Concluding, we have designed an RNA based method for MRD detection of fusion genes with promising results. Expanding the panel with other fusion genes will not influence the performance of the probes already in the panel and allows the analysis of multiple samples in one experiment without the need for optimization.

---

**Background:** Colorectal cancer (CRC) is one of the most common forms of cancer and is responsible for approximately 700,000 deaths per year worldwide. Because of this, colorectal cancer screening is recommended by the USPTF, but patient compliance can be low due to the invasiveness of screening colonoscopy. We had previously described ColonES, a highly accurate, non-invasive plasma-based screening assay to identify colorectal cancer at an early stage using ctDNA methylation haplotypes. Here we present an additional study utilizing the ColonES assay in an independent cohort of samples, further demonstrating highly accurate detection of early-stage colorectal cancer. **Methods:** Blood samples from 64 healthy individuals and 66 individuals diagnosed with colorectal cancer by colonoscopy were collected in EDTA tubes and immediately separated into plasma. Plasma samples were then processed using the Singlera Genomics ColonES assay, a targeted bisulfite sequencing method which identifies methylation haplotype patterns specific to early- and late-stage colorectal cancer. **Results:** In this independent test set, the ColonES assay was able to show a sensitivity of 89% in colorectal cancer patients with a specificity of 97% in healthy patients. **Conclusions:** We have shown that ctDNA methylation can be utilized to non-invasively screen for early-stage colorectal cancer with high sensitivity in two independent sample sets, paving the way for a primary blood-based colorectal cancer screening assay.

## **PgmNr 2421: NSCLC-UHS: Detection of hotspot mutations of non-small cell lung cancer patient with plasma samples. Ultra-high-sensitive mutation detection system.**

---

Circulating cell-free DNA (cfDNA) has great potential in clinical filed including care of cancer patients. Previously, prognostic and predictive value of cfDNA in non-small cell lung cancer (NSCLC) has been reported by several studies. Genetic mutations of EGFR, KRAS and BRAF genes in tumor derived cfDNA in patient with lung cancer could be applied as biomarkers for monitoring the early steps of tumor progression or a recurrence. However, low amount and extremely low tumor-derived DNA rate are recognized as hurdles to be overcome of cfDNA application.

In this study, we developed NSCLC-UHS (Ultra High-Sensitive) panel, which targets hot-spot mutations of BRAF, KRAS and EGFR in multiplex fashion using low amount cfDNA. Using the serially diluted positive samples, detection sensitivity of this panel was evaluated to be 0.05%. We performed targeted NGS analysis for detection of genetic mutations using FFPE tumor tissue DNA and matched cfDNA extracted from 0.4 ml plasma of 30 NSCLC patients, then, NSCLC-UHS panel test was done using cfDNA to compare the mutation patterns of EGFR, KRAS and BRAF genes. Focusing EGFR mutations, 20 of 30 cfDNA from NSCLC patients (66%) showed same mutation pattern with those of tumor tissue DNA by targeted NGS analysis. When considering the amount of applied cfDNA was very low from 0.1 ng to 1 ng, 66% detection sensitivity of NSCLC-UHS assay is very impressive. We expect that the sensitivity will be dramatically improved by increasing the input amount of cfDNA with higher starting volume of plasma.

In conclusion, Onco-UHS method is fast and cost-effective methods for a targeted set of mutations and can be used for selection of chemotherapy and for validation of NGS.

## PgmNr 2422: Digital PCR partitioning with near zero dead-volume for liquid biopsy applications.

Digital PCR (dPCR) has emerged as a promising technique to both detect and precisely quantify rare targets. This has made dPCR particularly attractive for monitoring rare mutations in liquid biopsy. Partitioning of a sample into large number of independent reactions is fundamental to dPCR. Although microfluidics has greatly aided the partition process, currently available partitioning technologies suffer from limitations in 3 critical aspects – partition volume consistency, partition number consistency and sample waste.

Variable volume results in variable distribution of targets inside the partitions and undermines the mathematical basis of dPCR analysis. Fluctuating partition numbers underscores the instability of the partitioning process and introduces unnecessary variables into an assay. Wasted sample or “dead volume” introduces subsampling error and reduces accuracy of the result. Subsampling error is a function of both the expected target concentration and degree of subsampling. The combination of rare targets with large dead volume greatly diminishes dPCR accuracy.

