statistically significant. Selected genes were also annotated with gnomAD missense Z-score, gnomAD pLI score and RVIS. Next, for each cohort investigated, we selected the genes that were more mutated among the patients than among the controls ( $p < 0.05$ ) and had a missense Z-score  $> 1$  or a pLI score  $> 0.9$  and an RVIS percentile  $< 25\%$ . This pipeline was applied to four different cohorts including a group of 16 probands with Tarlov cyst, 36 probands with hyperhidrosis, 24 probands with early-onset inflammatory bowel disease, and 7 probands with systemic artery to pulmonary artery malformation (SAPAM). The final candidate genes for each cohort are being further investigated as possible novel disease genes. As an example, the analysis of the SAPAM cohort study identified 3 candidate genes: *RNF145*, *EHMT1*, and *MCF2L*. Meanwhile, we had already identified the *MCF2L* gene as causative of this phenotype by our standard cohort analysis where we found this gene mutated in 3 out of the 7 families being investigated. Therefore, we expect that this alternative approach based on the burden test will enable novel disease genes discoveries by the identification of the most conserved genes that are more mutated among our cohort groups.

## PgmNr 1553: TransAnno: Novel LiftOver software for a new genome assembly.

### Authors:

Y. Okamura <sup>1,2</sup>; K. Kinoshita <sup>1,2,3</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Advanced Research Center for Innovations in Next-Generation Medicine, Tohoku University, Sendai, Miyagi, Japan; 2) Tohoku Medical Megabank Organization, Tohoku University, Sendai, Miyagi, Japan; 3) Graduate School of Information Sciences, Tohoku University, Sendai, Miyagi, Japan

---

Recently, ethnic specific genomes, such as AK1 (Seo, J., *et.al.*, (2016) Nature) or HX1 (Shi, L., *et.al.*, (2016) Nat Com) were published. These genome assemblies are promising to improve the discovery new disease-causing variations. However, thousands of studies have been performed on international reference genomes, such as GRCh37 or GRCh38, and a lot of information is only available at GRCh37 or GRCh38. When we use other genomes, we have to perform lift-over a lot of annotation data international reference genomes to ethnic genome.

To perform lift-over genomic variation annotations, CrossMap (Zhao, H., *et.al.*, (2014) Bioinformatics) and Picard (<https://broadinstitute.github.io/picard/>) are widely used. These tools work well to transfer among international reference genomes, but not work well to transfer among ethnic genomes. These tools have some problems to transfer annotations, when reference sequences were changed, and changes were introduced in de novo assembly based ethnic genomes. Especially, insertions and deletions were difficult to be handled with these tools.

Gene annotation is another major problem to use new genome. There is no commonly used tool to perform lift-over gene annotations. Since most software does not care about relationship among exons, transcripts and genes, we cannot use them to perform lift-over gene annotations. GENCODE project has software to transfer their annotation to GRCh37, but their algorithm could not be used to transfer other genomes.

To overcome these difficulties, we developed a new LiftOver tool, TransAnno. TransAnno can 3 tasks, the first task is creating a chain file from minimap2 (Li, H. (2018). Bioinformatics) result. Because of the great performance of minimap2, only a few hours are required to create a new chain file. The second task is performing liftover GENCODE or other gene annotations with considering exon and transcripts. The third task is performing liftover VCF file, even if reference sequence was changed. TransAnno can perform liftover important annotations and makes ethnic specific genomes more useful.

# PgmNr 1554: A new software ecosystem for high resolution ribosome profiling.

**Authors:**

H. Ozadam; C. Cenik

[View Session](#) [Add to Schedule](#)**Affiliation:** Department of Molecular Biosciences, University of Texas at Austin, Austin, TX.

---

Human genetic variation can alter protein function and gene expression to impact phenotype. Our understanding of how human genetic differences control RNA expression is rapidly expanding. Yet, protein abundance is poorly predicted by RNA expression alone. This discrepancy can be partially explained by translational control. The state-of-the-art method for transcriptome-wide measurements of translation is ribosome profiling. In this method, ribosome protected RNA fragments are sequenced to quantify transcript-level ribosome occupancy. In these experiments, sequence read lengths are variable and carry critical information about the translation state of the ribosomes. Therefore, analyzing ribosome profiling data involves computation and storage of multiple metrics for different ribosome footprint lengths. The current solution to this problem of naively using text files is inefficient in organization, computation and storage.

Here, we developed a complete software ecosystem including a new efficient binary file format for ribosome profiling. The first component, RiboFlow, is a pipeline that processes raw ribosome profiling reads to generate sequence alignments, and related statistics. RiboFlow is highly portable across a large number of computational environments with built-in capabilities for parallelization. Importantly, RiboFlow assembles the results into a new binary file format, that we named “ribo”. Ribo files store user-defined metadata and all quantities of interest grouped by different ribosome footprint lengths. The second component, Ribogadgets, provide an interface in Python and R, for writing and reading ribo files. Using Ribogadgets, users can efficiently access ribosome profiling metrics, generate plots and output results to text files.

Taken together, this new software ecosystem provides a complete solution for researchers to study translation seamlessly. Moreover, we provide ~20-fold improvement in storage compared to the conventional approach. As a case study, we will present an application of our software solution to a human ribosome profiling dataset exploring the impact of amino acid starvation. We expect our infrastructure to facilitate large-scale characterization of the relationship between human genetic variation and translation control.

## PgmNr 1555: MOPower: A multi-omics study power calculator to determine optimal sample size and choice of integration model.

---

Multi-omics studies are being increasingly used to uncover the underlying mechanisms of clinical phenotypes by integrating information from the genome to the microbiome. Correctly integrating these multiple data types is currently the biggest challenge, with each existing method suited to a different kind of dataset. This question becomes more complicated in rare disease studies where the sample size is small, and where individual omics approaches have failed to achieve significant results. To address this challenge, we have developed the interactive R-shiny web application and Python reporting tool MOPower. This program simulates data using statistical distributions or real study/reference data via bootstrap resampling to ensure realistic disease-specific simulations. Omics features included in the simulation are SNP's, gene expression and DNA methylation for binary, longitudinal or time-to-event outcomes. Users have control over the study design parameters such as fold change, the minor allele frequency of variants and mean gene expression per group. Each data replicate is analysed using multi-omics integration models such as multivariate projection models, factor analysis and cluster analyses. Depending on the integration model, power is interpreted as the correlation between omics features or the power to detect an association with the phenotype of interest through analysis of  $n$  number of replicates. The output from the power analysis is displayed on the screen, but a detailed report can also be produced in HTML or PDF format. This report is customizable by the user and can include power and sample size calculations on several different factors, displaying the corresponding power plot, a false discovery rate plot and a statement of results interpretation. Furthermore, a comparison is made between each integration model for the user's specific power calculation scenario. Initial results suggest that the number of omics features included per analysis with varying sample sizes influences power. Additionally, factors such as increased dispersion for gene expression correlates with decreased power. Ultimately, MOPower will support in the design of multi-omics studies, providing crucial information on the ideal sample size and choice of an analytical model.

## PgmNr 1556: A webtool for NGS data management, interpretation, and reporting.

### Authors:

Wang; T. Zhuang; J. Shen; X. Lu; T. Gao; Y. Yang

[View Session](#) [Add to Schedule](#)

**Affiliation:** AiLife Diagnostics Inc, Pearland, Texas

---

NGS has been widely used in research and clinical settings. However, data interpretation remains the bottleneck to fully realizing genomic data. For WES or WGS, it is inefficient and impractical to search for causal variants without the aid of prioritization tools. However, the sensitivity and reliability of such tools is currently unclear. In addition, current tools often lack the flexibility that enables users to test different hypotheses of genetic etiologies underlying the complex nature of genotype-phenotype correlations.

Here we report a cloud-based webtool to empower NGS data process. The tool includes modules of LIMS, QC, variant calling from VCF or FASTQ, annotation, knowledge database inquiry, data interpretation, and reporting in one secured system. To facilitate interpretation and reporting, a prioritization score for each variant is automatically calculated based on variant classification, population and research data, as well as phenotype and inheritance correlation with known disorders. The streamlined process also allows for flexibility so reviewers can modify the parameters and add additional information (e.g. conclusions from functional studies) and update the prioritization scores accordingly.

As a pilot study, we analyzed ~100 clinical WES cases, of which previous studies identified likely disease-causing variants in 30 cases. Each case had ~200 rare variants in disease genes, which were fully reviewed by the previous manual analyses. By using the prioritization score in this tool, the contributing variants were identified by reviewing only the top 20 ranked variants for all cases. However, one VUS that was called as possibly contributing by manual review in a proband only exome case was scored as having no phenotype overlap by the tool, due to that the phenotype associated with the gene was not included in the HPO database.

Our results showed that the new tool can effectively streamline the NGS process. In particular, the prioritization scores, which take into consideration of both genetic and phenotype evidence, can be used as a guide to facilitate data interpretation. It should be noted a small percentage of disease genes, esp. newly published ones, may not have HPO annotation. Therefore for cases with negative or uncertain results, or partial molecular diagnosis, further searches based on genetic evidence and manual phenotype evaluations should be performed to ensure a thorough analysis.

# PgmNr 1557: MMIRNA\_ER: A software package for studying miRNA and mRNA expression relationships.

**Authors:**

Z. Xu

[View Session](#) [Add to Schedule](#)**Affiliation:** Seven Lakes High School, Katy, TX.

---

**Background:**

MicroRNAs or miRNAs, an abundant family type of non-coding RNAs, participate in post-transcriptional regulation through binding to the 3' UTRs of target genes or mRNAs and have been reported prevalent in metazoan genomes. A single miRNA can target many mRNAs, while many miRNAs are able to cooperatively target a single mRNA. This allows for fine-tuned gene expression regulation. Most existing miRNA and mRNA data from biological experiments only have individual samples generated and are not ready to be deployed for downstream analysis. The types of data are from either related or unrelated individuals, or from the same individual but different stages of disease progression. To study the interactions between miRNAs and mRNAs, several preprocessing steps focusing on normalizing and grouping individual raw data files into a systematic format are often necessary.

**Methods and Results:**

In this study, we have developed an efficient software package which can automatically take a list of input files for miRNA and mRNA with expression information from multiple samples for a given genetic disorder to determine their relationship. The program can scan through two input expression files (e.g. miRNA and mRNA) filled with a list of samples to report target pairs and get average expression calculated for each target pair. We have processed the input files of miRNA and mRNA from multiple cancer types available in The Cancer Genome Atlas (TCGA) project and reported the output and statistics (e.g. running time).

**Conclusions:**

Our program is user-friendly and flexible and can be used to process data files for studying the relationships between miRNA and mRNA target pairs by providing an easy computation of fold change and target pairs between two or more biological conditions.

## PgmNr 1558: Systematic detection of consanguinity through runs of homozygosity facilitates molecular diagnosis of rare disease patients.

---

Autozygosity is known to be associated with an increased risk of genetic rare disease (RD) and is thus a relevant factor to take into consideration when undertaking clinical genetic studies. NGS technologies allow the precise detection of genomic regions where a reduction in heterozygosity is evident and offer the opportunity to estimate autozygosity at the exome and genome level. Here more than 2400 whole exome sequencing (WES) datasets from the RD-Connect Genome-Phenome analysis platform (GPAP) (<https://platform.rd-connect.eu/>) were analysed and autozygosity assessed based on detection of long (>1Mbp) runs of homozygosity (RoH) using the PLINK software. The relationship between the number and length of detected RoH and different clinical and experimental parameters such as patient continental origin, family history, WES quality metrics, reported consanguinity status in clinical records and sequencing strategy was evaluated. This allowed us to establish four consanguinity ranges ("consanguineous", "probably consanguineous", "probably non-consanguineous" and "non-consanguineous") based on the overall RoH length to indicate if an individual is likely to be the progeny of a consanguineous pairing or not. To validate these findings, a subset of 280 cases from NeurOmics and BBMRI-LPC projects were classified according to the consanguinity ranges, followed by genomic data analysis applying RoH specific region filtering (>1Mbp) in the RD-Connect GPAP. This approach resulted in the re-classification of the consanguinity status of 10% of the patients, either through the detection of possible unstated consanguinity or by empirically correcting the consanguinity reported in the corresponding clinical record. Moreover, filtering of genomic data to RoH regions in experimentally classified consanguineous cases enabled us to reduce by 40-60% the number of candidate variants to be assessed. Finally, pathogenic variants were found within a RoH in 40% of the consanguineous cases enabling to reach a final molecular diagnosis for those patients. The consanguinity ranges defined provide clinical geneticists with an estimate of the degree of

inbreeding within a pedigree, enabling confirmation or (re)classification of consanguineous status, hence facilitating and accelerating the molecular diagnosis of RD patients who undergone WES. We acknowledge NeurOmics and BBMRI-LPC consortium members for their contribution

## PgmNr 1559: Exploring exonic copy number variants within a large clinical cohort with a variety of Mendelian disease traits.

### Authors:

---

The Baylor-Hopkins Center for Mendelian Genomics (BHCMG) program has performed exome sequencing (ES) and rare variant family based genomics in > 3000 families with a wide variety of Mendelian disease traits. Novel discoveries involving pathogenic variant alleles in over 850 'disease genes' (Dec 2011-May 2018) have focused on rare single nucleotide variants (SNVs) and indels. Additional copy number variant (CNV) analysis may further contribute to molecular diagnoses and offer a starting point to understand disease pathobiology. Many small exonic copy number variants (eCNVs), i.e., intragenic duplication or deletion variants of a few exons or even single exon, are too small (< 30 kb) to be detected by clinical array. Sequencing methods provide a scalable and unbiased way to investigate eCNVs genome-wide. The current methods developed are only able to consistently detect medium-sized CNVs in whole-exome sequencing (WES) data but not small ones (e.g., most 'read depth' - based copy number algorithms are optimized to detect heterozygous CNVs encompassing at least three consecutive exons).

In this study, we developed eCNVFinder, an algorithm that improves the signal-to-noise ratio of a single exon by clustering read depth data from samples before CNV calling, enabling the detection of rare small eCNVs from WES. When applied the method to a set of orthogonal validated CNVs from BCHMG, the method successfully recalled 24 out of 27 heterozygous deletions ranging from 2.3 kb to 5 Mb in size, 7 out of 8 triplications ranging from 3.9 kb to 2.5 Mb, and 12 out of 22 heterozygous duplications ranging from 3.6 kb to 3.5 Mb. An overall recall rate of 75.4% was achieved and 2 events involving only 2 exons were able to be detected. Additionally, by applying this method to BCHMG ES database, we detected eCNVs of *PARK2* in 4 subjects within an early onset Parkinson family that were not detected by other CNV calling algorithms such asXHMM. These results show eCNVFinder can identify additional eCNVs and potentially improve pathogenic CNV variant detection, which may in turn augment molecular diagnosis for patients.

## PgmNr 1560: Haplotype-aware CNV detection using Parliament2 on the eMERGE III Network.

### Authors:

---

Structural variation (SV) is a common type of genomic variation in the human genome and is frequently associated with genetic diseases. In the eMerge Phase III project, a targeted next-generation sequencing panel was designed to target 109 genes and more than 1500 SNVs from over 25,000 participant samples. Atlas-CNV, a clinically-validated, coverage-based copy number variant (CNV) calling tool was applied for the detection of CNVs. However, this approach can be further improved by using alleles from population data, potentially increasing the resolution and sensitivity of the method.

To address this issue, we have applied Parliament 2, an approach that has been previously applied to whole-genome and whole-exome data from other NIH-funded large-scale sequencing programs. The cloud-based Parliament 2 analysis software leverages multiple SV analysis methods, allowing the detection of multiple SV types though focusing mainly on CNVs in this analysis. First, we remapped data from all 25,000 eMERGE participants (starting from FASTQ(HGSC) or BAM(Broad)) to the GRCh38 reference genome. This was done to ensure comparability to large population datasets derived from WGS sequencing projects. The resulting bam files then go through the Parliament2 analysis on DNAnexus. This process uses analysis tools such as Lumpy, Manta, Breakseq, Breakdancer, Delly, and CNVnator to call all SVs.

Next, using SURVIVOR, we are annotating CNV calls against population-level SV information from previous WGS and WES studies, assigning each CNV a population frequency that can aid in interpretation and pathogenicity assignment. In addition, we are comparing the harmonized eMERGE events to ethnicity-specific alleles and using this data to better resolve our current set of CNV calls as well as potentially identifying complex events that are difficult to identify using a single-ethnicity reference. Lastly, for deletions, we will assess the concordance of the CNV calls with SNP data, potentially reducing false-positives. Our analysis so far has resulted in the detection novel copy number variants in over 100 clinically-relevant genes such as DSC2, CYP2D6, LDLR, MYH11, F5, PMS2, TGFB1, BRCA1, BRCA2, and TP53.

## PgmNr 1561: An accurate and powerful method for copy number variation detection.

---

Integration of multiple genetic sources for copy number variation detection (CNV) is a powerful approach to improve the identification of variants associated with complex traits. Although it has been shown that the widely used change point based methods can increase statistical power to identify variants, it remains challenging to effectively detect CNVs with weak signals due to the noisy nature of genotyping intensity data. We previously developed modSaRa, a normal mean-based model on a screening and ranking algorithm for copy number variation identification which presented desirable sensitivity with high computational efficiency. To boost statistical power for the identification of variants, here we present a novel improvement that integrates the relative allelic intensity with external information from empirical statistics with modeling, which we called modSaRa2. Simulation studies illustrated that modSaRa2 markedly improved both sensitivity and specificity over existing methods for analyzing array-based data. The improvement in weak CNV signal detection is the most substantial, while it also simultaneously improves stability when CNV size varies. The application of the new method to a whole genome melanoma dataset identified novel candidate melanoma risk associated deletions on chromosome bands 1p22.2 and duplications on 6p22, 6q25, and 19p13 regions, which may facilitate the understanding of the possible roles of germline copy number variants in the etiology of melanoma.

## PgmNr 1562: DEFOR: Depth- and frequency-based somatic copy number alteration detector.

### Authors:

---

Somatic copy number alteration (SCNA) is the change in copy number that arises in somatic cells. SCNAs have been observed frequently in tumors, and recurrent SCNAs have also been identified in several types of tumors. SCNA detection plays an important role in studying the mechanisms of tumor development and in guiding therapeutics. In recent years, SCNA detection using high-throughput sequencing has become popular because of rapid developments in sequencing technology.

Although several bioinformatics methods have been developed for SCNA detection using exome-sequencing data, these methods rely on a strong assumption that the median or mean value of the copy numbers of the genome is two (normal status). This assumption is generally used to give an estimation of the depth or depth ratio that represents the normal status. The assumption usually holds for germline copy number variations, because most parts of the genome don't have copy number changes. However, the assumption may not hold in tumor cells where large scale copy number alterations were observed frequently. In such situations, the mean or median value of copy numbers across the genome may be not two, and so the copy number estimate based on that assumption would be no longer reliable. Therefore, existing methods may not perform well in calling SCNAs for the unstable tumor genomes. Samples from tumor tissue are usually contaminated with normal cells from nearby normal tissue, and the purity of different tumor samples varies substantially. Because the purity of the tumor sample affects the observed copy number, it adds another layer of variations in SCNA detection of tumor samples.

We developed a new method, DEFOR, to detect SCNAs in tumor samples from exome-sequencing data. DEFOR supports the estimation of copy numbers in six different statuses and adopts a model considering allele frequency, depth and purity. The performance of DEFOR is outstanding compared with the other five existing methods in the evaluation, even for unstable tumor genomes with a larger proportion of SCNAs.

## PgmNr 1563: Undiagnosed Diseases Program Database (UDPdb) of genomic data: A model for cohort data consolidation, insights and reanalysis.

### Authors:

N.J. Balanda <sup>1</sup>; D.L. Ross <sup>1</sup>; A.S. Brown <sup>1</sup>; B.N. Pusey <sup>1</sup>; C.C. Lau <sup>1</sup>; D.R. Adams <sup>1,2</sup>; W.A. Gahl <sup>1,2</sup>; Undiagnosed Diseases Network

---

The Undiagnosed Diseases Program (UDP) commenced in 2008 with its primary goal to uncover causes of previously undiagnosed diseases. The development of the program coincided with the development of genomic sequencing technology. As high throughput sequencing advanced, the UDP adapted these methods into its standard operating procedure, contributing to a diagnosis rate of ~25% for UDP patients. In the last 10 years, the UDP has sequenced more than 400 genomes and 1600 exomes of affected individuals and their genetically informative family members. Under standard procedure, this genomic data is analyzed on a per-case basis, leveraging the power of adding family members to the analysis when possible. The bioinformatic team in the UDP is constantly looking to test and develop new ways to revisit old data, with hopes of improving the diagnostic rate through reanalysis of old cases with new techniques. With a growing cohort, there is an increasing potential for interrogating the cohort as a whole. However, in order to ask high-yielding questions from the cohort, genomic information from all of the individuals must be consolidated. Here, we consolidate genomic variants from all available UDP sequence data into a comprehensive cohort sequence database. To do so, each genome/exome is reworked such that alignment, variant calling, and joint genotyping methods are standardized and uniform across all data. The resulting variant calls are then annotated and passed into GEMINI, a portable SQLite database, enabling novel interrogation of the existing UDP sequence cohort and supplemented analyses for new patients. Having data consolidated in this format enables efficient parallelization of reanalysis and rapid interrogation of gene or patient-specific questions. Through reanalysis, we have identified new diagnoses in our cohort in the genes *NTRK2*, *ACER3*, *NDUFA6*, *DHDDS*, and *RNF216*. Other potential diagnostic candidates are being investigated to confirm splicing effects. In addition to reanalysis, by leveraging the data of the entire cohort, we are able to prioritize bioinformatic outliers as gene discovery candidates by looking specifically at predicted deleterious mutations in genes that are intolerant to variation. The UDPdb is a model for large cohort data consolidation and empowers new analysis methodology in the Undiagnosed Diseases Program.

## PgmNr 1564: Compendium of Arab genetic variants and metabolic trait associations.

### Authors:

[View Session](#) [Add to Schedule](#)

**Affiliation:** Genetics and Bioinformatics, Dasman Diabetes Institute, Kuwait, Kuwait

---

The Arab region is characterized by a high prevalence of metabolic disorders. There is a lack of publicly-available data on genetic variants from Arab populations. We have developed a database of genetic variants comprising variants from Exome sequencing and genotyping arrays as identified on native individuals and catalogued from Kuwait. Further we catalogued statistical associations signals of metabolic traits with imputed genotypes using array data. We provide a user-friendly web query interface to access the genetic information.

### Data:

**Exome sequencing:** We sequenced 291 whole exomes of unrelated, healthy native Arab individuals from Kuwait to a median coverage of 45X and characterized 170,508 single-nucleotide variants (SNVs).

**Genome-wide genotyping:** of ~1300 & 1900 Arab ethnic individuals generated from Illumina human OmniExpress and cardiometabo arrays respectively.

**Imputation using 1KGP haplotypes:** We cataloged variants imputed from two GWAS data sets individually using 1000G Phase 3 reference panel.

**Genome-wide associations:** We subsequently statistically tested association of common ( $\geq 5\%$  frequency), well imputed variants across 13 metabolic quantitative traits with RAW and inverse normal variance traits. Importantly, this data includes 1222 unique variants (from 232 genes) from 1442 associations with  $p\text{-value} < 0.05$  for 13 metabolic traits in Arab population upon comparing with 313 metabolic trait variant associations published in GWAS Catalog.

The genetic variants were systematically annotated by way of using various other databases and tools in ANNOVAR package and we catalogued computational predictions of pathogenicity of variants such as SIFT, Polphen2, MutationTaster and MutationAssessor, FATHMM etc. In addition, variants were systematically annotated across a number of relevant databases.

We implemented the current trending technologies such as MongoDB (to store data), JQuery (web interface) along with Python framework called Django. Th queries can be performed using genetic

variant IDs (rsIDs), gene names, positions or ranges of genomic positions. This database is freely available at [www.dgr.dasmaninstitute.org](http://www.dgr.dasmaninstitute.org) for the academic and not for profit research institutions.

---

Since launching to the public in October 2018, the Gabriella Miller Kids First (Kids First) Data Resource Center (DRC), has made an increasing number of pediatric, especially trio and family focused, genomic studies available to the research community. By the end of 2019, genomic and clinical data from over 15,000 participant samples will be available across a variety of structural birth defect and pediatric cancer cohorts. The DRC has architected a secure, cloud-based platform that supports the ability of researchers to not only find, access and reuse data, but also integrate, collaborate, and analyze data quickly at scale. A “best-of-breed” approach has been taken to develop a portal, with reusable components from Overture, as the entry point for Kids First data. From there, users can use integrations with platforms such as Cavatica for bioinformatics workflows and pedCBioPortal for cancer genomic visualizations. Additionally, a set of framework services, powered by Gen3, provide a foundation for interoperability with other large-scale data sources, platforms and a growing ecosystem of analysis and visualization applications that provide capabilities for rapid in-place analysis without download.

Recognizing the value in both the source data collected by the original studies and the power in having harmonized genomic and clinical data for cross-study analysis, the DRC makes both available in the platform. The new “explore data” feature on the portal allows users to search and browse in real-time across all Kids First studies in order to identify virtual cohorts of interest for further study. Within the portal, these cohorts can be saved and shared with collaborators for iterative refinement and analysis. With appropriate approvals, the associated data can be accessed and analyzed seamlessly in Cavatica, or other platforms with interoperable framework services. To lower the barrier

to entry, the DRC has been piloting rapid-access cloud credits and providing support to researchers performing custom analysis on the platform. On the near term roadmap is the ability to create cohorts utilizing genomic features and improved visualizations for germline and family-based genomic data.

# PgmNr 1566: lncRNAKB: A comprehensive knowledgebase of long non-coding RNAs.

## Authors:

F. Seifuddin; A. Suresh; K. Singh; Y.C. Chen; V. Chaitankar; I. Tunc; M. Pirooznia

[View Session](#) [Add to Schedule](#)

**Affiliation:** Bioinformatics and Computational Biology, National Heart, Lung, and Blood Institute, National Institutes of Health, BETHESDA, MD.

---

**Motivation:** There are several databases that exist for annotation of human long non-coding RNAs (lncRNAs) that contain between 20,000 to 100,000 entries. These databases contain unique and overlapping lncRNAs that have been identified by next generation sequencing (NGS) methods. The information on lncRNAs provided in these databases is not rigorous thus, making it difficult to understand their molecular and cellular functions. Consequently, there is a need to systematically and carefully combine these annotations, create a non-redundant resource and provide valuable functional information on lncRNAs.

**Results:** We have created the long non-coding RNA knowledgebase (lncRNAKB) by methodically integrating six widely used lncRNAs annotation databases (CHESS, FANTOM, LNCipedia, NONCODE, MiTranscriptome and BIGTranscriptome). We present an annotation of a large number of unique lncRNAs ( $n=77,199$ ). The lncRNAKB incorporates coding potential, classification/localization with respect to messenger RNAs (mRNAs), gene expression, tissue-specificity scores, expression quantitative trait loci (eQTL)-regulated lncRNA genes, phylogenetic conservation and functional characterization to identify co-expressed mRNAs that would provide potential understanding on lncRNAs function. A machine learning approach was used to calculate the coding potential scores and classify the lncRNAs in the lncRNAKB annotation database as putative lncRNAs or mRNAs. Gene expression data of 9,074 RNA-seq samples, collected from the Genotype Tissue Expression (GTEx) project was used to provide tissue-specific expression profiles and tissue-specificity scores in 31 solid organ human normal tissues. Using whole genome sequence (WGS) genotype data of 652 subjects and tissue-specific gene expression data from the GTEx project we calculated *cis*-eQTLs in all tissues. We calculated and compared evolutionarily exon conservation between lncRNAs and protein-coding genes (PCGs) using an alignment of 30 vertebrate species. We used Weighted Gene Co-expression Network Analysis (WGCNA) to identify co-expression modules encompassing lncRNA-mRNA pairs that were subjected to enrichment analysis using Gene Ontology (GO) pathways to identify meaningful biological processes that lncRNAs could be potentially involved in and created dynamic Cytoscape networks for exploration and visualization. All components are provided in a user-friendly web interface. lncRNAKB is available at <http://www.lncnakb.org>

## PgmNr 1567: VISDB: A comprehensive database for human disease-related virus integration sites.

### Authors:

---

Viral infection is a significant cause of a variety of human disease, including cancer. Viruses may intrude human cellular system and even insert their genetic material into the host genomes, thus affecting the normal function of the molecules in the host cells. With the advance of next generation sequencing, many studies have discovered virus infection in the host cells and in some cases, integration to the host genomes. The studies also found that the integration sites (VIS) prefer next to oncogenes and common fragile sites. Viral integration can be a key driving event in virus related cancer such as hepatocellular carcinoma and cervical carcinoma. Thus, it is important to investigate the integration events in the human genome and understand the molecular mechanism of viral integration. In this study, we systematically collected and curated all the VIS in literature and databases, and developed the Virus Integration Site Database (VISDB, <https://bioinfo.uth.edu/VISDB/index.php>). The data features include characteristics of the malignant disease, chromosome region, genomic position, target and nearby genes, fragile sites, viral-host junction sequence and potential virus mediated host microRNAs (miRNAs). The current version of VISDB includes 77,336 integration sites in 5 DNA oncovirus (HBV, HPV, EBV, MCV, AAV2) and 4 RNA retrovirus (HIV, MLV, HTLV-1, XMRV) curated from 109 publications, and correlated with 14986 target genes (including 447 oncogenes and 678 tumor suppressor genes), 123 fragile sites, 27 diseases and 2276 human samples. The data was further curated by linking to public databases such as NCBI GenBank, OGene, TSGene, HumCFS, etc. We present a universal virus integration site model and provide a visualization method to display the integration event and target genes, upstream and downstream genes in the vicinity of integration site. VISDB provides several functions including data search, browse, curation, download and feedback and upload for the user. The database offers a unique resources that can help users for better understanding the fragile (risky) genes or loci by virus integration, especially oncogenes and suppressor genes in cancer cases.

## PgmNr 1568: TogoVar: Integrated database among Japanese genomic variation databases.

---

Population-specific information on genomics is important to reveal causal variations when conducting human genetic studies and interpreting the result. The Exome Aggregation Consortium (ExAC) and the Genome Aggregation Database (gnomAD) have been providing population-specific genomic information. However, there is a limitation on Japanese specific allele-frequency information in ExAC and gnomAD because the sample number of Japanese in those databases are only seventy-six. Thus, the Integrative Japanese Genome Variation Database (ijGVD) and Japanese Multi Omics Reference Panel (jMorp) are well-used databases as a reference for population-specific genetic database of Japanese due to the biggest sample number of Japanese Whole Genome Sequencing (WGS) data up to 3,554. Another reference database for allele frequency of Japanese is Human Genetic Variation Database (HGVD) which contains allele frequency information from 1,208 Whole Exome Sequencing (WES) samples. Because there is no database integrating information on allele frequency data from ExAC, ijGVD and HGVD, ClinVar information and related publication data, we launched TogoVar database (<https://togovar.biosciencedbc.jp/>) as one-stop service to obtain the information. Further, we created another two new databases of allele frequency named JGA-SNP and JGA-NGS. The former one contains allele frequencies from SNP-chip analyses and the latter one contains that from WES analyses. The original data are deposited in the NBDC Human Database (<https://humandbs.biosciencedbc.jp/en/>) that our database center has conveyed to share genomic-phenotypic data in cooperation with the DNA Data Bank of Japan since 2013. Thus, allele frequency information of both JGA-SNP and JGA-NGS will be updated when NBDC Human Database receive controlled-access data from data submitters.

TogoVar users can find variants interested in by using gene name, rs number, HGVS representation and disease name from over 80 million variants. Further, users can filter a range of data based on criteria they define: allele frequency, database name, genetic consequence, variant calling quality, and the score generated by SIFT and Polyphen2.

In the poster, the recent achievement on data integration and establishment for searching function will be presented.

## PgmNr 1569: Functional Annotation of Variants Online Resource (FAVOR).

---

Functional annotation data has proven effectiveness in wide variety of studies, including rare-variant association test, fine mapping, etc. We created a most comprehensive functional annotation database by merging functional annotation data from following major sources: popular functional annotation databases, Epigenetics database, annotation data from collaboration labs and also from many individual studies and publications. Currently our functional annotation database has more than 260 annotation channels, and the annotation database is growing rapidly and steadily.

To improve the conherency, efficiency and usability of applying functional annotation data in downstream analysis of genetic variants, we pioneered the effort of building in the functional annotation results into GDS format for the first time, resulted in the creation of AGDS. It represented a well-rounded solution for storing functional annotation results for genetic variants, with optimal search and retrieval performance while keep data size very small. In AGDS file genotype data is recorded with matched huge number of functional annotation scores for each variant, this increases the effective application of functional annotation data in variants analysis. As an R friendly data structure, AGDS achieves perfect format and software compatibility, with seamlessly conversation to other file formats and compatibility with all the tools that working with GDS.

Because functional annotation data is very useful for different fields, building an easy-to-access web portal will be critical to empower many studies. We created FAVOR (Functional Annotation of Variants Online Resource) using R Shiny, which is the first web portal implementation using GDS. FAVOR supports single variant query and batch annotation. For single variant query, users can input genomic position or rs number. For batch annotation, users can upload variant list to FAVOR with annotation results display in table format on web interface and also have options to download annotation results in three different formats (GDS, VCF, CSV). The back-end GDS database has removed the genotype data from all-in-one GDS, this modification is especially suitable for web portal development and also for public accessing and sharing. Moreover, the offline and online retrieval and query operations stay the same.

We hope our effort of creating the functional annotation database and FAVOR will be one of the core knowledgebases for genetics research.

---

A number of paradigm shifts in our ability to sequence DNA have paved the way to utilising whole genome sequencing in a clinical setting. Massively parallel sequencing (MPS) is now rapidly becoming the first tier test in clinical genomics with dramatic improvements in diagnostic yield and time to diagnosis. However, the enormous information content and sheer size of the generated data from a single MPS run represents a huge threshold for clinical implementation.

Variant calling format (VCF) or the binary equivalent (BCF) files are the ubiquitous storage formats for variant calls identified in a MPS data. In principle, they are not more than tab-delimited text files. They lack a powerful and standardized data model to enable sophisticated genetic analysis, which can be translated in a clinical setting. Converting VCF into a GEMINI database goes a long way to enable this type of complex processing. However, using this requires knowledge of SQL and the internal schema, which cannot be expected from a clinical or research user.

*Scout* is an open-source decision support framework for clinical diagnostics with graphical user interface (GUI) for MPS associated data. Scout lets you organize, collaborate, share, inspect, filter, annotate, explore and analyze variant calls in a GUI via a standard web browser. It provides a unified and intuitive interface for all loaded resources and can be used by anyone without computer programming literacy. It has already been used for processing of more than 5000 clinical rare disease samples in the Stockholm healthcare region, covering a wide range of genetic disorders and providing specific molecular diagnoses for several hundred patients.

## PgmNr 1571: An analytical pipeline for decreasing the burden of returning secondary findings.

### Authors:

---

**Background:** Advances in genomic sequencing technology have led to the use of exome and genome sequencing instead of panel testing, which has increased the potential to identify secondary findings (SFs). There is a need for new bioinformatic pipelines tailored to filter and analyze the large amounts of data associated with SFs beyond just medically actionable results in order to address guidelines for the disclosure of clinically relevant SFs.

**Aim:** We aimed to develop an analytical pipeline for the efficient analysis and return of SFs.

**Methods:** We expanded on and adapted Berg's 2011 binning framework for the analysis and return of SFs. Our pipeline consists of comprehensive gene lists for five categories ('bins') of SFs and incorporates filtration parameters for prioritization of variants in each bin. Gene lists were curated following evidence-based guidelines, established criteria and based on consultations with genetics experts. Our variant prioritization framework was developed by integrating disease-associations, population frequency, gene-variant databases and ACMG variant classification criteria. We applied the pipeline to 42 exomes to assess the feasibility and efficiency of the analysis and return of SFs.

**Results:** The five categories ('bins') of SF genes consisted of: (1) 90 genes associated with medically actionable diseases and 29 pharmacogenomics variants, (2) 17 common disease risk variants, (3) 3,854 genes associated with Mendelian diseases, (4) 7 genes associated with early-onset neurological disorders, and (5) 688 genes associated with carrier status. Analysis of the 42 exomes using our binning and variant prioritization framework resulted in a decrease of >98% of variants compared to the raw analysis, yielding a manageable number of variants for manual review and allowing for decreased cost and turnaround time for the return of SFs.

**Conclusions:** Our analytical pipeline increases the feasibility of analyzing and returning SFs in clinical practice and represents a flexible approach to accommodate alternate workflows, version updates and new guidelines for reporting SFs. Our bioinformatics pipeline for the analysis of SFs represents an effective and efficient step towards streamlining the return of SFs to realize their public health benefits.

## PgmNr 1572: From NGS data to diagnosis: Fast HPO-based variant filtering of NGS data using Moon by Diploid.

### Authors:

F. Sleutels <sup>1</sup>; H. Bruggenwirth <sup>1</sup>; L. Hoefsloot <sup>1</sup>; C. Kint <sup>2</sup>; P. Schols <sup>2</sup>

[View Session](#) [Add to Schedule](#)

1) Clinical Genetics, Erasmus medical center, Rotterdam, The Netherlands; 2) Diploid, Leuven, Belgium

Panel-based filtering of variants from Whole Exome Sequencing (WES) has been our standard for years. Such gene-driven analysis consists of a collection of genes ("the panel"), with known (or evidence-based) involvement in the clinical presentation. Panel-based filtering poses challenges when a mix of clinic is presented that does not easily match a specific panel or when the number of variants to consider grows (e.g. for large gene panels, WGS, diverse ethnic backgrounds and consanguinity).

The transition to a phenotype-based analysis is driven by our aspiration to increase throughput and accelerate and standardize our NGS powered genetic diagnoses. Essential tools that nurse this transition are the Human Phenotype Ontology project (HPO) and up-to-date genotype-phenotype databases (e.g. OMIM). Here we present our experiences to transit to a fast phenotype-driven NGS analysis using Moon by Diploid.

### Methods:

For retrospective analysis, patients were selected with a challenging clinical presentation, genotype or genetic diagnosis. 13 WES samples (5 singletons, 7 trios, 1 duo) and 2 WGS samples. For prospective analysis, 11 patients were enrolled (9 singletons and 3 trios), for which a panel-based analysis was requested. NGS data (Illumina) from WGS or WES (Agilent Sureselect captured) was variant called (GATK haplotype caller) yielding VCF files which were processed with our default analysis flow (Agilent Bench Lab NGS) and with Moon (Diploid).

### Results and Discussion:

Our gene-driven analysis flow is compared to the phenotype-driven approach and advantages and challenges are discussed. Advantages of the phenotype-driven analysis are: No need to administrate and update gene panels. Secondly, the standardized and objective data analysis shortlists the clinically most relevant variants. Moon links to Mastermind (Genomenon) to show the scientific literature for the variant at a glance. And finally, when new variants get shortlisted, users gets an attention warning.

Challenges that we encountered: For some oncogenetic traits, variants are not shortlisted because they are considered a risk factor with incomplete penetrance (e.g ATM). Defining and reporting risk factors is actively debated in the field. Finally, discovery of new disease-contributing genes is not catered for, but for most clinical genetics labs this is out of the scope of routine advise.

Future perfections of our NGS analyses: Automate reanalysis and automate intake of HPO-clinic using

Moons API.

## PgmNr 1573: Enhanced transcriptome-wide analytic framework identifies novel associations with metabolic and virologic traits in HIV-positive adults.

---

In studies to identify genes and biological pathways that underlie complex traits, it may be difficult to relate noncoding genetic variants with downstream genes that are affected. Various methods have been developed to overcome this difficulty. One such method is the transcriptome-wide association study (TWAS), which aggregates transcriptional regulatory effects of cis coding and noncoding variants to identify genes whose genetically-regulated transcriptional changes are associated with traits of interest. Available TWAS methods vary regarding underlying biological assumptions about tissue specificity of transcriptional regulatory mechanisms. This affected whether TWAS methods tend to identify tissue-specific or multi-tissue associations in our previous study. Thus, we designed a simulation analysis to examine how the interplay between selected TWAS methods and tissue specificity of genes affects power and type I error rate in gene prioritization. We found that eQTLs with higher prediction accuracy improved TWAS power. Importantly, single-tissue TWAS (i.e., PrediXcan) had greater power in prioritizing single tissue-expressed genes. But it was likely to prioritize false positive tissues for genes that are expressed in multiple tissues. For multiple tissue-expressed genes, cross-tissue TWAS (i.e., UTMOST) had overall equal or better power and controlled type I error rate. Based on simulation results, we applied an enhanced TWAS analytic framework to baseline (i.e. pre-treatment) laboratory values from AIDS Clinical Trial Group (ACTG) studies 384, A5095, A5142, A5202 and A5257. We identified several novel associations, including *KCND3* (which encodes subunits of voltage-gated rapidly inactivating potassium channels) with plasma log<sub>10</sub> HIV-1 RNA ( $p =$ ). *KCND3* has also been previously associated with immunologic response to vaccine. We identified novel pleiotropic genes, including *CWC22* (which encodes CWC22 spliceosome-associated protein homolog) with cholesterol, glucose, high-density lipoprotein cholesterol, and total bilirubin. Overall, when causal tissue is known, single-tissue TWAS will suffice. Otherwise, our simulation suggested using single-tissue TWAS for single tissue-expressed genes, and cross-tissue TWAS for multiple tissue-expressed genes, separately. This enhanced TWAS analytic framework which considers tissue specificity of gene expression, improves power and controlled type I rate for TWAS gene prioritization.

## PgmNr 1574: Pattern and trend of human genomic variations in the form of SNPs INDELs.

**Authors:**

P. Liang; V.K. Chundi

[View Session](#) [Add to Schedule](#)

**Affiliation:** Dept Biological Sci, Brock Univ, St. Catharines, Ontario, Canada

---

Single nucleotide polymorphisms (SNPs) and small insertions/deletions (INDELs) are the most common genetic variations in the human genome. They have been shown to associate with phenotype variation including genetic disease. Based on data in a recent version of the NCBI dbSNP database (Build 150), there are 305,651,992 SNPs and 19,177,943 INDELs, and together as all small sequence variants, they represent approximately 11% of the human reference genome sequences. In this study, we aimed first to examine the characteristics of SNPs and INDELs based on their location and variation type. We then identified the ancestral alleles for these variants and examined the patterns of variation from the ancestral state. Our results show that the frequency of small variants averages at 104 SNPs/kb and 6.5 INDELs/kb for a total of ~11% of the genome. Chromosome 16 and 21 represent the least and most conserved autosomes, respectively, while the sex chromosomes are shown to have a much lower density of SNPs and INDELs being more than 30% lower in the X chromosome and more than 85% lower in the Y chromosome. By gene context, these variations are biased towards genic regions, and further, they are biased towards protein-coding genes and intron regions within the genic regions. Within the coding regions, SNPs and INDELs are biased towards missense and frameshift variations, respectively. Further, genes with the highest level of variation showed enrichment in functions related to environmental sensing and immune responses, while those with least variation associate with critical processes such as mRNA splicing and processing. Through a comparative genomics approach, we determined the ancestral state for most of these variants and our results indicate that ~0.79% of the genome has been subject to SNP and INDEL variation since the last common human ancestor. Our study represents the first comprehensive data analysis of human variation in SNPs and INDELs and the determination of their ancestral state, providing useful resources for human genetics study and new insights into human evolution.

# PgmNr 1575: Leveraging large datasets accumulated through population carrier screening to inform variant classification.