Here we present a novel Microfluidic Array Partitioning (MAP) technique that utilizes injection molded arrays and fluidic control to overcome these limitations. Injection molding ensures all partitions have a consistent and defined volume regardless of inputted sample. Partition size is defined not by a stochastic process but by the physical limitation of the microwells. The partition array is of fixed geometry and ensures consistent number of partitions for all samples across experiments. The number of partitions is defined by the array geometry and is minimally susceptible to variation in the partitioning process. Enabled by a novel loading process, the MAP consumable utilizes >95% of inputted sample and significantly reduces subsampling error compared to other technologies that often partition less than three quarters of loaded sample.

To demonstrate the utility of the technique, we adapted a commercially available assay and performed dPCR quantitation using KRAS G12D mutation containing plasmids in a background of WT human genomic DNA. Using MAP devices, we were able to consistently quantify 10%, 1% and 0.1% mutant to wild-type DNA with consistent partition volume, minimal partition number variation and greater than 95% utilization of inputted sample volume. Taken together, the new technique provides a promising path towards bringing dPCR into the clinic for liquid biopsy applications.

## PgmNr 2423: Molecular cytogenetic characterization of a complex karyotype of a pediatric male patient with B-acute lymphoblastic leukemia.

An eight year old male patient was diagnosed with B-ALL. Chromosome studies of twenty G-banded metaphases of the bone marrow detected two abnormal clones with loss of 9p [i(9)(q10)] and loss of 17p [**der(17)(?:17q11.2->17p11.2::17p11.2->17qter)**] within the context of a complex karyotype in 8 metaphase cells. Four of these abnormal metaphases detected in addition additional material of unknown origin on 12 at p11.2 [add(12)(p11.2)]. The remaining 12 metaphases are cytogenetically normal.

FISH analysis of metaphases from a destained G-banded slide probed with KMT2A reveal an intact copy of KMT2A on the der(?). Metaphases were detected on the CDKN2A/CEP9, BCR/ABL1 and TP53/CEP17 interphase studies and revealed loss of CDKN2A on the add(9) and the i(9), 2 copies of ABL1 on the i(9), and loss of TP53 with gain of CEP 17 on the der(17). This complex karyotype was described as: 45,XY,+1,add(1)(q11),dic(1;8)(p11;p21),add(2)(p11.2),del(6)(p23p25),add(9)(q13),i(9)(q10),-11,-14,-16,der(17)(?:17q11.2->17p11.2::17p11.2->17qter),+der(?)(?:11q13->11qter),+mar[4].ish add(9)(CDKN2A-,CEP 9+),i(9)(q10)(CDKN2A-,CEP 9+,ABL1++),der(?)(KMT2A+),der(17)(TP53-,D17Z1+,D17Z1 dim+).nuc ish(CEP4x2,CEP10x2,D17Z1x2,D17Z1 dimx1)[35/200],(CDKN2Ax0,CEP9x2)[94/200],(ABL1,BCR)x2[500],(5'KMT2A,3'KMT2A)x2(5'KMT2A con 3'KMT2Ax2)[200],(ETV6,RUNX1)x2[200],(TP53x1,D17Z1x2,D17Z1 dimx1)[143/200]/45,idem,add(12)(p11.2)[4]/46,XY[12]

Deletion of 9p involving the CDKN2A locus (9p21) is seen in 7-11% of pediatric B-ALL. Although del(9p) does not appear to have an impact on prognosis in pediatric B-ALL, there is an overall poorer outcome compared with those lacking this abnormality. Abnormalities of 9p identify a subgroup of NCI standard-risk patients with increased risk of treatment failure.

The presence of the derivative chromosome (17), leading to loss of TP53, exerts an adverse influence on treatment outcome in B-ALL. Rearrangements of 12p [add(12)(p11.2)] usually occur as part of a complex karyotype (Heerema 2000). Complex karyotypes reflect genomic instability and are usually associated with poor prognosis (Heim and Mitelman 2015). Molecular cytogenetic characterization of complex karyotypes in B-ALL is an excellent tool to detect chromosomal abnormalities of prognostic

significance in B-ALL.

Clinical pathologic correlation of these results is recommended.

## PgmNr 2424: Common variants in PMS2CL that can present in *PMS2* as pathogenic variants with extremely low frequencies.

### Authors:

S. Pan; A. Brown; B. Leclair; M. Elias; D. Chen; J. Kidd; K. Bowles; B. Coffee; B. Roa; D. Mancini-DiNardo

[View Session](#) [Add to Schedule](#)

---

**Background:** *PMS2*, a Lynch syndrome-associated DNA mismatch-repair gene, often is included in NGS hereditary pan-cancer panels. Molecular testing of *PMS2* is complicated by the interference of highly homologous pseudogenes. The most homologous pseudogene, *PMS2CL*, is >98% identical to *PMS2* exons 11-15. Therefore, additional analysis is required for variants identified in exons 11-15 to determine whether they are located in *PMS2* or *PMS2CL*. Correct allocation of variants identified by NGS in this region is critical for proper clinical management.

**Objective:** The purpose of this analysis was to evaluate the frequency with which common *PMS2CL* variants occur in *PMS2*, with a focus on those that are considered pathogenic when they occur in *PMS2*.

**Methods:** Pathogenic/likely pathogenic sequence variants (PV/LPVs) detected from July 2016-April 2019 and large rearrangements (LRs) detected from May 2017-April 2019 in the *PMS2* pseudogene region (exons 11-15) were evaluated in individuals tested using an NGS hereditary pan-cancer panel. These variants were initially identified by NGS, then confirmed by orthogonal assays as being present in either *PMS2* or *PMS2CL*. PV/LPVs were selected for this analysis if they had >100 observations upon NGS testing but were confirmed to be in *PMS2* in <1% of cases.

**Results:** Two sequence variants and three LRs were assessed (four variants in exons 13 and 14; one in exon 15). Collectively, these variants were detected in 12,217 individuals. In 99.91% (12,206/12,217) of cases, the variants were confirmed orthogonally to be present in *PMS2CL*. In 11 (0.09%) individuals, the variant was located in *PMS2*. The rarest PV in *PMS2* was c.2186\_2187del (p.Leu729Glnfs\*6); only one (<0.01%) patient was confirmed to carry this PV in *PMS2*.

**Conclusion:** Comprehensive testing and a large testing population enabled identification of PV/LPVs that are predominantly present in *PMS2CL* but can occur in *PMS2* with extremely low frequency. These data highlight the need to disambiguate PVs in *PMS2* versus *PMS2CL*. It is tempting to assume that when certain sequencing variants and LRs are known to occur in *PMS2CL* >99% of the time, additional analysis is unnecessary. We have demonstrated that, though rare, these variants can occur in *PMS2*. Failure to confirm the PV/LPV location can produce a false negative result with significant implications for clinical management.

## PgmNr 2425: Germ line mutation analysis of the *RB1* gene in retinoblastoma patients in Sri Lanka.

---

**Introduction:** Retinoblastoma (RB) a tumour affecting those <5y has a prevalence of 1 in 20,000 with twenty cases/ year predicted in Sri Lanka. Unilateral RB (60%) present on average at 24 months, bilateral RB (40%) presents around 15 months. Family history reported in 10%. Many cases, diagnosed late in Sri Lanka, require enucleation. Genetic testing has been unavailable locally, but may enable better targeting of screening for patients and their siblings and reduce need for enucleation in affected cases.

**Materials and methods:** NGS sequencing of the *RB1* gene performed for 50 DNA samples from clinically diagnosed RB cases (bilateral (n=19(38%)), unilateral n=31) including two familial cases. NGS data were analysed using established bioinformatic tools (FastQC, BOWTIE 2, samtools, bcftools and vcftools software). Patients recruited following ethical clearance and informed consent.

**Results:** Pathogenic variants (2 missense, 7 stop gained, 1 splice donor, 8 frame shift variant) identified in 18/50 (34%) cases including 12/19(63%) bilateral cases and 6/31(19%) unilateral cases. Six were previously undescribed, likely pathogenic frameshift variants.

**Conclusion:** Germline mutations have been identified in 10-15% of unilateral, 80% bilateral and all familial cases worldwide. Detection rate of germline point mutation (36%) similar to worldwide data (40%). Germline mutation not identified in one familial case. Evaluation of NGS data for chromosomal rearrangements, which account for 10-15% of reported germline mutations, need to be identified in this sample.