**Authors:**

D.H. Tran; S. Cox; K.E. Kasenit; E. Collins; M. Meredith; E. Zmuda

[View Session](#) [Add to Schedule](#)

**Affiliation:** Myriad Women's Health, South San Francisco, California.

---

**Introduction**

Sequencing-based genetic testing requires real-time interpretation of variants encountered in patients. We have performed expanded carrier screening of recessive Mendelian disease genes for more than 1,000,000 samples, detecting more than 1,400,000 distinct variant alleles. Our variant database includes a substantial number of curated case-studies garnered from the literature along with allele frequencies in our sample cohort. Here we demonstrate how a centralized database of evidence enables accurate variant interpretation at scale and improves variant classification methodologies.

**Methods**

We collated data collected from more than 40,000 manual reviews of literature and database evidence accumulated on a variant-by-variant basis. To accurately estimate the proportion of disease alleles represented by a given variant, we calculated the total number of disease alleles from our curated literature database. We filtered for studies with greater than 20 cases with a valid Pubmed ID, resulting in 2672 studies encompassing 267 genes. In order to identify and remove potential double-counting of disease alleles, we assessed whether study cohorts were reported in multiple references.

**Results**

Focusing on 154 primarily single-gene diseases, we established an estimate of the total disease allele counts given our filtering criteria. Our estimates range from 32 disease alleles for HYS1-associated Hydrolethalus syndrome to 83,436 alleles for MEFV-associated familial Mediterranean fever. 26% of case studies (426/1639 studies) with overlapping authors were confirmed to have shared study cohorts; our curation SOP guards against overcounting these cohorts. We additionally report analyses that leverage high-resolution variant frequencies and variant co-occurrence information obtained in our CLIA sequencing lab.

**Conclusions**

We have described a database of literature cases, allele frequencies, and variant co-occurrence that was obtained in the course of population-scale expanded carrier screening. We are now using this resource to supplement variant classification protocols and improve assessment of variant pathogenicity.

## PgmNr 1576: Broad Institute's genomic platform portfolio leads support the research community.

---

In 2017, the Genomics Platform (GP) at the Broad Institute created a new set of roles (Portfolio Leads) to better support both the germline and somatic research communities. The creation of these roles have allowed the platform to roll out new products and improve existing products with a focus on the specific features required to serve the scientific questions our communities want to address. One of the key drivers for germline portfolio is Broad's Medical and Populations Genetics (MPG) group. When researching the requirements for the new exome, MPG investigators expressed a need for better mitochondrial coverage. After working closely with MPG, our R&D team, and TWIST Biosciences, a 100 fold increase in the mitochondrial genome coverage was achieved while still maintaining abundant and even coverage across the rest of the custom exome design. Another offering, portfolio has been instrumental in developing are the new single-cell RNA-seq products. A collaboration with Aviv Regev's lab, has successfully scaled the SmartSeq2M protocol with full automation from library construction to sequencing. The Platform now has the capacity to library construct and sequence 16 plates a week. Thus, allowing more researchers access to sequence either single-cell or populations for their full-length transcript capture methods. A suite of long read sequencing products are being developed. These aim to provide improved structural variation calling in human whole genome sequencing. The GP was an early access site for PacBio's Sequel II instrument with higher yielding 8M SMRT cells and longer run times. In GP's hands, the Sequel II has delivered raw average read lengths of ~50 kb with 50% of reads being >140 kb. These new offerings will continue to enable the science of our research community.

## PgmNr 1577: The Federated European Genome-phenome Archive.

### Authors:

T.M. Keane <sup>1</sup>; D. Spalding <sup>1</sup>; P. Flicek <sup>1</sup>; J. Rambla <sup>2</sup>; A. Navarro <sup>2,3</sup>; R. Guigo <sup>2</sup>; H. Parkinson <sup>1</sup>

---

The European Genome-phenome Archive (EGA), a joint project between EMBL-EBI and The Centre for Genome Regulation, Barcelona (CRG), has been a public resource since 2008 for permanent secure archiving and sharing of all types of potentially identifiable genetic and phenotypic data resulting from biomedical research projects. Its aim is to provide access to data, to foster data re-use, to enable reproducibility and to speed up biomedical and translational research in line with the 'FAIR' principles (Findable, Accessible, Interoperable, and Reusable). Access to EGA data must be approved by a Data Access Committee (DAC) and data must be appropriately consented for sharing. We have recently seen the emergence of genomic data from large cohorts of human samples from both national and regional healthcare in addition to traditional research projects. Many countries now have nascent personalised medicine programmes meaning that human genomics is undergoing a step change from being a predominantly research-driven activity to one funded through healthcare. We envisage that a significant subset of this data will be made available for secondary research (e.g., Genomics England). However, genetic data generated in a healthcare context is subject to national laws and health data from one country may not be exportable outside regional or national jurisdictions. In coordination with ELIXIR and the GA4GH, the EGA is committed to the establishment of a federated and interoperable network of human data resources to ensure continued sharing of human genetic data for research.

We are establishing a federated EGA node network consisting of three distinct node types: Central EGA, Federated EGA nodes, and EGA Community nodes. Broadly, Central EGA nodes (currently EMBL-EBI and CRG) will continue to accept international data submissions, provide international data distribution, and helpdesk support. Federated EGA nodes will offer submission and archiving services for submitters within a particular jurisdiction to accommodate use-cases where data must remain within a jurisdiction, and provide international data access and helpdesk for requestors of such data. EGA Community nodes will not offer external data submission services and rather act as data distribution nodes for datasets. In our presentation, we will provide a more detailed description of the network and nodes, initial use-cases and partners, and an update on the project implementation.

## PgmNr 1578: Expanding the scientific scope of the GWAS Catalog to include targeted and exome array studies.

---

The GWAS Catalog delivers a publicly available and manually curated collection of all published genome-wide association studies. It currently contains highly searchable results from approximately 7,000 GWAS and 4,000 publications. To increase the potential of the Catalog for downstream analyses and future research needs, we have recently extended its scientific scope.

New content includes a set of studies (prioritized by trait) using targeted genotyping arrays, such as the Metabochip, Immunochip, Oncoarray and Exome arrays. So far, a total of 150 targeted array studies and over 5,000 associations have been extracted and made available through the Catalog from 67 publications. In addition to curated data and metadata, full p-value summary statistics from 47 targeted and exome array studies have been made available through the Catalog. This expansion creates a more comprehensive and representative Catalog, particularly for immunologic, metabolic and oncologic phenotypes. For example, the most significant result reported in chronic inflammatory disease is a unique SNP-trait association in NOD2 (Ellinghaus, 2016) that would have been missed without the inclusion of targeted array data.

Curation of these studies is performed following our consistent curation procedure, including ancestry annotation and mapping of all traits to Experimental Factor Ontology (EFO) terms to support richer querying and integration of trait information. Targeted and exome array studies are identifiable in the search interface and in study pages by a “target” icon in the Catalog’s new web interface. The data download format and the RESTful API have been updated to include information on the targeted array type and new documentation is now available supporting this functionality.

We are working towards identifying and curating all published targeted and exome array studies. So far, through text-based searching, we have identified 250 additional publications based on targeted or exome array analysis from 2012 to 2019. To ensure systematic capture of all relevant publications, we are collaborating with PubTator (<https://www.ncbi.nlm.nih.gov/CBBresearch/Lu/Demo/PubTator/>) to develop a machine-learning based literature search.

These new data underpin research into common disease, enabling investigations to identify causal variants, understand disease mechanisms, and establish targets for novel therapies.

## PgmNr 1579: Increasing the availability of summary statistics in the GWAS Catalog.

### Authors:

JAL. MacArthur <sup>1</sup>; M. Cerezo <sup>1</sup>; A. Buniello <sup>1,2</sup>; J. Hayhurst <sup>1,2</sup>; P. Hall <sup>3</sup>; L.W. Harris <sup>1</sup>; L.A. Hindorff <sup>3</sup>; S. Jupp <sup>1</sup>; E. Lewis <sup>1</sup>; C. Malangone <sup>1</sup>; A. McMahon <sup>1</sup>; J. Morales <sup>1</sup>; E. Mountjoy <sup>2,4</sup>; E. Sollis <sup>1</sup>; D. Suveges <sup>1</sup>; O. Vrousseau <sup>1,2</sup>; P.L. Whetzel <sup>1</sup>; T. Burdett <sup>1</sup>; F. Cunningham <sup>1</sup>; P. Flicek <sup>1</sup>; H. Parkinson <sup>1</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) European Molecular Biology Laboratory, European Bioinformatics Institute, Wellcome Genome Campus, Hinxton, Cambridge, UK; 2) Open Targets, Wellcome Genome Campus, Hinxton, Cambridge, UK; 3) Division of Genomic Medicine, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 4) Wellcome Sanger Institute, Wellcome Genome Campus, Hinxton, Cambridge, UK

---

Recently many new methods have been developed which leverage summary statistics (SS) from genome-wide association studies (GWAS) to provide insights into the mechanisms of complex disease and predict disease risk. Having extended scope to meet this need, the NHGRI-EBI GWAS Catalog ([www.ebi.ac.uk/gwas](http://www.ebi.ac.uk/gwas)) contains over 6,000 full p-value SS datasets, making it the largest repository of GWAS SS. SS are available for 11% of all Catalog studies. The numbers are higher for recent studies, with 25% for studies published in 2018 and 32% for studies published in the first 3 months of 2019. SS are highly accessed, with over 13,000 SS downloads in the last 6 months. The most downloaded SS by trait are for hematological measurements, immune system disorders and metabolic disorders. By year the most highly accessed SS dataset is from 2016, indicating the importance of making available SS from older studies. Access to SS is provided from the GWAS Catalog FTP site ([www.ebi.ac.uk/gwas/downloads/summary-statistics](http://www.ebi.ac.uk/gwas/downloads/summary-statistics)), via API from a SS datastore ([www.ebi.ac.uk/gwas/summary-statistics/docs](http://www.ebi.ac.uk/gwas/summary-statistics/docs)) and via links within our query interface ([www.ebi.ac.uk/gwas/search](http://www.ebi.ac.uk/gwas/search)).

To ensure SS are consistent across studies and interoperable they are pre-processed and made available in a standard format. They are also harmonised, with respect to genome build and strand. We propose the GWAS Catalog format (Buniello et al., 2019; <https://www.ebi.ac.uk/gwas/docs/methods/summary-statistics>) as a standard format for reporting SS. We are seeking feedback from the community to ensure the standard format includes all data elements required for common analyses and is applicable to the full range of GWAS study designs and genotyping methods.

Despite the recent increase in publicly available SS through the GWAS Catalog, the majority of SS are not public, evidenced by >3,000 publications in the GWAS Catalog for which the SS are not freely available. Therefore, we are encouraging authors to submit their SS directly to the GWAS Catalog and have seen the rate of author submissions increase 3-fold over the last 6 months. To facilitate sharing and further increase the availability of SS we are developing a web-based author deposition interface.

The GWAS Catalog continues to engage with the community towards defining standards and incentives to promote and enable sharing of GWAS data. The broad availability of SS will vastly

extend the potential of GWAS for the needs of future research to improve disease understanding.

## PgmNr 1580: Genomics and Biobanking in African settings: The strides made and status quo.

---

### Introduction

Genomics wields the power to define and revolutionize modern day precision medicine due to its high-resolution power applied in the diagnosis and treatment of infectious diseases compared to the empirical methods especially in the research world. Genomics has witnessed a rampant evolution in the developed world as a consequence of the Bio-Banks and Biorepositories. Fully fledged Bio-banks are very critical and a one-stop shop for preserving, processing, accession and long-term storage of all kinds of biological specimens; some initiatives have been introduced in some resource-limited countries in terms of infrastructure and capacity building, especially in Africa like the H3Africa and B3Africa. However, these efforts have been limited to very few African countries, leaving the majority unaccounted for.

### Methods

We applied the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guiding principle to examine the strides that have been taken to introduce Genomics and Bio-Banks in Africa using the PubMed NCBI database.

### Results

We discovered very limited evidence of efforts and Bio-Banking infrastructure to support the fast-evolving Genomics discipline in African settings.

### Conclusion

We propose various approaches and models that when adopted will realize the increased outreach of Bio-Banks, Biorepositories and Genomics, consequently checking on the burden of infectious diseases on the African continent.

## **PgmNr 1581: Compound heterozygotes with oculocutaneous albinism as a special case of outbreeding depression in an admixed Colombian population.**

### **Authors:**

W.A. Cardenas <sup>1</sup>; A.B. Conley <sup>3</sup>; I.K. Jordan <sup>3,4</sup>; M.C. Lattig <sup>1,2</sup>

---

Autosomal recessive conditions are frequently associated with homozygous mutations within a common ancestral origin. However, an increasing number of compound heterozygotes have been documented, especially in admixed populations, most likely due to the elevated mating among populations that are occurring due to the ease of modern transportation. Oculocutaneous albinism type 1 and type 2 (OCA 1 and OCA2) are the most severe forms of albinism caused by mutations in TYR or OCA2 genes respectively. We evaluated the ancestral origin of mutations in these two genes in a sample of 32 individuals with either OCA1 or OCA2 previously described by our group. Haplotype analysis in regions containing these two genes was performed to determine the ancestral origins - European, African, Native American or Jewish. Genotyping was performed using the 24 OmniExpress Chip (Illumina) and Macrogen service (Seoul, Republic of Korea). Data was merged with the reference data panel from the 1000 genomes and Sephardic Jews using PLINK. Haplotype inference from genotype and local ancestry was performed using ShapIT2 and RFMix. MEGA was used to compare the probable haplotype obtained for the TYR and OCA2 genes in our samples with the haplotype in the reference's samples and the results were plotted using R software. Various Spanish haplotypes were found both in the TYR and OCA2 genes. Of special interest was a compound heterozygote individual that carries the G47D mutation in a Spanish haplotype and the 1379delTT deletion in an Amerindian haplotype exemplifying a case of outbreeding depression in admixed population, whereby chance two random individuals living in the same population and carriers of different mutations in the TYR gene mate and produce a child with oculocutaneous albinism.

## PgmNr 1582: The portrait of fully phased assembled diploid human genome.

Personalized de novo genome assembly offers potential benefits in discovering complex structural variants and unique sequences with less reference bias as compared to standard whole-genome resequencing. However, the challenge of variant calling from the assembly-based method is the heterozygous regions, which obscures the variant calls from the unphased assembled genome. Besides calling variants, genomic phasing is also useful in putting the genetic variation into context. This is critical to study allele-specific regulation, compound heterozygous mutations, or population genomics. For these reasons, the de novo assembly and phasing have become increasingly important in the study of personalized genomics. To date, the phasing of the assembled human genome is challenging due to the low heterozygosity of the human population.

Here we present the fully phased diploid human assembly from single molecule sequencing data of Oxford Nanopore Technology (ONT) using a trio-binning assembly approach. The ultra-long ONT data of the HG002 individual was provided by Genome In a Bottle Consortium (GIAB) and UCSC. These raw long reads were fully segregated into paternal and maternal reads using parental specific k-mer sequences from Illumina data of the parents. Then, the paternal and maternal raw long read data were successfully assembled into two 3 Gbp genomes and polished to improve their overall accuracy. Consequently, we explore the benefits of fully phased assembled genomes in the context of variant discovery. We compare between diploid-assembly-based variant calling and mapping-based variant calling against GRCh38 using the GIAB truth set as the ground truth. The fully phased assembled human genome is publicly available on the DNAnexus platform and the GIAB Consortium ftp site.

There is much interest in the human microbiome due to its association with various disease, including, but not limited to type 2 diabetes, ulcerative colitis, and colorectal cancer. A common concern that is raised about the microbiome is that it is highly variable, which has led to a lack of reproducibility of some findings. Microbiome composition has been found to be heritable at levels ranging from 10% to 40%, however, many identified genetic associations have not been replicated. This may be due in part to insufficient sample size and lack of control between studies. From off-target reads in whole-genome shotgun (WGS) sequencing of the microbiome, we are capable of retrieving human genotypes. Recently, it has been shown that chip-quality genotype can be imputed from low-coverage ( $> 0.1x$ ) alignment using standard genotype imputation software, such as BEAGLE. We leveraged this knowledge and developed a robust pipeline to generate a large cohort with both host genotype and microbiome. From the Human Microbiome Project (HMP) as well as several other studies, we aligned metagenomic WGS reads against the human genome, filtered for only human reads, called variants, and imputed genotypes using 1000 Genomes Project data as a reference. From off-target reads, we generated, on average, a 6.8x coverage alignment. From our alignment, we called and imputed over 15 million common genetic variants. To validate our imputed genotypes, we assessed concordance between our imputed genotypes and the array genotype for the subset of the HMP for which genotype array data was available. Using these datasets, we will conduct host genetics x microbiome interaction analyses, which will help elucidate the genetic architecture for microbiome composition and diversity.

## **PgmNr 1584: The Alliance of Genome Resources: A next-generation comparative genomics data ecosystem for functionalizing the human genome.**

For decades, Model Organism Databases (MODs) and the Gene Ontology Consortium (GOC) have expedited discoveries about gene function and biological principles of human biology through expert curation and integration of heterogeneous genetic, genomic, and phenotypic data from disparate sources. Open access to the collected knowledge about a model organism and about gene function in human readable and computation-ready formats as provided by these resources would otherwise require hundreds of hours for an individual researcher to assemble on their own. Despite their demonstrated utility as core community data resources, the lack of unified data access mechanisms and user interfaces--even for data types shared in common among model organisms--have prevented these resources from realizing their full potential for functionalizing the human genome. To address this usability gap, the GO Consortium and six MODs (Saccharomyces Genome Database, WormBase, FlyBase, Zebrafish Information Network, Mouse Genome Database, Rat Genome Database) have joined together in to form a consortium, the Alliance of Genome Resources (the Alliance). Through our web portal ([alliancegenome.org](http://alliancegenome.org)) with common user interfaces and our shared application programming interfaces (APIs), the Alliance has implemented an advanced comparative genomics platform making it easier than ever for researchers to perform multi-species comparisons of biological annotations for orthologs of human genes for such properties as gene function, expression, interaction, phenotype, and disease. The Alliance resource is designed to facilitate identification of relevant animal models of human disease and to evaluate the disease significance of human genes and variants of unknown significance identified from large scale clinical sequencing initiatives.

## PgmNr 1585: Mapping tolerance of intraspecific variation across the human and mouse genomes.

Regional differences in population-wide variation across the genome can be explained in part by constraint due to purifying selection, and provide a framework for interpreting the functional importance of genomic elements. Here, we use a sliding window approach to quantify intraspecific constraint across the human and mouse genomes. We highlight the relative enrichment and depletion of genomic annotations across the most and least constrained regions of the genomes, and show constraint is closely correlated between protein-coding regions and cis-regulatory elements for both species. Furthermore, we compare constraint across syntenic regions, and for pathogenic variants in human with an orthologous position in the mouse. Our results have implications for inferring when the mouse may be sufficiently analogous to serve as a model for human disease.

## PgmNr 1586: A model organism matchmaking software platform for clinical genetics research.

Clinician-scientists who identify novel disease genes or variants often wish to validate their findings in a model system, but identification of an appropriate model organism (MO) collaborator can be a challenge. To this end, we developed a web-based registry system for MO researchers, originally implemented as the central resource for the Canadian Rare Diseases Models and Mechanisms (RDMM) Network. Because the concept and implementation has broader applicability, here we describe our software platform and how it can be used to establish collaboration between MO researchers and human geneticists. The software is open source and is available at <https://github.com/PavlidisLab/modinvreg>.

The purpose of the Registry is twofold: 1) to provide a straightforward way for MO researchers to describe their research and relevant expertise at the gene level; and 2) to allow comprehensive searches of the registrants' information. Besides their contact information, affiliation and a brief research description, the researchers enter genes for each MO they use. Genes are organized in three tiers, based on the researcher's expertise: TIER1 and TIER2 genes are directly entered, while TIER3 genes are computationally inferred using Gene Ontology terms.

The Registry can be searched using researcher's name, research description keywords, or genes in their profile. Gene search can either be MO specific or, if the query gene is human, the orthology mapping is done automatically and search performed for all the orthologs.

The Registry currently supports multiple user-settable levels of privacy of MO researcher information. The default data privacy settings, user interface and documentation are all customizable on the application level to suit instance-specific needs.

As of mid-2019, the software is being adopted by other rare disease research networks. To enable federated interaction between these sites, we implemented an application programming interface (API) that enables remote querying and fetching of data between different software instances. As a result, a simple checkbox selection on the search page will include the search results from other instances, according to appropriate viewing permissions. The API also allows public data to be accessed and displayed by other applications and resources.

In conclusion, the RDMM Registry is a secure, customizable, portable, and linkable gene-based matchmaking platform that should be easily adoptable for other similar research collaborations.

## PgmNr 1587: Identifying very rare genetic variants in DNA microarray data using a population-specific reference panel for imputation.

While the ascertainment of individuals affected by rare clinically actionable disorders requires next generation sequencing (NGS) for accurate calling of carrier status, availability of these resources is not always feasible for population-wide screening due to cost. Estonian population-based biobank, that holds DNA microarray-derived genotype information for 52,274 individuals, has built a population-specific reference panel from NGS data (n=2,244) for imputation. We therefore aimed to investigate whether the utilization of a custom reference panel for imputing missing genotypes enables the ascertainment of very rare genetic variant (VRGV) carriers from microarrays.

We set to determine carrier status for 20 VRGVs linked with clinically actionable disorders that were identified in heterozygous state in NGS (allele counts between 1-7, n=34) from Illumina Global Screening Array-genotyped data of 33,277 individuals. To this end, six different approaches were applied: long-range haplotyping as well as basic (EAGLE/BEAGLE), read-aware phasing-based (SHAPEIT2/ BEAGLE) and non-pre-phased (IMPUTE2) imputation. As phasing of rare alleles is largely random, we additionally used allele switching. For that, we flipped the phased alleles in the reference panel to the other haplotype, and then imputed the variants of interest in a 20Mb window via basic and read-aware phasing imputation using created dummy haplotypes. Across six methods, 1079 putative VRGV carriers were identified and Sanger sequenced for validation. Carrier status was confirmed for 187 individuals for 16 VRGVs, yielding true positive rate of 18% across all methods. While 163 of 188 (87%) true carriers were identified via basic imputation, allele switching and long-range haplotyping facilitated to uniquely identify carriers for two (n=15) and four (n=5) AC=1 variants, respectively, not identified with any other approach, confirming random phasing of singletons.

Despite modest yield, these results demonstrate that microarray-based ascertainment of risk haplotypes using a custom population-specific reference panel for imputation provides a cost-effective strategy for identifying putative carriers affected with clinically actionable disorders at a population scale, when NGS is unavailable. While basic imputation allows to identify the majority of those with risk alleles, modification approaches are required for detection of singleton variants.

## PgmNr 1588: Quantifying phenotype similarity for complex harmonized disease cohorts.

The NIH Common Fund's Gabriella Miller Kids First Pediatric Research Program (KF) is a collaborative initiative focused on providing large-scale clinically-annotated genomic data for pediatric cancer and structural birth defect cohorts, including trio germline whole genome sequencing (WGS) and tumor WGS and RNA-seq. The KF Kids First Data Resource Center (KFDRC; <https://kidsfirstdrc.org/>) is charged with empowering collaborative research and discovery through integration of KF cohorts and external data. As of mid-2019, there are 33 GMKF unique disease cohorts funded through KF: 23 structural birth defect (SBD) and 10 pediatric cancer (PC) cohorts, with one mixed SBD & PC cohort. Approximately 7300 participants from 2300 SBD and PC families have been harmonized into the KFDRC since the launch of the portal in June 2018, making the KFDRC one of the largest pediatric data resources of its kind.

Currently, over 23,000 individuals (probands and families) have been funded by KF for sequencing and harmonization, representing approximately 7000 individual probands, all of whom have disease-specific clinical and phenotype data that must be harmonized against common classification sets for cohort analysis intra- and inter-operability.

We show how the Kids First Data Resource is working to harmonize clinical and outcome data across phenotypes and diseases using the Mondo Disease Ontology for disease classification, the Human Phenotype Ontology (HPO) for phenotype classification, the Uber-anatomy ontology (Uberon) for anatomical classification, and the National Cancer Institute's Thesaurus (NCIT), which classifies across many different levels and types of data in the cancer domain. Notably, we present work on quantification of individual and cohort-level phenotype content and pairwise similarities using metrics such as the Jaccard index. Quantifications are benchmarked using cohorts with co-occurring structural birth defects and against randomly generated null sets of phenotypes. Quantification of phenotype interoperability is useful for identifying not only cohort groups that may be more analytically interoperable in genetic analyses, but will also help inform contributing investigators as to the quality and interoperability of their own clinical phenotypic datasets with the rest of KF cohorts.

## PgmNr 1589: Identification of clinically relevant polyadenylation signals.

Polyadenylation is essential in maintaining nascent mRNA stability. Variants in polyadenylation signals (PAS) can result in reduced polyadenylation at the normal polyA sites and lead to reduced gene expression. Only 26 variants in PAS in 20 genes have been associated with mendelian disorders. We hypothesize that this is under-representative of this class of mutations. Here, we aimed to comprehensively identify clinically important PAS. PolyA sites were collected from the Alternative Polyadenylation Database (APADB) and the Polyadenylation Database Version 3 (PADB3) and examined for dominant polyA site usage activity (defined by > 50% of overall EST representation). We filtered for inclusion of polyA sites with only one canonical AATAAA PAS within 50 bases upstream. We also filtered for >=20x coverage in 90% of gnomAD samples and removed low complexity regions. Remaining sites from the two databases were intersected to produce the final list of PAS of interest. To understand constraint in the identified PAS, we compared the number of variants in the PAS of interest vs other control regions using gnomAD. We identified 3,242 canonical (AATAAA) PAS for further examination. Of these PAS, 1,727 were in genes in HGMD. Five of these 1,727 genes were among the previously reported 20 genes with disease-associated PAS variants in HGMD. The 3,242 PAS were at least 6 times more constrained than AATAAA hexamers occurring in intergenic regions, hexamers immediately upstream of the signal, and AAT or AAA triplets occurring in upstream 3' UTR regions. Interestingly, we observed position-specific substitution bias in the middle 4 positions compared to positions 1 and 6. A base-specific bias was also seen in middle positions, which favored guanine and cytosine substitutions. We identified 3,242 PAS of potential clinical relevance. The high constraint observed in these PAS supports their biological importance and potential clinical implications. We hypothesize that these sites harbor pathogenic variants for mendelian disorders. We are currently screening for variants in these 3,242 PAS in a cohort for clinical follow-up and validation.

Prediction of ethnicity and relatedness from genomic markers is a crucial step in Quality Control (QC) analyses for any large scale sequencing and genotyping study. By identifying any mislabelled samples at an early stage in the project, the researcher can investigate any potential issues in their laboratory/informatics pipelines, such as possible sample swaps or duplications, and to ensure the correct samples are included in the final dataset. Furthermore, by using an unrelated set, bias in population genetics parameters can be removed from the mainstream analysis. This allows for example for accurate calculation of Allele Frequencies (AF) for a particular mutation.

In the NIHR Bioresources , we have developed an R package: pretrel that supports initial SNP selection from the overall dataset, then calculates ethnicity and relatedness between samples and finishes by identifying a maximum set of unrelated samples. pretrel can be run on genotyping data obtained from a wide variety of platforms including Illumina sequencing data and microarrays. The full analysis suite scales to large sample size, and has been run on the GEL Whole-Genome Sequencing (WGS) data (~50,000 samples), NIHR BioResource WGS data, targeted NGS data for rare disease panels and data from Axiom arrays.

As a first step pretrel can select a reliable set of common SNPs from your dataset. The analysis also uses genotypes from a reference project such as 1000 Genomes project to infer ethnicities and part of the selection involves finding SNPs intersecting both the project data and reference samples. VCF files from the project and reference samples are then filtered for this SNP set whilst checking for data completeness, before being merged to one VCF file with high quality genotypes. The main statistical method used for predicting ethnicities is Principal Component Analysis (PCA) where the principal components are calculated using the reference set and the samples of interest are then projected onto the reference set using the GENESIS R package. By using these projections, we further assign ethnicities for each sample based on their similarity to the reference samples. Pairwise relatedness is then calculated with the GENESIS package, which starts with the ethnicity PCA loadings and then calculates the IBD ratios and a kinship score.

Only 6.4% out of the over 96,332 single nucleotide polymorphism (SNPs), from over 3,412 studies with reported trait associations of  $p < 1 \times 10^{-5}$  that have been curated in the NHGRI-EBI GWAS[1], are located in protein coding sequences with effects on protein structure. Overall, it is more easy to predict the functional impact of genetic variation in protein coding genes compared to variation in non-coding sequences, which generally do not have so well defined features such as codons or mRNA splice sites.

Noteworthy, non-coding DNA contains the gene regulatory information necessary for spatial and temporal gene expression patterns. Specifically, gene regulatory regions function by interacting with transcription factors (TFs) that bind to short, highly redundant DNA motifs. SNPs in gene regulatory regions that TF DNA binding sites have been implicated as causal variants in GWAS studies. However, there are numerous challenges (e.g. measure the effect in TF binding affinity) to unravel the impact of genetic variations in gene regulatory regions.

Here we describe var-tools, a set of programs within the Regulatory Sequence Analysis software suite [2], and present four case studies exemplifying their usage and applications. In brief, var-tools facilitate i) obtaining variation information, ii) interconversion of variation file formats, iii) retrieval of sequences surrounding variants, and iv) predicting the impact of the variation on the binding affinity of a given TF, estimated by matching the sequence with the annotated binding motif. The tools are available through a web interface that enables analysis of 5 Metazoa and 10 plant genomes, and can be further used in command-line with locally installed genomic sequences. Users can input personal variation and motif collections, providing flexibility in the analysis. In addition, haplotype phase information can be provided in the VCF file to estimate the joint effect of variants in close proximity on the same TF-binding event. Overall, RSAT var-tools provide a comprehensive resource to experienced and nonexpert users (accessible through a web interface) to analyze regulatory variants in several organisms.

---

**Background**

In single-cell RNA-seq analysis, clustering cells into groups and differentiating cell groups by marker genes are two separate steps for investigating cell identity. However, results in clustering greatly affect the ability to differentiate between cell groups. This interdependency often creates a bottleneck in the analysis pipeline in which researchers repeat these two steps many times by trying different clustering parameters to identify a set of cell groups that are more distinguishing and biologically relevant.

**Findings**

To accelerate this process, we develop IKAP – an algorithm identifying major cell groups that improves differentiating by systematically tuning parameters for clustering. We demonstrate that, without specifying any parameters, IKAP successfully identifies major cell types such as T cells, B cells, NK cells, and monocytes in two peripheral blood mononuclear cell (PBMC) datasets and recovers major cell types in a previously published mouse cortex dataset. In addition, those major cell groups identified by IKAP present more distinguishing marker genes compared with cell groups generated by different combinations of clustering parameters. Finally, we show that cell subtypes can be further identified by re-running IKAP within identified major cell types so that a cell ontology prototype can be automatically constructed using single-cell RNA-seq data.

**Conclusions**

IKAP can speed up single-cell RNA-seq analysis and cell type recognition by identifying major cell groups with distinguishing marker genes and can facilitate cell ontology curation using single-cell RNA-seq data.

Single-cell RNA sequencing (scRNA-seq) is a robust approach to identify cell types, cell status, and to discover novel genes for human diseases. Despite many computational methods and tools have been reported to analyze scRNA-seq data, accurately cell clustering remains challenging, which may substantially impact on downstream analysis. The challenges of cell assignment include data high dimensionality and instable clustering. In this study, we proposed a generalized linear model (GLM)-based cell mapping approach with cell-type “marker” genes curated from the literature to assign cell clusters to cell types. We first selected a reference gene panel based on the known signature genes in a given cell type and created a dummy matrix for gene expression of each cell type. We tested the association between gene expression in each cell and each cell type using GLM. We assigned one cell to one cell type by a predefined cut-off value. Then, the proportion of each assigned cell type was calculated for each cluster. The dominant proportions are used to assign one cluster to one cell type. For the cells falling between the clusters, we estimated a probability of the cell for each cluster and assigned cell into a cluster based on its probability using method based on Fuzzy c-means clustering. Briefly, we used the within-cluster cells for hyperparameter (weighting exponent) tuning in Fuzzy c-means clustering and chose the hyperparameter with highest prediction accuracy. Then, the probability of between-cluster cell belongs to each cluster was estimated by Fuzzy c-means. Finally, the cell type for each cluster was confirmed manually by cell type marker gene expressions mapping on the t-distributed Stochastic Neighbor Embedding (tSNE) plot. To test the performance of our method, we profiled four samples on the 10X Genomics platform and yielded a total of 15,973 human peripheral blood mononuclear cells and 21,430 genes. Our approach unambiguously deconvoluted the 15,973 cells among 21 clusters into eight cell subtypes: CD4+ T-cells (34.6%), IL7RCD4+ T-cells (8.4%), CD8+ T-cells (17.4%), B cells (13.2%), natural killer cells (12.3%), CD14+ monocytes (10.0%), FCGR3A monocytes (3.9%), and dendritic cells (DC) (0.3%). Our results demonstrated that GLM-based cell clustering is a robust approach for identifying cell types in scRNA-seq analysis.

---

One of the main limitations of single-cell RNA-Seq is its high cost which prohibits population-scale analyses that aim to connect population level variation (e.g., genetics and/or disease status) with single-cell transcriptomics. The most common population-scale analysis is eQTL mapping, which is a widely-used tool in functional genomics used to identify putative mechanisms underlying the connections between the genotypes and the phenotypes mediated through gene expression. Single-cell RNA-Seq enables cell-type-specific eQTL mapping, i.e. finding associations between genetic variants and cell-type-specific gene expression. Achieving high levels of statistical power in these studies requires a large sample size, a large number of cells, and a high-coverage sequencing. However, with a limited budget one can not increase all the three quantities simultaneously. We demonstrate that cell-type-specific gene expression can be accurately inferred with low-coverage single-cell RNA sequencing given enough cells and individuals. For example, we show on a single-cell dataset (Segerstolpe et al., 2016) that by aggregating reads across cells within a cell type, it is possible to achieve a high level of the average Pearson R<sup>2</sup> between the low-coverage estimates and the ground truth cell-type-specific gene expression. The power of a study with sample size N is approximately the same as the power of a study with sample size R<sup>2</sup> \* N (the effective sample size, ESS) and the true cell-type-specific expression. Thus, under a constant budget, using low-coverage sequencing can increase the sample size and the power of an eQTL study. We also show that even taking into account all related costs such as the library preparation ones, using low-coverage single-cell sequencing can considerably decrease the cost of a cell-type-specific eQTL study without sacrificing its power. For example, we show that ESS of 50 can be achieved by sequencing 56 individuals with 33000 reads per cell (2750 cells per individual) which costs \$50,000. With our proposed approach of using low coverage, the same ESS can be achieved by sequencing 96

individuals at 1500 reads per cell (2500 cells per individual) and the total costs \$25,000. We also provide a practical methodology on designing cell-type-specific eQTL studies which maximizes statistical power. Our results provide a clear pathway for the design of efficient cell-type-specific association studies that are scalable to large populations.

---

Clinical whole-exome sequencing (WXS) and whole-genome sequencing (WGS) are transforming how rare Mendelian disorders are being diagnosed. Although diagnostic yield is still low, it has the potential to be improved with more comprehensive support for integrative phenotype-genotype analysis and with better classification of variants that alter pre-mRNA splicing. Exomiser is a tool for annotation, filtering, and phenotype-driven prioritization of variants identified in WXS or WGS. Here, we demonstrate a method for improved identification of pathogenic splicing variants and integration into Exomiser to improve diagnostic yield.

Extensive review of published cases was performed to curate a collection of pathogenic variants (n=611) that cause splicing alterations leading to Mendelian diseases. We focused on variants at positions other than the canonical donor and acceptor dinucleotide sequences, such as those present in splicing *cis*-regulatory elements. The clinical data of the probands was recorded using Human Phenotype Ontology terms. The control set of splicing-neutral variants (n=657) was derived from ClinVar benign variants and from published variants where the absence of missplicing was demonstrated experimentally. A separate validation set of both pathogenic and benign variants was created in the same way. We developed schemes for scoring REF and ALT alleles of variants in different positions with respect to splice sites (e.g. exonic variant, variant in canonical splice site, etc.). The scoring schemes were based on the information content of the nucleotide sequence. Raw output of the schemes was then scaled between 0 and 1 in a way that maximized separation between pathogenic and benign cases. To evaluate the performance of the scoring schemes in simulations, we spiked pathogenic splicing variants into a VCF file from an unaffected individual and then analyzed the VCF together with the patient's phenotype. After the analysis, we measured how often the gene with pathogenic splicing variant was placed in any given rank among the full set of prioritized genes.

We will present current results of simulations, and demonstrate how to use the splicing prioritizer within the Exomiser framework for phenotype-driven analysis of WXS/WGS experiments.

# PgmNr 1596: Analysis of sequencing error profile across different next-generation sequencing platforms.

**Authors:**

J. Bai; X. Su; S. Li; L. Wu

[View Session](#) [Add to Schedule](#)

**Affiliation:** BerryOncology, Corporation, Beijing, China

---

**Background**

Next generation sequencing has revolutionized genome wide research and provided unprecedented amounts of data. Quality analysis is essential since a large number of erroneous basecalls were produced during sequencing procedures. Currently, raw base quality scores are widely used for quality analysis of next generation sequencing data. However, base quality scores are differently preset across different sequencers. Alternatively, sequencing of standard DNA and comparative analysis can be conducted in pipeline evaluations, but the conclusions of which would largely depend on data analysis strategies.

**Methods**

Exome sequencing data of six specimens were generated from three different platforms, including Illumina HiSeq2000, XTen, and NovaSeq6000 (two for each platform). Reads generated from same template molecules, which are often marked and removed by most analysis pipelines, were identified and defined as PCR duplication clusters. According to the origination of PCR duplicates, we defined loci that discordant within duplication clusters as erroneous basecalls. Total number of sequencing bases will be introduced to estimate the error rate of the sequencing run and under each Q score given by the sequencer.

**Results**

The overall sequencing error rates were 0.0444%/0.0493%, 0.0833%/0.0768%, and 0.0294%/0.0284%, for HiSeq2000, XTen, and NovaSeq6000, respectively. As expected, the basecalls with higher Q scores have magnificently lower error rates. Furthermore, using the erroneous substitution type as well as the context bases of the error loci, we analyzed the 'erroneous signatures' by non-negative matrix factorization. Interestingly, each of the three sequencing platforms tends to have a specifically dominant signature. For NovaSeq6000, the base mis-calling were often identified as T>G transversion at NpTpK contexts. Sequencing errors from HiSeq2000 are characterized by overrepresented of C>A and T>G transversion. Erroneous basecalls on XTen platform, on the other hand, are not showing any strong bias.

**Conclusions**

The tool we developed, ngsErrPro, defines actual sequencing errors from discordant bases within PCR duplication clusters. The results showing that even under the same quality score, error rates are different across sequencing platforms. Moreover, predominant erroneous signatures were identified for different sequencing platforms.

## PgmNr 1597: Linking pathogenic variants to expected disease phenotypes in electronic health records using UMLS.

### Authors:

---

Large scale next-generation sequencing of unascertained population cohorts paired with patients' electronic health records (EHRs) provides an excellent resource for the study of gene-disease associations, as demonstrated by the DiscovEHR and UK Biobank collaborations. In these types of studies, a common question arises: does an individual carrying a known or expected pathogenic variant in a disease-associated gene exhibit the predicted disease phenotype? Answering this question for each pathogenic variant is challenging because the process is manual and time-consuming, often requiring an expert to perform a literature search on each variant and a review of the carrier's EHR. To address this problem, we developed a method that partially automates the process of screening an individual's EHR for diagnosis codes that can be attributed to variants in many of the most well studied human genes associated with disease.

We used the National Library of Medicine's UMLS (Uniform Medical Language System) to identify mappings between human disease genes and International Classification of Diseases (ICD) diagnoses. The UMLS is a compendium of ~200 controlled vocabularies from the biomedical sciences (e.g., ICD-10-CM, SNOMED CT, HPO) where similar concepts from the source ontologies are mapped to a common UMLS concept while retaining the ontological relationships. We represented a subset of the UMLS as a graph database and used it to find ICD-code derived phenotypes that can be conceptually linked to a gene or variant. The result is a set of gene-phenotype mappings that are not readily available from any publicly available ontology. These mappings specify a conceptual pathway between genes and phenotypes to accelerate follow-up analysis and frequently include secondary phenotypes that might otherwise be overlooked.

We applied our method to ~300k predicted pathogenic variants (in ~2400 disease genes we mapped to ICD phenotypes using UMLS) identified in DiscovEHR (N=92k) exome sequencing participants. For each variant, we were able to screen for expected phenotypes in the variant carrier's EHR in just a few seconds. This process identified a predicted ICD code in a carrier's EHR in ~35% of cases, which is appropriate considering the prevalence of reported recessive disease genes, disease penetrance, and the incomplete nature of de-identified EHRs. Our method provided a first-pass analysis of predicted pathogenic variants, potentially saving significant manual work.

## PgmNr 1598: Systematic gene set analyses using MAGMA.

---

A major challenge in genetics today is to understand the biology that underlies regions of the genome identified by GWAS. An approach to tackling this problem has been the development of gene-set analysis tools such as MAGMA (Multi-marker Analysis of GenoMic Annotation). While MAGMA outperforms other similar methods, there are still questions concerning how variables such as gene-set size, SNP-heritability (SNP- $h^2$ ), the sample size of the GWAS, or even the method of phenotyping the trait can influence the results of gene-set analysis. We set out to characterize the behavior of MAGMA (using real rather than simulated datasets) when different types of traits or gene-sets are used in various combinations as inputs to the software. We find that there are differences in resulting effect sizes and degrees of significance depending on whether the gene-set was manually curated or computationally derived, and that specific categories of traits (namely metabolic) are consistently significant for computationally derived sets. Furthermore, we found that continuous traits tend to have a higher proportion of significant results than binary traits, regardless of the source of the gene-set. When considering sample size of the GWAS or the SNP- $h^2$  of the trait, we found no strong correlations with degree of significance. However, we observed a strong correlation ( $R^2 > 0.5$ ) between gene-set size and the magnitude of the regression coefficient between heritability and degree of significance, regardless of the source of gene-set. Similarly, gene-set size and degree of significance among the computationally derived sets were also found to be strongly correlated (Pearson correlations  $> 0.7$ ), though the same was not observed for manually curated sets. Thus, we find that factors such as gene-set size, gene-set type, and trait type should be taken into consideration when interpreting the results of MAGMA.

## PgmNr 1599: Scalable probabilistic PCA for large-scale genetic variation data.

---

Inference of population structure is a key step in population genetic analyses with applications that include controlling for confounding in genome-wide association studies. The naïve approach for principal component analysis (PCA), one of the most widely used methods for inferring populating structure, estimates principal components (PCs) by computing a full singular value decomposition, resulting in runtimes unsuitable for large data sets.

Several solutions have been proposed for the efficient computation of PCs. One approach taken by two recent scalable implementations (FastPCA and FlashPCA2) takes advantage of the fact that typical applications of PCA in genetics only require computing a small number of PCs. Another approach utilizes the parallel computation infrastructure of the cloud, an approach that is often cost-prohibitive. Furthermore, these implementations lack a full probabilistic model, making them challenging to extend to other settings.

In this work, we describe ProPCA, a scalable method to compute the top PCs on genotype data. While PCA treats the PCs and the PC scores as fixed parameters, ProPCA imposes a prior on the PC scores. This formulation leads to an iterative Expectation Maximization (EM) algorithm for computing the PCs. ProPCA leverages the structure of genotype data so that each iteration of the EM algorithm can be computed in time that scales sub-linear in the number of individuals or SNPs.

In both simulated and real data, ProPCA is able to accurately infer the top PCs while scaling favorably with increasing sample size. We applied ProPCA to compute the top five PCs on genotype data from the UK Biobank, consisting of 488,363 individuals and 146,671 SNPs, in less than thirty minutes. Leveraging the population structure inferred by ProPCA within the White British individuals in the UK Biobank, we scanned for SNPs that are not well-modeled by the top PCs to identify several novel genome-wide signals of recent positive selection. Our scan recovers sixteen loci that are highly differentiated across the top five PCs that are likely signals of recent selection. While these loci include previously reported targets of selection, the larger sample size that we analyze here allows us to identify eleven novel signals including a missense mutation in *RPGRIP1L* and another in *TLR4*.