---

Despite progress in the management of early breast cancer, a substantial number of patients relapse with metastatic breast cancer. Tumor derived mutations can be detected in circulating cell free DNA (cfDNA) of patients with metastatic breast cancer. We assessed whether analysis of cfDNA can be used to predict which patients will relapse following treatment of primary breast cancer.

First of all, we found anchor mutations that are expected to play a role as cancer drivers through NGS analysis of breast cancer tissues and then tracked them every three months from patient-derived cfDNA using a technique called UHS, which we previously developed a novel approach for high-throughput, multiplexed, ultrasensitive mutation detection and used it for detection of mutant sequence mixtures as low as 0.1-0.5% minor allele frequency.

Through this platform, it was confirmed that anchor mutations such as *CDH1*, *TP53*, *NOTCH2*, *NOCH4*, and *MAPK3* found in tumor tissues were also found in cfDNA from 5 patients with metastatic breast cancer of 11 breast patients group. In our study, anchor mutations were mainly found in the pre-anticancer stage of the group with metastatic cancer, and these mutations were not found in the cfDNA obtained from the plasma through the subsequent treatment process. The same method has been applied to a group of 200 patients with primary cancer to track anchor mutation with cfDNA to construct a system to predict metastatic cancer.

So, we have conducted a long-term follow-up study to access the hypothesis that monitoring of tumor-specific mutations in cfDNA can detect metastatic disease following primary surgery and serve as a sensitive, specific, and thus potentially clinically useful noninvasive biomarker in the breast cancer.

## **PgmNr 2427: Harmonizing tumor sequencing with germline genetic testing: Identification of at-risk individuals for hereditary cancer disorders.**

---

### **Background:**

Germline and tumor genetic testing are both increasingly used in precision treatment of individuals with cancer. These tests are frequently ordered separately in clinical practice but have the potential to inform one another. Recent studies report that approximately 10% of patient's tumors have clinically significant variants in genes known to predispose to hereditary cancer, however, it has been unclear which patients or findings deserve follow-up with germline testing (GT). Here, we retrospectively reviewed a cohort of individuals who had tumor testing followed by GT. We report the concordance rate between germline and tumor variants, and the impact on the patient's medical management and implications for their relatives.

### **Methods:**

Our study used de-identified data from 1043 consecutive patients who underwent tumor genetic testing followed by GT with NGS-based hereditary cancer gene panels.

### **Results:**

Tumor genetic testing results included variants in BRCA2 (290), BRCA1 (174), TP53 (158), ATM (70), MLH1 (65), APC (65), PMS2 (61), MSH6 (58), PTEN (54) and CDH1 (42). In 364/1043 cases (35%) the variant was detected as likely pathogenic or pathogenic (LP/P) in the germline. Genes in which variants were confirmed to be germline in >60% of patients included: FANCA, AXIN2, RAD50, MUTYH, BLM, PALB2, CHEK2, FANCD2, MITF, SDHB. Variants in FH, BRCA2, RET, ATM, SDHA, BRIP1, MSH2, BRCA1, BAP1, EGFR, and RAD51D were confirmed in the germline in <60% of patients. Variants were rarely detected as germline for TP53 (3%), APC (3%), PTEN (2%) and none were detected for CDKN2A, NF1 and STK11. In 24 (2%) cases a LP/P germline variant was detected but not reported in the tumor.

### **Conclusions:**

One-third of the patients with clinically significant variants in tumors were identified to carry the same variant in the germline, uncovering a previously unknown risk of hereditary cancer. Notably, some genes had a high probability of variants occurring in the germline, while others were primarily seen in tumors. Interestingly, 6% of the germline variants were not included in the tumor report due to technical and gene content differences in either assay or due to differences of clinical classification between tumor and germline testing. Performing simultaneous germline and tumor testing may inform susceptibility to a hereditary cancer disorder, identify targets for precision therapy, early

detection of secondary malignancies, and guide genetic counseling for relatives.

## PgmNr 2428: Synergy between next-generation sequencing, chromosomal microarrays, and conventional cytogenetics in the diagnostic evaluation of pediatric leukemias.