## PgmNr 1600: Cerberus: A laboratory information management framework in support of research and clinical operations.

---

The Center for Inherited Disease Research (CIDR) provides high quality next generation sequencing (NGS), genotyping and statistical genetics consultation to investigators working to discover genes that contribute to disease. The expansion of research and clinical genomic services from collaboration with other Johns Hopkins Genomics members have highlighted the need to create a new Laboratory Information Management System (LIMS) to support the breadth of current and future protocols. Previously we described the development of a MySQL database backed Java framework consisting of tools to reduce disruption to lab processing with module hot swapping, limit database schema complexity, and create a catalogue of reusable graphical user interfaces (GUI) to flexibly build and extend workflows for any protocol driven technology. Now named Cerberus, we present the first production use from this effort, the replacement of our legacy genotyping LIMS for all variations of Illumina Infinium assays. Lab managers create experiments in Cerberus by queuing samples from the in-house sample handling system and connecting these lists to job code templates that load wet-bench phases for user input (UI). Phase classes that are common between protocols can be reused for each job, reducing codebase complexity. All phase submission data is stored as XML metadata in the database reducing schema complexity and creating an audit of changes. Technicians scan one or more experiment entities that load UI for the next phase available to those entities. Custom validations are in place to help efficiently use lab automation resources, check expected reagent type suffixes, and prevent sample swapping. A robust comment tracking UI is easily accessible from any phase ensuring comments are not forgotten. Reports integral to downstream analysis have been implemented in a consolidated and efficient manner. Utility jobs restricted to administrative roles exist for the management of user access, validation of wet-bench inventory, and predefined data value modification. Multiple installations exist to aid in testing and transition of jobs from software developers to lab management and into production use. This model ensures that feature and unexpected behavior requests are adequately tested and approved before being deployed for production use. Having transitioned genotyping wet-bench operations to Cerberus use, we now target inclusion of research sequencing workflows.

# PgmNr 1601: A unified platform for scalable genomic data analysis.

**Authors:**

H. Davidge

[View Session](#) [Add to Schedule](#)**Affiliation:** Databricks, San Francisco, CA.

---

As the growth of genomic data continues to accelerate, single node tools are unable to keep pace. Distributed computing platforms, which provide high-level APIs to parallelize operations across thousands of CPU cores, allow practitioners to scale their analyses as data accumulates. Apache Spark has already gained traction as the engine that underlies popular tools like GATK4, Hail, and ADAM. This talk explores solutions that we have built on top of Spark and the Databricks platform to further scale common genomic query patterns.

A framework for efficiently assigning short reads to different nodes in a cluster has allowed us to distribute single node variant calling tools with roughly linear efficiency. With this method, we are able to use the GATK4 HaplotypeCaller to call variants on a 30x coverage whole genome sample in under 10 minutes for less than \$1 in AWS costs while producing results concordant with the reference single node implementation. When coupled with BWA, we can align and call variants in 24 minutes for under \$3.

We also describe techniques for accelerating ad-hoc analyses and joint variant calling. By extending the query optimizer built into Spark SQL, we achieve speedups of 10-100x on common query patterns such as genomic interval joins. Optimized readers for BGEN and VCF files enable these queries to run at biobank scale over genomics file formats or general purpose big data file formats like Apache Parquet. Our joint variant calling pipeline scales nearly linearly with the number of cores available and has successfully called cohorts of several thousand whole genomes.

# PgmNr 1602: High-throughput genetic variant classification for inherited cancer gene panels through an artificial intelligence inference engine.

---

A growing number of clinical labs are implementing cancer risk screening tests that sequence panels of cancer genes ranging from a few to over a hundred genes. This growth is driven by both the reduction of sequencing costs and the availability of reimbursement pathways for such tests. However, an important part of the cost involves the assessment of variant pathogenicity by trained clinical geneticists. The ACMG and AMP developed evidence-based guidelines to standardize variant assessment defining 28 criteria for supporting evidence of pathogenicity, which are then combined to classify a variant as either pathogenic, likely-pathogenic, benign, likely-benign, or uncertain significance. Although widely adopted in clinical interpretation of variants this process has remained largely manual and time-consuming. We recently developed an artificial intelligence-based forward-chaining inference engine implementing the ACMG-AMP criteria that takes as input annotated variants and codified gene-condition curation to automate the classification of variants. Here we analyzed with our engine 9,539 variants previously classified in a large Japanese survey of breast cancer patients and controls (7,051 cases and 11,241 controls), and for 50,000 individuals publicly released by Color Genomics. In addition, we analyzed variants from a cohort of 2,853 cancer patients of diverse histology whose genomes were sequenced as part of the International Cancer Genome Consortium. With this data we evaluated the performance of our classification inference engine for a 15-gene hereditary cancer risk panel we previously curated. We show up to 74% concordant classification of the variants previously classified by Color Genomics and in the Japanese cohort. Importantly, our engine produces zero misclassifications. Unclassified variants are annotated with the resolved criteria, enabling rapid manual classification. In addition, we are able to classify up to 46% of variants previously deemed VUS in these databases. On the ICGC donors we observe most variants benign, with just a few pathogenic, and <10% unclassified in need of manual review. Population screening for cancer risk by sequencing of cancer gene panels is actively being discussed by healthcare stakeholders, but cost is still posing a challenge. We demonstrate that our methods can allow clinical labs to scale-up in such tests while reducing processing effort and cost, potentially enabling wider adoption of cancer risk testing.

Lurie Children's Hospital of Chicago, Chicago, IL; 17) Pediatrics, Miller School of Medicine University of Miami, Miami, FL

**BACKGROUND:** The American College of Medical Genetics and Genomics (ACMG) and Association for Molecular Pathology standardized variant interpretation and classify many variants as variants of uncertain significance (VUS). VUS can cause confusion and a diagnostic dilemma for patients and providers. Recently a Naïve Bayes model was proposed to estimate a probability of pathogenicity based on several questionable assumptions: independent evidence and 10% prior probability of pathogenicity. We have sought to improve based on a quantitative model.

**METHODS:** We first quantified two pieces of evidence as exemplars: 1) PVS1 was presented as a probability of a null variant based on gene isoform expression in a relevant tissue; 2) PM2 was presented using minor allele frequency (MAF) in gnomAD exome dataset. Second, we summarized ACMG evidence using principal component analysis (PCA) and estimated the probability of pathogenicity in a case-control cohort. Cases (N=333) were participants of European ancestry enrolled in the Pediatric Cardiomyopathy Registry. Controls (N=11,736) were unaffected parents of European ancestry in SPARK (Simons Foundation Powering Autism Research for Knowledge). We compared our results with the previous Naïve Bayes model using 37 known cardiomyopathy genes in the case-control cohort.

**RESULTS:** In this dataset, 29% of the null variants had <30% probability of being truly loss-of-function, and would change a piece of very strong evidence. The first principal component (PC1) is correlated with pathogenicity score. The loadings of the PC1 indicated PM2 (MAF) and BP6 (benign records) explained most of the variance in assigning pathogenicity. We compared our scores with the Bayesian probabilities and the ACMG rules. For pathogenic and likely pathogenic definitions, the three

methods had nearly identical classification performance (112 estimated risk variants with 90% probability). For VUS, quantitative methods could better communicate pathogenicity likelihood and prioritize variants for validation. Our PCA approach provided a slightly higher positive predictive value of pathogenicity (72%) compared with the Naïve Bayes model (66%) given a similar number of estimated risk variants (N=138).

**CONCLUSIONS:** Quantitative modeling of ACMG guidelines offers an improved understanding and greater detail about variant pathogenicity. PCA reduces evidence correlation and outperforms the Naïve Bayes model. The improvement is not significant given a small dataset.

## **PgmNr 1604: RefSeq Functional Elements: An annotated dataset of validated non-genic elements for variant interpretation and functional discovery in the human genome.**

### **Authors:**

---

The human genome contains many non-genic elements that play roles in gene regulation, chromosome organization, recombination, repair or DNA replication. Human disease can result from sequence variation in those elements, with many genome-wide association studies indicating disease-associated variation in non-coding regions. The locations of gene regulatory elements can be predicted from several large-scale epigenomic mapping projects, but those data are not generally visible in traditional genome annotation, are difficult to interpret in the absence of specialized research knowledge or customized displays, and do not always show function when tested experimentally. NCBI has therefore introduced a more accessible dataset, RefSeq Functional Elements ([www.ncbi.nlm.nih.gov/refseq/functionalelements/](http://www.ncbi.nlm.nih.gov/refseq/functionalelements/)), which are annotated on the human genome alongside conventional genes. This curated dataset, which is restricted to known elements from published experimental data, includes richly annotated RefSeq records and accompanying descriptive records in the Gene database ([www.ncbi.nlm.nih.gov/gene/](http://www.ncbi.nlm.nih.gov/gene/)). The dataset includes known enhancers, silencers, recombination regions, and other non-genic regions with experimentally-validated function. As of NCBI's Updated Annotation Release 109.20190125 on the GRCh38.p12 genome assembly, the dataset includes over 3.7K GeneIDs and 8.8K feature annotations, with further growth expected for future NCBI annotation releases. The dataset is publicly available for FTP download ([ftp://ftp.ncbi.nlm.nih.gov/genomes/Homo\\_sapiens/](ftp://ftp.ncbi.nlm.nih.gov/genomes/Homo_sapiens/)). Feature annotation can be visualized in the 'Biological regions' track available in NCBI browsers, including the Genome Data Viewer. This data track is particularly useful when viewed alongside other available tracks, such as variation tracks from dbSNP, ClinVar or dbVar, or study-specific custom tracks or track hubs. These non-genic annotations provide insights into non-coding genome function. They are valuable for basic discovery of gene regulatory regions, interpretation of non-coding variants, or as known positive controls for genome-wide studies aimed at discovering additional elements. This presentation will provide further information on how to use and access the dataset, and specific examples of functional determination will be presented. This work was supported by the Intramural Research Program of the NIH, National Library of Medicine.

## PgmNr 1605: A framework for mapping GWAS loci to causal genes for common disease and traits.

---

A barrier to translate GWAS findings into clinical insights is mapping associated loci to causal genes for common disease. We use a positive control approach to identify genomic features that provide strong enrichment for causal positive control genes and a probabilistic method to evaluate whether a specific gene in an associated locus is causal.

Causal positive control genes for common diseases were obtained from Mendelian causes using OMIM and from the gene targets of approved medications. We selected 10 diseases — type 2 diabetes, atrial fibrillation, bone density, rheumatoid arthritis, diastolic and systolic blood pressure, height, low-density lipoprotein and triglycerides (combined as lipids) and inflammatory bowel disease — because all have large-scale GWAS findings, enabling testing of methods. GWAS loci were statistically finemapped to define a set of putatively causal SNPs (cSNPs). The genomic features mapped from each locus to one or more genes included those within 100 kb of a cSNP or closest to or overlapping a cSNP, or containing a deleterious coding cSNP, or a cSNP that maps to a cell-relevant open chromatin peak. For each trait, we trained logistic regression models using leave-one-out cross validation, where a single trait model was trained using all other traits using causal positive control gene status as the dependent variable.

We identified 488 positive control genes, where 380 and 108 are from Mendelian causes or medication targets, respectively. We finemapped 8,061 loci ranging from 91 to 3,286 for rheumatoid arthritis and height, respectively. Genes with predicted causal probability of >1% showed enrichment for positive control genes, with odds ratios ranging from 7 (95% confidence interval (CI): 2-20) for hypertension to 42 (95% CI: 18-90) for type 2 diabetes. Genes with causal probability of >5% had higher enrichment, with odds of 25, 95% CI: 3-103, and 160, 95% CI: 35-589 for hypertension and type 2 diabetes, respectively. However, these estimates are less certain due to the lower number of positive control genes per disease. The best predictors were cSNPs that overlapped open chromatin peaks (16, 95% CI 10-22) and those that were deleterious coding variants (82, 95% CI: 35-129).

Human GWAS evaluated with cell-specific genomic features can identify known causal genes across common diseases and traits. These methods formally test the strength of human genetic evidence

supporting a causal role for genes in human disease and traits.

## PgmNr 1606: When gold standards don't shine: Quality control of large genome datasets using genome fingerprints.

### Authors:

**Affiliation:** Institute for Systems Biology, Seattle, Washington.

---

The 1000 Genomes Project (TGP) is a foundational resource to modern human biomedicine, serving as a standard reference for human genetic variation. Three new versions of the TGP dataset were since released, expressed relative to the current version of the human reference sequence (GRCh38), and partially validated by benchmarking one genome (NA12878) against the reference for the same genome from the Genome In A Bottle Consortium.

We used our ultrafast genome fingerprinting method [1] to evaluate all four versions of the TGP: 1) the original cohort of 2504 individuals, relative to GRCh37; 2) the same 2504 individuals, 'lifted over' to GRCh38; 3) an expanded cohort of 2548 individuals, natively mapped onto GRCh38 and calling only biallelic SNVs; and 4) the same 2548 individuals on GRCh38, calling biallelic SNVs and indels. We also evaluated the smaller, supplemental cohorts of related individuals that have been released.

Our analyses revealed discrepancies of several different types. The increase of 44 genomes resulted from adding 45 new genomes, but also removing one. Of the 45 additional genomes, 34 have various unannotated relationships. Eight genomes from the original cohort, all from the ACB population, show changes so extensive that they are difficult to explain by differences between the reference sequences alone; eight other ACB genomes show less difference, but still substantially more than genomes outside of ACB. These differences include decreased SNV count, decreased heterozygosity, and poor genotype concordance with the prior version of the same genome. Finally, two sex-discordant genomes have nearly identical autosomes.

Our observations suggest that the quality of processes as complex as sequence mapping and variant calling, applied to a large number of samples, cannot be extrapolated from comparison of a single sample against a gold standard. When detailed comparison cannot be applied to all samples, a rapid, approximate evaluation of the kind provided by genome fingerprinting can identify additional, unexpected quality issues, and support the goal of providing the community with resources meeting a high quality standard. As the size of whole genome cohorts reach into the hundreds of thousands (e.g., the current TOPMed project) and beyond, rapid, comprehensive quality testing will become an important part of 'best practice' quality control.

### Introduction

Next generation sequencing has become an integral tool in the study of human genetics, with whole genome sequencing (WGS) typically targeting 30X coverage. To support population-scale studies, low coverage WGS (lcWGS, <5X coverage) can be used to survey genomes in a cost-effective manner and is not limited by pre-determined probe design as in array CGH and FISH. Copy number variation (CNV) is an important component of genomic diversity and has been linked to a number of diseases in a dosage-sensitive manner. Here, we assess the feasibility and accuracy of using lcWGS to detect CNVs and explore CNV across a set of multi-allelic genes.

### Methods and Results

Laboratory procedures were performed at the Color laboratory, with DNA was extracted from blood or saliva samples and sequenced using the NovaSeq 6000 instrument, at ~1X coverage. Using a bioinformatics pipeline developed for clinical detection of structural variants in a targeted NGS panel, we tuned read depth based calling (CNVkit) for use with lcWGS. We utilized the resulting data in two ways. First, we assessed detection performance using a set of 137 clinical structural variants that had been previously confirmed present by array CGH, MLPA, or Sanger sequencing. Using lcWGS, we were able to reliably call and detect deletions as small as 20 kb and deletions greater than 100 kb; duplications had lower sensitivity, with reliable detection achieved at over a megabase. Notably, in one clinical sample a CNV near *NBN* was initially called from the targeted NGS panel data as a 3 MB copy number gain, but lcWGS and array CGH detected a chr8 trisomy. Given the sensitivity in detecting these larger events, we further characterized rare, larger structural variants and compared them against those found in gnomAD-SV. Second, we explored CNV across a set of multi-allelic genes using set of 949 clinical samples. We observed unique genomic structures in the *AMY1* region across a subset of 149 samples with high copy number. We also compared samples with extreme copy number within genes such as *LPA* to explore the relationship of dosage with available phenotypic data.

### Conclusion

lcWGS provides a rich data type with a number of unique characteristics. For CNV detection, it can allow for greater resolution in multi-allelic gene regions with high copy number and reliable detection of large and rare structural events, with further research and validation required to understand its utility for clinical use.

## PgmNr 1608: Multisample metrics for genome-wide single-position-resolution sequence quality assessment.

### Authors:

---

In a clinical setting, it is essential to understand sequence quality issues affecting each locus, both to evaluate variants called and to understand the probability of failing to call a variant that actually exists in the patient. While resources such as the Genome in a Bottle consortium and Platinum Genomes provide ground truth data for labs to sequence and quantify the accuracy of variant calls compared to an external standard, they do not cover most reference positions and are unlikely to cover the loci of pathogenic variants, which are rare by definition. Therefore it is highly desirable to understand a priori which loci have sufficient quality to be reliably called. Genome-wide measures of sequencing quality, such as the percentage of basecalls exceeding a certain quality threshold or the percentage of sites covered to at least a certain depth, may be of limited relevance at a specific locus of interest. On the other hand, locus-specific information from a single sample has little power to expose pipeline and platform biases affecting a site.

We have developed a software tool to aggregate sequence-quality metrics (e.g. read depth, base quality and mismatch rate) from many WGS samples. We applied this to groups of samples processed with consistent sample preparation, sequencing platform, and software pipeline. Based on these sequence-quality metrics, we identified deviations from normal sequencing quality at each position of the genome. By drawing on information from up to 150 samples, we were able to identify anomalies in the data with much greater robustness than would be possible with a single sample.

We give an overview of the means by which multi-sample sequence quality metrics are generated and discuss the designation of outlier regions with respect to those metrics. We report on the prevalence of genomic regions with highly consistent sequencing behavior, and compare our list of confident regions to other resources and to validated pathogenic variant calls. We further investigate how machine-learning methods and automated segmentation of the genome can be used to extend this work and potentially recover additional regions of reliable variant callability along with other annotations of interest.

## PgmNr 1609: Medical Genomics Japan Database (MGeND): 2019 update.

### Authors:

[View Session](#) [Add to Schedule](#)

**Affiliation:** Graduate School of Medicine, Kyoto University, Kyoto, Japan

---

To accelerate the implementation of genomic medicine in clinical practice, it is required to accumulate and share associations between genotypes and clinical phenotypes. Several databases containing genetic information and their clinical significance have already been constructed. However, the genomic information stored in those databases has been primarily obtained from US and European populations, and it is reported that genes and genotypes associated with the risk of onset of several diseases can vary between ethnic groups. Moreover, since some diseases are known to be triggers for other diseases, interpretation of variants across diseases is necessary to elucidate variants and diseases with unknown mechanisms.

For this reason, we developed a database, Medical Genomics Japan Database 'MGeND' (<https://mgend.med.kyoto-u.ac.jp/>) that provides disease-related genomic variants and corresponding clinical information in Japanese individuals. The first version of MGeND was released in March 2018 with genomic variations collected from Japanese research groups in the fields of “cancer,” “rare/intractable disease,” “dementia,” “infectious disease,” and “hearing loss”.

The number of data in MGeND has been increasing since it has been released; as of May 2019, 21260 SNVs/CNVs/Fusions, 22772 susceptibility variants for diseases identified using GWAS analysis, and 6195 HLA allele frequencies are published.

In addition, the target disease field has been further expanded. We are particularly focusing on polygenomic diseases, such as type 1 diabetes and narcolepsy, and genomic and clinical information has begun to be collected.

MGeND has disease-specific viewers to provide appropriate information for each disease field. In dementia, it is known that the genotype of the Apolipoprotein E (ApoE) gene is involved in the onset risk. Thus, we developed a viewer that can confirm the distribution of ApoE gene's genotypes based on selected phenotype in collaboration with research group of dementia.

Analysis of the registered data of MGeND has identified several variants common to different diseases. It is expected that investigating these variants will assist in clarifying the underlying onset mechanisms for each disease.

In the presentation, we will introduce the latest version of MGeND, and future prospects.

## PgmNr 1610: Development of semantic APIs for biomedical databases standardized in Med2RDF.

### Authors:

T. Katayama <sup>1</sup>; M. Kamada <sup>2</sup>; S. Kawashima <sup>1</sup>; M. Nakatsui <sup>2</sup>; R. Kojima <sup>2</sup>; Y. Okuno <sup>2</sup>

---

In the previous ASHG, we reported the Med2RDF project (<http://med2rdf.org>) which aggregated major biomedical databases as Resource Description Framework (RDF) based on the Semantic Web technologies. The resulting resource has a lot of potential for driving clinical genome medicine by developing data analysis methods such as artificial intelligence (AI) and machine learning (ML) technologies. However, the usage of this integrated resource can vary depending on the user's purpose, and also writing an effective "SPARQL Protocol and RDF Query Language (SPARQL)" query requires an in-depth understanding of the data models of each dataset. Therefore, it is demanded to provide reference SPARQL queries for typical cases as a set of APIs so that it can be easily used for data extraction and application development.

In this work, we stored RDF data in our SPARQL endpoint and introduced the SPARQLList application (<https://github.com/dbcls/sparqlist>) to provide REST APIs for executing complex SPARQL queries and subsequent data transformation at once. With SPARQLList, we provide APIs which extract biomedical facts and relations of the entities including genes, variants, diseases, drugs, and interactions from the integrated RDF datasets. These APIs can be used for visualizing data on a Web application which consumes JSON data. For example, at the National Bioscience Database Center (NBDC) and the Database Center for Life Science (DBCLS), we develop the TogoVar database (<https://togovar.biosciencedbc.jp>) for accumulating comprehensive Japanese genomic variations, in which we show annotation data obtained from the SPARQLList APIs using the TogoStanza framework (<http://togostanza.org>).

Further, these APIs are expected to contribute for accelerating AI and ML analysis by providing a relevant subset of the entire graph as a training set for the method to develop. Our group in the Kyoto University is developing methods for predicting pathogenicity of variants and relations of variation-drug to help experts curating variants of uncertain significance (VUSs). Then the curated interpretations will be incorporated into our Medical genomics Japan Variant Database (MGeND; <https://mgend.med.kyoto-u.ac.jp>). During the course of development, it is required to refine the training set for AI/ML methods. It can be easily accelerated with SPARQLList because each API is documented in the Markdown-formatted text and can be forked and edited to make a customized API for this purpose.

## **PgmNr 1611: Identifying clinically relevant results in 145,000 exomes: Experiences and lessons learned from population genomic screening in the Geisinger MyCode® Community Health Initiative.**

### **Authors:**

---

The Geisinger MyCode® Community Health Initiative is a biorepository with >240,000 consented patient-participants; exome sequencing and linked electronic health record (EHR) data are currently available for >145,000 participants, known as the DiscovEHR cohort. Participants consent to receive clinically relevant results after confirmation in a CLIA certified/CAP accredited laboratory. Reportable results are limited to pathogenic and likely pathogenic variants in 61 genes reviewed for actionability using internal criteria and definitions proposed by the CDC and the ACMG secondary findings recommendations.

Timely identification of clinically relevant results from a dataset at this scale requires an efficient and systematic filtration pipeline. To meet this need, we shifted from the standard patient-centered approach that focuses analyses on a single patient and developed a variant-first method utilizing both bioinformatics-based filtration and manual review to collate a list of variants across our cohort. In the first 92,456 participants, we identified 73,983 variants passing variant-quality thresholds in our genes of interest. Additional filtering based on population frequency, predicted impact, and ClinVar classification and star status reduced the number to 801 variants in 1,978 participants. These variants then underwent manual review by a variant scientist, further reducing the number selected for clinical confirmation by 34% to 527 in 1,139 participants, resulting in a clinical confirmation cost savings of 42%.

Variant annotations from external sources are versioned and stored in a database that seamlessly recognizes changes as annotations evolve, facilitating identification of variants requiring re-review. Technical hurdles included harmonizing variant nomenclature across annotation sources. Interpretive challenges arose around the variant-first approach, including identification of inaccurate variant calls, complex variants, and compound heterozygous individuals.

Large-scale population genomic screening poses new challenges compared to current patient-centered interpretation pipelines. We have developed a scalable, variant-first method for timely identification of clinically relevant results and a dynamic data management strategy that accounts for the evolving nature of genomic knowledge. By combining bioinformatics-based filtration with a focused variant scientist review, we have increased the specificity and the cost-effectiveness of our approach.

## PgmNr 1612: Implementing a scalable sequencing analysis pipeline for clinical whole-genome samples using pipeline accelerators.

---

**Abstract:** Decreasing costs in next-generation sequencing (NGS) and the increasing importance of non-coding regions in clinical interpretation have prompted a shift from whole-exome sequencing to whole-genome sequencing (WGS) in clinical sequencing projects. The Baylor College of Medicine Human Genome Sequencing Center (BCM-HGSC) sequences and analyzes over 2,000 human whole-genome samples per month from multiple projects and collaborators, with a growing number of these samples as part of clinical studies. Adapting WGS analysis to clinical projects introduces additional analysis requirements, such as shorter turn-around times and the reliable detection of variants with known clinical significance.

We present a sequencing analysis pipeline for analyzing whole-genome clinical samples sequenced on the Illumina NovaSeq platform from FASTQ sequences to alignment, variant calling, and variant annotation. This pipeline is modeled from NHLBI TOPMed analysis specifications, using the GRCh37 human reference genome, with optimizations for computational scalability. We utilize software with low computational resource requirements in various pipeline steps, including xAtlas, a lightweight SNV and small indel variant caller developed at BCM-HGSC. Further improvements being evaluated in scalability are the use of Sentieon NGS data processing software or Illumina's DRAGEN platform. Sentieon's highly optimized BAM and CRAM-processing produces alignments that are nearly identical to those processed by more conventional sequencing analysis software, while providing a two-fold to eight-fold decrease in processing time for BAM and CRAM-processing pipeline steps. DRAGEN Platform uses high configurable FPGA to provide hardware-accelerated implementations of genome analysis.

We hope to show comparisons on WGS runs of various validation samples which will include numerous variants. Once complete we wish to show results describing variant recovery and computation performance improvements due to the accelerators used.

Our pipeline is implemented as a Snakemake workflow, which allows flexible control of pipeline and execution parameters. Clinically significant variants, including those from ACMG and OMIM panels, were confirmed to be detectable by analysis in validation samples.

## PgmNr 1613: Joint taxa/gene analysis of metagenomic sequencing data.

In microbiome research, metagenomic sequencing generates enormous amounts of data. These data are typically classified into taxa for taxonomy analysis, or into genes for functional analysis. However, a joint analysis where the reads are classified into taxa-specific genes is often overlooked.

To enable the analysis of this biologically meaningful feature, we developed a novel bioinformatic method, accompanied by a software toolkit, MetaPrism, to analyze sequence reads for a set of joint taxa/gene analyses: 1) classify sequence reads and estimate the abundances for taxa-specific genes; 2) tabularize and visualize taxa-specific gene abundances; 3) compare the abundances between groups, and 4) build prediction models for clinical outcome.

We illustrate these functions using a published microbiome metagenomics dataset from patients treated with immune checkpoint inhibitor therapy and showed the joint features can serve as potential biomarkers to predict therapeutic responses.

MetaPrism is freely available at <https://github.com/jiwoongbio/MetaPrism>.

## PgmNr 1614: Database and supercomputer resources for human data at DDBJ.

### Authors:

Y. Kodama <sup>1</sup>; A. Fukuda <sup>1</sup>; T. Hachiya <sup>2</sup>; C. Hata <sup>1</sup>; J. Mashima <sup>1</sup>; T. Fujisawa <sup>1</sup>; M. Kawashima <sup>3</sup>; L. Toyooka <sup>3</sup>; N. Mitsunashi <sup>3</sup>; O. Ogasawara <sup>1</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Bioinformation and DDBJ Center, National Institute of Genetics, Mishima, Shizuoka, Shizuoka, Japan; 2) Genome Analytics Japan Inc., Tokyo 162-0067, Japan; 3) National Bioscience Database Center, Japan Science and Technology Agency, Tokyo 102-8666, Japan

As a centralized repository, the Japanese Genotype-phenotype Archive (JGA, <https://www.ddbj.nig.ac.jp/jga>) provides access to raw and processed personal genomes from array-based and next-generation sequencing platforms, and related phenotype data, in collaboration with the National Bioscience Database Center (NBDC) of the Japan Science and Technology Agency (<https://humandbs.biosciencedbc.jp>). NBDC has established data sharing guidelines and policies, and its Data Access Committee (DAC) permits submission and access requests to JGA. Summaries of available JGA studies are listed at <https://ddbj.nig.ac.jp/jga/viewer/view/studies> (100 studies, 236,593 samples and 72 terabytes of data files as of 28 May 2019).

The JGA system is connected to our secure supercomputer through a high-speed network so that users can smoothly download and analyze data with pre-installed bioinformatics tools on the supercomputer.

We have improved our database and supercomputer resources by implementing the Global Alliance for Genomics and Health (GA4GH) standard ontologies and tools. 1) Data use restrictions (policies) of the JGA datasets have been tagged with the Data Use Ontology codes (DUO, <https://github.com/EBISpot/DUO>) to allow searching use conditions such as 'datasets available for cancer research'. 2) The standard variant-call pipeline is made available in Common Workflow Language (CWL) (<https://github.com/ddbj/human-reseq>) so that users can reproduce calling results by running the same workflow on different computers.

To promote group collaboration using pre-publication research data, we also started a new service "DDBJ Group Cloud (DGC)" in February, 2017. One example is the "AMED Genome Group Sharing Database (AGD)" for sharing human genomes among researchers funded by AMED (Japan Agency for Medical Research and Development). AGD and JGA use the identical data model, and AGD data can be easily transferred to JGA upon data publication.

In the poster, we present recent developments of our database and supercomputer systems for archiving, sharing and analysis of human data.

## PgmNr 1615: Surfing petabytes of genomic data from your laptop.

As terabyte-scale human genetic datasets become increasingly ubiquitous, advanced programming and technical skills are becoming necessary for participation in genomic research. Analysis at such scales exceeds the capabilities of all but the largest computational clusters and makes interactive data exploration impractical. In order to empower scientists with a broader range of computational backgrounds, we present a simplified genomic analysis framework built on scalable software. Recent projects like Hail and Bystro have addressed this challenge of scale in two different ways. Hail is a powerful toolkit that enables a wide range of analyses on arbitrarily-large datasets, used on projects like gnomAD to generate public summary statistics. However, it is relatively complex, and is optimized for processing entire datasets at the cost of lower efficiency on some individual tasks, like variant/sample annotation and filtering. In contrast, Bystro provides efficient variant/sample annotations, as well as millisecond natural-language queries in a simple web interface, but is less flexible.

Here we introduce Bystro Analyze, which combines the strengths of both methods and makes genomics at petabyte scales available in an easy-to-use, modern web application. It enables researchers to perform tasks such as variant/sample quality control, natural-language filtering, and association tests on datasets at the scale of UK Biobank and gnomAD, without requiring programming experience. Most importantly, we introduce a searchable analysis exchange, where users can share custom analysis pipelines for others' benefit. These editable widgets enable non-programmers to build and share complex analyses at scale. For instance, one could perform ancestry PCA based on gnomAD loadings in a few clicks with this system.

To demonstrate its abilities, we used Bystro Analyze to re-analyze all 125,748 whole exomes and 15,708 whole genomes from gnomAD. Annotation was completed with roughly 500-fold greater efficiency than previously described. The natural-language search engine was then used to perform a number of tasks with nearly interactive performance. For instance, identifying the number of high-confidence predicted loss-of-function mutations in the gnomAD dataset took roughly 1 second. In short, Bystro Analyze dramatically simplifies genomic analysis at large scales, bringing into reach for a diversity of scientists tasks previously only possible at the most resource-rich institutions.

## PgmNr 1616: A flexible simulation toolkit for designing and evaluating ChIP-sequencing experiments.

---

Chromatin immunoprecipitation followed by next-generation sequencing (ChIP-seq) is a widely used technology for genome-wide mapping of the location of DNA-associated proteins, such as transcription factors (TFs), histone modifications (HMs), and chromatin regulators (CRs). Dozens of methods have been developed for quantitatively analyzing ChIP-seq data, including peak callers (e.g., MACS2, HOMER) and differential binding tools (e.g. diffbind, DESeq2). A major challenge in training and evaluating these methods as well as interpreting their results is a lack of reliable ground truth data: in most cases, the actual location and strength of binding sites is not known and cannot be reliably measured using orthogonal experimental techniques. Accurate simulation of ChIP-seq data can mitigate this challenge, but existing frameworks are either too cumbersome to use or do not capture important sources of variation present in real data such as pulldown non-specificity or fragment length variability. Here, we present Tulip (Toolkit for simULating IP-sequencing data), a flexible toolkit for rapidly simulating ChIP-seq data based on realistic statistical models of key steps of the ChIP-seq process. Tulip simulates four key steps of ChIP-sequencing: Shearing, Pulldown, PCR, and Sequencing. Tulip consists of two modules, learn and simreads. The learn module infers model parameters such as shearing fragment length distribution, antibody specificity, and PCR duplicate rates, from existing data (Peak and BAM file). These parameters can then be used as input to simreads, which simulates ChIP-seq reads in FASTQ format based on specified model parameters. We demonstrate the utility of Tulip with two use cases: (1) measuring power to detect binding sites under a range of experimental conditions and (2) analyzing the effects of spike-in normalization controls. Tulip is implemented using C++ with multithreading capabilities and is currently available on github. Overall, Tulip is an efficient, versatile ChIP-Seq simulation framework with the capabilities to generate realistic datasets over a flexible range of experimental conditions.

## PgmNr 1617: Machine learning models for classification of small sample size RNA sequencing data.

**Authors:**

S. Listopad; T.M. Norden-Krichmar

[View Session](#) [Add to Schedule](#)

**Affiliation:** University of California, Irvine, CA, USA

---

**Background:** Most studies are limited to small numbers of samples due to the high costs of recruitment, sequencing, data storage, and analysis. This results in many data sets with a low number of samples and large number of features, making classification challenging for machine learning (ML). For example, our study has RNAseq data from 36 individuals with alcoholic hepatitis (AH) and from 20 healthy controls. Our overall aim is to establish the best ML model for classification of gene expression counts to correctly distinguish AH from healthy samples.

**Methods:** We examined four types of ML models for classification of the RNAseq samples: Logistic Regression, Gaussian Naïve Bayes, k Nearest Neighbors (kNN), and Support Vector Machines (SVM). We used the Python scikit-learn implementation of these models with the default settings. The samples were obtained from the Southern California Alcoholic Hepatitis Consortium, RNA sequenced with 2x100 paired-end Illumina HiSeq, followed by standard RNAseq quality control. The Tuxedo pipeline generated distribution normalized counts for every sample. We performed 10-fold cross validation with feature selection of the top differentially expressed genes (DEGs) using CuffDiff. The top DEGs were filtered for  $\text{abs}(\log_2(\text{fold change})) \geq 1.0$ ,  $\text{FPKM} \geq 1$ , and significance at FDR-adjusted  $p\text{-value} \leq 0.05$ . The ML classifiers were then trained and validated with the top ( $p=10, 20, 35, 50, 100, 250, 500$ ) DEGs. Accuracy was used as a performance metric.

**Results:** Our initial testing indicated that all four models required at least 50 features to achieve classification accuracy of 90% or higher. As the number of features increased, the performance increased until it plateaued around 500 features. Gaussian Naïve Bayes was the best performing classifier at 98% accuracy with a large number of features ( $p = 250$  and  $500$ ). Regularized logistic regression and regularized linear SVM classifiers also performed well at 95% ( $p=250$  and  $500$ ). The kNN algorithm ( $k=7$ ) performed the worst across all feature sets, but still achieved classification accuracy of 92% ( $p=500$ ).

**Conclusion:** Preliminary results for our small sample size RNAseq dataset indicated that Gaussian Naïve Bayes was the best performing classifier given a large number of features. With a smaller number of features, classification accuracy near 90% was reached across all models. Transforming the features and tuning each individual model can obtain further improvements in accuracy.

# PgmNr 1618: DeepRepeat: De novo identification of tandem repeats on electric signal data from Oxford Nanopore sequencing.

## Authors:

Q. Liu <sup>1</sup>; K. Wang <sup>1,2</sup>

[View Session](#) [Add to Schedule](#)

## Affiliations:

1) Raymond G. Perelman Center for Cellular and Molecular Therapeutics, Children's Hospital of Philadelphia, Philadelphia, PA 19104, USA; 2) Department of Pathology and Laboratory Medicine, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA 19104, USA

---

**Background:** Tandem repeats represent a common type of genomic sequence variation in human genome. Several repeat expansions have been associated with different types of human diseases. These repeats can range from hundreds of bp to thousands of bp, and are much longer than the read length of short-read sequencing platforms. Long-read sequencing on the PacBio and Oxford Nanopore platform have been used to detect repeat expansions due to the ability to generate longer reads than repeat regions. For example, we previously developed RepeatHMM, which uses a hidden Markov model on long reads to quantify the number of repeats in known repeat regions. However, the error rates of base calls in repeat regions are higher than other regions due to the low complexity, which poses a challenge for repeat quantification from sequence data alone. Several recent studies showed that signals from Nanopore sequencing may be used to identify repeats with sophisticated machine-learning techniques.

**Methods:** We developed a computational method called DeepRepeat, which uses deep learning to estimate self-similarity of Nanopore signals of adjacent subsequences with repeat length, and then automatically detect repeat regions in long reads. To do that, long reads are aligned with a reference genome, and then the portions in long reads which are aligned with candidate repeat regions are identified. The signals distribution of events in the identified regions and adjacent events are used as input of DeepRepeat to make the predictions on whether the events are repeat units in a repeat region, outside a repeat region, insertions or deletions in a repeat region.

**Results:** From analysis of real data, we demonstrated that regions with tandem repeats show highly characteristics signal intensity patterns compared to neighboring regions. We next evaluated DeepRepeat on several whole-genome sequencing data sets and amplicon sequencing data sets generated by Oxford Nanopore sequencing. We compared the results with those obtained from analyzing sequences of long reads directly. Our analysis demonstrated that DeepRepeat can improve the quantification of repeat counts in tandem repeat regions, and can perform de novo detection of novel repeat expansions.

**Conclusion:** Our evaluation suggests that Oxford Nanopore sequencing together with DeepRepeat provide a useful tool to identify tandem repeats at a genomic scale, and may facilitate the discovery of repeat expansions associated with human diseases.

## PgmNr 1619: Entanglement mapping: A model-free approach to detecting interactions among predictive features.

### Authors:

---

In many genome-wide association studies (GWAS), the proportion of variation in disease risk or quantitative trait measurement that can be attributed to individual significantly-associated genetic variants has tended to be small. One possible reason is that most GWAS look at only single risk factors or independent features, and do not examine potential interactions among all such features. That is, individual features, such as genotypes and environmental measures, may be only weakly predictive in themselves, but strongly predictive when part of a subgroup of other features. We provide a scheme for identifying such *entangled communities* of interacting features and demonstrate its performance on simulated data.

This scheme for locating entangled features requires only a single pass through the full (potentially large) list of features. The method removes or randomizes a feature and determines which of the remaining features are also down-weighted in importance (using any reasonable feature importance method) when compared to the analysis with all features. All the features in the identified subgroup are *jointly* necessary for good prediction, but individually may be only weakly predictive. For each down-weighted subgroup, this entire set of features must be included for good prediction. Simulations show the algorithm can detect: (1) higher order interactions of more than two features, (2) interactions that don't follow the multiplicative model, (3) multiple sets of interacting features, and (4) interactions in the presence of noise features and main effects.

This is a model-free, parameter-free scheme for detecting jointly predictive features and works with any learning machine.

## PgmNr 1620: ClinGen Linked Data Hub: Scalable infrastructure for aggregation of diverse types of variant information to support pathogenicity assessment.

Variant pathogenicity assessment requires evaluation of numerous data types such as functional, population, case-level and in-silico predictors. The ClinGen Linked Data Hub (LDH) aggregates structured data from a diverse set of sources, ensuring variant curators have access to current evidence. LDH is a scalable and extensible infrastructure to facilitate efficient access to collated information about any subject such as genes, variants and others to support curation efforts. Using newly developed W3C Linked Data technologies, LDH enables contributors to link information about variants registered in the ClinGen Allele Registry (CAR) and store a subset of relevant structured information within the LDH itself. LDH tracks provenance of the information and provides a permanent reference for inclusion as supporting evidence in variant interpretations. Select data and links are stored in LDH as “quotes” indicating that specific information (i.e. “*Linked data*”) about the variant (i.e. the “*Subject*”) was provided by a specific source at a specific time (“*provenance*”). The “quote content” is modeled using the ClinGen/GA4GH community standards.

LDH is implemented using the Genboree platform, which also provides cloud-hosted tools for modeling, validation, and hosting of detailed information which may be linked through LDH. It is accessible via a user interface linked through the CAR and also via APIs for use by ClinGen curation tools including the Variant Curation Interface (VCI), the Pathogenicity Calculator as well as by the tools developed outside of ClinGen. LDH can/will support notification capabilities over all tools, thus facilitating resolution of discrepancies due to stale information, and keep variant knowledge up to date. LDH integrates with the ClinGen community annotations available through Hypothes.is, and also with the WikiData Gene Wiki project. Here, we present the beta version of the LDH resource linking information from 40 genes and over a million variants for use by the VCI. We demonstrate tools for modeling and linking layers of variant evidence from Genboree-hosted Functional Data Repository (FDRRepo), Case-level Data Repository (CDRepo) and other external data sources, tracking provenance and provision of permanent references. Finally, we explore the future potential of the novel approaches for exchanging genomic information first implemented by LDH to empower clinical

genomics and genetics and also to open new roads to discovery in genomics.

## PgmNr 1621: Evaluation of bioinformatic pipelines performances in detecting germline variants.

**Authors:**

R. Minillo; M. Cervato; M. Caraciolo; G. Carvalho; R. Reis; T. Almeida; J. Filho

Bioinformatic pipelines have become crucial components in interpreting next generation sequencing (NGS) data. However, there is high variability between pipelines performances currently used in routine clinical genetic diagnosis. In order to minimize this issue we developed a web platform for costumed annotation and analysis of NGS data called Varstation. We evaluated the performance of six bioinformatic pipelines suitable for Varstation ([www.varstation.com](http://www.varstation.com)) and also used by Genomika Einstein laboratory for routine clinical diagnosis. We sequenced sample NA12878 with comercial kits used in our laboratory and we compared the list of variants found using six pipelines that were available at Varstation with gold standard variants of sample NA12878. We used FASTQ files as well as other entry files and performed all bioinformatic steps at Varstation. All pipelines analyzed have mapping, aligning reads to reference genome, variant calling and variant annotation steps. In each step, quality measurements were performed in order to guarantee a good quality of the data. The main germline pipelines available at Varstation were evaluated according to good international guidelines for variant calling. Our analyzis showed that these pipelines reached precision of 99%, sensitivity higher than 95% and accuracy higher than 96%. We report the performance of bioinformatic pipelines available at the web platform Varstation and our results show high precision, sensitivity and accuracy in identifying variants of sample NA12878. This analyzis is important for checking the performance of these tools and should be implemented in every center that analyzes NGS data.