### Affiliations:

1) Dept. of Pathology and Laboratory Medicine, Children's Hospital Los Angeles, Los Angeles, CA; 2) Children's Center for Cancer and Blood Diseases, Children's Hospital Los Angeles, Los Angeles, CA

Chromosomal microarrays (CMA) and next generation sequencing (NGS) panels are increasingly used with standard cytogenetics (karyotyping) and fluorescent in situ hybridization (FISH) in the diagnostic evaluation of pediatric leukemias. To assess the clinical utility of NGS and CMA and develop optimal diagnostic algorithms, we analyzed 173 bone marrow samples by karyotyping, FISH, CMA and our OncoKids<sup>®</sup> NGS panel. OncoKids<sup>®</sup> is a DNA and RNA-based AmpliSeq pediatric cancer panel designed to detect sequence variants and RNA fusions. Pediatric B lymphoblastic leukemia (B-ALL; n=137) and acute myeloid leukemia (AML; n=36) samples were included in this retrospective analysis.

In B-ALL, FISH had the highest diagnostic yield as a single test (67%), and the combined use of CMA and OncoKids<sup>®</sup> had a similar overall detection of primary drivers (70% of B-ALL cases) as cytogenetics and FISH. With the exception of IGH rearrangements, CMA and OncoKids<sup>®</sup> detected all alterations identified by cytogenetics and FISH, but also revealed primary abnormalities in 11 cytogenetically negative cases. These alterations included 'Ph-like' fusions (n=4), ZNF384 fusions (n=3), PAX5 fusions (n=2), a MEF2D fusion (n=1) and a KMT2A fusion (n=1). Importantly, CMA and NGS also revealed secondary clinically significant variants including IKZF1 deletions (n=32) and JAK1/JAK2 mutations (n=15).

In AML, OncoKids<sup>®</sup> had the highest yield for detection of both primary and secondary DNA mutations and RNA fusions (81% of AML cases). All abnormal fusions revealed by cytogenetics/FISH were identified with OncoKids<sup>®</sup>. Additionally, in 12 cases, OncoKids<sup>®</sup> identified the key driver that was not observed with cytogenetics/FISH. These 12 cases included seven gene fusions (NPM-MLF1, CBFA2T3-GLIS2, three KMT2A fusions, and two NUP98-NSD1 fusions) as well as clinically significant sequence changes in NF1, GATA1, RUNX1 and FLT3.

Our data highlights that CMA/NGS and karyotyping/FISH are complementary in B-ALL testing. Due to rapid turnaround time (TAT), FISH may be useful as an initial screening test but may ultimately miss important primary driver alterations and secondary abnormalities that could be helpful in treatment decisions. Therefore, the optimal testing algorithm for B-ALL must integrate clinical utility with information regarding cost, TAT, and institutional resources. For pediatric AML, our data suggests that NGS testing may represent a superior alternative to karyotyping as a first line test.

## PgmNr 2429: A case of a lymphoplasmacytic lymphoma with trisomy 12 in the lymphoid population and deletion 13q of myeloid origin.

---

An 89 year old male patient who presents with lymphoplasmacytic lymphoma (LPL)(WHO 2016) involving 80% of the marrow cellularity with circulating lymphoma cells. Chromosome studies detected two unrelated abnormal clonal populations. One clone has trisomy 12 [9 metaphases] as the sole abnormality. The other clone has a 13q- [6 metaphases] as the sole abnormality. The remaining cells are cytogenetically normal. This karyotype was described as 47,XY,+12[9]/46,XY,del(13)(q12q21)[6]/46,XY[5]

Trisomy 12 (found in the B-cell mitogen stimulated cultured cells) is the most frequently reported chromosome abnormality in B-cell chronic lymphocytic leukemia (B-CLL) . However it has been seen also in other B-cell lymphoproliferative disorders including lymphoplasmacytic lymphoma. This finding was detected also by FISH using the FISH CLL panel analysis which is a statistical and morphology based study where only round, non-segmented cells are scored.

Deletions of 13q (found in the cells from the non-stimulated culture) have been identified in B-cell malignancies , non-Hodgkin's lymphomas [NHL] as well as myelodysplastic syndromes and chronic myeloproliferative neoplasms (Heim and Mitelman, 2015). However, due to this finding (13q- clone), the trisomy 12/13q- FISH slide was reviewed looking at the segmented cells. Fifty segmented cells were scored and a 13q- pattern was detected in 36% (18/50) of the cells suggesting that this finding (the 13q-clone) may be myeloid in origin. Clinicopathologic correlation of these results was recommended.