## PgmNr 1622: Unsupervised deep representation learning for genetic variant-based clustering of individuals.

Clustering of individuals based on their genetic variation is a fundamental step towards identifying novel disease subtypes and precisely tailored treatments as well as geographic population structures. The next-generation sequencing technology allows researchers to capture accurate genome sequences in reads. The optimization in secondary analysis such as Microsoft Genomics service substantially accelerates reads-to-variants workflow identifying genome-wide variants at scale. However, the extreme high-dimensionality of the variant data and the relatively small amount of available data points limit its utility for unsupervised learning in the tertiary analysis. Here, we propose to utilize Deep Embedded Clustering (DEC), an unsupervised deep learning approach that transforms the high-dimensional genetic variants into low-dimensional latent representation and that iteratively refines the learned representation to be suitable for clustering analysis. More specifically, we pre-trained deep autoencoder model to get initial representation. Then, the weights and biases of the encoder network have been additionally updated by feeding clustering loss as an objective which forces ambiguous sample points to be nudged toward the most probable centroid in the latent space based on Kullback-Leibler divergence between the student's t-distribution and the target distribution. We compared our approach with baseline models which are equipped with widely-used dimensionality reduction algorithms, such as Principal Component Analysis (PCA), Multi-dimensional Scaling (MDS), Locally-Linear Embedding (LLE), and Isomap, and the following clustering algorithms, including k-Means, Gaussian Mixture Model, and Spectral Clustering. To evaluate clustering performance, we used Microsoft Genomics service to call variants of 448 individuals in the 1000 genome project and clustered their origins (African, British, Chinese, Colombian, and Finnish) in an unsupervised manner. Our approach successfully recovered the population structure of different origin and surpassed the best performing baseline method in terms of clustering accuracy (increased by 28%). Potential applications of our approach include identification of novel disease subtypes based on genetic variation and characterizing patient groups to optimize medical treatments.

## PgmNr 1623: OpenCRAVAT: A customizable annotation and prioritization pipeline for genes and variants.

### Authors:

K. Pagel <sup>1</sup>; L. Zheng <sup>1,2</sup>; R. Kim <sup>3</sup>; K. Moad <sup>3</sup>; M. Ryan <sup>3</sup>; R. Karchin <sup>1,4,5,6</sup>

The modern genetics researcher is confronted with hundreds of published methods to interpret variants. There are databases of genes and variants, phenotype-genotype relationships, algorithms that score and rank genes, and in silico variant effect prediction tools. Because variant prioritization is a multi-factorial problem, a welcome development in the field has been the emergence of decision support frameworks, which make it easier for users to integrate many resources in an interactive environment. Current decision support frameworks are limited by closed proprietary architectures, access to a restricted set of tools, lack of customizability, web dependencies that expose protected data, and limited scalability.

OpenCRAVAT is a new open source, scalable decision support system to support variant and gene prioritization, relevant to inherited disease and cancer. It offers a dynamic biologist-friendly GUI, allowing users to: install with a single command, easily download tools from an extensive resource catalog, create customized pipelines, run jobs at speeds that exceed current variant annotation API services, and explore results in a richly detailed viewing environment. OpenCRAVAT is distinguished from similar tools by the amount and diversity of data resources and computational prediction methods available, which span germline, somatic, common, rare, coding and non-coding variants. We have designed the OpenCRAVAT resource catalog to be open and modular to maximize community and developer involvement, and as a result the catalog is being actively developed and growing larger every month.

We will present several case studies to illustrate the design of custom workflows to prioritize causal variants. OpenCRAVAT is freely available for non-profit use at <https://opencravat.org>

## PgmNr 1624: Integrative multi-omic approach to identifying functional amino acids.

Each of the 20 common amino acids have unique side chains that confer chemical property differences. This diversity contributes to the challenges presented in the clinical interpretation of missense variants from whole exome sequencing data. Various computational methods have been developed to predict missense deleteriousness. However, the predictive power of these tools is somewhat limited, particularly for poorly characterized genes. We hypothesize that further integration of protein-level information with these predictive algorithms will allow us to better interpret the potential effects of missense mutations. Here we investigate the relatedness between protein composition and gene intolerance to change. We used the non-redundant UniProtKB H. sapiens proteome as our reference proteome, quantified each amino acid's abundance per protein and normalized by protein length, and used pLI gene constraint scores provided by gnomAD. We found that the abundance of certain amino acids is significantly associated with higher odds that the gene is constrained (pLI > 0.9). When proteins are binned into three equal-sized groups based on normalized amino acid abundance (low, medium, or high), we found that abundance groups with the highest odds ratio for the occurrence of gene constraint were low leucine (OR 1.98, CI 95% 1.82-2.15), high serine (OR 1.67, CI 95% 1.54-1.81), and high aspartic acid (OR 1.66, CI 95% 1.52-1.80). Constrained genes have lower proportions of leucine and cysteine (mean difference -0.012 and -0.005, respectively) and higher serine and aspartic acid (mean difference 0.006 and 0.005, respectively) compared to non-constrained proteins. By probing questions like the one presented here through the integration of multi-omic datasets, we hope to identify important associations between features corresponding to different levels of the central dogma, and ultimately advance our understanding of functional variation.

## PgmNr 1625: LocusFocus: A web-based tool to prioritize genes and tissues for study from genome-wide association studies.

The majority of genome-wide association studies (GWAS) have identified trait-associated loci that fall within noncoding regions. Understanding how associated loci impact disease requires significant investigation since they can be extensive and encompass several genes. Integration of GWAS association results with expression quantitative trait loci (eQTL) can demonstrate colocalization of these independent sources of data and generate hypotheses about the responsible mechanism, gene and tissue of origin to guide functional investigation. Tools to visualize GWAS with eQTL data along with formal evaluation of statistical significance of colocalization across genes and tissues are needed.

We developed the locusFocus tool to facilitate the visualization and formal statistical testing of the colocalization of GWAS and eQTL data. Several approaches to statistical testing of colocalization of GWAS and eQTLs have been proposed, including our own *Simple Sum* (SS) approach (Gong et al 2019) that provides advantages over previously published methods with ability to detect colocalization in the presence of high LD and/or allelic heterogeneity without requirement for specific causal variation assumptions. The locusFocus tool was developed to visualize GWAS summary statistics with GTEx or user-specified eQTL p-values at a given locus in one web-based interactive plot. eQTL p-values from GTEx are obtained from Ensembl via API calls, and positions of genes from GENCODE v19. Pairwise linkage disequilibrium for a user-defined SNP can be displayed for user-selected populations from the 1000 Genomes Project for the GWAS summary statistics. Statistical evaluation for colocalization using the SS for all local genes and user-selected GTEx tissues is carried out and displayed in an interactive heatmap, demonstrating the gene(s) and tissue(s) that are most correlated with the GWAS evidence.

In summary, locusFocus facilitates the standard hypothesis-generating data-integration analyses following GWAS by prioritizing tissue(s) and gene(s). LocusFocus and its full documentation are available at <https://locusfocus.research.sickkids.ca> (Jun. 6, 2019).

## PgmNr 1626: Detecting transcriptional regulatory modules using machine learning.

### Authors:

N. Patel; W.S. Bush

[View Session](#) [Add to Schedule](#)

**Affiliation:** Cleveland Institute for Computational Biology, Department of Population and Quantitative Health Sciences, Case Western Reserve University, Cleveland, OH, United States, Case Western Reserve Univ, Cleveland, Ohio.

Binding of different transcription factors (TFs) in a gene's regulatory region is a pivotal step for the process of transcription. TFs can exert significantly different influence over a gene's expression via the nature of their binding. Although TF binding models such as additive sequential binding of individual TFs and non-additive binding of multiple interacting TFs ("regulosome") have been described, genome-wide characterization of these models has been limited. In this study, we have developed a novel machine learning based approach to estimate the impact of linear additive binding and non-linear binding of individual TFs and TF regulosomes respectively on gene expression. We used elastic net regularized linear regression (ENET) and multilayer perceptron (MLP) based prediction models to predict gene expression for 11,778 protein coding genes. These models were informed using inputs from multiple TF based transcriptional regulatory mechanisms such as TF-TF cooperativity, TF-target gene (TG) binding affinity and gene co-regulation. We aggregated ENET effect estimates and MLP layer weights across all genes to determine the influence of 149 individual TFs and their regulosomes respectively on gene expression in lymphoblast cells. We computed interaction scores using an algorithm called neural interaction detection (NID) for all the possible combinations of TFs to capture their non-linear interaction effects. TFs with the highest effect estimates included the crucial initiation factors (*TBP*, *TAF1* and *POL3RG*), as expected since they are often the first TFs to recognize and bind the transcription start sites (TSS). We also detected 10,391 multi-way TF regulosome complexes binding in the regulatory region (50kb upstream/downstream) of the genes that significantly influenced their expression. Of these, 6,195 were pairwise interactions with the most influential regulosomes (NID scores > 0.1) containing chromatin remodeling TFs such as *CBX5* and *ATF2* and TFs important for hematopoiesis namely *SMAD5* and *POU2F2*. Lastly, we found important regulosome modules regulating genes enriched for terms like Alzheimer's disease (*BHLHE40*, *ELF1*, *SMARCA5*, *CTCF*, *SMARCA5*, and *CREM*, *MEF2B*) and MAPK signaling (*BCL3*, *STAT1*, *TAF1*, *ZNF217*, and *ATF2*, *NFIC*), some of which were novel. Thus, we have devised a framework to efficiently detect and characterize different TF modules that may help us to understand their influence on gene expression as well as on specific phenotypes of interest.

## PgmNr 1627: Enhanced interpretation of genome-wide regulatory data using consensus set of enhancer-target gene assignments.

**Background:** Revealing the gene targets from distal regulatory elements is critical to interpret genome-wide study results, as “cis-regulome” is highly enriched for disease-susceptibility loci. However, this is hampered by limited knowledge about the association between enhancers and their target genes. High resolution experiment/association-derived enhancer-gene links are restricted to a small set of cell types, and their reliability and generalization remain elusive due to the lack of a systematic evaluation. **Methods:** By cross-linking different combinations of enhancer-defining methods across cell types (UCSC ChromHMM tracks, ENCODE DNase hypersensitive sites [DHSs], distal DHSs with correlated promoter DHSs, and FANTOM5 regions) to their target genes using spatial and *in silico* approaches (ChIA-PET links, FANTOM5 links, correlation between promoter and distal DHS signals, and enhancer-gene pairs within the same CTCF loops), we generated ~2,800 human genome-wide distal **Enhancer** (>5kb from a transcription start site [TSS]) to **Target** gene locus **Definitions** (**EnTDef**). We also extended EnTDefs by adding links between non-enhancer distal regions and the nearest TSS to increase the genome coverage up to 90%. **Results:** Using functional annotation and enrichment analysis on 87 independent ChIP-seq datasets of 34 transcription factors (TFs) among ENCODE tier-1 cell lines, we illustrated how the 741 top ranked EnTDefs significantly outperformed simply linking distal regions to the genes with the nearest TSS (FDR < 0.05). Interestingly, enhancers defined by ENCODE DHSs, FANTOM5, and/or DHS signal correlations performed better than those by ChromHMM tracks, and the ChIA-PET links surpassed other enhancer-gene linking methods. The performance of the top 10 EnTDefs on ChIP-seq data from ENCODE non-tier-1 cell lines was close to that from the tier-1 evaluation cell lines, indicating that the selected EnTDefs can be generalized to other cell types. Significantly, the consensus set of EnTDefs across cell types showed comparable results to those generated using the cell-type-specific ChIA-PET links, suggesting the power of our approach to provide cell-type-specific genome-wide interpretation. Therefore, our top ranked EnTDefs provide a valuable resource to interpret cis-regulome data from a variety of cell types.

## PgmNr 1628: SNP ReMap: A tool for updating GWAS summary data across genome builds.

### Authors:

Genome Wide Association Studies (GWAS) have now been performed for more than a decade and have been incredibly successful in identifying disease associated loci, in part due to the widespread sharing of GWAS summary statistics allowing large, well powered meta-analyses to be undertaken.

The data from many of these individual GWAS studies remains available today however they are often not aligned to the latest genome build and in some cases can be several releases older, a problem when attempting to reuse these data sets in current analyses.

Imputation and reanalysis using the relevant genome build would be the best option to resolve this but often is not possible for a variety of reasons, such as an inability to access the original genotype data or contact the original analysis team.

Whilst options do exist to allow the bulk update of variant positions across genome builds they generally do not provide information on changes to the strand orientation of the variants, information critical to the incorporation of the summary data into any analyses.

To address this problem we have extended to GWAS summary data the concept we previously developed for directly genotyped array data, namely that of utilising the mapping of variant flanking sequences to a reference genome to derive their positions on multiple genome builds.

In this instance we have used the fasta sequences for every dbSNP variant from build 151 to provide the variant flanking sequence data. These have been aligned to the reference genomes using BLAT utilising settings designed to maximise the number potential alignments. To ensure the widest compatibility we have used all the genome builds relevant to the GWAS time period from NCBI35 to GRCh38. The alignments for all variants are then parsed to determine the best match to the genome in terms of both length and concordance. From this the position and strand orientation are derived for all aligned variants. Variants not matching the genome to the required concordance are noted as are variants exhibiting no discernable match. Variants showing multiple high quality matches are also recorded along with their alternate positions.

To date we have successfully used the program to update multiple data sets as part of our latest meta-analysis efforts and at the moment have been able to update on average more than 98% of the

variants successfully for both position and strand. We plan to further optimise this to increase the number of successful alignments.

## PgmNr 1629: Integration of best practice RNA-Seq workflows into cloud-based translational analysis platform.

The Broad Institute has a long history in genomic sequencing and in the development of tools for researchers to analyze these data. With improvements in technology and reductions in cost, the rate of sequence generation is increasing, which necessitates a platform to scale the associated analyses. We also need to be able to apply our best practice methods across a range of complex workflows to support the breadth of science among our users. This challenge is what spurred the creation of the Translational Analysis Group (TAG) within the Genomics Platform at the Broad Institute. Over the past two years, our group has developed and maintained over 30 validated, version-controlled workflows and has run over 20,000 analyses on Terra, the Broad Institute's cloud-based analysis platform. Until recently, we have mainly focused on supporting germline and somatic variant analyses on whole genome and exome libraries, however, there is high demand to integrate RNA-sequencing (RNA-seq) into the analyses. In this presentation, we introduce our new RNA-seq workflows for bulk and single-cell RNA experiments. Our suite of RNA-seq workflows starts with mapping RNA reads to a reference genome and then profiles gene and the isoform expression. The bulk RNA-seq outputs can be used as inputs for the downstream workflows to perform differential expression and RNA variant calling analysis. For evaluating the workflows, we benchmarked with publicly available datasets such as GTEx to check the expression and the RNA variant calls against the matched exome. The development of our RNA-seq analysis capabilities increases the scope of projects, both internal and external, for which TAG can provide analysis services with the reproducibility, scalable resources, and version control necessary for consistency in studies which extend over a long period of time, such as clinical trials.

In medical genetics and related fields, Human Phenotype Ontology (HPO) analysis has become one of the standard methods for diagnostics. Current algorithms such as Exomiser and Phenomizer use a variety of semantic and statistical approaches to prioritize the typically long lists of genes with candidate pathogenic variants, but do not provide robust estimates of the strength of the predictions beyond the placement in a ranked list, nor do they provide measures of how much any individual phenotypic observation has contributed to the prioritization result. Here, we present an approach to genomic diagnostics that exploits the clinical likelihood ratio framework to provide an estimate of the posttest probability of candidate diagnoses, the likelihood ratio for each observed HPO phenotype, and the predicted pathogenicity of observed variants. These tools will help clinicians interpret the contribution of each individual phenotypic abnormality. The odds ratio for the variants provides a measure of the probability of the gene to harbor rare, predicted pathogenic variants in the general population.

We curated a collection of 236 detailed clinical case reports from a wide range of Mendelian diseases, capturing clinical abnormalities as HPO terms and recording the disease-causing variants and the diagnosis. We spiked the variant into an otherwise “normal” VCF file and then ran LIRICAL. The correct diagnosis was placed at rank 1 in 178 of 236 cases (75%), within the top three candidates in 92% and within the top ten in 97%. The performance of Exomiser on the same dataset was 51% at rank 1, 56% within the top 3 ranks, and 83% within the top 10 ranks. On a set of solved 108 cases from the 100,000 Genomes Project, LIRICAL ranked 50/108 as the top hit, and put 82/108 in the top 5. This compares to 76/108 and 98/108 for Exomiser 12.0.0., suggesting that the performance of genomic diagnostic algorithms can be dataset dependent. By setting a minimum threshold of 75% posterior probability, LIRICAL was effective at limiting the number of candidates that require detailed manual review by diagnosticians. Additionally, LIRICAL provides a graphical output of the contribution of each query HPO term to the diagnosis. In summary, LIRICAL provides clinically interpretable results for phenotype-driven genomic diagnostics with performance comparable to current state of the art tools.

## **PgmNr 1631: Disease-specific enhancement for biological networks improves prioritizing candidate disease genes.**

### **Authors:**

P. Ruan <sup>1</sup>; S. Wang <sup>2</sup>

[View Session](#) [Add to Schedule](#)

### **Affiliations:**

---

Biological networks-based strategies have been proven to be useful in prioritizing candidate genes in various diseases. A number of comprehensive human gene networks have been developed, such as HumanNet, GIANT and STRING. However, these comprehensive human gene networks are not disease-specific and cannot be used to represent true gene interactions for a specific disease. Here, utilizing an established human gene network, the HumanNet, we propose a framework that enhances the comprehensive gene network for a specific disease using disease-specific omics data through a diffusion process. This diffusion process uses a doubly stochastic transition matrix generated from disease-specific omics data. The enhanced disease-specific gene network thus has weak edges from the original network being removed and disease-specific gene connections being enhanced. Through a random walk, the enhanced disease-specific network helps prioritize candidate disease genes for a specific disease. Applications to gene expression data of multiple cancers from The Cancer Genome Atlas (TCGA) project suggest that more prioritized candidate genes by the enhanced disease-specific networks are cancer-related than those by the original general human gene network as well as those selected using omics analysis only.

## PgmNr 1632: Improved detection of allele-specific expression via personalised mapping approaches.

---

A key feature of the genetic architecture of complex traits is that many variants associated with disease are in non-coding regions and overlap significantly with variants modulating gene expression, thus making a strong case for the role of gene regulation in disease. On a population scale, variants influencing gene expression are detected through expression quantitative trait loci (eQTL) mapping, but this is not possible when sample sizes are small, or variants are rare. In these cases, detection of an imbalance in the expression of two alleles within a gene (allele-specific expression, ASE) is potentially more informative about genes that are undergoing genetic regulation in *cis*. However, this approach is susceptible to false positives due to technical factors affecting RNA-seq data such as read mapping bias. We have developed a pipeline that minimises errors in ASE detection through multiple steps of filtering, and incorporating isoform-aware parental genome mapping and haplotype structure resolution. We apply this pipeline to simulated RNA-seq and whole-genome sequencing data and show that it dramatically improves the accuracy of ASE calls, particularly in regions surrounding indels and rare variants. We also use the pipeline on real data from the HipSci project ([www.hipsci.org](http://www.hipsci.org)), where we see better coverage around heterozygous sites and reduced reference allele bias, thus facilitating more accurate detection of ASE events. We anticipate our pipeline to be useful when sample size is small, particularly for rare diseases.

## PgmNr 1633: Efficient and rapid clustering of identity-by-descent tracts in biobank-scale datasets.

### Authors:

---

Community detection for clustering of identity-by-descent (IBD) segments along the genome offers a powerful approach for rare disease mapping in massive population-based biobanks. However, when developing methods that scale efficiently, several challenges need to be addressed. First, methods that detect IBD in massive datasets use approximate matching techniques and are more prone to higher error rates. Second, IBD sharing in biobank-sized datasets poses a scale challenge, with the potential for billions of IBD segments to be present in modern datasets, such as the UKBiobank. This intensifies the need to rely on robust clustering techniques able to accurately identify IBD patterns and account for error at scale.

To remedy this situation we have developed a clustering method that employs robust community detection algorithms to scalably and accurately cluster IBD-haplotypes. iCURL (Identity-by-descent ClUstering of Related Loci) uses an efficient implementation of Markov Clustering in sliding windows along the genome to characterize overall patterns of relatedness and modularity diverse population settings. It also uses parallel computing libraries, available on scientific computational clusters, to further improve its performance. We also describe a novel community simulation technique to simulate realistic patterns of IBD clusters determined from real data in order to measure the performance of each algorithm and optimize its parameters. These simulations help us understand the effects of different windowing methods utilized by IBD mapping tools to reduce runtime and memory use, while calibrating clustering thresholds to improve statistical power. We compare iCURL with DASH-CC, a greedy algorithm designed for scalability. For the PAGE Study dataset of ~52,000 individuals with 15 million segments shared by IBD, iCURL took 132 minutes, compared to 466 minutes for DASH-CC, while both running on a single thread. Using a less restricted sliding technique, iCURL runtime can be reduced to under 5 minutes in the same dataset. We describe our strategy for running iCURL on UK Biobank to cluster IBD segments estimated from our ultra-rapid IBD method iLASH. iCURL allows tuning of the clustering inflation parameter that provides the ability to look for both fine-grained and coarse-grained communities sharing IBD. In summary, iCURL enables the investigation of IBD clusters, communities, and modularity with applications for IBD mapping in modern, large-scale datasets.

## PgmNr 1634: Leveraging natural genetic variation to discover DNA motifs mediating transcription factor binding and function.

---

Genome-wide association studies have identified thousands of disease-associated genetic variants. The majority of variants fall into non-coding regions, making the interpretation difficult. Many causal variants influence the binding of transcription factors (TFs) by altering TF binding sites, also called motifs. TF binding can induce the activation of enhancers or promoters and ultimately regulate gene expression. One locus often has more than one altered TF motif, and a genetic variant can alter multiple motifs simultaneously. Prioritizing functional motifs is important but remains challenging. Currently, there is a lack of tools that can identify causal motif alteration for differential TF function.

Here we introduce a statistical framework, MAGGIE (Motif Alteration Genome-wide to Globally Investigate Elements), to discover DNA motifs mediating TF binding, chromatin accessibility, and enhancer activity. We leverage the measurements of TF functions corresponding to at least two genotypes such as different alleles, individuals, or mouse strains. For loci with differential function, the locus-wise motif alterations between genotypes are aggregated and tested against the null hypothesis, which expects a random alteration for motifs that do not contribute to the function of interest.

By simulating genetic variation, we demonstrate that MAGGIE is able to identify motifs more precisely than conventional motif discovery tools. To validate its ability to reveal causal motif alterations responsible for changes in TF function, we tested MAGGIE on allele-specific binding sites computed from ENCODE data. Many TFs solely have their corresponding motifs as significant output by MAGGIE while other tools report many more motifs that are enriched but likely not required for TF binding. Finally, we applied MAGGIE to uncover motifs necessary for activation and repression of inflammatory gene enhancers in macrophages by leveraging H3K27Ac signals from five mouse strains. MAGGIE reports p65 as necessary for activated enhancers and p50 for repressed enhancers even though both TFs belong to the nuclear factor-kappa B (NF- $\kappa$ B) family and their motifs are indistinguishable by other tools. This relationship is validated by experimental assays measuring genome-wide binding of these TFs. Enhancers co-bound by p65 and p50 are activated in response to inflammatory signals, while enhancers bound by p50 alone are repressed.

## PgmNr 1635: CAVERN: Computational and visualization environment for RNA-seq analyses.

### Authors:

**Background:** Over the last decade, there has been an exponential increase in the application of next-generation sequencing technologies to generate transcriptomic datasets. RNA-sequencing is being used increasingly to study gene expression profile in samples and to assess the differential gene expression between conditions in biological research. **Motivation:** The analytical approach of transcriptomic data involves multiple steps. First, the alignment of sequencing reads to a reference genome for each sample. Then quantification of gene expression for multiple samples belonging to 2+ conditions that are compared using statistical approaches to determine differential expression between conditions. This analytical approach requires intermittent checkpoints to control data quality, bioinformatics expertise, large computational resources, and the ability to interact with downstream results. While there are well developed tools for individual steps, few exist that integrate multiple steps into a comprehensive analytical pipeline to provide researchers with an end-to-end solution to quickly and easily process RNA-sequencing data. **Methods:** We developed CAVERN as an analytical resource to facilitate the end-to-end analyses of transcriptomics datasets. CAVERN comprises of a user-friendly interface GROTTTO and an interactive sandbox ALCOVE. GROTTTO allows a user to provide relevant information regarding input files for multiple samples, reference genome sequence and annotation, and to select from multiple analytical modules that support different aspects of the pipeline. A user can modify parameters that influence different analytical steps. GROTTTO enables pipeline creation, monitoring, and the ability to download relevant results. GROTTTO provides a quick overview of the results via a sampling of descriptive illustrations and tables. Alternatively, a user can access relevant data and results within ALCOVE, a R-based Shiny-server application. ALCOVE provides researchers with an interactive environment to view pertinent results, modify analytical features, and make inferences about their biological research questions. CAVERN has been implemented using the Docker framework to enable quick setup for use across multiple operating systems. **Conclusions:** Overall, we were able to develop a user-friendly computational and visualization environment for transcriptomic analyses that is available to the scientific community at <https://github.com/adkinsrs/ergatis-docker-recipes.git>.

## PgmNr 1636: Clinical actionability curation tools and knowledge repository of the ClinGen consortium.

The ClinGen Adult and Pediatric Actionability Working Groups (AWG) assess the clinical implications of human genes and genetic disorders using a standardized protocol. The product of the AWG is evidence-based summary reports that define a known ability to intervene and avert a poor outcome due to a previously unsuspected high risk of disease. These reports of curated evidence provide a resource to aid decision makers as they determine best practices regarding secondary findings. To facilitate generation and dissemination of clinical actionability curation knowledge in both human and machine readable formats, we have developed the following informatics tools: (1) the Actionability Curation Interface (ACI), which is a web-based curation portal, (2) a knowledge repository of curation summaries and reports and (3) REST-APIs to programmatically access structured content.

ACI has been developed to streamline the curation of actionability knowledge in both adult and pediatric contexts and capture the curation workflow, which includes searching literature for evidence, documenting the references, performing an early survey to determine if the topic is actionable and if so, associating sets of gene-disease pairs with outcome-intervention pairs, applying semi-quantitative scores by experts and generating consensus scores, making assertions on the clinical actionability of genetic variations and abstracting data into a structured format. The application provides a transparent and systematic way to access supporting evidence and previous summary report versions, thus facilitating critical evaluation of current as well as prior recommendations in light of evolving evidence.

The ACI and associated services are developed using Genboree Stack, following the microservices architecture and implemented as Redmine Ruby-on-Rails plugins. The application includes role-based access control, allows tracking version histories and a web interface for browsing, filtering, searching and export of curated knowledge. REST-APIs enable retrieval of reports and summaries of individual and consensus scores and structured representation of curated evidence using the SEPIO ontology framework. As of June 2019, 92 genetic disorders have been evaluated and released in the adult context and 18 in the pediatric context. The summary reports and scores are publicly accessible through [actionability.clinicalgenome.org](https://actionability.clinicalgenome.org) and are integrated with other curation efforts of ClinGen through [clinicalgenome.org](https://clinicalgenome.org).

# PgmNr 1637: Memory bandwidth-aware seeding for genome sequencing.

The process of identifying the locations of short substrings of a read in a candidate reference genome, known as seeding, is one of the most time-consuming step in whole genome secondary analysis. For example, in the widely used read alignment software BWA-MEM, seeding consumes 56% of the overall runtime (measured on 50x coverage reads from Illumina Platinum Genomes). In addition, seeding is also a performance bottleneck in several metagenomic classification tools such as Centrifuge.

Seeding is commonly performed using a highly-compressed index structure called the FM-index. While FM-index is highly space efficient (4.3 GB for a human genome), standard seeding algorithms using FM-index are memory bandwidth limited. Our key observation is that this trade-off is not optimal for modern systems which have availability of much large main memory (192 GB on Amazon c5n.18xlarge instance).

FM-index based seeding requires character-by-character processing of a read. Thus, each base-pair in every seed of every read issues a separate lookup into the 4.3 GB FM-index with little to no memory locality. On average, a 101 pb short read requires 108 KB of data from main memory and a complete human genome 158.4 TB of data in 2.72 T DRAM accesses, resulting in a severe memory bandwidth bottleneck.

Our proposed seeding algorithm is based on a new data structure called Enumerated Radix Tree (ERT) designed to addresses this bandwidth bottleneck: it trades-off a larger memory footprint for a significant reduction in memory bandwidth. Instead of using one monolithic large structure for representing all suffixes of the reference genome, like the FM-index, ERT groups together suffixes that share the same K-length prefix and enumerates all such prefixes in a K-mer index table with 1B entries. The suffixes for each prefix are then represented using a radix tree that naturally allows processing of multiple characters using a single lookup. Radix tree nodes that are likely to be accessed sequentially are placed close together in memory to reduce memory accesses during tree traversal. As a result, ERT enables multi-character lookup per memory access while the data structure is sufficiently compact to fit within 64GB of main memory.

Using ERT, we significantly improve the performance of seeding in BWA-MEM by 3.7x and its bandwidth efficiency by 7.57x on a 72-thread AWS c5n.18xlarge instance, while guaranteeing an identical (exact bit-equivalent) output as BWA-MEM (a de facto standard).

## PgmNr 1638: I-pute: A fast genotype imputation method based on positional Burrows-Wheeler transform.

---

Missing genotype data is a major barrier to genome-wide association studies. Modern imputation methods typically leverage a large reference haplotype panel. At this scale, fast methods with low-memory use and high accuracy are needed. We introduce a new computational tool, I-pute, using matching haplotype blocks in the positional Burrows-Wheeler transform (PBWT) matrix in the panel to impute missing data, without external references or complicated statistics methods. PBWT sorts similar haplotypes into blocks of matches at each site. It is very likely that a missing haplotype value remains the same as its neighbor haplotypes at the same site. We can impute a missing haplotype if it is within a block of haplotype matches and the surrounding neighbors have the same value. We compared our approach with Beagle on UK BioBank (UKB) SNP data and 1000G sequencing data with no reference. The results show I-pute runs 2 times faster than Beagle and is at least 10% more accurate on UKB SNP data and at least 3% more accurate on 1000G sequencing data. Non-reference based I-pute provides a fast imputation with high accuracy while avoiding using or choosing reference.

## PgmNr 1639: A bioinformatics-to-lab bench workflow to identify and characterize tandem repeats.

**Authors:**

D. Vandenberg; E. Domico

[View Session](#) [Add to Schedule](#)

**Affiliation:** Biobehavioral Health, Institute for the Neurosciences, Penn State Univ, University Park, Pennsylvania.

---

The “missing heritability” problem for complex traits is proving to be difficult to address. One possible reason is that the most common type of variant assayed (SNP) does not capture the genetic information of nearby variants of different classes. We have chosen to focus on Simple Tandem Repeats (STRs) based on recent results showing that STRs in or near the *AVPR1A* and *CACNA1C* genes are associated with phenotypes that are not associated with nearby SNPs (Landefeld, *et al.*, 2018; Song, *et al.*, 2018). Thus, characterization of repeats in the genome could provide insight into the genetic basis of disease, and it provides a platform for long-term undergraduate student engagement at both the bioinformatic and laboratory levels in a more real-world setting than is often accomplished in short summer internships.

Computational tools have been developed to enable researchers to identify important sequence elements with a focus on short tandem repeats in this project. A workflow was created using “etandem,” (Rice, *et al.*, 2000) to scan through sequence data to identify tandem repeats. It is run within Galaxy (Afgan *et al.*, 2018), a bioinformatics web interface hosted at Penn State, which aids in documenting the work. Resulting STRs were visualized using the UCSC Genome Browser and a candidate STR was chosen for wet-lab analysis by PCR to detect variation in the number of repeats. Pilot tests were done using an STR in the 5′-flank of *SLC6A3* (*DAT1*).

## PgmNr 1640: Searching efficiently through (genomic) sequences with vantage point trees.

Many tasks in computational biology involve determining sequence homology: given one or more DNA, RNA, or protein sequences, find the most similar sequence in a database of known sequences. Examples of this include determining the function of an unknown gene in a gene catalog, or assigning taxonomy information to a bacterial amplicon by finding the closest matching sequence in a database of sequences and taxonomies such as RefSeq.

From a computational perspective, to be able to process large volumes of data in a reasonable amount of time, this lookup must be fast as well as accurate. Standard tools such as Blast are able to provide fast lookups at the expense of some accuracy, whereas more accurate assignments can be obtained with tools such as glsearch or ggsearch (part of the fasta3 package), which perform a slower yet more accurate local-to-local or global-to-global alignment.

We will present a way of indexing databases of sequence data (DNA, RNA, protein, or arbitrary strings) into a vantage point tree, a datastructure which allows fast yet accurate query lookups by building a tree of 'near' and 'far' sequences. We will discuss the theoretical foundations of vantage point tree search, outlining how they achieve the best of both worlds: returning the most accurate match, without any approximations, with lookup time logarithmic in the size of the database. We will compare the behavior of our algorithm against standard tools such as Blast, ggsearch, or the RDP classifier, and we will discuss our reference implementation, showing in particular how a vantage-point tree can be stored efficiently as an array of offsets. This results in a simple, cache-friendly algorithm that can easily be ported across languages and platforms.

Most of our work is centered around databases of 16S amplicon data, for which global alignment distance is most appropriate, but vantage point trees can be used with other notions of distance metric as well. We will finish with a brief discussion of other distance functions and their use in computational biology.

## PgmNr 1641: Scandium: Sequencing coverage annotation database with uniformity metric.

### Authors:

With next-generation sequencing (NGS) technologies becoming routine in biological research and clinical diagnostics, the need for effective tools for quality control, sequence analysis, and annotation are essential to manage an active NGS pipeline and to fully capitalize on the resulting data. While many bioinformatic tools provide post alignment quality control metrics, none report the details of sequence coverage annotated by SNPs, gene, transcript or CDS (coding sequence). Those analyses are particularly useful in the clinical setting for applying stringent quality cutoffs before reporting disease-causing alleles.

To address this need, **Scandium** was developed in C as in-house open-source software. **Scandium** delivers comprehensive sequence QC and coverage metrics, including a newly developed WGS coverage uniformity metric. This metric measures the deviation of sequencing coverage from the central tendency. A low uniformity value alerts users to data variability, whereas a high uniformity value implies a uniform dataset, providing confidence in downstream analysis. Therefore, this metric reveals areas of the genome that are under-represented, with greater efficiency than by measuring average coverage.

For annotation, **Scandium** uses a backend MySQL database populated with publicly available annotation resources with all HGNC approved genes, but users can instead provide custom annotation via a bed file. **Scandium** calculates 'percentage of coverage' for each annotation type in NGS data which users can further customize by specifying cutoffs based on mapping quality, read quality or depth of coverage.

Finally, to visualize these metrics, an additional module creates user-friendly plots for uniformity across specific chromosomes and additional plots to highlight CDS or gene coverage as well as various exome-based and WGS-based coverage distributions.

**Scandium** employs OpenMP, a C/C++ multi-threading API, for faster processing of sequenced data. For a 35X WGS sample Scandium uses only 12 GB of memory and 1 hour of computation time, which is suitable for large sequencing centers and individual laboratories with limited computational resources.

**Scandium** has been used for clinical applications at the HGSC-CL to develop coverage metric paradigms across clinically reportable genes and to assess pathogenic variants at various coverage models.

## PgmNr 1642: A new annotation tool BioSplicer improves variant effect prediction of splice region variants using splicing context-specific alignment.

---

Interpretation of variants called by next generation sequencing data requires accurate annotations of variants, especially for their predicted biological effects. Multiple variant annotation tools have been developed for this purpose and are utilized by research and clinical laboratories. In order to assess the performance of annotation tools, we designed a comparison study between five commonly used programs. We analyzed annotations generated by Alissa (v5.1.3, Agilent), VEP (release 96, Ensembl), VarSeq (v2.1.0, Golden Helix), SnpEff (v4.3T) and ANNOVAR (wANNOVAR, 2019May) for >200,000 variants with matching transcripts from the HGMD database annotations (HGMD\_pro\_2019.1). In reviewing the discrepancies, we found that annotations associated with splice site regions as one of the major sources of inconsistency among these tools. Further analysis showed that alignment of indel variants around intron-exon boundaries is the cause of most of these errors. Discrepancies were observed in all six sources indicating that this is a persistent problem for all tools. Although it is appropriate at the variant calling step to utilize the left-alignment rule for genomic representation of indels, annotation algorithms should be adjusted relative to both the donor/acceptor and intron/exon directions to ensure that the annotations correctly predict the impact on splicing. Our study showed that 50% of the indel variants in and around the splice site regions predicted an incorrect impact in all the annotation tools. Therefore, we developed a new tool "BioSplicer" to automatically re-annotate splicing region indels with biologically correct alignments in order to predict the splicing effect with greater detail and accuracy. This tool can be integrated into a clinical diagnosis pipeline before the mainstream annotation tools are utilized to correct the alignment errors. With BioSplicer installed, all variants affected by this issue were reanalyzed and 78% of them had different annotations. Importantly, 55% of corrected annotations demonstrated category changes, such as a change from a predicted intron-skip to a frameshift and an intron-skip to an in-frame deletion. We expect this tool to facilitate more accurate and reliable variant annotation and disease diagnosis.

## PgmNr 1643: Whole genome sequencing for precision medicine.

### Authors:

Q. Wang; D. Kalra; K. Walker; H. Doddapaneni; J. Hu; R. Raj; Z. Momin; C. Nessner; C. Kovar; S. Dugan-Perez; J. Santibanez; N. Osuji; Z. Khan; J. Farek; S. Kalla; E... Venner; Y. Han; H. Dinh; R. Gibbs; D.M. Muzny

**Affiliation:** Baylor College of Medicine, Human Genome Sequencing Center, Houston, TX.

High-throughput nucleotide sequencing has revolutionized genomic research and reshaped applications in clinical diagnostics. The NovaSeq 6000 platform expanded these opportunities by providing unprecedented capacity and the opportunity for routine clinical whole genome sequencing (WGS). In acceleration to the growing field of precision medicine, the Human Genome Sequencing Center Clinical Laboratory (HGSC-CL) has validated a germline WGS protocol in line with CLIA and CAP molecular requirements. The pipeline is built on more than a decade of experience with WGS of personal genomes, resulting in many process improvements. The development of a new pooling strategy to increase consistency across multiplexed samples, where sequencing libraries are first pooled based upon qPCR quantification and then re-pooled based on the first “calibration” sequencing results, has improved the coefficient of variation (CV) for an 81-plex pool from 17% to 6.4%. We also increased our sequencing yield, generating an average of 3.4 Tbases for each S4 flow cell with 27 WGS samples to yield an average 37x coverage, which exceeds the vendor’s specification. For clinical requirements, we determined that, at 35x average coverage, over 95% of clinically relevant genes (OMIM) are fully covered at 15x. The WGS pipeline now includes more than one hundred quality assessment metrics, including tests for sequencing coverage, sample integrity and representation of expected variants. Sequence coverage routinely exceeds 95% of the genome covered at 20x with a minimum of  $86 \times 10^9$  mapped, aligned bases with Q20 or higher.

An HGSC-CL workflow management system, HgV, is employed for all primary and secondary genome sequence analyses, executing base calling, mapping, merging, variant calling, post-processing and QC metric collection for all single-lane and multiplexed samples. The deliverables include alignment to either human reference GRCh37 or GRCh38, depending on project needs and a coverage analysis with annotation by SNPs, gene, transcript or coding sequence analyzed by Scandium. The pipeline also automates the first step of clinical interpretation, by using the in-house developed tools Cassandra and Mendelian Afterburner to annotate and filter the GRCh37 variants, reducing the review burden of the board-certified clinical geneticist team.

This WGS pipeline will be utilized for clinical WGS programs, including the NIH’s Fetal Genomes Sequencing project, and the National All of Us Research Program.

## **PgmNr 1644: MARRVEL 2.0 (Model organism Aggregated Resources for Rare Variant ExpLoration): A web-tool for human genetics and cross-species data collection.**

Genes and variants of unknown significance are one of the major challenges in understanding the cause of genetic disorders. There currently exists many tools that are useful for assessing the significance of genes and variants to establish a hypothesis that can be experimentally tested. However, the compilation of these dispersed data usually demands either a lot of time or bioinformatics skills. MARRVEL (Model organism Aggregated Resources for Rare Variant ExpLoration) provides a simple, easy-to-use tool for non-computational users interested in gathering data dispersed throughout dozens of tools and databases across the world-wide-web.

MARRVEL2.0 is a complete upgrade from MARRVEL1.0 which has accumulated more than 1600 users per month since 2017. The overall design, features, and backend have all been upgraded to improve user experience, expand functionality, and ensure the ability to stay up to date. The design of the tool emphasizes assistance with data interpretation and ease of navigation. The new features include commonly used pathogenicity prediction algorithms such as CADD and PolyPhen as well as an expanded set of model organism data such as phenotype and gene ontology ribbons that enable at-a-glance comparison across species.

## PgmNr 1645: Model-based autoencoders for imputing discrete single-cell RNA-seq data.

### Authors:

---

Deep neural networks have been widely applied for missing data imputation. However, most existing studies have been focused on imputing continuous data, while discrete data imputation is under-explored. Discrete data is common in real world, especially in research areas of bioinformatics, genetics, and biochemistry. In particular, large amounts of recent genomic data are discrete count data generated from single-cell RNA sequencing (scRNA-seq) technology. Most scRNA-seq studies produce a discrete matrix with prevailing 'false' zero count observations (missing values). To make downstream analyses more effective, imputation, which recovers the missing values, is often conducted as the first step in pre-processing scRNA-seq data. In this paper, we propose a novel Zero-Inflated Negative Binominal (ZINB) model-based autoencoder for imputing discrete scRNA-seq data. The novelties of our method are twofold. First, in addition to optimizing the ZINB likelihood, we propose to explicitly model the dropout events that cause missing values by using the Gumbel-Softmax distribution. Second, the zero-inflated reconstruction is further optimized with respect to the raw count matrix. Extensive experiments on simulation datasets demonstrate that the zero-inflated reconstruction significantly improves imputation accuracy. Real data experiments show that the proposed imputation can enhance separating different cell types and improve the accuracy of differential expression analysis.

## PgmNr 1646: A rapid, accurate approach to inferring pedigrees in endogamous populations.

Despite the availability of multiple software packages for inferring relationships among individuals and reconstructing pedigrees, accurate assignment of relatives from genetic data remains a challenging problem. Certain algorithms are trained only on urban European-descent families, which are 'outbred' compared to many other global populations. Moreover, relationship categories can be difficult to distinguish between relationships with the same kinship coefficient (e.g., half-sibships versus avuncular) without external information. Furthermore, several published packages cannot accommodate endogamous populations where there may be reticulations within a pedigree, or may rapidly become computationally intractable. We designed a simple, rapid algorithm which initially uses only high-confidence 1st degree relationships to seed a machine learning step based on the number of identity by descent segments and a novel summary statistic called a haplotype score. We tested our approach in a sample of ~700 individuals from northern Namibia, sampled from an endogamous population. Due to the culture of concurrent (non-marital) relationships in this population, there is a very high proportion of half-sibships as well as cryptic relatedness. Further, we apply our algorithm to the Colorado Center for Personalized Medicine Biobank at the University of Colorado to detect unknown relationships in a multi-ethnic dataset with sparser training data. Our method accurately identifies all categories in 1st-3rd degree relationships, including differentiating half-sibships from avuncular relationships. Accurate reconstruction of pedigrees holds promise for tracing allele frequency trajectories, improved phasing, and other tangible population genetic and genomic questions.

## PgmNr 1647: *De novo* assembly and characterization of a breast cancer reference sample using multiple whole genome sequencing technologies.

---

The advancements of DNA sequencing technology and genome assembly provide an unprecedented opportunity to comprehensively study the instability of cancer genome, and accurately pinpoint the full spectrum of the underlined genomics changes that contribute to cancer development, thereby uncovering important genetic markers for cancer diagnostic and drug development. Here we present a framework that combines multiple sequencing technologies, including Illumina short reads, 10X Genomics linked reads, Pacbio long reads, and Hi-C (high-throughput chromosome conformation capture) reads, to reconstruct the genomes of a paired human triple negative breast cancer (TNBC) cell line and a matched normal cell line. The reference-grade *de novo* assembly of normal sample consists of 1,715 scaffolds with 2.9 Gb, of which 2.69 Gb is from top 50 scaffolds, and is the most contiguous so far with a scaffold N50 size of 69.96 Mb, in comparison to 67.79 Mb for GRCh38, and 44.85 Mb for AK1, respectively. Conversely, the *de novo* assembly of the tumor sample comprises 2,808 scaffolds with a total basepairs of 2.85 Gb and a scaffold N50 size of 27.57 Mb. We have identified a set of high confidence heterozygous sites using short reads mapping to the normal genome, then utilized the long reads to perform phasing using multiple phasing methods, the accumulated length of the phased blocks is 2.23 Gb. The qualities of the *de novo* assemblies have been carefully assessed with BUSCO, QUAST, AUGUSTUS, and GRCh38 alignments. Among 50,052 RefSeq NM transcripts, 49,467 transcripts (98.82%) have been mapped on to the *de novo* assembly of the normal sample with at least 95% alignment coverage, indicating that the high quality of the assembled normal genome has been achieved. We have also mapped all the sequencing reads to the assembly of the normal sample, and in combination with alignments from tumor assembly to normal assembly mapping, we have identified a list of personal-genome based somatic events including SNVs, indels, and structural variations. The well-characterized tumor-normal pair genomes from this work will enable us to provide more insights into understanding the tumor biology of breast cancer.

## PgmNr 1648: LFMD: A new likelihood-based method to detect low-frequency mutations without molecular tags.

---

As next generation sequencing (NGS) and liquid biopsy become more prevalent in clinical and research area, especially cancer diagnosis, targeted therapy guidance and disease surveillance, there is an increasing need for better methods to reduce cost and to improve sensitivity and specificity. Since the error rate of NGS is around 1%, it is difficult to identify mutations with frequency lower than 1% accurately and efficiently because of low Signal-to-Noise Ratio (SNR). Here we propose a likelihood-based approach, low-frequency mutation detector (LFMD), combining the advantages of duplex sequencing (DS) and bottleneck sequencing system (BotSeqS) to maximize utilization of duplicate sequenced reads. Compared with DS, the new method achieves higher sensitivity (improved ~16%), higher specificity and lower cost (reduced ~70%) without involving additional experimental steps, customized adapters and molecular tags. In addition, this method can also be used to improve sensitivity and specificity of other variant calling algorithms by replacing a step in traditional NGS analysis: removing polymerase chain reaction (PCR) duplication. Thus, LFMD can be a promising method used in genomic research and clinical fields.

## PgmNr 1649: Statistical analysis of spatial expression pattern in spatially resolved transcriptomic studies.

Recent development of various spatially resolved transcriptomic techniques have enabled gene expression profiling with spatial information. Identifying genes that display spatial expression pattern in these studies is an important first step towards characterizing the spatial transcriptomic landscape. However, as we will show here, existing approaches for detecting spatially expressed genes often fail to control for type I error, can suffer from substantial power loss, and/or are computationally inefficient for even moderate sized data sets. Here, we developed a new method, SPARK (Spatial Pattern Recognition via Kernels), for statistical analysis of spatial expression pattern that addresses these previous limitations. SPARK directly models count data generated from various spatial resolved transcriptomic techniques. With a new penalized quasi-likelihood based algorithm, SPARK is scalable to data sets with tens of thousands of genes measured on tens of thousands of spatial locations. Importantly, SPARK relies on newly developed statistical formulas for hypothesis testing, producing well-calibrated  $p$ -values and high power. We illustrate the benefits of SPARK through extensive simulations and in-depth analysis of four published data sets. In the real data applications, SPARK is 1.5-10 times more powerful than existing approaches and identifies new genes that reveal the importance of neuronal migration in the formation of the olfactory system as well as the importance of immune system and cytoskeleton in tumor progression and metastasis.

## PgmNr 1650: CentroFlye: Assembling centromeres with long error-prone reads.

Long-read technologies (such as Pacific Biosciences and Oxford Nanopore) have greatly increased the contiguity of genome assemblies as compared to short-read technologies. However, although the existing long-read assemblers, such as Falcon, Miniasm, Flye, HINGE, Canu, Marvel, and wtdbg2, have been used in many sequencing projects, they typically fail to resolve long segmental duplication and long tandem repeats. We focus on the latter challenge – assembling long tandem repeats, and specifically on centromere assembly, the problem that was viewed as intractable until recently. Centromeres represent longest tandem repeats in human genome (also known as *satellite DNA*) that are often repeated thousands of times with extensive variations in copy numbers in the human population. Centromeres are the biggest gaps in the current human genome assembly. As the result, studies of associations between sequence variations and genetic diseases currently ignore  $\approx 3\%$  of the human genome. Although variations in centromeres have been linked to cancer and infertility, they still represent the “dark matter of the human genome” that has withstood all previous attempts to develop an automated tool for centromere assembly. Although long read technologies facilitated partial closing of some centromere gaps in the human assembly, no software tool for centromere reconstruction has been described yet and it remains unclear how accurate are the centromere reconstructions that resulted from previous semi-manual efforts. To assemble centromere and other “dark matter of the human genome”, the recently established Telomere2Telomere consortium aims to generate the first complete assembly of the human genome. We describe centroFlye, the first centromere assembly tool, apply it for assembling the human X chromosome using long error-prone reads, and evaluate the accuracy of the resulting assembly. Our analysis opens a possibility to automatically close the remaining multi-megabase gaps in the human genomes.

We applied single molecule real-time (SMRT, or PacBio) sequencing, which is capable to observe methylation status along the long reads, for observing personal diploid methylomes, CpG methylome pairs of homologous chromosomes that are distinguishable with respect to phased heterozygous variants (PHVs). The task has been considered challenging due to scarcity of PHVs (<1% within genes) and high error rate of sequencing reads which was as high as 15%. We demonstrated, however, the phasing error rate of CpG sites can be reduced to 1% if the positions of PHVs are given. With this method, we examined *GNAS* complex locus known for a combination of maternally, paternally, or biallelically expressed isoforms, and observed allele-specific methylation pattern almost perfectly reflecting their respective allele-specific expression status, demonstrating the merit of elucidating comprehensive personal diploid methylomes and transcriptomes[1].

The success of the method indicated that, to distinguish highly homologous regions in a genome, we could utilize variations much less frequent than sequencing error rate, if the variant sites are known beforehand. Thus, we extended the logic to calculation of read overlaps, designing an optimal scoring scheme under the given variation model. Then, we applied it to *de novo* assembly task to see whether it would be able to resolve higher order repeats (HOR) arrays making up human centromeres, which has been considered one of the *un-sequenceable* parts of the genomes. We assembled the chromosome X where >99% identical 2 kbp HORs are tandemly arranged >1000 times (each unit is characterized by a specific combination of 12 alpha-satellite monomers). We elucidated structures of several regions of >100 kbp. Comparison of the results from several publicly available PacBio datasets informed us the evolutionary patterns of centromeric regions. Therefore, we concluded that not only generating longer reads, which may span and thus trivialize the whole repeats, but also handling small variations within repeats in a proper theoretical way is another promising road to complete genomes.

---

ClinVar is a public database of submitted interpretations of variants and their relationships to disease, maintained by the National Center for Biotechnology Information (NCBI) at the National Institutes of Health (NIH). Many kinds of data are submitted to ClinVar by many types of organizations. Thus the ClinVar team uses both automated and manual steps to validate, aggregate, and add value to submitted data. Automated validation includes checking consistency of variant and gene data; validating database identifiers for conditions; and validating the required fields of clinical significance, affected status, allele origin, and collection method. ClinVar curators manually review submissions, e.g. to confirm the submitter's intent for rare combinations of data; to request the date that the interpretation was last evaluated; and to check consistency of data in comments and structured data. The curators communicate with ClinVar submitters in an iterative process to ensure that each submission can be processed and that it represents the data as the submitter intends. Each submitted record is assigned an SCV accession number, which is used for retrieval and to provide updates for the record. Once processed, submitted data are aggregated such that a user can review all data submitted for a variant (the VCV record) or a variant-condition pair (the RCV record) together. ClinVar adds value to RCV and VCV records by providing an identifier for the variant or set of variants that was interpreted (Variation ID); calculating HGVS expressions on genomic DNA, cDNA, and protein; calculating genomic location on GRCh37 and GRCh38; calculating a predicted molecular consequence; annotating the gene(s) that colocalizes with each variant; annotating allele frequency; calculating an aggregate clinical significance and indicating consensus or conflict; calculating a review status; and providing links to other databases. Upcoming improvements to submission processing include pre-validation of file submissions in the ClinVar Submission Portal. This feature will give the submitter quick feedback on the validity of variant descriptions when the submission file is uploaded. Validation for other types of data will be added in later phases. Validation of data upon upload will allow submissions to be processed faster. This will make submitted data publicly available in ClinVar sooner, so that clinical laboratories and other users have access to accurate and up-to-date information.

## PgmNr 1653: Accurate and high-resolution copy number variant detection in clinical germline screening.

**Introduction:** Structural variants, especially copy number variants (CNVs), can cause genomic disorders. CNVs can bring genomic coordinates that are distant in the reference genome into contact in a sample genome, forming “breakpoints.” Determining exact CNV breakpoint sequences (physical deletion or duplication boundaries) across individuals is crucial for clinical germline screening and associating genotype to phenotype. For targeted sequencing, the majority of the current tools rely only on the depth of coverage, which reports approximate genomic coordinates only. Here, we report a hierarchical approach for detecting high-resolution CNVs that integrates read-depth signal and reads that align in split fashion to discontinuous loci in the reference genome (split-reads) containing breakpoints.

**Methods:** Our approach first applied a Hidden Markov model (HMM) CNV caller that calls CNVs by observing sequencing depth, which reflects the copy number, for ~100 base-pair segments tiled along the targeted region of interest (ROI). CNV breakpoints were determined by the probe coordinates that targeted the CNV region in the HMM CNV caller. To generate the high-resolution CNV breakpoints, we developed a CNV breakpoint annotator to identify split reads that have soft-clipped bases on the side on which the depth-based CNV is located and replaced the CNV breakpoints with breakpoints defined by supporting split-reads.

**Results:** We first validated our HMM CNV caller and it achieved 100% concordance, emitting positive calls for 50 orthogonally confirmed CNVs and negative calls for 685 samples not known to have CNVs in the ROI. We then validated our breakpoint annotator by comparing the performance to open-source CNV caller LUMPY on 1,700 random selected in-house patient samples. We identified 310 CNVs in these samples through the HMM CNV caller. Our approach refined breakpoints for 70 (22.6%) CNVs, and 67 were confirmed by LUMPY. Confirmation analysis showed that 69 of the 70 breakpoints identified by our approach were accurate. Together our hierarchical approach showed high CNV calling accuracy and also provided precise breakpoints.

**Conclusions:** The approach described here for detecting high-resolution CNVs ensured accurate calling of important CNVs and reduced the burden of manually refining the CNV breakpoints in the downstream variant interpretation. With split reads, the accuracy of calls increased resolution from 100-300bp to 1-3bp.

## PgmNr 1654: Simple ClinVar: An interactive web server to explore and retrieve gene and disease variants aggregated in ClinVar database.

---

Clinical genetic testing has exponentially expanded in recent years, leading to an overwhelming amount of patient variants with high variability in pathogenicity and heterogeneous phenotypes. A large part of this information is aggregated in public databases such as ClinVar. However, the ability to explore this rich resource and answer general questions such as “How many genes inside ClinVar are associated with a specific disease?”, “In which part of the protein are patient variants located?” or “has a ClinVar variant been observed in the general population” is limited and requires advanced bioinformatics processing. Here, we present Simple ClinVar (<http://simple-clinvar.broadinstitute.org/>) a web-server application that is able to provide variant, gene, and disease level summary statistics based on the entire ClinVar database in a dynamic and user-friendly platform. The ClinVar database is downloaded from the ClinVar ftp site and processed internally to produce a pre-filtered ClinVar file for the user to explore on the web-server. The pre-filtering step is designed to reduce the complexity of ClinVar entries as well as to provide fast access to high-quality entries. Interactive summary statistics, variant mapping, and visualization were developed with the Shiny framework of R studio software. App deployment, hosting, and update is performed with Google Cloud services. At the time of abstract submission, our web server holds information for 499,389 ClinVar entries. Summary statistics are available for 18,523 genes and 11,265 unique phenotypes. Overall, our web application is able to interactively answer basic questions regarding genetic variation and its known relationships to disease. By typing a disease term of interest, the user can identify in seconds the genes and phenotypes most frequently reported to ClinVar. Subsets of variants can then be further explored, filtered, and visualized in the corresponding protein sequences. In addition, variants reports are connected to external resources such as the genome aggregation database (gnomAD) and commonly used variant interpretation scores (e.g. CADD, Polyphen). Finally, we enabled a 'submission' feature that allows the user to map their own variants on top of ClinVar reports. Our website will follow ClinVar monthly releases and provide easy access to ClinVar resources to a broader audience including basic and clinical scientists.

# PgmNr 1655: Improving the informativeness of Mendelian disease pathogenicity scores for common diseases and complex traits.

---

Despite considerable progress on pathogenicity scores prioritizing both coding and non-coding variants for Mendelian disease (Eilbeck et al. 2017 Nat Rev Genet), little is known about the utility of these pathogenicity scores for common disease. We sought to answer two questions: (1) how informative are Mendelian disease pathogenicity scores for common disease, and (2) how can we improve their informativeness for common disease?

To answer the first question, we applied stratified LD score regression with the baseline-LD model v2.1 (86 genomic annotations; Gazal et al. 2017 Nat Genet) to assess the informativeness of new annotations based on top prioritized variants from various pathogenicity scores (e.g. CADD, ReMM, Eigen) across 41 independent common diseases and complex traits (average  $N=320K$ ), meta-analyzing the results across traits. We considered two metrics: enrichment = (% of heritability)/(% of SNPs) and  $\tau^*$  = proportionate change in per-SNP heritability per 1 s.d. change in annotation value conditional on baseline-LD model annotations. Many pathogenicity score annotations were highly informative, e.g. enrichment=19.5 ( $P<1e-20$ ) and  $\tau^*=0.82$  ( $P<7e-19$ ) for the top 0.5% of SNPs from Regulatory Mendelian Mutation score (ReMM; Smedley et al. 2016 AJHG), while others were conditionally uninformative, e.g. enrichment=5.7 ( $P<2e-12$ ) and  $\tau^*=0.07$  ( $P=0.04$ ) for the top 1% of SNPs from Eigen-PC (Ionita-Laza et al. 2016 Nat Genet); proportions of top SNPs were optimized on a coarse grid to maximize informativeness.

To answer the second question, we developed a variant reprioritization framework to predict/impute and reprioritize existing pathogenicity scores using a supervised machine learning approach, gradient boosting. We used annotations from the baseline-LD model as features and subsets of scored variants as training data, reprioritizing pathogenicity scores without using disease data. Gradient boosting attained high predictive accuracy (AUPRC=0.74-0.97) and substantially increased informativeness for common disease both for previously informative scores, e.g. enrichment=17.0 ( $P<1e-20$ ) and  $\tau^*=1.17$  ( $P<1e-20$ ) for the top 1% of SNPs from boosted ReMM (conditional on baseline-LD + existing ReMM annotations), and for previously uninformative scores, e.g. enrichment=6.3 ( $P<4e-32$ ) and  $\tau^*=0.67$  ( $P<9e-7$ ) for the top 5% of SNPs from boosted Eigen-PC. The newly reprioritized scores have high potential to improve gene discovery and fine-mapping for common disease.

## PgmNr 1656: Polygenic risk score ensembles across methods and diseases increase disease prediction accuracy.

### Authors:

---

Predicting an individual's risk to a disease may lead to more precise prescription dosages, screening schedules and lifestyle adjustments – changes that improve disease treatment. The current genetics-based disease prediction paradigm is the polygenic risk score (PRS). Multiple methods have emerged to produce PRSs that limit various sources of noise. Each of these methods has been evaluated upon only a few diseases and compared against only a few other competing methods, and never within any ensemble. This work evaluates a total of 11 methods on 16 different diseases. Scores were generated from GWAS summary statistics and evaluated on the UK Biobank. There was no clear superior method on all traits, however the simpler methods (clumping and LDpred) had the top average performance. Analysis of each trait revealed a wide distribution in predictability measures. Ranking traits by full model AUC, including covariates such as sex and age along with the PRS, showed age-related traits such as gout and psoriasis are the most predictable (AUCs = 0.79, 0.71). Ranking by AUC Improvement, the difference between the covariate only and full model, showed that autoimmune traits such as celiac and inflammatory bowel disease received the greatest benefit from adding PRS (AUC Improvement = 0.17, 0.14). To utilize the 1,792 scores produced among all parameters, elasticNet models were generated that ensemble together either various models or diseases. The disease ensemble model showed poor performance with only 6 diseases having increased accuracy. Simple decision tree models were also generated on multiple diseases yet showed only a slight increase in accuracy. The methods ensemble model showed strong performance with 14 diseases exhibiting increased accuracy, and with 6 traits seeing AUC improvements greater than 0.1. This increased performance indicates that individual methods are not capturing a disease's full genetic architecture, whereas, ensembles are able to partially overcome this complexity - illustrating their clear utility in disease prediction. The disease ensembles suggest that as ensembles get more advanced, disease prediction accuracy will increase further.

## PgmNr 1657: Systematic comparison of different evidence sources for predicting GWAS effector genes.

While genome wide association studies (GWAS) have identified an ever-increasing number of complex trait-associated genomic loci, gleaned biological insight from these associations has proven difficult. A complete mechanistic understanding of a GWAS association describes a causal variant, an effector gene that mediates its effects, a tissue or cell type of action, and an impaired biological process. Many analytical techniques and datasets are often used to heuristically prioritize variants or genes; e.g., observation of an epigenomic annotation overlapping a variant, an expression quantitative trait locus (eQTL) coincident with the disease association, or enrichment of a biological process for genetic associations. A natural question is therefore: how consistent are these evidence sources with one another, and how are prioritizations affected when they are viewed alongside one another? Here, we systematically compare >15 sources of evidence for effector genes (including MAGMA, MetaXcan, DEPICT, eCAVIAR, and model organism phenotypes) across >50 complex traits. We present a visualization framework, FOCUS (Find Optimal Computational Support), which provides a standardized means to compare any set of methods or datasets that prioritize variants, genes, and/or tissues (or relationships among them). Application of FOCUS immediately emphasizes the limitations of coincident eQTL analysis to prioritize genes: while for many loci, promising candidate effector genes are the target of a coincident eQTL, in most cases (a) many other genes within the same locus are also the target of a coincident eQTL; (b) the eQTL also exists across many tissues with no evidence of disease-relevance; and (c) three different eQTL co-localization methods produce significantly different results. At the type 2 diabetes (T2D) *GPSM1* locus, for example, *DNLZ* initially seems a promising effector gene, based on a rare variant association and a coincident eQTL (predicted by eCAVIAR) in the pancreas. However, two other colocalization methods applied to the same data (COLOC and MetaXcan) do not replicate this prediction. These results suggest that current methods for prioritizing effector genes can be misleading when viewed in isolation or when only results for candidate genes are examined. FOCUS is available for use via a public web portal for T2D and related traits ([type2diabetesgenetics.org](http://type2diabetesgenetics.org)), with plans to extend it to more complex diseases in the next year.

## **PgmNr 1658: Recurrency approaches using Random Forests to identify genetic risk factors while controlling family-wise false positive rates.**

Non-parametric machine learning methods are robust to complex models such as are hypothesized for complex genetic diseases and traits. Machine learning methods such as Random Forests (RF) can identify complex effects. We have developed an RF-based variable selection method called relative recurrency variable importance metric (r2VIM) to address hurdles in using RF to identify variables (features) that increase risk of complex phenotypes in genome-wide analyses.

Previously, we have shown that r2VIM improves false positive control and power to identify important features compared to RF, especially when non-linear effects contribute to the phenotype. The relative recurrency approach estimates the probability that a feature is important. Here, we use permutation of trait status to control family-wise error rates in variable selection to achieve a selection criterion that better scales with the number of SNPs evaluated and compare performance of several schemes for maximizing power to detect causal variants in simulated data. These data were simulated using GWAsimulator and the 1000 genomes European (EUR) haplotypes to create a set of subjects with linkage disequilibrium structure similar to the actual EUR population, pruned to match the SNP density of a typical 1M SNP chip and creating a trait due to: (1) one interaction between 2 SNPs with no main effects on maps of 10,000 to 100,000 SNPs and (2) both interaction effects and independent main effects. The effects of stepwise procedures on power are also being evaluated. Power is affected by multiple factors, including effect size of the causal features, sample size, number of trees and other parameters of the RF analysis.

This recurrency approach has the potential to elucidate novel biological pathways which could improve both treatment and prediction of complex human diseases.

## PgmNr 1659: Identifying distinguishing gene-level and protein-level features associated with gain-of-function and loss-of-function mutations.

---

Gain-of-function (GOF) and loss-of-function (LOF) mutations in the same gene may result in different phenotypes/diseases and hence require different treatments. Therefore, identifying the functional consequence of mutations is an important step for understanding disease mechanisms. Currently the only way to do so is performing experimental methods which is costly and time consuming. Although, there are numerous computational tools predicting the pathogenicity/deleteriousness of genetic variants (i.e., CADD, SIFT, PolyPhen-2) that help prioritizing causal variants, these methods cannot predict whether the variant results in gain-of-function (GOF, enhanced protein product) or loss-of-function (LOF, reduced protein product). To address this need, we searched for discriminating gene-level and protein-level features of GOF and LOF mutations. We generated the first database of all currently known disease-causing GOF and LOF mutations using natural language processing (NLP) on the available abstracts of the Human Gene Mutation Database (HGMD). We identified 1,209 GOF mutations in 302 genes and 11,452 LOF mutations in 1,628 genes. We then annotated all GOF and LOF mutations with gene-level and protein-level features including gene ontology terms, mode of inheritance, mutation position, amino acid changes, protein domain, secondary structure, solvent accessibility, and disordered regions. The results indicate significant discriminative power of some features, including mode of inheritance, mutation type, and protein domains, to distinguish GOF from LOF and neutral variants, and suggest a machine learning method to efficiently classify mutations by functional consequence.

## PgmNr 1660: Interactive, shareable plots of GWAS data with LocusZoom.

Genome-wide association studies (GWAS) are a powerful tool for identifying trait-associated loci. It has long been recognized that GWAS results require context for interpretation. Since 2010, LocusZoom has provided a means to visualize GWAS results overlaid with linkage disequilibrium, recombination rate, and nearby genes, among other annotations. Our web-based service ([locuszoom.org](http://locuszoom.org)) has been used to generate more than 700,000 static plots of user-provided summary statistics. To support more dynamic and exploratory workflows, we have extended LocusZoom from a service that generates static PDF plots into an interactive tool that relies on standard web technologies. Users are now able to interact with results by panning and zooming, or adding and removing annotation tracks for context. We generate a Manhattan plot of the results, which makes it easy to quickly jump to significant variants of interest. The user can also zoom into arbitrary genomic regions, identified by gene name, genomic coordinates, or variant rsID. Multiple GWAS result sets can be visualized together for comparison. Annotations can be customized to include result sets such as NHGRI-EBI GWAS catalog and prior PheWAS results (such as those from analysis of UK Biobank and other rich datasets) or to include genomic features (such as chromatin accessibility or enhancer tracks). These new visualization options can be used in multiple ways: researchers have a choice to upload and explore their data on our remote server (with enhanced functionality) or, alternatively, visualize local files without sending any data ("LocalZoom"). If data are uploaded, plots can be shared publicly (or only with selected collaborators); both options also support exporting plots as SVG images. We are currently extending LocusZoom to natively support on-the-fly analyses that are based on GWAS summary statistics, such as credible set determination or gene-based burden tests. We expect to add additional analysis types and improved access for public datasets in the future, based on user input.

## PgmNr 1661: Analysis of the n-of-one problem in human genetics.

---

Assessing the significance of rare variants in a single exome remains challenging even with the expansion of allele frequency information in large population databases. We previously developed a statistical inference system, PSAP (population sampling probability), to evaluate the significance of a genotype observed in a single patient based on *in silico* variant annotations. These p-values are calculated by simulating gene-specific null models and are able to prioritize 39% of disease genotypes as the most damaging unit in over 5 million simulated cases.

In our current study, we describe an analytic approach to calculating these gene-specific null models, introduce the hemizygous inheritance model, and integrate both gender and ethnicity factors. We compare the calibration and performance of PSAPs derived from different variant scoring methods, including FATHMM (Functional Analysis through Hidden Markov Models), MetaLR (Meta Logistic Regression), DANN (Deleterious Annotation of genetic variants using Neural Networks), fitCons (Fitness Consequence), REVEL (Rare Exome Variant Ensemble Learner), and CADD (Combined Annotation Dependent Depletion). We explore how using ExAC (the Exome Aggregation Consortium) and gnomAD (the Genome Aggregation Database), which contains twice sample size of ExAC, to parameterize our null models influences the behavior of PSAP. Finally, we evaluate the performance of our updated PSAPs in true n-of-one scenarios through simulation by “spiking-in” HGMD or ClinVar variants into the genomes of control individuals.

Using our analytic approach, PSAP p-values have improved resolution as compared to the original, implicating better power to identify variants of significance. Ethnicity-specific and gender-specific PSAPs both provide better calibration and performance, whereas we observe little difference when using ethnicity-match frequency parameters from gnomAD as compared to ExAC. We also found that using CADD as the scoring parameter in our PSAP calculations provides the most comprehensive annotation of the genome, and the best null-model calibration and performance. Using our updated PSAPs, we are able to identify 52% of disease genotypes as the most damaging unit in over 5 million simulated cases. PSAP is currently being used to identify potential pathogenic variants in studies of sporadic cases of disease, including ciliopathies and male infertility.

## PgmNr 1662: Representation learning for variant interpretation.

Despite efforts to sequence and catalogue genetic variation within human populations, predicting the clinical and functional effect of a given variant is still difficult, particularly in noncoding regions of the genome. To understand this variation, computational tools have been developed to predict whether missense single nucleotide variants (SNV's) disrupt protein function and whether noncoding SNV's are associated with differences in gene expression profiles. Many such tools rely on classifiers built using manually curated genetic and epigenetic predictive features. Although many SNV's affect the expression of distant genes, most features used for variant effect prediction are local to the SNV.

In this work, we use deep learning based language models to generate features that capture the larger genomic context surrounding a variant of interest. To build these features, we train language models on the entire human reference sequence, using k-mers of varying lengths as tokens. We explore methods to optimize these features by fine-tuning them on several different genetic and epigenetic annotations. We evaluate the use of these learned representations as predictive features, either alone or in combination with canonical genomic annotations, for variant effect prediction tasks, including expression quantitative trait loci (eQTL) prediction. Our results demonstrate the importance of the surrounding genetic context for variant interpretation and the use of feature representations from language models to capture this information.

## PgmNr 1663: A toolkit for accelerating genomic analysis using NGS index formats.

As genomic technologies move from the research laboratory to the clinic, the scale of genomic data is growing at an increasingly rapid pace. It is critically important for researchers, clinicians, and patients that data analysis pipelines do not become a bottleneck to diagnosis and treatment. Acceleration of next-generation sequencing (NGS) pipelines requires creative approaches to optimization that are informed by simultaneous consideration of biology, informatics, and systems architecture, especially in cloud-based computing environments. Common index formats, such as BAM Index (BAI) and Tabix (TBI), contain coarse-grained information on the density of NGS reads along the genome that may be leveraged for rapid approximation of read depth-based metrics. We present IndexTools, an open-source toolkit for extremely fast NGS analysis based on index files. We demonstrate that IndexTools 1) substantially accelerates parallel processing of BAM and VCF files by optimizing file splitting based on estimated read density; 2) provides reasonably accurate estimates of genome coverage (similar to indexcov, Pedersen et al., 2017); 3) is able to infer relative sex chromosome and mitochondrial genome number relative to the autosome; 4) is able to accurately call large deletions and copy-number expansions in minutes (compared to hours for traditional CNV pipelines). We further show that small variant and CNV calling pipelines implemented using IndexTools on the DNAnexus platform save considerable time and cost compared to equivalent non-accelerated pipelines. We expect that IndexTools will substantially reduce the turn-around time to deriving insight from NGS data.

## PgmNr 1664: Simultaneous multi-sample approaches significantly improve the accuracy of RNA-seq data analysis.

Transcript assembly from RNA-seq reads and differential splicing (DS) analysis are two key objectives of transcriptomics applications. However, despite significant advances in designing accurate analysis tools, both transcript reconstruction and DS detection are not meeting their full potential. The current framework for RNA-seq analysis, where each sample is processed independently and results are merged across all samples, improves coverage but inherits the errors of individual data sets, limiting both accuracy and the ability to identify splice variants, in particular rare and low expression events. Parting with the traditional one-at-a-time approach, we developed two tools that simultaneously analyze all samples in an RNA-seq collection to produce significantly improved results. The first tool, PsiCLASS, is a novel transcript assembler that combines features from multiple samples into a unified splice graph data structure, which increases accuracy and consistency. Its algorithmic underpinnings include mixture statistical models for cross-sample subexon selection combined with splice graph based dynamic programming algorithms and a weighted voting scheme for transcript selection. PsiCLASS achieves significantly better sensitivity-precision tradeoff and precision up to 2-3 fold higher than the StringTie system and Scallop plus TACO, the two best current approaches. It is also highly scalable, assembling 667 GEUVADIS samples in 9 hours, and has robust accuracy with large numbers of samples. The second tool, MntJULiP, extracts a reliable set of introns from a set of RNA-seq samples and detects introns differentially present between groups of samples. In particular, it uses a Bayesian approach to model read counts of introns under a negative binomial model, combined with hypothesis testing to determine introns that are differentially *expressed* between conditions, and a Dirichlet multinomial model to detect differential *usage* (splicing) of introns within a gene. MntJULiP compares favorably in accuracy to existing DS tools, including LeafCutter, MAJIQ, rMATS and Junction-seq, and scales up to data sets of hundreds and thousands of samples. Collectively, PsiCLASS and MntJULiP represent a new generation of tools that leverage the latent information in a collection of related RNA-seq samples to enable more accurate, highly scalable and efficient transcriptomic analyses. Availability: <https://github.com/splicebox>. Funding: NSF DBI-1356078 and NIH R01-GM124531.

## PgmNr 1665: Predicting missense variant pathogenicity with C-MIP.

More than a third of rare and pathogenic mendelian variants are missense, resulting in an amino acid substitution. However, not all missense mutations are deleterious and accurately deciphering variant impact on protein function remains a challenge. Advancement of machine learning paradigms and increased availability of relevant genomic data have lead to the development of several novel methods to address this. Specifically, three core ideas have driven the development of these tools: multiple sequence alignments to evaluate conservation, prediction ensembles, and learning complex motif patterns using neural networks. We evaluated eight recent predictors that applied one or more of these core ideas (EVMutation, PrimateAI, Envision, MutationAssessor, MCAP, Polyphen2 HDIV, Polyphen2 HVAR, SIFT). We also introduce a new method, ClinVar Missense Impact Predictor (C-MIP), a gradient boosting ensemble predictor. We validated the performance of these models using pathogenicity classification from ClinVar and several deep mutagenesis experiments. We found that EVMutation, a method that utilized multiple sequence alignments and utilizes deep learning, outperformed other predictors. However, this method was limited to 18% of the proteome. Where EVMutation is not defined, C-MIP outperformed other methods. We compiled a comprehensive evaluation framework of these methods across four independent datasets and highlight the performance of EVMutation and C-MIP for predicting variant impact on protein function.

## PgmNr 1666: PEMapper2 and PECaller2 improve trio-based genotype calling results and allow for direct comparisons of cell-line and blood derived WGS samples.

### Authors:

H.R. Johnston <sup>1</sup>; M.R. Bishop <sup>1</sup>; P. Chopra <sup>1</sup>; S. Gabriel <sup>2</sup>; E.J. Leslie <sup>1</sup>; S.L. Sherman <sup>1</sup>; D.J. Cutler <sup>1</sup>

---

The original versions of PEMapper and PECaller allowed for fast and accurate analysis of whole-genome sequence data in an unbiased fashion. Here we present PEMapper2 and PECaller2. Each program has been improved, allowing for faster, more accurate analysis. PEMapper2 is improved primarily by shrinking output file sizes, enabling large savings of disk space in big studies. Building on the naïve calling models introduced in PECaller, PECaller2 includes dramatically improved priors for genotype models, more precise handling of model parameters, and improved detection of model parameter misconvergence. As a result, PECaller2 genotype calling for both SNPs and INDELs is significantly improved, and demonstrably better than GATK best practices.

For SNP calling, PECaller2 and GATK give remarkably similar results, but to the extent that they differ (which is rare), there is strong evidence that PECaller2 makes better calls. In a dataset of 395 European trios with over 33 million segregating sites, we observed 99.95% concordance in genotype calls; 43.9 billion genotypes were identical and 21.2 million were called differently. Of those differing calls, there were 19.2 million Mendelian inconsistencies in the GATK results, and only 0.74 million in the PECaller2 data, suggesting that when PECaller2 and GATK calls differ, the error occurs with GATK ~95% of the time.

The differences between GATK and PECaller2 are particularly noticeable for INDEL calling. Only 58% of sites called as INDELs by GATK are confirmed by PECaller2. At sites called an INDEL by both GATK and PECaller2, genotype calling agrees ~99% of the time. However, INDELs called by GATK produce 27.3 million Mendelian errors, or ~1 error per 11.5 INDEL calls. PECaller2 is more conservative in its calls and results in 63x fewer errors than GATK.

PECaller2 can also be used with a variety of sources of DNA. In our experiment, sequence was obtained at 30x depth from DNA derived from blood and from low-passage cell lines taken from 10 unrelated individuals. Data were mapped and called in two separate batches, standard QC applied, and final datasets compared. 99% of all sites called a SNP in one experiment were also called a SNP in the other. Conditional on a site being called a SNP in both experiments, the genotype calls agreed 99.98% of the time. For INDEL calling, only 90% of INDELs were called in both experiments, but conditional on the INDEL being called in both, the genotypes agreed of 99.5% of the time.

## PgmNr 1667: DeepClean: Correcting sequencing errors using unique molecular barcode based deduplication method.

### Authors:

---

A key objective of high-throughput sequencing experiments is the exact quantification of the total number of DNA molecules. However, PCR amplification produces multiple copies of the same molecule and it becomes challenging to distinguish among identical copies of the distinct DNA molecules. Unique Molecular Identifier (UMIs) are short oligonucleotide sequences, made by the random combination of nucleotides. One UMI is attached to one original DNA molecule and is carried over to all of the PCR amplified molecules. Because UMIs are randomly generated, identical copies from distinct original DNA molecules will have different UMIs and can be distinguished accurately. The introduction of UMIs allows very simple and accurate deduplication of PCR sequences. However, this simple process is challenged due to the erroneous nature of sequencing that introduces: i) sequencing errors in UMIs and ii) sequencing errors in the replicates of the same DNA molecule. In the context of the variant calling, errors in UMIs lead to the wrong quantification of DNA molecules (inaccurate variant allele-frequency) and errors in the replicates introduce false positive variants. We have developed a PCR sequence deduplication algorithm that overcomes both the challenges described above. The algorithm is implemented via software package DeepClean, written in python language. First, DeepClean accommodates the errors in UMIs by using a tree-based network model. DNA replicates that belong to the same UMI tree are clustered together. In the second step of error correction, DeepClean eradicates the errors among replicates of a cluster, based on the error-frequency and reference-base to alternate-base ratio. Improvement in quantification accuracy is demonstrated using both the simulated data and Tru-Q7 (1.3% Tier) reference standard cell line data. We also compared DeepClean with already published similar tools. DeepClean significantly reduced the general error rate post deduplication, as compared to PCR amplified data. DeepClean produced data showed the allele-frequency of Tru-Q7 expected variants with high accuracy along with the comparatively lower number of false positive variants. DeepClean will be made available to the public as an open source software package.

## PgmNr 1668: Exploring the feasibility of data augmentation while using smaller biobank data sets.

### Authors:

C.J. Lee <sup>1</sup>; A.R. Hsieh <sup>2</sup>; C.S.J. Fann <sup>1</sup>

[View Session](#) [Add to Schedule](#)

1) Institute of Biomedical Sciences, Academia Sinica, Taiwan, R.O.C.; 2) Department of Public Health, China Medical University, Taiwan R.O.C.

Empowered by new computing technology and low genotyping cost, large biobank projects like UK Biobank (UKB) have had fruitful results in the advancement of biomedical sciences. However, there are several smaller biobanks sampling from different ethnic groups and the statistical power to detect any association from these datasets is lower. Data augmentation by synthesizing unobserved samples show promising results in the application of machine learning algorithms. Here, we hypothesized that augmentation of small biobank data can increase statistical power and detect reliable association signals.

A two-step strategy was adopted. First, control samples were filtered using Partition Around Medoids Algorithm, using the entire phenome to divide controls into clusters according to comorbidity. To reduce the heterogeneity, only samples not in the same cluster for the phenotype of interest were used as controls. Second, cases and controls were stratified by age and gender. By applying Synthetic Minority Oversampling Technique on each stratum, artificial cases and controls were generated. In this study, we chose to use asthma as the phenotype. Dataset from Caucasians in UKB (UKB-C,  $N_{\text{C-total}}=204,893$ ,  $N_{\text{C-case}}=31,303$ ) and a random sample were selected (UKB-CS,  $N_{\text{CS-total}}=24,000$ ,  $N_{\text{CS-case}}=3,612$ ). Fourteen linkage disequilibrium peaks ( $p \leq 10^{-8}$ ) from UKB-C GWAS were used as targets for comparison. Only HLA region was replicated using UKB-CS. Our strategy was then applied to UKB-CS. The real-to-artificial sample ratio (RAR) ranged from 4 (4 real and one artificial sample) to 1. Compared to targets from UKB-C data, 4 peaks were replicated when  $\text{RAR}=4$ , 5 when  $\text{RAR}=3$ , 6 when  $\text{RAR}=2$  and 11 when  $\text{RAR}=1$ . HLA region was prominent for every RAR. When  $\text{RAR}=2$ , false positive peaks seemed modest; almost half of the signals could be replicated when roughly 1/9 of the UKB-C samples were used.

The above procedure was applied to data from Taiwan Biobank (TWB,  $N_{\text{T-total}}=23,942$ ,  $N_{\text{T-case}}=2069$ ). Without augmentation, only HLA region was significant. When  $\text{RAR}=2$  for TWB and UKB-CS, GWAS results showed a similar trend. In addition to HLA region, only two other regions were replicated for TWB. Population heterogeneity may contribute to this discrepancy. Our results showed that data augmentation is promising, however caution needs to be taken with respect to input data quality and possible stratification, etc. More testing of augmentation algorithms should be done to further evaluate for performance.

## PgmNr 1669: New GeneHancer data in the UCSC Genome Browser displaying new interact track type.

---

The UCSC Genome Browser has a new interact track format, used in native Browser tracks and available to users for their own custom tracks or hub tracks. Interact is used to display pairwise interactions as arcs or half-rectangles connecting two genomic regions on the same chromosome, and can represent cross-chromosomal interactions. The format can be used to display physical low-density chromatin interactions, such as Chromatin Interaction Analysis by Paired-End Tag Sequencing (ChIA-PET), as well as virtual (regulatory) relationships such as enhancers or SNP-gene interactions. The first native Browser track to use this new format displays data from the GeneHancer database linking human regulatory elements (enhancers and promoters) as arcs to their inferred target genes. Over 1 million regulatory elements obtained from seven genome-wide databases by GeneHancer are visualizable on the human hg19 and hg38 assemblies as color-coded curves ending on their respective target (<https://genome.ucsc.edu/s/PublicSessions/GeneHancer>). Recent new enhancements to the new track type include an option to invert the view from hills to valleys, an improved pack and squish mode and a cluster mode, which combines directional interactions with the same named target or source to display as a single bundled element.

## PgmNr 1670: Using genome graphs for native alignment and variant calling of non-reference sequences in African Americans in the Million Veteran Program.

Despite the current usefulness of the human genome reference, its limitation on representing human genetic diversity has been consistently described (Yang *et al*, *Genome Biol.* 2019). Whole genome sequencing (WGS) studies of multiple human populations have reported novel non-reference contigs that are not present in hg38. A graph genome pipeline can efficiently represent these non-reference sequences as alternate paths through the graph and can be used to directly align reads and identify variants on the graph. The overall performance of this graph applied genome-wide has recently been published (Rakocevic *et al*, *Nat Genet*, 2019), and has subsequently been applied to non-repetitive, non-reference (NRNR) sequences from Kehr *et al*, *Nat Genet*, 2017. Applying the NRNR graph on 49 EUR individuals from the 1000 Genomes Project showed that the frequency of the NRNRs obtained from the graph pipeline had an  $r^2$  of 0.96 with the frequency reported by the Icelandic study. Furthermore, the genotypes of the NRNRs correlated well with the genotypes of SNPs in linkage-disequilibrium with the NRNRs.

Here, we applied this graph-based pipeline to 20 African American and 20 European American individuals of the Million Veteran Program (MVP). We compared alignment and variant calls from the BWA-GATK best practices pipeline against a global graph pipeline that incorporates all alternate contigs of hg38, as well as a curated set of high confidence variants. Although the graph pipeline had on average 40% lower compute cost, the overall results of the two pipelines were highly consistent. We observed 40% fewer reads with mates that map to different chromosomes and identified 4% more indels when the graph pipeline was used. To further improve performance, we developed an MVP graph by incorporating additional contigs recently identified from 3 trios of the 1000 Genomes Project (Chaisson *et al*, *Nat Commun* 2019) and the African pan-genome study (Sherman *et al*, *Nat Genet* 2019). We then used the gnomAD-SV statistics to filter for SVs that were present with at least 5% frequency in relevant populations. This led to 2,789 unique contigs, which amounted to 3.6 Mbp of human sequences not present in hg38. Finally, we independently reassembled the contigs using the Simons Genome Diversity panel and re-mapped them as alternate paths for optimal aligner performance. We demonstrate that the custom MVP graph has better alignments and variant call metrics than the global graph.

## PgmNr 1671: Secondary analysis of 1000 genomes in a week using 4 servers.

**Authors:**

M. Samadi; A. Sethia; S. Mahlke; T. Harkins

[View Session](#) [Add to Schedule](#)

**Affiliation:** Parabricks, Ann Arbor, Michigan.

---

As more and more organizations start using Whole Genome Sequencing (WGS) data for deeper analysis and insights, the demand for WGS analysis is rising rapidly. It is common to process hundreds of genomes in a week and there are predictions that analysis of 1000 genomes per week will become standard. But, there are large computational, infrastructural, and cost-related challenges in analyzing such a large number of genomes while maintaining the accuracy and fidelity of the analyses. To enable researchers to efficiently analyze trends in genomic data from entire populations, hospitals/clinics must be able to process large numbers of genomes every week at a reasonable time and cost, these challenges have to be overcome.

On the computing front, traditional general-purpose microprocessors (CPUs) no longer scale performance according to Moore's Law, thus they will not be able to meet the computing demands of WGS. Many compute intensive domains have adopted compute accelerators in the form of commodity Graphics Processing Units (GPUs) to scale performance at reasonable costs. GPUs are well suited for the parallel computation in genomic analysis and are already gaining a foothold in genomic analysis. We have developed a full suite of WGS secondary analysis software (GATK best practices, deepvariant, cnvkit, etc.) that is optimized for GPUs. Results demonstrate 30 to 50 times faster processing with GPUs and users can process a 30x whole genome in under an hour using 8 GPUs. Another major advantage of GPUs is that they are general purpose so they can be used for other computing tasks and readily available in the majority of the computing centers.

Using our software suite, 1000 Genomes can be analyzed every week by a center with commodity hardware using 4 GPU servers. Over a period of 5 years, this represents an analysis cost of one dollar per genome. This represents a marked departure from traditional clusters where thousands of nodes and tens of thousands of cores must be deployed to accomplish the same analysis. This large reduction in infrastructure, cost, and management overheads can provide significant advantages to organizations looking to scale their analysis of WGS data.

## **PgmNr 1672: Here, there, and everywhere: NCBI resources for genomic analysis and visualization in local, web, and cloud environments.**

Genome-scale analyses play a central role in basic and clinical research. Decisions surrounding tool selection for these types of studies must consider many factors, including data size and available compute power, privacy concerns and the bioinformatics skill level of the analyst. Specifically, these parameters impact the user interface and the environment in which a tool must run. NCBI's collection of genome analysis and visualization tools supports a diverse range of user needs. Here, we highlight several of these, focusing on recent updates and new features. Genome Workbench is a desktop sequence analysis package that integrates analysis tools, such as BLAST, with graphical displays and whose local processing ensures data privacy. The functionality of this powerful tool has now been extended to support preparation of genome submissions to GenBank. Additionally, NCBI offers a suite of command-line alignment tools, such as BLAST+, IgBLAST and Magic-BLAST that can be run locally. Recent updates to BLAST+ will be discussed, including enhanced support for search limits and corresponding changes in BLAST databases. For users who prefer graphical interfaces, NCBI offers a diverse suite of web-based alignment tools, and we will present features of the redesigned BLAST results page. Genome Data Viewer (GDV) is NCBI's web-based genome browser. We will show recent performance enhancements and new features, such as track overlays, improved alignment displays, and expansions to our support for track hubs. Users looking for analysis inputs at the NCBI website, such as genome assemblies and annotation data, can now take advantage of an improved search experience that supports plain language queries, and presents results in a simple interface that supports data retrieval. We will demonstrate the features of this search and results display. NCBI also offers BLAST in the cloud. We will present recent developments in this area, including a BLAST+ Docker image that can be used to run analyses in the Google Cloud Platform and ongoing work to offer a web-based interface for BLAST searches that run remotely in the cloud. This collection of local, web, and cloud-based resources provides users with tools for genomic analyses that best fit their computational needs. This work was carried out by staff of the National Library of Medicine (NLM), National Institutes of Health, with support from NLM.

## PgmNr 1673: Accelerating research with the NCBI Sequence Read Archive on the commercial cloud.

### Authors:

---

The NCBI Sequence Read Archive (SRA) is NCBI's comprehensive collection of next generation sequence data from human and non-human organisms. At over 10 petabytes, SRA is NCBI's largest research archive and has exceeded the capability of most sites to replicate locally. Recognizing this, NCBI and NIH have recently replicated SRA content to both Amazon and Google commercial cloud platforms as part of the NIH STRIDES program. NCBI is providing community education, and training opportunities to build relationships with SRA users through webinars, online tutorials and a series of NCBI-hosted hackathons that bring together users to work with topical and problem-relevant subsets of SRA data.

Taken as a broad collection of sequences sampled across the tree of life, SRA data are mined for new discoveries about genomic sequence, natural variation, antimicrobial resistant genes, gene expression, methylation states, and previously undescribed genes and species, strains, or viral isolates. By size, SRA is equal parts public and controlled access data — public data includes non-human sequences and human RNAseq and genomic data where individual consent has been provided for the open and unrestricted use of their data. Controlled access data is sequence information from human research study participants supported by NIH and access is restricted and controlled through dbGaP approval protocols.

Moving SRA data to cloud platforms will benefit users by enabling meaningful and timely access to the exponentially growing corpus of SRA data. This migration of data is accompanied by improvements to the SRA Run Selector, a new data model that supports access to both submitted and normalized data formats, improvements to the SRA toolkit, and conformance to NIH's new standards for Identity and Authorization Management. Researchers are invited to join the NCBI cloud user community, participate in Codeathon events, and explore our developing knowledge base of self-directed education resources to design powerful and affordable cloud-based analysis workflows.

This presentation will describe new SRA resource content, procedures for data access and use, and new cloud-related educational resources.

## PgmNr 1674: Human Cell Atlas data distribution: Curation of harmonized open access single cell datasets.

**Authors:**

J. Zamanian; J.A. Hilton; J.S. Strattan; J.M. Cherry; Human Cell Atlas Data Coordination Platform Team

[View Session](#) [Add to Schedule](#)

**Affiliation:** Genetics, Stanford University, Stanford, CA, USA

---

The Human Cell Atlas (HCA) is an international scientific collaboration with the aim of generating a comprehensive map of human cell types. The completed atlas will connect molecular profiling with cell location and morphology information across healthy human tissues. This open access resource will enable researchers to accelerate scientific discovery and support the development of new diagnostic tools and medical treatments across diverse disciplines and diseases.

Data are collected and processed for the HCA through the HCA Data Coordination Platform (DCP) being developed as a collaboration between the Broad Institute, Chan Zuckerberg Initiative, the European Bioinformatics Institute, University of California Santa Cruz, and Stanford University. The DCP enables search and delivery of single-cell genomics data in raw and standardized formats with associated metadata files containing experimental details. All standardized processing pipelines used by the DCP are approved by the HCA community and are available to the public. An additional matrix service delivers gene by cell matrices for custom subsets of primary data.

In this poster we discuss the curation and analysis of harmonized single-cell transcriptomic data for open access by the scientific community. Data suitable for integrative analysis and biological interpretation are released in collections for consumption by researchers. We welcome scientific community engagement in developing primary data and analysis outputs useful for supporting research goals. Come visit the HCA website at <https://data.humancellatlas.org/> to learn more and to express an interest in contributing data.

## PgmNr 1675: An approach to develop multi-ethnic polygenic scores using GWAS meta-analysis and mega training cohort.

J. Zhan; S.B. Laskey; K. Lin; J. Shi; P. Fontanillas; Y. Jiang; B.L. Koelsch; 23andMe Research Team

[View Session](#) [Add to Schedule](#)

**Affiliation:** 23andMe, Mountain View, California.

---

Polygenic scores (PGSs) have been used extensively to predict individuals' genetic liability for a range of phenotypes, from morphological traits to disease predispositions. PGSs are most often developed in European cohorts because individuals of European descent comprise the overwhelming majority of genetics research participants. However, Europeans represent a minority of global genetic diversity, and these PGSs typically perform worse — often dramatically so — in non-European cohorts. While efforts are being made to engage more non-European individuals in genetics research, it is also possible to leverage existing, abundant European genetic data to draw more generalizable scientific conclusions.

Adopting this approach, here we present a method to build PGSs that reduces performance disparities between European and non-European cohorts. This method consists of two steps: 1. Feature selection from a meta-analysis of GWASs integrating multiple populations, Europeans included, to identify tagging variants that are shared across ethnicities; 2. Model training on individual-level phenotype and genotype data from a mega-cohort of European and non-European individuals that leverages the power of the larger European cohort to boost predictive performance in non-European cohorts.

We tested this method on a broad set of phenotypes from the 23andMe database, using data from consented research participants of European, Hispanic/Latino, African/African American, East Asian, and South Asian descent. Comparing the performance of PGSs generated by this method with the European-only PGSs, we observed that our proposed method yields improved performance across response phenotypes and target populations. Specifically, using area under the receiver operating characteristic curve (AUROC) as a standard metric of model performance, we found that PGSs built with this method have significantly improved predictive accuracy for several non-European populations, with some models performing equivalently well in non-European and European cohorts. We believe that this method holds great potential for the development and implementation of PGSs across domains, with implications from direct-to-consumer genetics to clinical practice.

## PgmNr 1676: Increasing the precision of structural variant calls using machine learning.

**Authors:**

A.C. English; S.N. Shekar; A. Mangubat

[View Session](#) [Add to Schedule](#)

**Affiliation:** Spiral Genetics, Seattle, WA.

---

Structural Variants (SVs), genetic changes of at least 50bp, have been associated with an increased risk of neurological and cardiological conditions as well as in rare disorders. For SV calling to be widely adopted in clinical practice, it may be important to ensure that there are few false discoveries that may increase the risk of incorrect clinical diagnoses and unwarranted treatment.

However, in calling structural variants using short read Illumina data, the events are often larger than the unit of observation, a read, making it difficult to disambiguate between events in genomic repeats. Further, structural variant callers may be susceptible to false positives from calling structural variants using alignment information of reads where only part of the read maps to the reference or when using the expected mate pair distance, resulting in reference bias (<https://doi.org/10.1038/s41588-018-0145-5>).

We address this by calling variants by assembling whole reads across the genome, keeping track of paths that diverge and return to the reference. Applying the caller on the read data of HG002 sequenced at 40x using 150bp reads on an Illumina HiSeq, we recover 50.1% of the structural variants in the Genome in a Bottle Consortium Tier1 SV call set with a precision of 58.5%. Further investigation indicates that the false positives appear to represent sequence variation against the reference but with a location that does not match a call in the Tier1 set.

We take the VCF file of calls from HG002 that includes for each SV, the read coverage and minimum nucleotide overlap across the assembled reads. Taking 75% of all calls made at random, we apply the random forest machine learning method. We take the derived model and then apply it back to the data, we observe a recall of 46.7% of true positive SVs from the GIAB Tier1 set and a precision of 83.9%, a 25.4% increase.

It is further possible that dividing the variants into groups based on where they are located in the genome before running a random forest model may further improve precision without a reduction in sensitivity.

Overall, the application of a machine learning derived filter may increase precision and allow for the more regular use of structural variant calls in the bioinformatics analysis of rare disorders in clinical practice.

## **PgmNr 1677: AnnoSV for annotation and prioritization of complex coding and noncoding structural variants in human diseases.**

---

Recently, long-read sequencing technologies, such as linked-read sequencing, optical mapping, Oxford Nanopore sequencing and PacBio SMRT sequencing, are becoming increasingly used in human genetic studies, offering an unprecedented resolution to detect structural variants (SVs) that are missed by microarrays or short-read sequencing. Generally, over 20,000 SVs can be detected from an individual genome, but it remains challenging to pinpoint a small subset of SVs that are related to human diseases or contribute to phenotypic variations. Existing variant annotation tools offer limited functionality to understand the functional consequences of SVs, especially small non-coding SVs, complex translocations, nested SVs and those SVs located in highly repetitive genomic regions. In this study, we present AnnoSV, a software tool to provide comprehensive functional annotation for SVs including insertions, deletions, inversions, duplications, translocations, and complex events. AnnoSV can utilize gene annotations from GENCODE or NCBI RefSeq database, and annotate the affected genes/regions of an SV. In addition, AnnoSV searches and annotates the repeat sequences involved within or surrounding SV events, facilitating the understanding of the mechanism of SV generation. We also built a region importance score (RIS) to prioritize functionally important SVs, including non-coding SVs. RIS was built from multiple resources including population-based CNV/SV call sets, known disease-associated SVs, gene-disease association resources (such as predictions from Phenolyzer), functional annotations of genes (such as Gene Ontology), tissue-specific annotation of functional elements (such as those from Epigenome Roadmap Project, ENCODE and PsychENCODE), tissue-specific inter-chromosomal interactions. To test the performance of AnnoSV, we used AnnoSV to annotate the SV calls from a whole-genome long-read sequencing data set on the JIH-5 cell line. Among all SV calls, AnnoSV correctly identified two intra-chromosomal translocations as prioritized variants, including EP300-ZNF384 and EP300-CHD4 gene fusions, with the former being a recurrent alteration in B cell acute lymphoblastic leukemia. AnnoSV can take input files in VCF format and is compatible with output files of major short-read and long-reads SV callers such as Delly, and Sniffles. In summary, AnnoSV will facilitate annotation and clinical interpretation of SVs, especially non-coding SVs and complex SVs.

## PgmNr 1678: Improving the prioritization and characterization of structural variants detected by long read sequencing.

We describe a method for improved prioritization and characterization of structural variants using long read sequencing. A prioritization score for each SV is derived using information about overlapping neutral and disease-associated SVs, effect of SVs on gene elements (deletion, interruption, rearrangement, or duplications of exons), haploinsufficiency, and triplosensitivity. The effect of SVs on gene regulation is assessed based on information about the location and tissue specificity of enhancers and other regulatory sequences. We have previously shown that SVs that disrupt Topologically Associated Domain (TAD) boundaries are not uncommon and that they can be computationally prioritized by relating the phenotypes and tissue specificity of enhancers and genes on either side of a TAD.

Our Exomiser tool couples the calculation of phenotype similarity between human diseases and genetically modified mouse models with the evaluation of variants according to allele frequency, pathogenicity, and mode of inheritance. Exomiser compares HPO-encoded phenotype profiles with human diseases and mouse models; in cases where genes have no reference phenotypes, uses a guilt-by-association protein-interaction network approach. Here, we present software that integrates the assessment of SVs with the Exomiser in a way that allows phenotype-driven prioritization of SVs in long-read diagnostic genome sequencing. We present results of our algorithm on a suite of case reports encoded as Phenopackets (<https://github.com/phenopackets/phenopacket-schema>) and demonstrate how to use the software.

## PgmNr 1679: A graph genome of the Arab population with base pair accurate structural variation for population level variant genotyping.

Our recent exploration of ancestral populations' genomes has shown that the widely used Human reference genome (GRCh37/GRCh38) lacks the diversity needed to represent populations of specific ethnicities. By incorporating Single Nucleotide Variants (SNVs) and indels found by alignment-based variant calling into GRCh37, a population-representative reference can be created which increases the proportion of alignable reads from an individual of the same population. Incorporating structural variants (SVs) would further improve alignment.

To more thoroughly capture structural variation in a sequenced individual would in principle require aligning their reads to a continually updated reference graph of all previously called variation. To avoid introducing erroneous variation, such a graph must be made up of accurate breakpoints. Currently, the detection of SVs from short-read data using inference methods can lead to inaccurate breakpoints, unresolved insertion sequences and high false discovery rates. Using a rapidly assemblable read graph-genome representation, BioGraph Assembly recalls on average 48.9% true positive SVs in the GIAB v0.6 Tier1 set across 5 replicates of HG002, higher than any other caller using Illumina whole genome reads. Calling to VCF completes in an hour on a 32 core AWS instance with 32GB of RAM.

Further, by aligning paired reads to a graph reference of SVs called in any of 5 WGS replicates of HG002, the number of true positive variants recalled across ALL 5 individuals increased to 57.5%. Similarly, by aligning reads to a graph genome of the variants discovered using BioGraph Assembly across the parents, the recall of true positive GIAB SVs in HG002 increases by 11.3%. By aligning reads to an Arab Graph Genome of variation from 106 WGS Qatari individuals, we show that we are sensitive to a greater number of SVs in an N+1 genome than from discovery alone in that genome.

Within the 106 individuals, there were 48, 17 and 19 individuals of Bedouin, Sub-Saharan African and Persian ancestry respectively. There were variants unique to each ancestry including >1000bp regions of the reference that had an alternative nucleotide sequence that reads could not map to (N locations =68 Persian, =259 Bedouin, =143 Sub-Saharan African) and sequence resolved insertions >1000bp (N = 5 Persian, =57 Bedouin, =6 Sub-Saharan African).

This suggests that aligning to an Arab Graph Genome of nucleotide resolved calls could improve SV recall over calling against GRCh38.

## PgmNr 1680: ClipSV: Structural variation detection by read extension, spliced alignment, and local *de novo* assembly.

### Authors:

P. Xu; Z. Chong

[View Session](#) [Add to Schedule](#)

**Affiliation:** University of Alabama at Birmingham, Birmingham, Alabama.

---

Structural variations (SVs) are important sources of genomic mutations and are potential causes of various human diseases. Due to their relatively large mutation size (>50 bp), SVs are difficult to accurately detect using short reads from the next-generation sequencing (NGS) platforms. In previous studies, several methods have been developed to detect SV events, such as split reads, discordant read-pairs, (local) *de novo* assembly, and/or a combination of these methods. However, these methods are usually limited by low sensitivity, and the detected SV events are usually biased towards deletions.

In this study, we introduce ClipSV, which primarily relies on the spliced alignment of long sequences reconstructed from clipped reads and local *de novo* assembly to comprehensively characterize SVs. ClipSV searches the signals of SVs by collecting short reads that are clipped during genome alignment. To alleviate the limitation of read length, ClipSV generates longer sequences by iteratively overlapping of the clipped reads. After extending the read length, ClipSV performs spliced alignment to detect deletions and small insertion events (50~200 bp). For large insertions (>200 bp), ClipSV employs both read-pair alignments and local assembly approaches to increasing the overall sensitivity.

To evaluate the performance of ClipSV, we constructed a nonrandom simulation dataset by spiking in 12,745 known SV events of HG002 from the Genome in a Bottle project. ClipSV was able to discover 75.1% of the total true SVs at 30X coverage with 250bp paired-end reads, which is higher than Manta (59.5%), Lumpy (30.6%) and svABA (10.0%) at a comparable precision. Then, we evaluated the performance of ClipSV on the 30X 2x250bp real dataset of HG002, which has a high-confidence callset from multiple platforms. ClipSV was able to detect 8,423 (66.1%) true SV events, while Manta, Lumpy and svABA can only detect 6,002 (47.1%), 4,124 (32.4%), and 1,367 (10.7%) events, respectively. The better sensitivity of ClipSV was mainly due to its higher power in detecting insertions. Therefore, ClipSV will serve as an important tool for SV detection based on the NGS platforms which are still the mainstream sequencing capacity for routine genomic applications.

The source code is freely available at <https://github.com/penguab/ClipSV>.

## PgmNr 1681: Curation and quality assessment of 16S rRNA databases through natural language processing.

A fundamental step in genomic and metagenomic data analyses is taxonomic annotation, which maps sequences onto known taxonomies, using tools such as Blast, HMMER and others. The underlying computational algorithm has an effect on the taxonomic assignment, but precision is also greatly influenced by the quality of the reference database. In the context of 16S rRNA sequencing there is a wide collection of curated and uncurated databases, including RDP, GRD, Silva, RefSeq and Core but it isn't always clear how accurate the information contained in these is, nor whether the information is consistent across sources. In fact some authors report that roughly one in five of these predictions might be wrong and others report significant differences in the accuracy of taxonomic ranks depending on the database used.

We have developed tools to automate the creation of a reference database combining inputs from any number of separate sources while at the same time assessing the quality of the reference data. To build the database we use natural language processing techniques that parse the information available in each one and map the input sequence names to NCBI taxonomies. The resulting matches are scored and low quality matches are flagged either as rejected or needing additional reviewing. We are able to map entries to NCBI taxonomies with a high degree of certainty for over 99% of the input sequences from Core, RDP, GRD and RefSeq combined.

In order to quantify the quality of each entry in the newly created database we use two criteria. First we look for sequences that are similar but have been assigned to a different taxonomy at a given rank. By clustering the sequences, we assign a score to each entry based on similarity to other taxonomies in the same cluster. The second criteria analyzes entries with the same taxonomy at a given rank but significantly different underlying sequences. We group sequences by taxonomy and use multiple alignment to assign each entry a score, representing how much difference there is between sequences sharing the same taxonomy. Combining the results from these two criteria, we are able to quantify the reliability of taxonomic assignments made in our 16S rRNA data analysis pipeline and track the provenance of the assigned sequence to the database of origin.

Though we have mostly applied our tools to 16S databases, they are general enough to be applicable to a wide range of sequence databases.

## PgmNr 1682: Evaluating the general utility of common phenotype algorithm refinement rules that define many GWAS cohorts.

Published phenotype algorithms are proliferating and may serve as guidelines for construction of generalized computable methods for automated cohort selection. One frequent component of these algorithms is an initial screening rule applied to structured phenotype data available in Electronic Health Records (EHR). The purpose of these rules is to reduce false positives in the cohort. These filters take the form of requiring a qualifying patient's EHR record to contain a set minimum number of unique-day encounters associated with disease or condition relevant ICD diagnosis codes and can be combined with similar requirements for medications or lab test results. We use a simple version of this rule on approximately 1600 EHR-derived phenotypes using the ICD diagnosis code groupings based on PheWAS codes (Denny et al. 2013) and apply it to a biobank of over 65,000 patients with more than 1.5 million encounter-related ICD diagnosis codes. The rule applied here requires presence in an individual's health record of two or more unique-day in-person encounters associated with one or more of the ICD codes in a PheWAS grouping. We define an in-person encounter as a face-to-face encounter with a clinical practitioner. For example, office visits, inpatient stays and implemented medical procedures qualify, while phone calls, canceled or no show visits and letters do not qualify. Over 450 PheWAS phenotypes had 500 or more candidate samples from our biobank and these were used for further analysis. We found the percentages of candidates filtered by the visit type and visit count restrictions to be similar within ICD-CM Chapters. For these 450 phenotypes the visit type restriction to in-person visits had a minimal effect with 314 phenotypes having 2 percent or less of samples filtered out, and 434 phenotypes having 5 percent or less filtered out. However, the removal of candidates based on having only one relevant ICD code had a very significant impact and is a severe restriction. 14 of the 17 ICD Chapters represented by these 450 phenotypes had on average more candidates with only one relevant in-person ICD code encounter than candidates with more than one in-person encounter. Other computable rules for identifying likely false positives in a phenotype cohort are also considered.

## PgmNr 1683: Evaluating the informativeness of variant-level deep learning annotations for human disease.

Deep learning models have shown great promise in predicting genome-wide regulatory effects from DNA sequence (Eraslan et al. 2019 Nat Rev Genet), but their informativeness for genetic associations to disease is currently unclear. We evaluated variant-level annotations that predict function from DNA sequence (based on the reference allele), trained using three deep learning models: two models previously trained to predict chromatin marks (DeepSEA and Basenji) and a new model that we trained to predict other genomic annotations (BiClassCNN). We applied stratified LD score regression to 41 diseases and complex traits (average  $N=320K$ ) to evaluate each annotation's informativeness for disease heritability, conditional on a broad set of coding, conserved, regulatory and LD-related annotations (including Roadmap and ChromHMM annotations). We meta-analyzed two metrics across traits: enrichment = (% of heritability)/(% of SNPs) and  $\tau^*$  = proportionate change in per-SNP heritability per 1 s.d. change in annotation value, conditional on other annotations.

In an analysis of all 41 traits, DeepSEA and Basenji annotations that were aggregated across tissues produced no conditionally significant signals ( $\tau^*$  all non-significant), despite high accuracy in predicting chromatin marks (AUC up to 0.97); the BiClassCNN annotations for coding and TSS regions were conditionally significant, but these signals could be entirely explained by local GC-content.

We next considered tissue-specific deep learning annotations. In an analysis of 11 blood-related traits, blood-specific DeepSEA and Basenji annotations produced no conditionally significant signals ( $\tau^*$  all non-significant). On the other hand, in an analysis of 10 brain-related traits, two brain-specific deep learning annotations were jointly conditionally significant after correcting for hypotheses tested: DeepSEA-H3K4me3 (enrichment=3.6,  $P=5e-8$ ;  $\tau^*=0.35$ ,  $P=1e-4$ ) and Basenji-H3K27ac (enrichment=2.3,  $P=1e-08$ ;  $\tau^*=0.27$ ,  $P=5e-6$ ); a sequence motif analysis of the brain-specific DeepSEA-H3K4me3 annotation identified enrichments of proximal ( $\pm 1kb$ ) CpG-rich motifs, potentially implicating nucleosome occupancy.

We conclude that deep learning models can provide powerful tissue-specific signals for diseases. However, high accuracy in predicting chromatin marks does not imply conditional informativeness for disease, underscoring the importance of appropriate evaluation procedures that incorporate disease data.

## **PgmNr 1684: Detecting methylation quantitative trait loci using a generalized genetic random field method.**

The patterns of DNA methylation may be regulated by the genetic variants within a genomic region, referred to as a methylation quantitative trait locus (mQTL). The changes of methylation levels can further lead to stable alteration of gene expression, and influence the risk of various complex human diseases. Detecting those mQTLs may provide insights into the underlying mechanism of how genotypic variations and gene-by-environment interactions may influence the disease risk. In this article, we propose a generalized genetic random field (GGRF) method to detect mQTLs by testing the association between the methylation level of a CpG site and a set of genetic variants within a genomic region. The proposed GGRF has two major advantages. First, it considers multiple genetic variants, both common and rare, within a genomic region for genetic-epigenetic association. Second, it uses a beta distribution to model the methylation levels at a CpG site. Through simulations, we demonstrate that the GGRF may have improved power over other existing methods, especially when the sample size is small, which is a common scenario for methylation studies with specific tissue types. We further apply our method to a study of congenital heart defects with 84 cardiac tissue samples.

## PgmNr 1685: Colocalization of GWAS and regulatory QTL with incomplete summary statistics.

GWAS have uncovered hundreds of thousands of loci associated with complex traits and for many of these traits, it has become clear that the underlying genetic architecture is much more complex than many imagined. From one perspective, the results of GWAS have less direct utility for risk prediction or medical decision making due to each effect being relatively small. From another perspective, if GWAS associations point us toward causal mechanisms of disease, they may still have great utility for guiding drug discovery and development. Large efforts to understand the effects of genetic variation on low level cellular phenotypes such as the Gene Tissue Expression (GTEx) Project have greatly aided in generating hypothesis that explain the mechanisms of GWAS associations. However, there are sufficiently large numbers of trait associated and expression associated loci that significance of association of a single variant with both is not sufficient to assume a shared causal mechanism. Colocalization is used to determine whether the same variant is causal for multiple phenotypes and is stronger evidence for understanding mechanism than shared significance. Current colocalization methods require full summary statistics for both traits, limiting their use with the majority of reported GWAS associations (e.g. GWAS Catalog). We propose a new approximation to the popular coloc method (Giambartolomei et al. 2014, PLOS Genetics) that can be applied when summary statistics for one trait are only available for the top associated SNP. Our method imputes missing summary statistics using LD structure, and performs colocalization between the imputed statistics and full summary statistics for a second trait. As test of whether we are able to approximate the posterior probability of colocalization, we apply our method to colocalization of UK Biobank phenotypes and GTEx eQTL. We show good correlation between posterior probabilities of colocalization computed from imputed and observed UK Biobank summary statistics ( $R^2 = 0.92$  compared to using full summary statistics). Finally, we apply this method to estimate colocalization of GWAS Catalog traits and eQTL and use the results to prioritize drug targets. We find that colocalized trait-gene pairs are enriched in tissues relevant to those complex traits. Further, we find colocated gene-trait pairs are more likely to predict Mendelian disease genes for the same trait.

## PgmNr 1686: Quantifying the regulatory effect size for conditional eQTL data.

---

Analysis of expression Quantitative Trait Loci (eQTL), genetic variants that affect expression in specific genes, is a widely used approach for functional characterization of the genome and its relation to higher level phenotypes such as disease. In recent years, conditional eQTL analysis has extended this analysis in large cohorts to allow for identification multiple independent loci impacting the expression in each gene. Previously, we introduced allelic Fold Change (aFC), as a unifying notion of effect size for eQTLs and Allele-Specific Expression (ASE) data that is biologically interpretable.

Here, we introduce a new tool to generalize aFC estimation to conditional eQTL data. We apply our method to Genotype Tissue Expression (GTEx) ver. 8 data to derive effect size estimates for 471,726 *cis*-eQTLs spanning over 34,548 genes in 49 human tissues. The data includes up to 16 independent eQTLs per gene in a tissue with ~26% of the genes associated with more than one eQTLs in each tissue. We use ASE data from phased genotypes of 838 individuals with WGS in GTEx data to show that these effect size estimates are consistent with observed allelic imbalance in ASE data at the population-level. We quantify the fraction of genetic regulatory variation at the individual level that is mechanistically described by known eQTLs. Next, we show how our estimates of regulatory effect size for conditional eQTLs can be used in a phasing-aware model of *cis*-regulation to impute gene expression in genotyped individuals for the purpose of estimating local gene expression heritability and transcriptome-wide association study. We compare the performance of our gene expression imputation method to standard regression-based models.

## **PgmNr 1687: TigeRFISH: A computational pipeline to design genome-scale oligonucleotide hybridization probes to visualize novel tandem repeats.**

More than half of the human genome is comprised of repetitive sequences such as tandem repeats. These regions have been implicated in 3D genome organization and the maintenance of genome stability. Although these regions have established roles in the regulation of long noncoding genes, studying local repetitive elements has remained a technical challenge. Tandem repeats are not accessible with many conventional assays and these regions are not mappable which poses substantial roadblocks for visualization and mapping applications. FISH applications enables researchers to visualize the distribution of RNA and DNA in fixed samples. However more recent optimizations in synthetic biology has since provided researchers with the opportunity to construct FISH probes from oligonucleotides (oligos). Oligo-based FISH is a powerful single cell technique that allows researchers to control aspects of probe design such as binding energy and specificity. Here, we present TigeRFISH - a computational pipeline that allows for the design of optimal oligo FISH probes for tandem repeats genome wide. We implement existing computational tools including Tandem Repeat Finder coupled with OligoMiner to conduct k-mer based enrichment analysis to assess chromosome specificity followed by thermodynamic simulations of each probe. With TigeRFISH's capabilities to identify target repetitive candidates, we proceed with high-throughput microscopy at the single cell level to gain novel insight of the role these repetitive regions play in genome organization. Furthermore, the application of this technology as a part of the OligoMiner workflow may be used more broadly to facilitate the design of hybridization probes for a variety of applications genome-wide.

## PgmNr 1688: CasCADE: A fully integrated and open source pipeline to design CRISPR mutagenesis experiments.

CRISPR-mediated genome editing has enabled researchers to perform mutagenesis experiments with relative ease. Though tools exist for guide RNA (gRNA) design and predicting their off-target sites, there exists a need for a comprehensive platform to design, view, evaluate, store, and catalogue gRNAs and their associated primers. CasCADE (Cas Computer-Aided Design) integrates existing open source tools such as JBrowse, Primer3, BLAST, bwa, and Silica to create a complete allele design and quality assurance pipeline. It is available both from a public github repository and as a Docker image, for ease of installation and portability. CasCADE stores data locally, eliminating the security and privacy concerns that make external web-based applications less desirable. For any organism of interest, CasCADE downloads the genome along with annotations for genes, transcripts, and regulatory regions from Ensembl and loads them as tracks into the genome browser, JBrowse. Users can then select specific regions of interest, specify PAM sequences and design gRNAs to target these regions. Importantly, CasCADE provides the user with specificity scores for gRNAs and predicted off-target sites to assist with gRNA choice and then saves the information for user-selected gRNAs along with custom notes to an internal Mongo database. Once the gRNAs have been added to the database, users can trigger Primer3 to design primers for both the wild-type and mutant alleles. Primers are checked for specificity in the genome using BLAST and an *in silico* PCR check is performed with Silica. Selected gRNAs and primers are displayed visually as JBrowse tracks and stored permanently in the database. This allows users to retrieve information related to an experiment and re-analyze the target, if necessary. Additionally, once a design has been finalized, CasCADE generates files containing the guides, primers, and exons for a gene, which can be edited by sequence annotation tools such as SnapGene or ApE (A plasmid Editor). If a design fails, unsuccessful guides can be marked and their scores, off-targets, and genomic context used to make an informed decision about redesign. Currently only deletion alleles are supported, but future versions will allow for the design of point mutations (variants), conditional alleles, and mutations in non-coding regions.

## PgmNr 1689: Aggregated genome quality metrics can predict variant calling reproducibility in individual samples.

### Authors:

The advent of next generation sequencing has enabled a growing number of large-scale whole-genome sequencing projects. A critical aspect of these studies is variant calling accuracy. Multiple steps contribute to the final variant calls and each represents a potential source of variability: library preparation, sequencing platform, instrument calibration, operating conditions and software pipeline. Resources such as Genome in a Bottle or Platinum Genomes provide validation data for assessing variant calling performance but are limited to a subset of “confident regions” in a few samples. Alternatively, reproducibility analysis measures genotype concordance between different sequencing experiments of the same sample and does not rely on high-confidence variant truth sets. It can thus be applied to any sample as a complementary way to assess laboratory data quality.

To demonstrate the value of reproducibility analyses we sequenced the 17 members of the Platinum Genomes pedigree under a variety of conditions and compared SNV and indel calls between experiments. TruSeq DNA PCR-Free bulk libraries of the samples were sequenced on 2 runs on 1 HiSeq X instrument and on 6 runs on 2 NovaSeq instruments, with each run also containing 2 distinct libraries of one of the samples. Combined, each sample was sequenced at least 8 times and we calculated genotype concordance between all experimental combinations.

We found variant concordance ranges from 98.2% - 98.7% for SNVs and 93.1% - 95.4 % for indels, with different experimental conditions having comparable variability. Additionally, we hypothesized that discordant variants are not distributed equally across the genome, but tend to cluster in challenging regions. To test this, we aggregated data from a large cohort of samples and used per-base sequence-quality metrics to detect anomalous regions, predicting that these will correlate with lower variant calling accuracy. Indeed, stratified results show that while variant calls in confident regions are highly consistent (99.5% - 99.8% concordance for SNPs and 97% - 98.8% for indels), anomalous regions are hotspots for variability (80.3% - 87.9% concordance for SNPs and 89.8% - 92.9% for indels). Using aggregated data from multiple samples proves to be a promising approach for predicting variant call reliability in individual samples based only on the underlying genome quality, with potential clinical applications as a measure of confidence for candidate variant calls.

## PgmNr 1690: High-specificity variant filter enables joint analysis of whole genome sequence data from multiple studies and sequencing centers.

Joint analysis of whole genome sequencing (WGS) datasets can boost statistical power to detect disease risk-altering alleles. Here we focus on increasing power of a WGS case-control study by incorporating genetic ancestry-matched external WGS samples as additional controls. A first step to ensure data harmonization is to use a functionally equivalent pipeline to map and process alignments. However, in our experience, false positive associations in the resulting genome-wide comparisons still occur due to between-study differences in sequencing protocols or depth. Our goal is to develop high-specificity variant filtering procedures to eliminate such variants, and enable comparisons of WGS studies processed in a compatible manner.

To illustrate the challenges, we execute a joint analysis of African American WGS samples from the NIMH InPSYght study (N=3K controls, N=5K schizophrenia or bipolar cases, average depth 27x) with control samples of the same ancestry from the NHLBI TOPMed Project (N=15K, average sequencing depth 37x). Samples were sequenced at five centers, but sequence data were jointly processed and genotypes called together. We start with a comparison of InPSYght controls versus TOPMed controls, a scenario where we expect no true positive association signals. We adjust for genetic relatedness, sex and four principal components of ancestry, but observe a modest number of false positive associations: 113 common or low-frequency variants reach genome-wide significance ( $p \leq 5 \times 10^{-8}$ ) and an additional 158 also deviate from the expected null distribution. These false positive variants consistently had lower depth and genotyping quality in carriers, which we hypothesized could be driving the spurious associations.

We evaluate strategies for variant filtering using information such as duplicate concordance, Mendelian inconsistencies, sequencing depth and genotype missingness. We show that a strict set of variant filters that remove ~3% of variants (1,153,945 of 41,732,031 variants with allele count  $\geq 10$ ) enable joint analysis. Specifically, we remove variants with either a  $\geq 0.5\%$  discordance between duplicate samples or where  $\geq 2\%$  of the pairs have a missing genotype. In the variant-filtered control versus control comparison no variants reach genome-wide significance nor deviate from the null. Our duplicate-based variant filtering strategies allow for the addition of external controls in WGS datasets to boost power to detect disease associations.

The utility of whole genome sequencing (WGS) to characterize germline variation across the genome has been well-documented, particularly with application to rare disease diagnosis. Compared to whole exome sequencing (WES) alone, WGS delivers more uniform coverage of exonic regions; enables the identification of expanded variant classes including copy number variants (CNVs), structural variants (SVs), and repeat expansions—all of which have been associated with clinical phenotypes; and allows for the detection pathogenic variants outside of the targeted exome.

We anticipate widespread adoption of clinical WGS in the near term for germline variant detection; however, given the range of available library preparation kits and analysis pipelines, it is critical to establish robust quality metrics to define and evaluate the clinical genome. Here we demonstrate the relationship between various sequencing-based metrics and performance of variant calling across different variant classes. While some correlations are intuitive and well-established—such as locus depth with small variant calling—others are more nuanced and novel. We summarize our observations across multiple library preparation techniques and analysis pipelines and demonstrate that our metrics are robust for evaluating clinical genomes across a range of conditions. Finally, we present our proposed evaluation strategy and resulting quality metrics. This evaluation framework can be leveraged to evaluate different clinical WGS protocols, or to evaluate the quality of individual sample results during routine clinical processing. Ultimately, the implementation of uniform quality metrics to define the clinical genome will facilitate both broader adoption of WGS as well as downstream data aggregation efforts to support genotype-phenotype studies.

## PgmNr 1692: High-quality human genomes achieved through HiFi sequence data and FALCON-Unzip Assembly.

*De novo* assemblies of human genomes from accurate (85-90%), continuous long reads (CLR) now approach the human reference genome in contiguity, but the assembly base pair accuracy is typically below QV40 (99.99%), an order-of-magnitude lower than the standard for finished references. The base pair errors complicate downstream interpretation, particularly false positive indels that lead to false gene loss through frameshifts. PacBio HiFi sequence data, which are both long (>10 kb) and very accurate (>99.9%) at the individual sequence read level, enable a new paradigm in human genome assembly. Haploid human assemblies using HiFi data achieve similar contiguity to those using CLR data and are highly accurate at the base level<sup>1</sup>. Furthermore, HiFi assemblies resolve more high-identity sequences such as segmental duplications<sup>2</sup>. To enable HiFi assembly in diploid human samples, we have extended the FALCON-Unzip assembler to work directly with HiFi reads. Here we present phased human diploid genome assemblies from HiFi sequencing of HG002, HG005, and the Vertebrate Genome Project (VGP) mHomSap1 trio on the PacBio Sequel II System. The HiFi assemblies all exceed the VGP's quality guidelines, approaching QV50 (99.999%) accuracy. For HG002, 60% of the genome was haplotype-resolved, with phase-block N50 of 143Kbp and phasing accuracy of 99.6%. The overall mean base accuracy of the assembly was QV49.7. In conclusion, HiFi data show great promise towards complete, contiguous, and accurate diploid human assemblies.

# PgmNr 1693: Mappa monstrix: The benchmarking of alignment tools to establish best practices in long-read whole human genomics.

## Authors:

Long-read sequencing (LRS) technologies, including nanopore-based and single-molecule real-time sequencing, are capable of sequencing single reads spanning repetitive genomic regions and, potentially, entire chromosomes. This potential for *de novo* human assembly has led to studies vetting basecalling, assembly, and polishing tools for this application. In comparison, use of LRS for alignment to references, which has proven useful for smaller genomes, amplicons, and metagenomics, has been considerably less vetted for high-coverage human whole genome sequences (WGS). The number of tools available for alignment is growing in response to need, but the practical differences between alignment pipelines are not yet known.

Upon inspection of LRS alignment tools for their suitability for human WGS, we found some monsters lurking at the fringes of the genome maps. To slay some, we benchmarked the LRS alignment tools with the datasets generated from a healthy white human female, NA12878, on Oxford Nanopore's MinION-platform by the Whole Genome Sequencing Consortium and on the Pacific Biosciences SMRT-sequence data by the National Institute of Standards and Technology. We compared computational performance (peak memory utilization, CPU time, file size/storage requirements), genome depth (X-coverage), and differing breakpoints of structural variants between maps.

We serially ran tools, including minimap2, NGMLR and GraphMap, on the George Washington University high performance compute cluster, Pegasus, to understand the how consistent alignment files generated from each tool under the same conditions were across runs. We then compared read alignments and leveraged structural variant-calling tools, including Sniffles and NanoSV, to assay the physical difference between the maps generated by each alignment tool. Our investigations established that different alignment tools produced different maps and, subsequently, different structural variant callsets. The differences were largely found from comparisons across alignment tools, but also within tools, across runs. Based on these experiments, we propose best practices for use of these tools in long-read human WGS alignment.

## PgmNr 1694: Exploring genetic variation in 132,345 deep whole genomes with BRAVO.

---

The NHLBI Trans-Omics for Precision Medicine (TOPMed) program aims to improve our understanding of heart, lung, blood and sleep disorders by adding deep whole-genome sequencing data to existing high-priority studies of these conditions. To date, TOPMed sequenced >130,000 samples. Harmonized data for the majority of participants are available through dbGaP. In addition to enabling phenotype-genotype association analyses, single nucleotide and short indel variants identified in the TOPMed data, when coupled with annotation, inform human genetic analyses. The TOPMed online variant browser (BRAVO - BRowse All Variants Online) enables researchers to access, explore, and analyze genome variation and supporting data. With BRAVO, researchers have access to ~705M genetic variants in a subset of 132,345 deeply sequenced (>38x) genomes from the latest TOPMed data set (Freeze 8), of which 215M variants (30%) are novel and 323M variants (46%) are singletons (observed in one heterozygous individual). Among the 8M protein-coding sequence variants, 458,513 are predicted loss-of-function, including stop-gain, splice site, and frameshift variants. Short indels constitute 53M (8%) of all identified variants. For each variant, BRAVO provides summary level information including sequencing depth, quality metrics, allele frequency, numbers of heterozygous and homozygous individuals, allele deleteriousness score (CADD), and putative functional consequences. Supporting reads are shown for each variant from anonymized, randomly selected individuals. BRAVO code is publicly available and enables other studies to establish their own compatible variant browser. Future work will enable browsers to communicate, facilitating comparisons of variant list and sequencing depth and other characteristics across studies. TOPMed data is available in BRAVO at <https://bravo.sph.umich.edu>.

## PgmNr 1695: A robust benchmark for germline structural variant detection.

---

New technologies and analysis methods are enabling genomic structural variants (SVs) to be detected with ever-increasing accuracy, resolution, and comprehensiveness. Translating these methods to routine research and clinical practice requires robust benchmark sets. We developed the first benchmark set for identification of both false negative and false positive germline SVs, which complements recent efforts emphasizing increasingly comprehensive characterization of SVs. To create this benchmark for a broadly consented son in a Personal Genome Project trio with broadly available cells and DNA, the Genome in a Bottle (GIAB) Consortium integrated 19 sequence-resolved variant calling methods, both alignment- and de novo assembly-based, from short-, linked-, and long-read sequencing, as well as optical and electronic mapping. The final benchmark set contains 12745 isolated, sequence-resolved insertion and deletion calls  $\geq 50$  base pairs (bp) discovered by at least 2 technologies or 5 callsets, genotyped as heterozygous or homozygous variants by long reads. The Tier 1 benchmark regions, for which any extra calls are putative false positives, cover 2.66 Gbp and 9641 SVs supported by at least one diploid assembly. Support for SVs was assessed using svviz with short-, linked-, and long-read sequence data. In general, there was strong support from multiple technologies for the benchmark SVs, with 90% of the Tier 1 SVs having support in reads from more than one technology. The Mendelian genotype error rate was 0.3%, and genotype concordance with manual curation was  $>98.7\%$ . We demonstrate the utility of the benchmark set by showing it reliably identifies both false negatives and false positives in high-quality SV callsets from short-, linked-, and long-read sequencing and optical mapping. GIAB is working towards a new version of the benchmark set that will use new technologies and methods such as PacBio Circular Consensus Sequencing and ultralong Oxford Nanopore sequencing to expand to more challenging genome regions and include more challenging SVs such as inversions. We are also developing a robust integration process to make calls on GRCh37 and GRCh38 for all seven GIAB samples.

## PgmNr 1696: Scalable prediction of polygenic risk from summary statistics in multiple traits.

---

Polygenic risk scores (PRS) aggregate the estimated effects from many variants to predict disease risk or other phenotypes, where the effects are traditionally estimated from a genome-wide association study (GWAS) on the trait of interest. However, one can improve the predictive power of the risk score by incorporating information from multiple related traits. Existing multi-trait approaches require individual level data for related traits, which may be difficult to obtain, or use GWAS summary statistics with strong assumptions about the genetic correlation across traits. Typically, variant effects in each trait are assumed to be drawn from a polygenic model where the correlation across traits is identical across all regions of the genome. This ignores patterns of local genetic correlation and can lead to inaccurate effect size estimates in regions where the global genetic correlation pattern is a poor match for the true pattern of correlation. To address these issues, we extend existing multi-trait approaches by modeling effects as drawn from a mixture of distributions with different correlation patterns across traits. Our method is flexible yet computationally efficient, and only requires summary statistics to obtain effect size estimates, which are then used for improved risk score prediction. We demonstrate the utility of this multi-trait approach in simulated data and the UK Biobank data in a variety of traits.

## PgmNr 1697: A scalable framework for identifying genetic variant set associated with polygenic-traits in UK Biobank.

---

Genome-wide association studies (GWAS) have been instrumental for discovering disease and trait-associated genetic variants, typically single-nucleotide polymorphisms (SNPs). While GWAS can identify SNPs that are marginally associated with traits using univariate tests, most traits in humans are polygenic – where a trait is influenced by more than one gene. Recently, lasso (least absolute shrinkage and selection operator) has been used as a multivariate prediction model for selecting a set of relevant SNPs that are useful for predicting a phenotype of interest. This regression method simultaneously performs variable selection and estimation.

UK Biobank, a large prospective population-based cohort study, collects extensive genotypic and phenotypic data of 500,000 individuals, aged 40-69 years, from the UK. The study includes genome-wide genotyping data (805,426 measured variants per individual), and more than 2000 health-related phenotypes. This ultra-high dimension, large-scale cohort makes finding subsets of genes associated with a polygenic trait statistically possible in human populations. However, the data size leads to a computational challenge in fitting the entire cohort into limited storage and memory. Recently, Qian et al. proposed a batch screening iterative lasso (BASIL) algorithm that reduces the problem to a manageable size by implementing lasso in an iterative fashion and parallelizing the screening problem in each iteration. Though it works with subsets of predictors, it does not compensate by providing an approximate solution. They implemented BASIL as a highly optimized R package, `snpNet`, and provided examples of finding SNP sets that can predict two quantitative traits (height and BMI) and two qualitative traits (asthma and high cholesterol). Using BASIL, they were able to calculate results 20% faster than other alternatives, and with better I/O efficiency.

In this study, we packaged `snpNet` into a portable docker image and deployed it into a cloud environment. After reproducing the discovery of SNP subsets associated with the original four phenotypes, we further extended the analysis to another 1000 phenotypes. Leveraging the flexible capacity of cloud computing, we are able to discover all SNP sets associations efficiently without worrying about overloading a local server. The `snpNet` docker image and cloud app enables easy adoption of the tool and leverages the massive cloud resource for analyzing high-dimensional datasets like UK Biobank.

## **PgmNr 1698: Joint modeling of winner's curse and study-specific confounding explains replication variability in genome-wide association studies.**

---

Genome-wide association studies (GWAS) have identified thousands of genetic variants associated with complex human traits, but only a fraction of variants identified in discovery studies achieve significance in replication studies. The “replication crisis” in GWAS studies has been well-studied in the context of winner’s curse, which is the inflation of effect size estimates in underpowered studies. Multiple methods have been proposed to correct for the effects of winner’s curse. However, winner’s curse is often not sufficient to explain lack of replication. Another reason why studies fail to replicate is that there are fundamental differences between the discovery and replication studies. A confounding factor can create the appearance of a significant finding while actually being an artifact that will not replicate in future studies. We propose a statistical framework that utilizes GWAS replication studies to estimate the effect of confounders in GWAS summary statistic data. We jointly model the effect of winner’s curse and study-specific confounders and correct for these effects. We apply this framework to 100 human GWAS studies and 22 CFW mouse GWAS studies and show that modeling both winner’s curse and study-specific confounding better accounts for replication between studies compared to an approach that only accounts for winner’s curse.

## PgmNr 1699: Matchmaking patterns at the Undiagnosed Diseases Program site of the Undiagnosed Diseases Network.

The Undiagnosed Diseases Program (UDP), established in 2008, was created to evaluate and research study participants with severe diseases that remained undiagnosed despite extensive clinical workup. The UDP joined with other medical and research centers across the country to start the Undiagnosed Diseases Network in 2013. Clinical genomics has been an important tool for evaluating undiagnosed cases. Diagnostically unrevealing genome and exome studies are commonly encountered and are a research focus at many UDN sites. When non-diagnostic, genomic data is frequently used to generate research hypotheses around genes not currently associated with human disease. Matchmaking, through the Matchmaker Exchange (MME), PhenomeCentral, GeneMatcher and other mechanisms is used to in an attempt to identify interested researchers and build patient cohorts. In an effort to assess the effectiveness of our approach to matchmaking, we reviewed submitted and successfully matched cases from the UDP. For example, PhenomeCentral (our default MME node) contained 542 matches to 65 unique cases. Of those cases, evidence sufficient for a clinical diagnosis was eventually reached in 69% of cases (45)—although not all directly from matchmaking. Some form of matchmaking contributed to clinically actionable or publication suitable results in 38 instances overall. The mechanisms for successful matchmaking were highly diverse, including direct interactions, use of third-party databases and submission to multiple MME nodes. For example, 15 cases were solved via submission to GeneMatcher. Although use of potentially useful phenotypic matching could be demonstrated in PhenomeCentral, essentially all historically successful matches were accomplished via gene names. This observation does not likely account for person to person communication about cases of interest.

Matchmaking is a useful tool for building cohorts and establishing ample evidence to assert a gene-phenotype relationship. However, best practices have not been established and our own activity encompasses heterogeneous approaches. We present data from our own experience with matchmaking, including updated data, plans for refinement of approaches to case matching, and phenotype-based case matching.

## PgmNr 1700: Go Get Data: Simple, reproducible access to genomics datasets and annotations.

### Authors:

M. Cormier<sup>1,2</sup>; B. Pedersen<sup>1,2</sup>; J. Belyeu<sup>1,2</sup>; J. Köster<sup>3</sup>; A. Quinlan<sup>1,2,4</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

---

A common and frustrating problem in genomics is managing the vast datasets and annotations germane to one's experiments. Common problems include the many disparate data and annotation repositories, differences in genome builds, inconsistencies with chromosome labeling, and different coordinate system standard among the various genomic data file formats. Researchers consequently waste valuable time identifying, collecting, and processing relevant datasets for integrative analysis with their experiments. Ultimately, this inhibits reproducibility and constrains research creativity.

Similar problems have existed with software access and usability, motivating the development of software package managers. Inspired by these modern software package management systems, we have developed a data management system, Go Get Data (GGD). GGD utilizes the Conda package management system, along with the infrastructure of Bioconda, to mitigate the many complexities with procuring and curating genomic data.

GGD provides a standardized system delivering simple, reproducible access to a growing number of data "recipes" for automatic data retrieval and processing. Each data recipe contains the set of instructions used to obtain, transform, and standardize genomic datasets, providing fast, easy access to processed genomic data.

Put simply, the GGD tools provide a simple, new approach for reproducible data recipe searching, retrieval, processing, and installation on one's computer. GGD utilizes Amazon cloud storage for data package caching, allowing for rapid data retrieval and processing. GGD allows and encourages community contribution, with multiple tools provided to help scientists easily develop and contribute new data recipes to the GGD ecosystem. This process is further simplified by the application of a continuous integration system within the GGD infrastructure for automatic data recipe testing, uploading data recipe to the cloud, and other system-wide tests. Moreover, GGD is structured to manage diverse -omics data, allowing for the extensive use of multiple data structures and types.

We will present the current GGD framework, existing recipes, and describe future plans for new functionality, along with the development, collection, community contribution, and distribution of data recipes. We anticipate that GGD will become a standard, community-driven ecosystem for -omics data access and data reproducibility.

## PgmNr 1701: WGS sequencing at scale: Experiences from a national genome sequencing project.

### Authors:

P. Fox; A. Hodgkins; D. Bunford-Jones; M. Nelson

[View Session](#) [Add to Schedule](#)

**Affiliation:** Congenica Ltd, Biodata Innovation Centre, Wellcome Genome Campus, Hinxton, CB10 1DR, UK

---

### Introduction:

The UK 100,000 Genomes Project (100K) was launched to develop a national healthcare service based on whole genome sequencing (WGS) in order to halt the diagnostic odyssey experienced by patients and enable system wide transformation.

Congenica's platform was chosen as a clinical decision support platform provider for the 100K in 2015 and, after rigorous competitive evaluation, was announced in 2018 as the exclusive provider for the UK National Genomic Medicine Service (GMS)

**Objectives:** To provide a national clinical decision support platform capable of processing WGS at scale for the new UK GMS

### Methods:

From experience gained in deploying the 100K system the following activities were carried out to allow the system to scale and be operated at the levels required

Database and application code performance engineering to ensure that data was handled efficiently and that users were presented with the necessary data for clinical decisions to be made effectively and quickly.

Moving the system from static hardware to an auto scaling cloud based securely deployed in a cloud environment. The migration from a fixed data centre to a cloud environment enabled a high availability system to be engineered but also hardware to be used on demand rather than incurring high fixed capital costs.

Examining user and administrative actions to simplify and automate where possible, allowing large number of samples to be processed and acted upon with minimal human interaction.

### Results:

Congenica's clinical decision support platform has been successfully deployed on AWS infrastructure to support the new UK GMS. The expected processing capacity of 200+ WGS/day has been met, with flexibility to increase to 400 as required. The system has been iteratively designed to provide the necessary secondary, tertiary analysis and decision support systems to enable physicians and scientists to efficiently interrogate phenotypic and genomic data for diagnosis. The GMS and Congenica's clinical decision support platform is now being rolled out nationally.

### Conclusions:

Through careful engineering and working with users to gain an in depth understanding of the basis of clinical decision making processes it has been possible to produce a secure scalable clinical decision support platform that provides health professionals with standardised auditable workflows, integrated tools and a plethora of contextually relevant data and information to enable accurate clinical decision-making.

## PgmNr 1702: Explore expression patterns of blood cells for patients of non-hematological diseases.

**Authors:**

W. Hsieh; S. Li

[View Session](#) [Add to Schedule](#)

**Affiliation:** National Tsing Hua University, Hsinchu City, Taiwan, Taiwan

---

Gene expression profiles are often studied for tissues at illness. It is interesting to know how the expression patterns of blood cells are affected when people get tumor at certain tissue or are ill with systemic problems such as chronic fatigue. Our study aims at finding the natural grouping of gene expression patterns of blood cells and looking for the common characteristics across diseases. It is also interesting to know if there are any disease-specific markers present in the blood.

Blood expression profiles are generally not available from studies of non-hematological diseases. We collected four expression datasets of moderate sizes from the GEO database. All of them are from peripheral blood cells profiled on the same array platform, Affymetrix HG-U133A, and none of them are from hematological diseases. To better identify potential patterns, we only consider the studies with sample size large enough. Control samples are also provided from each study for contrast. It also facilitates our normalization step.

We propose an iterative clustering strategy based on Sparse K-means and BUS (Batch effects correction with Unknown Subtypes) in search of subgroups of general population and biomarkers. The simulation based on specific design approved the effectiveness of the methodology. The real data analysis explored the difference across patients of lung cancer, chronic fatigue, peripheral arterial disease and different types of breast cancer, and there seemed to be a strong signal from malignant breast cancer in the blood.

## PgmNr 1703: The complete linear assembly and methylation map of human chromosome 8.

---

Obtaining a complete high-quality, sequence-resolved human genome is essential to understand the genetic basis of human health and disease. Recent efforts to assemble human chromosomes from telomere to telomere have led to the successful assembly of the X chromosome and draft assemblies of many others (Miga, Koren et al., unpublished). However, the assembly of a human autosomal chromosome has not yet been completed. Here, we utilize a combination of long-read sequencing technologies, including Oxford Nanopore Technologies (ONT) and Pacific Biosciences (PacBio), as well as a novel sequence assembly algorithm we developed, to complete the linear assembly of human chromosome 8. Specifically, we generate 20-fold coverage of ultra-long-read ONT data (16.6X > 100 kbp) and over 100-fold coverage of PacBio long-read data from the human hydatidiform mole, CHM13. We barcode each ultra-long ONT read with a set of singly unique nucleotide k-mers (SUNKs), which occur only once in the human genome and distinguish regions of the genome from one another. Then, we apply a novel assembly algorithm to link the barcoded ONT reads together, as well as a segmental duplication assembly algorithm to resolve sequence collapses, resulting in the linear assembly of the chromosome 8 centromere and two major segmental duplication blocks on the p- and q-arms. Using 24X PacBio HiFi (high-fidelity) reads, we polish each subassembly and incorporate these into the CHM13 assembly of chromosome 8. We validate the assembly with several orthogonal technologies, including BioNano Genomics, Strand-seq, targeted BAC sequencing, and HiFi reads. Using the polished chromosome 8 assembly, we identify methylated DNA bases, creating a chromosome-wide methylation map. We find that methylated cytosines are specifically enriched at the pericentromeric transitions, consistent with the repressed gene expression reported in these regions. Together, our work reveals the complete linear sequence of chromosome 8 and provides a framework for understanding chromosome-level biology.

## **PgmNr 1704: Toward a joint standardized “default” transcript set: Matched annotation from the NCBI and EMBL-EBI (MANE).**

Understanding the impact of clinically-relevant variants is dependent on accurate and comprehensive annotation of genes and transcripts. However, the large number of alternatively spliced transcripts per locus and the lack of standardized “default” transcripts for clinical reporting and for display across resources present challenges in the clinical context. To address this, EMBL-EBI and NCBI, the two providers of comprehensive and complementary human transcript annotation, are working together on the Matched Annotation from the NCBI and EMBL-EBI (MANE) project. This new initiative aims to generate a genome-wide transcript set that: 1) matches GRCh38, 2) includes pairs of Ensembl/GENCODE (ENST) and RefSeq (NM) transcripts that are 100% identical at the CDS and both UTRs and 3) is high-confidence based on conservation, expression and overall support. The initial output, the MANE Select set, will include one transcript at each protein-coding locus across the genome that is representative of biology at that locus. To select transcripts, each Institute developed independent computational approaches, taking into account evidence of functional potential such as expression levels, evolutionary conservation, and clinical significance. Transcript ends are defined using CAGE data from the FANTOM consortium and polyA data from conventional and nextGen sequencing efforts. Curators from both groups provide a layer of manual review to ensure that automated selections are ideal or to make transcript decisions for complex loci. The MANE Select set will be fairly stable, only allowing updates if absolutely required. To encourage widespread adoption as “default” on browsers and in clinical workflows, we are working closely with clinical partners to prioritize genes deemed to have high gene-disease validity. Currently, we have released MANE Select transcripts for 53% of protein-coding loci and expect an increase to ~ 75-80% by the autumn, with the ultimate goal of achieving genome-wide coverage by 2020. In addition, we intend to release an expanded set of transcripts, the MANE Plus set, to include additional transcripts per locus that capture significant features not present in MANE Select transcripts. Released transcripts are available on all genome browsers and on the NCBI’s FTP site. This work is supported by: Wellcome Trust-WT200990/Z/16/Z; EMBL-Core-Funds; NIH-U41HG007234 and NIH-Intramural-Research-program.

## PgmNr 1705: 5utr: A framework for the interpretation of 5' UTR variants in rare diseases.

---

The importance of untranslated regions (UTRs) in the regulation of gene transcription and translation has been widely appreciated. However, the UTR variants associated with Mendelian disorders have been understudied and underreported in comparison with protein-coding variants despite being captured by exome sequencing. Across all Mendelian disorders, there are less than 300 pathogenic 5' UTR variants reported in ClinVar and medical literature. This is due to our inability to interpret the functional impact of UTR variants and a lack of clear interpretation guidelines. In addition, computational tools applied on 5' UTR variants rarely consider surrounding sequence context, which is critical to assess the functional impact on the upstream open reading frames (uORFs), secondary structures, the effect on translational efficiency, Kozak sequence, and transcription factor binding sites. Taken together, these known functional elements in the 5' UTR can form a framework to assist the annotation and interpretation of rare UTR variants. We have implemented this framework called 5utr and plan to release it as a Variant Effect Predictor plugin.

To validate this framework we annotated a set of published pathogenic 5' UTR variants compared to common benign variants in ClinVar. Approximately 50% of pathogenic variants generated a novel start codon compared to 1% of benign variants. Variants generating novel uORF overlapping with the main ORF have the largest functional effect among 5' UTR variants. Also, reported pathogenic variants had a lower mean predicted translational efficiency and a trend to be more likely in TF binding sites. In contrast, changes in minimum free energy of dsRNA and G4 quadruplex in RNA secondary structure did not differ significantly between variant sets. Interestingly, pathogenicity prediction tools separated pathogenic and benign variants, however the differences were not sufficient for classifying each individual variant.

We show the utility of the framework by classifying variants reported as disease-causing in the literature, as well as present results from large neuromuscular disease cohorts where we have applied this framework to improve the interpretation of UTR variants. A framework to predict the functional impact of UTR variants will become increasingly important as routine efforts to re-analyze existing exome data in undiagnosed Mendelian disorders will require additional novel approaches to improve the overall diagnostic yield.

## **PgmNr 1706: Development of a clinical summary tool that reduces clinical note review time and standardizes phenotype terminology.**

Clinical laboratory testing requires accurate evaluation of physician notes to interpret patient phenotypes. This has become especially important with whole exome sequencing (WES), as it can be used in the molecular diagnosis of a wide range of diseases. As WES testing continues to become more prevalent, a need arises for both efficient clinical note interpretation, and standardization of phenotype terminology. We have developed a computer application, the Clinical Summary Clerk (CSC), that improves the rate and accuracy of clinical note interpretation using autocomplete entry fields and phenotype synonym matching. By using the terminology provided by the Human Phenotype Ontology (HPO), the CSC combines synonyms and standardizes patient phenotypes. Phenotype language is important for patient database consistency and using HPO terms improves querying ability by reducing the number of missed patients due to unknown synonymous or misspelled phenotypes. Additionally, variant prioritization software, such as Codified and Emedgene, often require a list of HPO terms to describe patient phenotypes. The CSC helps provide these terms without any additional time input, as list files are automatically generated. With the reduced time for HPO term or synonym lookup, quick phenotype list editing, and automated file generation, the CSC can reduce time spent summarizing clinical notes by more than 30%. While human interaction is still required for clinical interpretation, it is important to have tools like the CSC to reduce human error and improve efficiency.

## PgmNr 1707: Comprehensive haplotype resolved MHC sequences from whole genome shotgun sequencing from single individual.

---

During the three-day Hackathon organized by UCSC gathering researchers and developers to explore approaches for pan-genomic DNA sequencing analysis in March 2019, we formed a team targeting resolving the MHC regions of a single individual HG002. The recent advance in long-read DNA sequencing technologies has made routinely assembling new human genomes less-daunting tasks than before so we can get a comprehensive view of each human genome in the near future. Meanwhile, not all regions of a human genome will be resolved equally due to variable complexity of the genome sequences. Major Histocompatibility Complex region is one of the many such examples. Given the medical importance of this region, various targeted approaches have been developed before to get additional haplotype resolved sequences that currently are as ALT contigs in GRCh38. In this work, we explore the possibility to reconstruct the haplotype resolved contigs for MHC using just single individual whole genome shotgun sequencing data.

While there are already many de novo human genomes published recently, most of them do not have fully resolved contigs for the MHC region due to either the accuracy or read-length limitation. Our work examines all currently available data from multiple sequencing vendors (10x Genomics, Pacific Biosciences, Oxford Nanopore Technologies) for HG002 collected by the Genome In A Bottle project. With the multiple independent sequencing datasets to complement to each other, we derive a strategy to increase the accuracy on phasing the SNPs and reads for a haplotype-resolved assembly. The multiple technology approaches overcome the accuracy and read-length limitation of each technology used along. We build reproducible pipelines in Jupyter notebooks for assembling de novo contigs, one for each haplotype, spanning the whole MHC region. We construct variant graphs representing intricate large-scale differences to a reference. The SNP-phasing accuracy is validated with the phased variants using the maternal and the paternal genomes. A full spectrum of all variations is identified in the MHC region from the variant graphs and contigs. We hope such comprehensive variation catalog of the MHC region will lead to the insight into the associated biology. Our reproducible pipeline ensures the reproducibility for such complicated bioinformatics tasks and makes the approach re-usable for future work on building better MHC genomic sequences for future pan-human genome projects.

## PgmNr 1708: Accurate, scalable and integrative haplotype estimation.

**Authors:**

O. Delaneau

[View Session](#) [Add to Schedule](#)**Affiliation:** Department of Computational Biology, University of Lausanne, Lausanne, Switzerland

---

Combinations of alleles carried on the same chromosome, called haplotypes, are important genetic features to consider in disease or population genetics studies. As they cannot be experimentally measured, computational methods for their statistical estimation are therefore routinely used. Nowadays, the number of human genomes being genotyped increases exponentially and haplotype estimation methods able to process this amount of data in reasonable times are therefore required.

In this work, we present a new method, SHAPEIT4, which substantially improves over other methods to process large genotype and sequencing data sets. It notably provides very accurate haplotypes and has the nice property of having running times that scale sub-linearly with sample size. We compared SHAPEIT4 with widely used software such as Beagle5, Eagle2 and SHAPEIT3 on a gold standard data set, the UK biobank containing half a million samples. At this scale, SHAPEIT4 is able to provide highly accurate haplotype reconstructions in relatively short running times that are often correct across entire chromosomes.

In addition, we also describe an additional extension of the SHAPEIT4 core model. We notably show how it can conveniently incorporate phasing information naturally present in paired-end, long or barcoded sequencing reads as those provided by Illumina Hi-seq, PacBio or 10x Genomics sequencing technologies, respectively. Using this data together with population level information results in haplotype reconstructions for whole genome sequenced individuals with error rates as low as 0.1%.

Overall, SHAPEIT4 is particularly well suited to fully exploit the potential of the next generation of large datasets being generated using either SNP arrays or new sequencing technologies.

## PgmNr 1709: PoolHapX: De novo haplotype reconstruction from pooled pathogen next-generation sequencing data.

---

Pooled sequencing (pool-seq) is a next-generation sequencing (NGS) strategy where the genomes of several individuals from a population are grouped together and bulk-sequenced. Pool-seq provides an efficient and cost effective alternative to genome sequencing of individuals or single cells, especially in contexts where pathogen genomes are inherently mixed. To determine the frequencies of individual-level polymorphisms and linkage disequilibrium (LD) from a population, the aggregated variation data must be de-convoluted in silico into linkage blocks, or haplotypes, that ideally span whole genomes. Global haplotype reconstruction for genomic sequences estimates the likelihood that variants called from sequencing data occur in the same individual, thereby parsing bulk sequencing data at the single-molecule level. The PoolHapX program approximates the genotypic resolution of single-cell sequencing using only pool-seq data by integrating population genetics models with genomics algorithms to reconstruct haplotypes. PoolHapX first determines locations of long-range linkage uncertainty using short NGS reads, and then divides the full genome into shorter regions. Regional haplotypes are solved for and joined together for a parsimonious global distribution of haplotypes. Complex mixes of whole-genome HIV sequences, each representing the 'pool' of viruses from a patient, were simulated to mimic the diversity found in a HIV outbreak. 100 variant positions were scattered across the genome. Applying a prototypic version of PoolHapX to NGS reads simulated from these patient HIV populations resulted in an average of 99% accurate reconstructions of regional haplotypes. (J. He, C. Cao, L. Mak contributed equally)

## PgmNr 1710: MatchY: The Yale Matchmaker Exchange Node.

### Authors:

---

Over the last few decades, researchers have sought to establish causal links between gene variants and rare Mendelian diseases. Identifying more rare disease patients with variants in the same gene can help validate the causality of novel disease genes. To bolster automated data sharing among rare disease centers across the world, the MatchMaker Exchange (MME) federated network has allowed researchers and clinicians to both share and query cases based on genotypes and/or phenotypes. Moreover, an increase in the number of MME nodes and updates of current node features can further augment data sharing efforts. So far, the MME network contains over 65,000 cases among seven member organizations and eight additional participating institutions.

Here, we present a new node of the MME network: *MatchY*, an open-source, web-accessible, and user-friendly platform for data sharing. This node implements the MME Application Programming Interface (API) and currently contains a substantial cohort of neurological and neuromuscular diseases. The scoring algorithm contained within *MatchY* allows users to match on gene, genotype, and phenotype and facilitates free-text phenotype matching to Human Phenotype Ontology (HPO) terms. In addition, we have added the flexible feature to match on equivalent functional classes of variants instead of restricting matches to the exact variants. For example, matching a nonsense variant with loss of function variants (i.e. nonsense, frameshift and essential splice) within the respective gene. Lastly, the implementation using an elasticsearch data will empower more advanced internal matching as this node grows in size. In summary, we believe *MatchY* can galvanize rare disease research by connecting researchers to more rare disease cases through the addition of cases from the Yale Center for Mendelian Genomics.

## PgmNr 1711: Circulating cell-free DNA detection on the GenapSys sequencer for organ transplant applications.

**Authors:**

M. Fallahi; S. Paliwal; A. Nabi; M.R. Barmi; H. Nezamfar; S. Bagchi; E. LoPrete; B. Dong; X. Gomes; M. Jouzi; A. Thomas; N. Tangprasertchai; H. Esfandyarpour

**Affiliation:** GenapSys Inc., Redwood City, CA

---

Circulating cell-free DNA (cfDNA) can be used as a biomarker for transplant rejection in organ transplant patients. A cfDNA-based assay offers several advantages over traditional invasive tissue biopsy approaches, including lower cost, reduced complications, and reduced interpretation bias. Next generation sequencing (NGS) technology has enabled the accurate determination of the fraction of donor derived cfDNA in a transplant recipient's blood sample, which can be correlated with the potential for organ rejection.

GenapSys has developed a novel, portable, and cheap NGS technology that uses electronic detection to sequence DNA. Implementation of a cfDNA assay for organ transplant rejection on this platform could lead the way to enabling low cost and accessible point-of-care testing for transplant patients in the future.

We evaluated a comprehensive NGS-based cfDNA assay for organ transplants on the GenapSys sequencing platform and developed bioinformatic algorithms for determination of donor-derived cfDNA fraction. Amplicon libraries that target >200 single-nucleotide polymorphisms were generated from samples which contained donor-derived DNA at a range of different fraction levels, including 0% (control), <0.5% and >1%. Libraries were sequenced on the GenapSys sequencing system and sequencing data was analyzed using a custom bioinformatics approach. Briefly, adapter sequences were removed using cutadapt v1.16 and trimmed reads were aligned to the hg38 reference genome using BWA-MEM. The allele frequencies of heterozygous and homozygous SNPs were calculated using BCFtools mpileup and calibrated with reference to control samples.

We demonstrate successful implementation of the cfDNA assay on the GenapSys sequencing platform and the ability to accurately detect donor-derived cfDNA fractions at expected values, including for fractions lower than 0.5%. Additionally, sequencing replicates for a given library correlated well, indicating robust and reproducible performance.

## PgmNr 1712: Finding complex pathogenic variants using nanopore long reads.

---

A variety of complex genomic changes (e.g. tandem-repeat expansions/contractions, chromothripsis, transposable element insertions) are known to cause rare human genetic diseases. These changes are hard to find using conventional methods (e.g. short read sequencing). We have been developing new methods to find such complex genomic changes using long read sequencing data from patients with rare genetic diseases. We will present our two new pipelines; 1) *tandem-genotypes* which can predict tandem repeat copy number changes and prioritize possible pathogenic changes by comparing to healthy controls, 2) *rearranged-sequence-clumps* which can find patient-only rearrangements by subtracting rearrangements present in controls, and reconstruct them. Our methods are easy to use, applicable to multiple long read sequencing platforms and in fact can efficiently find pathogenic variants. We hope wider application of long read technologies will find pathogenic complex genomic changes that have been overlooked by short read sequencing.

## PgmNr 1713: AdaFDR: A fast, powerful, and covariate-adaptive approach to multiple hypothesis testing.

Multiple hypothesis testing is an essential component of modern data science. Its goal is to maximize the number of discoveries while controlling the fraction of false discoveries. In many settings, in addition to the p-value, additional information/covariates for each hypothesis are available. For example, in eQTL studies, each hypothesis tests the correlation between a variant and the expression of a gene. We also have additional covariates such as the location, conservation and chromatin status of the variant, which could inform how likely the association is to be due to noise. However, popular multiple hypothesis testing approaches, such as Benjamini-Hochberg procedure (BH) and independent hypothesis weighting (IHW), either ignore these covariates or assume the covariate to be univariate. We introduce AdaFDR, a fast and flexible method that adaptively learns the optimal p-value threshold from covariates to significantly improve detection power. On eQTL analysis of the GTEx data, AdaFDR discovers 32% and 27% more associations than BH and IHW, respectively, at the same false discovery rate. We prove that AdaFDR controls false discovery proportion, and show that it makes substantially more discoveries while controlling false discovery rate (FDR) in extensive experiments. AdaFDR is computationally efficient and can process more than 100 million hypotheses within an hour and allows multi-dimensional covariates with both numeric and categorical values. It also provides exploratory plots for the user to interpret how each covariate affects the significance of hypotheses, making it broadly useful across many applications.

## PgmNr 1714: pCNN: A phylogeny-regularized convolutional neural network for predictive modeling of microbial data.

---

With the development and decreasing cost of next-generation sequencing technologies, the study of the human microbiome has become an important research field accounting for huge potentials in clinical applications such as drug response predictions, patient stratification, and disease diagnosis. Thus, it is essential and desirable to build a microbiome-based prediction model for clinical outcomes based on microbiome profiles consisting of taxon abundance and a phylogenetic tree. One important characteristic is all microbial species are not uniformly distributed on the phylogenetic tree but tend to be clustered at different phylogenetic depths. Thus, the phylogenetic tree represents a unique correlation structure of microbiome, which might be an important prior information for the prediction. However, prediction methods that consider the phylogenetic tree in an efficient and rigorous way are under-developed.

We develop a deep learning prediction method pCNN (Phylogeny-Regularized Convolutional Neural Network) to predict phenotype/outcome (either quantitative or qualitative) by using both the taxon abundance and the phylogenetic tree. pCNN designs different convolutional layers to capture different taxonomic ranks (e.g. species, genus, family, etc.) with different convolutional kernels on each convolutional layer to capture the signals of evolutionary close microbiome species in a local receptive field. Together, the convolutional layers with its built-in convolutional kernels capture microbiome signals at different taxonomic levels while encouraging local smoothing induced by the phylogenetic tree. Comprehensive simulation studies demonstrate that pCNN outperforms other competing methods in the scenarios of large signal cluster or the dense signal clusters, while pCNN is still on par with other methods in other scenarios when the tree is informative. Moreover, pCNN has comparable prediction performance with other methods when the tree is non-informative. We further apply pCNN to two real datasets and find pCNN could predict age and gender more accurately compared to other methods.

## PgmNr 1715: Phylogeny-enhanced prediction tools for microbiome data.

**Authors:**

T. Wang; S. Wang

[View Session](#) [Add to Schedule](#)

**Affiliation:** Department of Biostatistics, Mailman School of Public Health, Columbia University, New York, NY

---

Associations between microbial community and human health have been well-studied and established. Sophisticated statistical methods have been developed to examine associations between microbiome data and health outcomes utilizing the distinctive features of microbiome data, i.e., large number of compositional and sparse taxa and the phylogenetic tree structure for taxa. Researches have also been done to predict health outcomes using microbiome data. However, these studies applied existing prediction tools directly, such as random forest (RF) or k-nearest-neighbors (KNN), when these methods ignore the unique feature in microbiome data, namely the phylogenetic tree structure. Here we propose a general framework that 1) enhances the existing prediction tools by accounting the phylogenetic tree structure through re-weighting the contribution of samples using multiple microbial distance metrics that capture various aspects of association between microbiome data and health outcomes, and 2) optimally selects one microbial distance metric that most accurately predicts outcomes of interest. We demonstrated the performance of the proposed general framework in enhancing in RF and KNN and developed phylogeny-enhanced RF (PhyEn-RF) and phylogeny-enhanced KNN (PhyEn-KNN). Simulation studies suggest the superior performance of PhyEn-RF and PhyEn-KNN over the original RF and KNN when different associations between microbiome and health outcomes were considered. We applied PhyEn-RF and PhyEn-KNN to gut microbiome data of malnourished Bangladeshi children (ENA: PRJEB5482) and found that the proposed methods consistently outperform the original ones in predicting several microbiome-related health outcomes using microbiome data.

## PgmNr 1716: Using mutual information to detect correlations between nucleotide positions in noncoding DNA.

### Authors:

J. Dannemiller

[View Session](#) [Add to Schedule](#)

**Affiliation:** Psychological Sciences, Rice University, Houston, Texas.

---

**Background:** The base at a given position in a coding DNA sequence is correlated with the bases at downstream positions because of biases in codon usage. This leads to a 3 bp periodic signal in base occurrence in coding DNA. Noncoding sequences lack this periodicity, but one might still expect to find some degree of predictability from upstream to downstream locations because of various conserved features (e.g., transcription factor binding site motifs in promoters) or because of sequence-dependent 3D conformational constraints. The goal of this research was to examine noncoding DNA sequences for evidence of significant short-range, distance-dependent correlations between base locations. **Methods:** Bias-corrected Mutual Information (bcMI) was used to quantify the dependency between any two locations in sequences of a) promoters, b) introns, and c) exons (at least 20,000 sequences for each type). Exon sequences were included as a check on the use of bcMI as the measure of dependency. bcMI was estimated at distances of 1 to 21 bp from various initial locations. Randomly shuffled sequences were used as negative controls; they showed bcMI values near 0 at all distances. **Results:** For all sequence types, bcMI generally fell (the downstream base became less predictable) with increasing distance between the two locations. There was, as expected, a clear 3 bp periodicity in the bcMI vs. distance function in exon sequences. This 3 bp periodicity was absent from the promoter and intron sequences, but there was a trend-reversing rise in bcMI at a distance of 6 bp in both sequence types with weaker evidence of another signal at a distance of 12 bp. Remarkably, this rise in predictability at a distance of 6 bp survived random misalignments (+/- 40 bp range) of the promoter sequences with respect to each other suggesting that it is a delocalized property of promoter sequences. The 6 bp signal in bcMI was also artificially produced by randomly inserting hexamer double tandem repeats in the shuffled promoter sequences. **Conclusions:** This rise in predictability at a distance of 6 bp in noncoding DNA can be seen in previous reports (e.g., Grosse et al., 2000), but its significance as a general property of noncoding DNA has heretofore not been articulated. It could reflect the presence of many short tandem repeats in noncoding DNA. Another possibility is that it reflects constraints on nucleotide sequence imposed by energetic or structural properties of the helical molecule.

# PgmNr 1717: Validation of germline structural variation reporting from clinically oriented ultra-deep amplicon sequencing.

## Introduction

Structural variants (SV) are genetic variation spanning >50bp. Pathogenic SVs are found in >0.24% of human genomes. Techniques that estimate SV from next-generation sequencing (NGS) data have emerged & exemplify the versatility of genome & exome sequencing. These methods rely on depth of coverage (DOC) variation, split reads, & paired-end mapping to find SV breakpoints in areas of relatively uniform coverage. Amplicon sequencing is a robust & affordable alternative to WGS & WES. The extreme DOC for target regions supports novel variant discovery & highly accurate variant calling. Determining SV from amplicon sequencing is challenging due to variation in DOC across a target region & non-random read start positions. We developed & validated a DOC based method (ArielCNV) for amplicon-resolution SV estimation from a proprietary amplicon panel based on the Illumina AmpliSeq chemistry (San Diego, CA).

## Development

ArielCNV is implemented in the Nim programming language & utilizes a stepwise approach for CNV estimation, loosely adapted from the CNVPanelizer method described by Oliveira, et al. The tool uses input from a sample BAM file (unknown), a bed file that defines the contigs & a reference BAM file. Aligned read counts for the sample & reference samples meeting a MAPQ cutoff (e.g. 30) are counted for each contig. Read counts are normalized using the trimmed mean of M method. Bootstrap analysis of contigs within a given gene are subsampled & used to calculate a DOC ratio. A mean ratio & 2.5% - 97.5% quantile range are reported for each gene. Individual contig ratios are compared to baseline to estimate contig level copy changes by comparing the z score relative to all samples, then calculating a two-sided p value with subsequent correction with the Benjamini-Hochberg false discovery rate.

## Preliminary Validation

Samples of known CNV were sequenced with the proprietary Ariel panel. Cell lines/DNA samples were obtained from the NIGMS Human Genetic Cell Repository at the Coriell Institute for Medical Research. Initial validation tested *CYP2D6* and *CEL*, which have SV and fusions with their neighboring pseudogene. Within four known samples, correct CNV detection was reported in all cases.

## Conclusions

ArielCNV is a novel method for the estimation of SV from amplicon sequencing. Preliminary validation showed concordance in known samples for *CYP2D6* and *CEL*. Future work will seek validation in other clinically relevant genes and clinical implementation of SV.

## PgmNr 1718: Doc2Hpo: A web application for efficient and accurate HPO concept curation.

Phenotype terms from electronic health record (EHR) narratives can be used to improve the interpretation of sequencing data and expedite clinical diagnosis of patients with suspected Mendelian diseases. However, the process for clinical researchers to manually curate the standardized phenotype terms such as Human Phenotype Ontology (HPO) concepts from the clinical text remains laborious and can be error-prone.

To address the critical need for efficient and accurate HPO concept curation, we developed Doc2Hpo, a novel web application based on the human-computer collaboration design principle for semi-automatically extracting phenotype terms from the clinical text with automated concept normalization using HPO. Doc2Hpo automatically highlights clinical entities with their corresponding HPO mappings to facilitate manual review and revision if needed. Users can edit the HPO concepts automatically extracted by Doc2Hpo in real time, and export the final list of HPO concepts to gene prioritization tools for further analysis. Our evaluation showed that Doc2Hpo significantly reduced manual effort while achieving high accuracy in HPO concept curation.

Doc2Hpo is freely available at <https://impact2.dbmi.columbia.edu/doc2hpo/>. The source code is available at <https://github.com/stormliucong/doc2hpo> for local installation for protected health data.

## PgmNr 1719: Biological discovery and consumer genetics activate latent privacy risk in omics data.

**Authors:**

S.E. Brenner; Z. Hu

[View Session](#) [Add to Schedule](#)**Affiliation:** University of California, Berkeley, California.

---

Privacy risks from individuals' genomic data have garnered increasing attention. Sharing genomes without personal identifiers is common practice. However, recent studies and forensics underscored the ability to re-identify a person, using genomic relatives and quasi-identifiers, such as sex, birthdate and zip code. The additional availability of omics data, such as transcriptomics and methylation data, has implications for privacy, as it may also be linked to the genome, potentially allowing privacy breach. For example, sex and ethnicity information may be inferred directly from a genome, and the study may provide zip code. This could be linked to RNA-seq data from a disease study with attached birthdates and income. These combined quasi-identifiers may uniquely identify the person, and the study reveals the person's disease status.

Sequence reads from any experiment contain genetic variants, and thus can be directly linked to the genome. To avoid this risk, researchers may release only processed data instead of raw reads. For example, studies generating RNA-seq data may release only gene expression, isoform expression and exon read count data. However, a recent study suggested that gene expression data can be linked the genome based on genotypes inferred from expression QTLs (eQTLs). Splicing data has been reported as safe, as splicing QTLs (sQTLs) are 200 times lessas 0.5% abundant than as eQTLs, but we demonstrate that splicing data can be reliably linked to a single genome, from a population of thousands. Such a linking for DNase hypersensitive sites and gene expression data now enables the identification of a genome uniquely from the world population. This new risk has arisen due to growing biological knowledge, including from increased data that allow the identification of more molecular QTLs. Additionally, consumer genomics databases have made rendered many more individuals potentially recognizable, including via their relatives. Our study implies further hidden privacy risks in existing data, which will only manifest over time. While it is accepted that the security of many cryptographic security methods degrade over time, the need to preserve individuals' genomic privacy for their lifetime and beyond (for descendants) poses unique challenges to the effective sharing of high-throughput molecular data.

# PgmNr 1720: A sparse deep learning model for phenotype prediction.

**Authors:**

J. Chen; X. Shi

[View Session](#) [Add to Schedule](#)**Affiliation:** Dept. of Bioinformatics and Genomics, UNC Charlotte, Charlotte, NC.

---

**Motivation:**

Phenotype prediction has been widely utilized in many areas to help understand disease risks and susceptibility, and improve the breeding cycles of plants and animals. However, there are several barriers that make it extremely challenging to develop robust and powerful methods for phenotype prediction, including high dimensionality and collinearity in genomics data. Most of phenotype prediction are based on regularized statistical approaches which only consider linear relationships among genetic variants. Several recent studies have reported that deep learning has strong potentials to address high dimensional problems for prediction tasks in various domains including image analysis and natural language processing. Hence, we will explore novel deep learning models for phenotype prediction on high dimensional genomic data.

**Methods:**

In this study, we propose a Sparse Convolutional Predictor with Denoising Autoencoders (SCP\_DAE) for phenotype prediction. Our novel SCP\_DAE model takes the advantages of sparse convolutional network (CNN) and denoising autoencoder (DAE) architectures to address two critical challenges in high dimensional genomic data analysis. First, we utilize a sparse CNN to capture local structure information or correlations in genomic data and introduce model sparsity by incorporating an L1 regularization on the weight matrix to avoid overfitting. Second, we use an efficient representation of genotype data derived from DAEs in an unsupervised way and pretrain model layers to improve model performance.

**Results:**

We comprehensively evaluated the performance of our proposed models on a yeast genomic dataset that contains the genotypes of 28,820 genetic variants and 20 traits assessed in 4,390 samples. We first show that adding an L1 regularization to a CNN based predictive model can prevent overfitting and improve the prediction performance. Next, by adding DAE pretrained weights, our final model of SCP\_DAE significantly outperforms other methods including SCP without DAE, Lasso, elastic net, and random forest.

**Conclusion:**

This study demonstrates that a novel deep learning model based on sparse CNNs coupled with DAE pre-trained weights can significantly improve phenotype prediction on high dimensional genotype data. This new model for phenotype prediction can provide insights on how to better understand disease susceptibility and risks, and allocate resources for improving plant and animal breeding.

## PgmNr 1721: Expansion of the 1000 genomes project resources in the International Genome Sample Resource (IGSR).

### Authors:

S. Fairley; E. Lowy; G. Aldam; E. Perry; P. Flicek

[View Session](#) [Add to Schedule](#)

---

The 1000 Genomes Project created the largest fully public catalogue of human genetic variation, including openly available reference resources, which continue to be widely used. IGSR was established to maintain and expand those resources.

IGSR aims to make resources available on GRCh38, include new data types and add to the collection of openly consented samples.

The 1000 Genomes Project was based on GRCh37. IGSR has realigned the low-coverage whole genome and exome data from 1000 Genomes to GRCh38. These alignments have been used as the basis for calling variants from the 1000 Genomes data directly on GRCh38. This used GATK, BCFtools and FreeBayes for site discovery, GATK for genotyping and BEAGLE and SHAPEIT2, to produce an imputed and phased call set, which was shared in 2018.

Cell lines created for the 1000 Genomes samples continue to be used in data generation. The New York Genome Center (NYGC), funded by NHGRI, have sequenced the genomes of the 2,504 samples in the 1000 Genomes phase three panel to ~30x coverage. In addition, NYGC have shared a GATK call set generated from this data. IGSR hosts this data and makes it available alongside other data generated from 1000 Genomes cell lines and other openly consented samples.

Data in IGSR currently includes a wide variety of data types generated by the Human Genome Structural Variation Consortium (HGSVC), including Oxford Nanopore, PacBio and 10X Genomics data. The resources also include data on samples which were not present in 1000 Genomes. These are from the Gambian Genome Variation Project (GGVP), the Human Genome Diversity Project (HGDP) and the Simons Genome Diversity Project (SGDP).

Through our freely available analysis pipelines, we continue to extend the range of available open genomic data on GRCh38.

To support users in locating and using the data, our website contains a data portal, enabling exploration of available data by data type, population, collection or sample. Our website contains further information on data access and we also provide an email helpdesk, providing bespoke support for those using the data.

IGSR makes openly consented genomic data accessible to the wider community through collaboration

with data generation groups. We continue this work and remain open to establishing new collaborations where we can provide support for data sharing.

## PgmNr 1722: Ancestry clustering and classification in large-scale data using neural networks.

It is well known that allele frequencies vary between populations of differing ancestry. This so-called population structure has an impact across multiple domains, including the diagnosis and treatment of disease in the clinic, and the identification of disease-associated loci in the lab. However, there is no publicly available way to quickly and easily answer the question, “Genetically, what is this individual’s ancestry?” In order to answer this question, we propose the use of two kinds of neural networks – an autoencoder to perform dimensionality reduction and clustering, and a multi-layer perceptron to perform classification.

An autoencoder is a type of deep neural network that operates by reconstructing its input data after passing it through a low-dimensional space that serves as a bottleneck. The fact that the data can be reconstructed implies that its more compact representation at the bottleneck is a meaningful way to encode the input data. We used the autoencoder to determine 2-D representations of SNP array data for tens of thousands of patients in the Children's Hospital of Philadelphia biobank. Plotting the results reveals distinct clustering by ancestry. We further used the autoencoder representations as inputs to the multi-layer perceptron classifier.

A multi-layer perceptron is a neural network that consists of multiple layers of artificial neurons. These successive layers are capable of learning complex features of the input data. Our network is designed to output probabilities of an individual’s membership in various racial or ethnic groups. Our approach achieved 98.7% accuracy in early tests with the sample restricted to Causasians and African Americans. Work to expand the number of classification groups is underway. Ultimately, we aim to return a probability distribution for each individual’s ancestry, which would be particularly useful in the case of admixed individuals.

## PgmNr 1723: Considering natural isotopes in peptide de novo sequencing: An implementation in R.

Proteomics, as an -omic science, has made a massive progress in the past decade, generating a tremendous amounts of data that show considerable challenges for their interpretation. With the revolution of high resolution Mass Spectrometry, the mining of this flood of data for analysis and interpretation becomes possible. However, to supply the suitable biologically interpretation, an accurate identification of all proteins present in the sample is needed. Tandem Mass Spectrometry-based de novo peptide sequencing is a valuable tool for protein identification. Peptide de novo sequencing technology attempts to derive a peptide's amino acid sequence from the input spectrum. Several software based on different algorithms and programming language for de novo sequencing have been developed. To date, no tool performing de novo sequencing exists in R, the user-friendly programming language for biological researcher. Furthermore, existing tools doesn't handle isotopic information. It is popularly assumed that considering natural isotopes will considerably improve protein identification accuracy.

In this following work, we propose a novel R tool for de novo peptide sequencing. The tool implements UniNovo in R with considering the natural isotopes.

Our experimental results demonstrate that our tool significantly improves the accuracy of protein identification taking into account the isotopic information. In addition, our tool will be a valuable alternative for the R researcher community.

## PgmNr 1724: Uncovering causal noncoding regulatory variants in human disease through allelic protein-RNA.

---

It has become evident that a majority of genetic variants associated with human diseases reside in non-coding genomic regions which may play a role in regulating multiple steps of gene expression. A comprehensive catalog of precisely mapped regulatory variants (RVs) in human populations, along with the ability to determine disease-causing RVs in individuals, holds great promise for improving disease diagnoses and ultimately patient care. However, causal noncoding RVs remain extremely difficult to identify in most cases due to the insufficient resolution of genetic mapping and our incomplete understanding of gene expression regulation. In this study, we develop **approaches to identity causal noncoding RVs modulating post-transcriptional gene expression regulation, such as RNA splicing and stability**. Since RNA-binding proteins (RBPs) and their interactions with target transcripts play central roles in these regulatory steps, **SNPs affecting protein-RNA interactions represent one major source of disease-causing RVs**. We performed a proof-of-principle study to analyze CLIP data of over 100 RBPs in human cell lines from ENCODE and precisely mapped SNPs affecting protein-RNA interactions. In particular, the heterozygous SNPs showing allelic imbalance between reference and alternative alleles provide direct experimental evidence of altered protein-RNA interactions with potential impact on downstream post-transcriptional gene expression regulation and individual phenotypes. Furthermore, the concordance between the allelic imbalance of CLIP tags and changes in motif scores provides unbiased validation that the motifs reliably reflect RBP binding specificity and the impact of SNPs on protein-RNA interactions is direct. With this approach, we determined the specificity of a list of *de novo* candidate motifs for many RBPs that were previously poorly characterized. Our analysis also identified a list of SNPs as allelic protein-RNA interaction sites with high confidence and thus candidate RVs. Our approach overcomes the low signal-to-noise ratio associated with bioinformatic predictions of RBP binding sites and provides a valuable resource to annotate noncoding variants.

## PgmNr 1725: Covariate adjusted rare-variant association (CARVA) testing for millions of samples.

**Authors:**

R. Bohlender; Y. Yu; J. Chen; C. Huff

[View Session](#) [Add to Schedule](#)

---

As biobank scale sequencing datasets become more common, statistically rigorous and computationally efficient tools for the analysis of these data have become increasingly important. Covariate-adjusted permutation offers a robust and generalizable solution for assessing the statistical significance of rare variant association tests but has been underutilized due to computational concerns. Thus, analysis of biobank scale sequencing datasets has generally been limited to statistical analysis methods with analytical approximations. Here, we introduce the software package Covariate Adjusted Rare-Variant Association (CARVA), which is designed to conduct fast and memory efficient multithreaded association analysis of large sample sets, with support for highly scalable covariate adjusted permutation. CARVA currently supports 10 statistical tests, including CMC, SKAT, SKAT-O, WSS, VT, and VAAST. The core innovation in CARVA is a highly-optimized, adaptive permutation engine that implements two novel approaches for covariate-adjusted permutation of large datasets. First, CARVA permutes only minor allele carriers, which are the only samples that contribute to the statistical significance of a gene. Second, CARVA supports approximate binning of individuals with similar odds of being a case, reducing the number of categories to permute. In addition to adaptive permutation, these steps greatly reduce the computational burden of permuting large datasets. To limit memory usage, CARVA leverages sparse matrices where possible. CARVA is implemented in C++ using efficient linear algebra libraries, which further enhances memory efficiency and computational scalability. As such, it is possible to analyze a data set with one million samples on a 2015 MacBook Pro with a 2.2 Ghz Intel Core i7 and 16 GB of ram. Total run time for the analysis of a set of 500 genes in 500,000 cases and 500,000 controls, running on 5 threads was approximately 5 hours on the above laptop, with maximum memory usage at roughly 1.6 GB. Speed and memory usage scales roughly linearly with the number of threads. CARVA provides the means to conduct robust rare variant association studies on very large data sets that will be available in the foreseeable future.

## PgmNr 1726: Identifying effects of rare variants on gene expression with likelihood ratio test.

---

Genome-wide association studies have discovered numerous non-coding genetic variants associated with complex diseases and traits. It has been hypothesized that those non-coding variants may affect diseases or traits by regulating gene expression, and expression quantitative trait loci (eQTL) studies have identified many common variants with regulatory effects. Recently, sequencing studies have started to identify roles of rare variants in complex diseases and traits, but regulatory effects of rare variants have not been thoroughly investigated. A traditional statistical approach to detect effect of a genetic variant through a single marker test may be underpowered for rare variants as their low occurrence limits power. To address this challenge, group-wise test methods that aggregate effect of rare variants in genes have been proposed. As these methods are susceptible to power loss when non-causal variants are included in tests, they often utilize prior information on variants such as minor allele frequency, Polyphen-2 or SIFT to remove non-causal variants from the analysis. In eQTL studies where many of eQTLs are in non-coding variants, prior information such as CADD scores and distance to a transcription start site may be used to prioritize causal non-coding variants. Here, we present LRT-q, a likelihood ratio test method that incorporates genotype data and prior information of genetic variants in a nonlinear manner to infer causal rare variants. It then uses this finding to identify rare variants associated with gene expression, assuming that individuals with abnormal gene expression are likely to enrich for causal rare variants. We demonstrated through simulations that LRT-q has higher power than other methods, including widely used SKAT-O. We also showed that LRT-q detected more novel genes regulated by rare variants that were not detected by common variants analysis in six tissues in Genotype-Tissue Expression (GTEx) by incorporating prior information about variants, in comparison with previous methods.

## **PgmNr 1727: Actionable Genomic Interpretation System (AGIS): A comprehensive and accurate knowledgebase system for variant clinical interpretation using ACMG-AMP standard guideline.**

### **Authors:**

W. Ding; C. Chen; J. Li; Q. Zhang; Y. Wan

[View Session](#) [Add to Schedule](#)

**Affiliation:** Admera Health, South Plainfield, New Jersey.

---

With the continued development and adoption of massively parallel next-generation sequencing (NGS) technologies, one major hurdle in making precision medicine a reality is to turn genomic data into clinical information that can be easily used in medical practice. A truly effective solution at minimal requires: 1) a fully automated data analysis and interpretation workflow from raw data to clinically actionable report; 2) a comprehensive and high-quality database for fast and accurate clinical interpretation of variants; 3) a scalable and reliable IT infrastructure; 4) a clinically validated process that meets regulatory requirements; and 5) being demonstrated in real medical practice with great satisfaction. We have developed a web-based Actionable Genomic Interpretation System (AGIS) that has all above features with automated interpretation step and a manual adjustment step. Strictly following the 28 criteria provided by ACMG-AMP standards and guidelines, we also implemented an automated process to systematically integrate comprehensive information from Human Gene Mutation Database (HGMD), ClinVar, 1000 Genome Project, dbSNP, and other population, disease-specific, and sequence related databases, as well as a number of in silico predictive algorithms. The AGIS system is able to provide reliable and consistent genetic variant interpretation with the five-tier classification system (Pathogenic/Likely pathogenic/Benign/Likely Benign/Uncertain significance) and help human interpreters understand the clinical significance of genetic variants intuitively. Our implementation allows any potential new variants to be included and provides the most updated information to the scientific community. Currently it contains three major modules that can be used separately or in combination: Pharmacogenomics Module for guiding personalized disease treatment; Disease Risk Module for disease risk assessment; Genetic Disease Module for diagnosing hereditary diseases. The AGIS system can be easily used by researchers and clinicians, and will significantly enhance our understanding of the functional consequences of genetic variants in human diseases. The AGIS system is available at: <https://agis.admerahealth.com/>

## **PgmNr 1728: Assessment of statistical batch effect correction methods for different RNA sequencing data types.**

### **Authors:**

G. Cai <sup>1</sup>; S. Ni <sup>1</sup>; F. Xiao <sup>2</sup>

[View Session](#) [Add to Schedule](#)

### **Affiliations:**

---

RNA-sequencing has rapidly become the mainstream method to profile and characterize transcriptome. However, batch effect makes downstream data analyses such as differential expression detection challenging and may affect the final conclusion. A handful models and methods have been developed and shown power in removing the batch effect in RNA-seq data. However, there is no clear guideline for method selection and application. Typically, two RNA-seq data formats are widely used for analysis, one is discrete RNA-seq raw read count and the other is transformed continuous FPKM/RPKM or CPM value. Researchers frequently ask which of these two formats should be used for batch effect correction. To rigorously answer this question and guide the method selection, we perform a systematic assessment of 13 existing batch effect removal methods for read count (edgeR, DESeq, limma-voom, SVASEq, RUVSeq, PCA) or continuous value (limma, LS, ComBat, SVA, RUVg, RUVs, RUVr, PCA). We evaluate their performance by the correction of between-batch variance, influence on within-batch variance, the AUC and type I error of downstream differential expression analysis. 6-site generated RNAseq data from the third phase of the MicroArray Quality Control (MAQC-iii) project were used. We also simulated outliers into the dataset to evaluate the robustness of batch effect removing. We found no one single method was superior than others in all scenarios. Based on the evaluation, we discuss the advantages, disadvantages, application scopes and matching data formats of these batch effect correction tools. We expect to provide a valuable application guide for researchers to make wise choices RNA-seq data batch effect correction accommodating to their specific experimental designs and analysis strategies.

## PgmNr 1729: IRNAA: An integrated shiny-based interface for differential expression analysis of RNA sequencing data.

**Authors:**

C.C. Huang; R. Azondekon

[View Session](#) [Add to Schedule](#)

**Affiliation:** Zilber School of Public Health, University of Wisconsin, Milwaukee, WI

---

**Background:** Given the significant progress made in the analysis of next-generation sequencing (NGS) data, numerous tools/packages have been developed for facilitating the downstream analysis of NGS data. Up to now, several R packages have been developed for differential gene expression analysis. Yet, those tools remain difficult to use for many researchers as they require extensive programming skills. In addition, they are difficult to integrate and to install without basic knowledge of command line scripting. More importantly, they lack the capacity to streamline RNA sequencing (RNA-seq) alignment, read quantification, and downstream analysis such as differential expression (DE) and pathway analyses.

**Implementation:** We present IRNAA, an integrated shiny-based interface for DE analysis of RNA-seq data, available for Ubuntu and related Linux distribution, as well as Microsoft Windows operating systems. IRNAA is built as a dashboard with multiple analysis components organized in boxes. In its GNU/Linux compatible implementation, IRNAA integrates the Salmon pseudo-aligner, FastQC and MultiQC, two bioinformatics tools for quality check assessment of RNA-seq reads, downstream DE analysis by DESeq2, limma-voom, edgeR, and pathway analysis by gProfile and WebGestalt. The application source code is freely available at <https://www.github.com/rosericazondekon/irnaa>.

**Conclusion:** IRNAA is very easy to install and does not require any programming experience or knowledge to preprocess RNA-seq FASTQ files and/or conduct DE analysis. IRNAA has the potential to facilitate the application of NGS methods in transcriptomics research.

## PgmNr 1730: A comprehensive evaluation of preprocessing methods for single-cell RNA sequencing data.

**Authors:**

S. Chu<sup>1,2</sup>; Q. Liu<sup>1,2</sup>; Y. Shyr<sup>1,2</sup>

[View Session](#) [Add to Schedule](#)

**Affiliations:**

1) Department of Biostatistics, Vanderbilt University Medical Center, Nashville, Tennessee, United States of America; 2) Center for Quantitative Sciences, Vanderbilt University Medical Center, Nashville, Tennessee, United States of America

---

**Background:** Normalization and batch correction are critical steps in the preprocessing single cell RNA sequencing (scRNA-seq) data, which remove unwanted technical effect and systematic biases that unmask biological signal of interest. Although numerous computational methods have already been developed, there is no guidance for choosing the appropriate procedures in different scenarios.

**Method:** We benchmarked 23 procedures combining normalization and batch correction methods on both synthetic and real datasets in multiple scenarios, which considered relative magnitude of batch effects compared to biological effects and imbalanced cell compositions. The performance was evaluated by the capabilities to reduce batch effects, as well as to recover biological effects of interest, and the execution time.

**Result:** Batch effects can be removed at least by 60% on most procedures when they are not confounded with biological effects and they are not the major contributor to the variations. When batch effects confound with biological effects or their variations are larger than biological variations, the performance depends on their underlying mathematical models of batch correction (i.e., using linear model, nonlinear transformation, or linear-nonlinear combined adjustment).

**Conclusion:** The performance assessment of popular scRNA-seq preprocessing procedures can serve as a guideline to help users select the best method in the different scenarios.

## PgmNr 1731: Visualization and analysis of single-cell RNA-seq data by alternative clustering.

---

Single-cell sequencing technology provides higher resolution for both cell differences and gene expression patterns, enabling unbiased global transcriptomic analysis. As the assay no longer targets a specific purpose, cells may be classified from various perspectives. For example, cells from macula and peripheral regions of retinae from multiple donors may be classified by their types or regions. Current visualization (e.g., tSNE, UMAP) and clustering (e.g., hierarchical clustering) methods only give an arbitrary single view of the data, which dissipates the power of scRNA-seq. Current batch effect removing methods may suppress one aspect to emphasize the others. However, they are widely criticized for exaggerating confidence in downstream analyses, because the differences between regions or donors are not technical noise and directly manipulating the expression data is problematic.

In this work, we focus only on discovering clusterings from different perspectives. We introduce “Varactor”, Visualization and Analysis of single-cell RNA-seq data by Alternative CLUSTERing. Varactor takes the expression matrix and the alleged nonpreferred clustering, which are either labeled beforehand, or previously discovered from the data. It redefines the pairwise distance of the cells, where the effect of the unwanted clustering is controlled, and use tSNE (which can be substituted with any distance-based clustering methods) on the new distances. It simply provides a new perspective for inspecting the similarity of the cells, instead of manipulating the expression data. The differential expression analysis may then be performed on the original data with the batches considered either strata or covariates.

On our retina dataset, we observe that Varactor successfully give tighter clusters for cell types validated by known marker genes while keeping subtle heterogeneity among donors as the detailed structure of each cluster. In contrast, even after performing Multi-CCA, Seurat still needs gene selection to give clear clusters, and cells from all donors are exaggeratedly mixed together. On a human brain single-cell dataset, we also observe that Varactor outperforms Multi-CCA implemented in Seurat in finding meaningful clusters, and the visualization result is comparable with the ones on a carefully selected gene sets provided in the original report. The new distance also adapts many clustering and trajectory inference methods. We expect Varactor to evoke more *ab initio* findings.

## PgmNr 1732: Surface protein imputation from single cell transcriptomes by deep neural networks.

---

Recent technological advances allow the simultaneous profiling, across many cells in parallel, of multiple omics features in the same cell. In particular, high throughput quantification of the transcriptome and a selected panel of cell surface proteins in the same cell is now feasible through the REAP-seq and CITE-seq protocols. Yet, due to technological barriers and cost considerations, most single cell studies, including Human Cell Atlas (HCA) project, quantify the transcriptome only and do not have cell-matched measurements of relevant surface proteins that can serve as integral markers of cellular function and targets for therapeutic intervention. This motivates our inquiry of whether protein abundances in individual cells can be accurately imputed by the cell's transcriptome. Here we propose single cell Transcriptome to Protein prediction with deep neural network (cTP-net), a transfer learning framework that harnesses a multi-branched deep neural network to accurately predict single-cell surface protein relative abundances from scRNA-seq data.

We benchmark cTP-net's prediction on a diverse testbed of immune cell populations, and show that it achieves correlation  $> 0.9$  for the 10 proteins examined in a traditional holdout validation scheme. We also found cTP-net to have good generalization power, retaining high accuracy in tissues, cell types and technologies that differ from, but related to, the training data. cTP-net improves upon Seurat3, achieving higher accuracy in both the holdout scheme and generalization to unseen cell types. We generate predictions of 12 cell surface proteins for 530,000 cord blood and bone marrow mononuclear cells (CBMCs and BMMCs) that were deposited in the HCA portal and illustrate that multimodal data analysis by cTP-net can achieve a more detailed characterization of cellular phenotypes than transcriptome measurement alone. In addition, through interpolation analysis, we reveal that cTP-net utilizes a combination of cell type markers and genes related to RNA processing, protein localization and biosynthetic process to achieve multiscale imputation accuracy. With the accumulation of CITE-seq and REAP-seq data, cTP-net can be retrained to improve in accuracy and diversify in predictable protein targets. The results here underscore the need for more diverse multi-omic cell atlases and demonstrate how such resources can be used to enhance future studies. The cTP-net package is available at <https://github.com/zhouzilu/cTPnet>

# PgmNr 1733: NanoVar: A deep neural network for accurate detection of SNPs and Indels from long-read sequencing data.

## Authors:

M. Ahsan <sup>1</sup>; Q. Liu <sup>1</sup>; K. Wang <sup>1,2</sup>

[View Session](#) [Add to Schedule](#)

## Affiliations:

1) Raymond G. Perelman Center for Cellular and Molecular Therapeutics, Children's Hospital of Philadelphia, Philadelphia, PA 19104, USA; 2) Department of Pathology and Laboratory Medicine, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA 19104, USA

**Purpose:** Long-read sequencing technologies, such as Oxford Nanopore and PacBio SMRT, produce substantially longer reads than Illumina short-read sequencing. Their unique advantage in detecting structural variants from sequence alignments enables examination of complex and repetitive regions of the human genome. However, their high base call error rates (typically >10%) complicates the detection of SNPs and Indels. Currently available software, such as GATK, show high variant calling accuracy for short-read data, but perform poorly on long-read data. But, recent developments in deep learning have shown promising results in improving the variant calling accuracy for long-read data.

**Methods:** We developed NanoVar, a deep convolutional neural network (CNN) that exploits error-prone Nanopore sequence reads for accurate variant calling. Using reads from a BAM file, it generates pileup images for candidate variant sites, which contain base information for a 33bp region around the site. The images consist of 5 feature channels; the first 4 record presence of the 4 bases and the 5th channel records base quality with reference match information. Pileup images are fed into a CNN model consisting of 3 convolutional and 3 fully connected layers, to predict alleles and genotype at the candidate sites. In a second neural network nearby variants sites are aggregated together to utilize haplotype information and re-score true variants and alleles. The model is subject to continuous adjustments and improvements.

**Results:** NanoVar was trained on both HG001 and HX1 whole-genome sequencing data and tested independently on chromosome 1 of each dataset. Ground truth calls for HG001 was sourced from Platinum Genomes Project, and high confidence variant calls for HX1 were generated from high-coverage Illumina data. NanoVar shows fast I/O run-time by leveraging parallel processing and outperforms variant callers designed for short-read sequencing data such as GATK. It also performs competitively against other variant callers designed for long-read data, including Longshot and deep neural network variant caller Clairvoyante.

**Conclusion:** Our preliminary analysis showed that NanoVar enables SNPs/Indel calling from long-read sequencing data, and can be easily adapted for a range of sequencing technologies. We conclude that long-read sequencing can generate accurate SNPs/Indels calls as a competitive alternative to short-read sequencing for genome analysis, at the expense of higher coverage.

## PgmNr 1734: An Omics Analysis, Search and Information System (OASIS) for mining association summary statistics from biobanks and knowledge portals.

### Authors:

J.A. Perry; B.D. Mitchell; J.R. O'Connell

[View Session](#) [Add to Schedule](#)

**Affiliation:** Program for Personalized and Genomic Medicine and Division of Endocrinology, Diabetes and Nutrition, University of Maryland School of Medicine, Baltimore, MD, 21201, USA

---

**Introduction:** Billions of associations between omic (e.g. genomic, transcriptomic, methylomic) variation and thousands of phenotypes have been computed and are quickly becoming publicly available. Knowledge Portals and Biobanks are already sharing summary statistics from their association analyses on public websites and a trend toward “open access” for data generated by government sponsored research is spreading worldwide. But there is a void in the arena of “scientist-friendly” tools for mining association results and transforming them into biological discovery. And while many annotation, visualization, and functional mapping resources are available, they are not automated or integrated into a meaningful process for discovery. Here we describe a tool for automating the mining process and integrating association results with functional annotation, data visualization and a variety of fine-mapping techniques.

**Methods:** An Omics Analysis, Search and Information System (OASIS) was constructed for mining data from the UK Biobank and from the data repositories used to populate the Type 2 Diabetes Knowledge Portal. OASIS is a web-based tool with robust, multi-faceted search capabilities. It provides on-demand linkage disequilibrium (LD) calculations, visualizations (e.g. boxplots, histograms, LocusZoom plots), and a broad spectrum of functional annotation. OASIS’s unique display of query results seamlessly integrates with online resources (e.g. dbSNP, genomAD, GTEx) and user-provided “known loci lists” to facilitate novel omic discoveries. User-generated summary statistics (i.e. GWAS or meta-analysis from the user’s lab) can also be loaded into OASIS for comparison with Biobank and Knowledge Portal findings.

**Results:** Association results from multiple repositories and user-generated analyses can now be easily mined and compared. Results for all variants within a locus can be viewed as a group and compared by LD values and functional annotation. Any set of variants can be selected for a customized display in the UCSC Genome Browser to understand which variants, of those with high LD, lie in regulatory regions (e.g. Dnase hypersensitivity sites, promoter/enhancer regions).

**Conclusion:** Transforming massive volumes of association results into “biological discovery” has been made dramatically easier. OASIS allows both analyst and non-analyst easy access to summary statistics from large repositories and uniquely integrates with multiple bioinformatic resources.

## PgmNr 1735: HiC-ACT: Improved chromatin interaction calling from Hi-C data via aggregated Cauchy test.

---

Genome-wide chromatin conformation capture (3C) technologies such as Hi-C are commonly employed to study chromatin spatial organization. In particular, to identify statistically significant long-range chromatin interactions from Hi-C data, most existing methods such as Fit-Hi-C and HiCCUPS assume that all chromatin interactions are statistically independent. Such an independence assumption is reasonable for low resolution data (e.g., 40Kb bin), but is invalid for high resolution data (e.g., 5 or 10Kb bins) since spatial dependency of neighboring chromatin interactions is non-negligible in high depth data. When the independence assumption is violated,  $p$ -values corresponding to chromatin interactions may not be accurate. There is an urgent need to develop approaches that can not only capture spatial dependence, but are also computationally efficient and scalable. To address these challenges, we develop HiC-ACT, an aggregated Cauchy test (ACT) based approach, to improve the identification of significant chromatin interactions by post-processing calling results from methods relying on the independence assumption. HiC-ACT can be applied to results from any existing Hi-C interaction calling methods, enabling  $p$ -value local smoothing with negligible computational cost. To evaluate the performance of HiC-ACT, we re-analyzed publicly available deeply sequenced Hi-C datasets. Our results demonstrate that HiC-ACT improves sensitivity for the existing Hi-C interaction calling methods.

## PgmNr 1736: The *ped suite*: A collection of R packages for pedigree analysis.

### Authors:

M. Vigeland <sup>1</sup>; T. Egeland <sup>2</sup>

[View Session](#)[Add to Schedule](#)

We introduce a suite of packages for pedigree analysis in R. These packages, referred to as the *ped suite*, cover a wide range of topics and applications, but are built on the same fundamental data structures and coding principles. The packages are designed to work together, facilitating analysis of complex problems. A novel feature of the *ped suite* is the ability to handle *inbred founders*, leading to several improvements over existing methods.

The main packages in the *ped suite* are as follows:

**pedtools**: A comprehensive tool set for creating, manipulating and visualizing pedigrees and marker data. This is the core of the *ped suite*, imported by all the other packages.

#### Packages for marker-based analysis

**pedprobr**: Probability computations in pedigrees. The main content of this package is an implementation of the Elston-Stewart peeling algorithm for exact genotype probabilities in a given pedigree.

**forrel**: Forensic pedigree analysis and relatedness inference. This package also offers simulation of marker data, possibly conditional on known genotypes.

**pedbuildr**: Reconstructing small/medium-sized pedigrees from genotype data. The purpose of this package is to find the most likely pedigree connecting a collection of genotyped individuals.

**pedmut**: A framework for modeling mutations in pedigree computations.

#### Packages for marker-free analysis

**ibdsim2**: Simulation of the gene flow through pedigrees. In particular, such simulations can be used for studying distributions of chromosomal segments shared *identical-by-descent* by pedigree members.

**ribd**: Computation of pedigree-based relatedness coefficients, including kinship coefficients and Jacquard's identity coefficients. Both autosomal and X-linked coefficients are computed, in pedigrees of any complexity (including selfing). More specialized coefficients include generalized kinship coefficients and two-locus coefficients.

## PgmNr 1737: SAIGEgds: An efficient statistical tool for large-scale PheWAS with mixed models.

**Authors:**

Zheng; J.W. Davis

[View Session](#) [Add to Schedule](#)**Affiliation:** Genomics Research Center, AbbVie Inc, North Chicago, IL

---

Phenome-wide association study (PheWAS) is known to be a powerful tool in discovery and replication of genetic association studies. The recent development in the UK Biobank resource with deep genomic and phenotyping data has provided unparalleled research opportunities. To reduce the computational complexity and cost of PheWAS, the SAIGE (scalable and accurate implementation of generalized mixed model) method was proposed recently. However, it is still computationally challenging to analyze the associations of thousands of phenotypes with whole-genome imputed and whole-exome variant data, especially for disease diagnoses using the ICD-10 codes.

Here we develop a new high-performance statistical package (SAIGEgds) for large-scale PheWAS using mixed models. In this package, we implement the SAIGE method with optimized C++ codes and fully take advantage of sparse structure of genotype dosages. SAIGEgds supports efficient genomic data structure (GDS) files including both integer genotypes and numeric dosages. Benchmarks using the UKBiobank White British genotype data (N=430,235) with coronary heart disease and simulated cases, show that SAIGEgds is 5 to 6 times faster than the SAIGE R package in the steps of fitting null models and p-value calculations. When used in conjunction with high-performance computing (HPC) clusters and/or cloud resources, SAIGEgds provides an efficient analysis pipeline for biobank-scale PheWAS.

## PgmNr 1738: Coexpression is not a network.

**Authors:**M. Farahbod<sup>1,2,4</sup>; P. Pavlidis<sup>1,2,3</sup>[View Session](#) [Add to Schedule](#)**Affiliations:**

1) The University of British Columbia, Vancouver, British Columbia, Canada; 2) Michael Smith Laboratories, University of British Columbia, Vancouver, British Columbia, Canada; 3) The UBC Department of Psychiatry, University of British Columbia, Vancouver, British Columbia, Canada; 4) Graduate program in Bioinformatics, University of British Columbia, Vancouver, British Columbia, Canada

---

Coexpression analysis is commonly used as an aid to interpreting transcriptomic studies of disease. A motivation behind such analyses is the idea that coexpression is due to coregulation and/or that it reflects direct relationships between gene products. These assumptions are reinforced by the common representation of coexpression as a network. Here we show through computational analysis that much of observed coexpression identified in bulk brain tissue studies is due to the effects of cellular composition variation between samples. Therefore, interpretations of coexpression as a network representing physical or regulatory interactions is unlikely to reflect underlying biology. We focused on analysis of human neocortex, which has been the topic of many studies using coexpression to probe numerous psychiatric and neurological conditions. We first show that for most genes, differences in expression between brain cell types explain a large fraction of the variance of observed expression in bulk tissue (median adjusted  $R^2 = 0.34$ ). We then show that the similarity of expression patterns across cell types predicts the tendency for genes to be coexpressed in bulk tissue. These observations explain functional enrichment analysis of gene clusters in bulk brain tissue as simply reflecting cell-type-specific gene expression patterns. We also show that robust coexpression patterns observed in single nucleus RNA-seq data are highly distorted in bulk tissue, due to the effect of cellular composition. The impact of these results is several-fold. First, it accounts for the most prominent reported characteristics of coexpression as arising from differences in gene expression between cell types, not regulation per se. Second, it implies that the ability to extract regulatory information from coexpression is confounded by cellular composition effects, and therefore dramatically limited, helping explain why many algorithms designed to do so have high error rates. Third, it shows that interpretations of coexpression as networks can be highly misleading, and in particular the concept of “hubs” in coexpression does not parallel features of any physical network. While our analysis is of brain tissue, the same phenomenon is likely to explain coexpression in other tissues. Overall our findings urge a rethink of the value and interpretation of coexpression as a routine part of transcriptome analysis workflows.

# PgmNr 1739: Ranking transcription factor binding motifs in ChIP-seq data without p-values.

## Authors:

---

**Introduction:** Transcription factor binding *in vivo* is mapped by techniques like chromatin immunoprecipitation-sequencing (ChIP-seq) and cleavage under targets and release using nuclease (CUT&RUN). Sequence motifs found more frequently near the center of these methods' peaks often represent direct DNA binding by the targeted transcription factor.

The most common approach to quantitatively rank motifs enriched in peak centers uses p-values. For each candidate motif, this approach examines  $n$  peaks and identifies the number of peaks  $X$  where the best motif match is in a central window. It then calculates a  $p$ -value using a binomial distribution for  $X$  with parameter  $\theta$  (the probability for a sequence being aligned to a center window), under the null hypothesis of no central enrichment. Finally, it ranks motifs by their (one-sided) binomial  $p$ -values. Unfortunately, the use of  $p$ -value here is problematic because the  $p$ -value magnitude is dominated by severe heterogeneity in the number of peaks between motifs.

**Methods:** We created a new method for ranking central enrichment of sequence motifs that measures effect size instead of  $p$ -value significance. Our method ranks motif central enrichment by the lower bound of the confidence interval for the parameter  $\theta$ , after adjusting for multiple testing.

We compared the rankings of our method with three different classes of alternative methods in both simulated and published ChIP-seq data. First, we compared with the binomial  $p$ -value approach above. Second, we compared with Bayesian credible regions using either conjugate prior or AshR (Stephens 2017), an empirical Bayes method. Third, we compared with Cliff's  $\delta$  (Cliff 1993), which quantifies central enrichment of one distribution over another.

**Results:** Extensive simulation studies showed that our method outperforms the binomial  $p$ -value approach when sample sizes vary independently of, or are inversely proportional to, effect sizes. All approaches performed similarly when sample sizes stay constant between tests or vary proportionally to effect sizes.

Using published ChIP-seq data for GATA3, our method ranked the known targeted motif highest, even

among similar motifs for other GATA factors. Our method also ranked the known motif highest for SRF. In both cases, the  $p$ -value approach failed to assign the top rank to the known motif. While other effect-size methods performed similarly, we recommend the confidence interval method for its simplicity and ease of implementation.

## PgmNr 1740: A method to discover combinatorial variants within transcription factors that are associated with gene expression variability.

**Authors:**

Y. Tang; A. Gottlieb

[View Session](#) [Add to Schedule](#)

**Affiliation:** Center for Precision Health, University of Texas Health Science Center at Houston, 7000 Fannin st, Houston, TX, 77030.

---

**Background:** Gene expression plays a key role in determining cellular states. Estimating the genetic component underlying gene expression can thus help our understanding of disease etiology or predict disease risk.

Recent approaches to estimate the genetic component of gene expression involve polygenic models that include combination of variants with large cumulative effects called “transcriptome imputation”. However, transcriptome imputation have thus far manages to explain only a small portion of expression variability for most genes. As it has been limited to variants in the *cis* regions of the gene, this suggests that other genetic components may be involved.

**Results:** We hypothesize that variants within transcription factors (TFs) may also contribute to variability in gene expression. We developed models to identify combinations of these variants. We introduce three models, corresponding to possible mechanisms by which variants in TFs can affect gene expression: effect on TF expression, on TF binding affinity or on both. We applied our TF models to four tissues – skeletal muscle, subcutaneous adipose, skin and whole blood and show that our TF models are robust across tissue types. We identified combinations of variants in TFs that explain the expression of 80 genes better than *cis* models and in 27 of the genes, the TF models include variants with higher association with expression than *cis* variants. These variants were undetected individually as trans-eQTLs.

Among our discoveries, we highlight variants discovered in TF models applied to adipose and muscle tissues associated with Type 2 Diabetes, including the genes *IRS1* and *ABCC8* and their corresponding TFs, *TCF3* and *REST*. Similarly, we highlight variants in TFs associated with basal cell carcinoma discovered in skin tissue.

**Conclusions:** Our approach is useful for identifying regulation mediated by combinatorial effect of genetic variations within TFs and can improve our understanding of genetic component of gene expression and ultimately the connection between genotype and phenotype.

## PgmNr 1741: Machine learning-based prediction of gene expression modifiers prioritizes non-coding variants causal for rare disease.

### Authors:

Q. Wang <sup>1,2</sup>; D. Kelley <sup>3</sup>; R. Tewhey <sup>4</sup>; Y. Reshef <sup>5</sup>; K. Karczewski <sup>1</sup>; L. Francioli <sup>1</sup>; A. O'Donnell-Luria <sup>1</sup>; D. MacArthur <sup>1</sup>

---

Whole genome sequencing (WGS) has the potential to elucidate non-coding regulatory mutations responsible for severe phenotypes. However, identifying non-coding causal variants from WGS data is still challenging. The availability of large-scale functional genomics resources, genomic constraint metrics, and direct measures of the effect of genetic variation on RNA expression provides an opportunity to improve the prioritization of such variants.

Here we propose to integrate functional genomics data and sequence-based regulatory activity prediction into a single score by training a predictor of the effects of SNVs on the expression of proximal genes. Our predictor combines publicly available epigenetic and transcriptional activity features (ENCODE/ROADMAP/FANTOM5) with sequence-specific features from the neural network-based method Basenji to output a tissue-specific Expression Modifier Score (EMS). We trained our predictor on fine-mapped expression quantitative trait loci (eQTLs), and used known literature-derived non-coding causal variants as test data.

When using eQTL data from Geuvadis, our predictor distinguished between variants with posterior probability (p.p.) of having a causal effect on gene expression  $>0.9$  ( $n=198$ ) and variants with  $p.p.<0.2$  ( $n=991$ ), with 76.8% true positive rate at 20.0% false positive rate, higher than using Basenji features or epigenetic features alone (70.0%, 68.4%).

We then hypothesized that a large fraction of non-coding variants causal for rare disease act by modifying the expression of proximal genes, and tested our predictor's ability to identify a set of such variants curated from the literature ( $n=209$ ). We defined two sets of negative control variants based on allele frequency, and tested the predictor's ability to prioritize causal variants over the control sets. The area under curve (AUC) ranged from 0.68 to 0.72, slightly higher when the rare control variants are used, suggesting that EMS could be useful in rare variant prioritization, despite relying on a training data set of common eQTLs.

Finally, we will present our ongoing analysis of causal variants in GTEx dataset, quantification of constraint in non-coding regions in large population genomics database (gnomAD), and show our framework for integrating such large-scale data to enhance the power of causal variant discovery.

## PgmNr 1742: PopSTR2 enables population-scale and clinical genotyping of microsatellites.

### Authors:

S. Kristmundsdóttir <sup>1,2</sup>; H. Eggertsson <sup>1,3</sup>; G. Árnadóttir <sup>1</sup>; B. Halldórsson <sup>1,2</sup>

---

Microsatellites, also known as short tandem repeats (STRs), are tracts of repetitive DNA sequences containing motifs ranging from one to six bases. Microsatellites are one of the most abundant type of variation in the human genome, after single nucleotide polymorphisms (SNPs) and Indels. However, microsatellite variations are rarely considered in whole-genome sequencing studies and clinical sequencing, in large due to a lack of tools capable of analyzing them.

PopSTR2 is an update and extension of our previous work 'PopSTR a population based microsatellite genotyper'. Given a list of samples and microsatellite markers it genotypes each sample at each marker. Microsatellites are highly polymorphic and often show a high somatic polymorphism rate. PopSTR2 automatically adjusts parameters to account for variable sequencing accuracy and has user specified parameters related to the sequencing read length. We supply a kernel to quickly estimate a sample specific slippage rate, making the genotyping more sensitive to each sample's properties. For clinical sequencing purposes, a panel of known pathogenic repeat expansions is provided along with a script to quickly check all markers in the panel for reads supporting an expansion.

Like its predecessor, PopSTR2 allows for the joint genotyping of samples at a population scale. To increase the power of downstream association we also provide a binning method to make markers more amenable to analysis within standard association pipelines.

# PgmNr 1743: Quantifying the quality of small INDELs called in sequencing analysis.

## Authors:

H. Dai; Y. Guan

[View Session](#) [Add to Schedule](#)

**Affiliation:** Biostatistics and Bioinformatics, Duke University School of Medicine, Durham, NC.

Current quality score of INDEL call generated by various variant calling bioinformatics tools were not well calibrated. Here we present a method to quantify the variant calling quality for small INDELs using calibrated posterior probability.

Our method is based on Nubeam, which can quantify the genetic difference between collections of reads. Nubeam represents nucleotides by matrices, transforms a read into a product of matrices, and based on which assigns numbers to reads. A collection of reads becomes a collection of numbers that form an empirical distribution. The genetic difference between collections of reads is quantified by the distance between empirical distributions.

When an INDEL is called, we obtain three collections of sequencing reads: reads used to call the INDEL (denote  $R_1$ ), reads simulated from alternative allele (denote  $R_2$ ), and reads simulated from reference allele ( $R_3$ ). We then calculate the Nubeam distance between  $R_1$  and  $R_2$  (denote  $d_{12}$ ) and that between  $R_1$  and  $R_3$  (denote  $d_{13}$ ). We obtain a likelihood ratio as  $L(d_{12}, d_{13}) = \exp(-\beta d_{12}) / \exp(-\beta d_{13})$  and treat it as a naïve Bayes factor (nBF), where  $\beta$  is a tuning parameter. The population frequency of the called INDEL is taken as the prior odds. Multiplying the nBF and prior odds we obtain the posterior odds, from which we calculate the posterior probability (which is a function of  $\beta$ ). We then tune the parameter  $\beta$  to calibrate the posterior probability.

We first used simulations to demonstrate that the nBF can predict if a collection of reads originates from alternative allele or reference allele. We simulated INDELs at random positions across human genome; for each INDEL, we simulated two collections of  $R_1$  reads, one originates from heterozygous alleles and the other from homozygous reference alleles. When  $\beta$  takes one, we predicted that the  $R_1$  originates from heterozygous alleles if  $\text{nBF} > 1$  and from homozygous reference alleles if otherwise. The accuracy was 100% in 1,000 simulations even when INDEL size was one. We then randomly selected 3,000 heterozygous INDELs from Genome in a Bottle (GIAB) benchmarking variant calls. Using reads from Illumina 2×148bp 300× WGS dataset, an nBF cutoff of one classified 97% of them as true variants. The preliminary results using nBF show that our method is promising in quantifying the INDEL calling quality by calibrated posterior probability.

## PgmNr 1744: GraphTyper2 enables population-scale genotyping of structural variation using pangenome graphs.

---

Analysis of sequence diversity in the human genome is fundamental for genetic studies. Structural variants (SVs) are frequently omitted in sequence analysis studies although each has relatively great impact on the genome. We present GraphTyper2, which uses pangenomes to genotype SVs along with small variants using short-reads. We use public datasets to show that our SV genotyping is sensitive and variant segregation in families demonstrates the accuracy of our approach. We generated long-read sequences from 41 Icelanders to assess the quality our short-read SV calls. Using the long-reads, we validated 67.7% of our 8,568 high-confidence SVs on average per genome. We show that GraphTyper2 can simultaneously genotype tens of thousands of whole-genomes by characterizing 60 million small variants and half a million SVs in 49,962 Icelanders, thereof 80 thousand SVs with high-confidence. GraphTyper2 is a valuable tool for characterizing sequence variation in large-scale sequencing studies.

## PgmNr 1745: Evaluating variant calling best practices in a non-European population.

Analyzing human DNA sequence data allows researchers to identify variants associated with disease, reconstruct demographic histories of human populations, and further understand the structure and function of the genome. Currently, different strategies exist to genotype variants, remove false positives, and identify false negatives within sequence data. However, many current methods have been optimized for studying European populations. With the number of sequences analyzed from non-European populations growing, it is increasingly important to re-evaluate the “best practices” that guide the processing of human DNA sequence data and to assess how different methods may impact downstream analyses. Here, we evaluate the concordance and accuracy of different variant calling strategies such as joint and single-sample genotyping as well as different filtering procedures such as Variant Quality Score Recalibration (VQSR) and hard-filters within whole genome and whole exome sequences from individuals from Northwest Kenya. Since human males typically have one X chromosome and one Y chromosome and since current methods are optimized for genotyping the autosomes, we also evaluate how to best genotype the sex chromosomes. In addition, we compare the ability of joint and single-sample genotyping to accurately identify rare variants which may be associated with disease but are difficult to distinguish from sequencing errors due to their low frequency. We generated variant call sets for the autosomes, mitochondrial chromosome, and sex chromosomes using joint and single-sample genotyping and filtered using both VQSR and hard-filters. Genotype concordance between call sets was assessed, and the accuracy of variant calls was measured by comparing call sets to highly confident SNP array genotype data. We also evaluated the concordance between singleton sites found on the array and sites found in the joint and single genotyped call sets. Since both whole genome and exome sequencing are commonly used to obtain measures such as nucleotide diversity and the site frequency spectrum, we also evaluated how different genotyping and filtering techniques impacted these summary statistics. Characterizing the concordance and accuracy between these variant calling and filtering methods and comparing the differences in haploid and diploid genotyping of the Y chromosome will establish a more effective protocol for variant discovery in non-European populations and within the sex chromosomes.

## PgmNr 1746: Performance evaluation of different approaches for insertion and deletion variation detection from next generation sequencing data.