## PgmNr 2430: ADAM32 amplification in pediatric malignancies.

---

DNA microarray techniques allow the simultaneous detection of vast number of copy number alterations (CNA) in cancers, including previously unknown ones. The study presented here was aimed at surveying the genes and types of CNA found in the pediatric cancer patient population in the west texas region and was done at TTUHSC, Lubbock. Towards this goal, we performed a retrospective analysis of data obtained from Cytosure Constitutional v3 Microarray that is used for studies of developmental disorders. 198 cases over the previous 5 years were selected for study. The majority of cases were of pediatric malignancies, though some adult cancers and benign hematological diseases were included. We found that the most frequent CNAs were at the following loci: 14q11.2 (127 cases), 8p11.21-8p11.22 (98 cases), 15q11.1-15q11.2 (82 cases), 14q32.33, 9p24 and 9p13. The most affected locus being 14q11.2 was expected as ALL was strongly represented. The 8p11.21-8p11.22 locus was of interest because in this pediatric population, we found that gains outnumbered losses by 4.8-fold (81 vs 17 cases) at this locus, greater than for any other locus. LOH of 8p is reported to be frequent in human breast cancer and also found in other endodermal origin adult solid tumors, but not previously reported for pediatric patients (PMID: 29682206). Genes at this locus previously shown to be involved with gains or amplifications include DUSP26 (gain 14%, loss 34%), ZNF703 (gain 26%, loss 20%) (REF). In this (primarily pediatric) population, CNAs were most frequent at ADAM32 and found in all types of cancer: T-cell Lymphoma, ALL, Enchondroma, AML, Wilm's Tumor, Hepatocellular Carcinoma, Breast Cancer, Neuroblastoma, Rhabdomyosarcoma, Fibromatosis, Chondroblastoma and Giant Cell Tumor of the Bone. Other affected genes at this locus were KAT6A, TACC1, GPAT4 and TM2D2. Chromosomal translocations with breakpoints at these loci have been reported in breast and other cancers. To investigate whether these genes could be involved in promotion of cancer growth, we conducted studies to determine whether siRNA knockdown would affect growth of adult cancer cell lines. Interestingly, we found relatively small and inconsistent effects of ADAM32 knockdown. In contrast, knockdown of TACC1 kills inhibited cancer growth by 34-68%. Consistent with its function in the mitotic spindle, TACC1 knockdown resulted in abnormal metaphases. Our studies suggest TACC1 is a potential therapeutic target.

## PgmNr 2431: Integrative copy number analysis of uveal melanoma reveals novel candidate genes involved in tumorigenesis including a tumor suppressor role for *PHF10/BAF45a*.

---

Uveal melanoma (UM) is a primary malignancy of the eye with oncogenic mutations in *GNAQ*, *GNA11*, or *CYSLTR2*. Approximately 50% of UMs are at high risk of metastasis to the liver and most have undergone loss of one copy of chromosome 3 and developed mutations in *BAP1* (Chr 3p21). The remainder of UMs generally harbor *SF3B1* or *EIF1AX* mutations and have less chance of metastasis. There are other characteristic chromosomal alterations in UM but their significance is not clear. For example, ~20-30% of UMs undergo hemizygous loss of chromosome 1p, and ~70% undergo 8q gain. *SF3B1* mutant tumors with 6q loss are also more likely to metastasize. To investigate genes driving chromosomal alterations we integrated copy number, transcriptome and mutation data from three independent cohorts and followed up key findings. We observed significant enrichment of transcripts on Chromosomes 1p, 3, 6, 8 and 16q and seven shared focal copy number alterations on Chr 1p36, 2q37, 3, 6q25, 6q27 and 8q24. Integrated analyses revealed clusters of genes in focal copy number regions whose expression was associated more strongly with metastasis and worse overall survival (OS) than the broad chromosomal changes. For example 8q gain is associated with poor prognosis and upregulation of 13 transcripts from Chr 8q24.3 including *PTK2* and *PTP4A3* were correlated with poor OS. Downregulation of 11 transcripts from chr1p36 were associated with poor OS. At Chr 6q27 we identified two tumors with homozygous deletion of *PHF10/BAF45a* (encoding a PBAF complex member involved in chromatin remodeling). A third UM had a frameshift mutation with concomitant loss of the wild type allele. SiRNAs knockdown of *PHF10* in three UM cell lines followed by RNA sequencing revealed enrichment of pathways involved in development, regulation of angiogenesis, and focal adhesion. Functional analyses revealed less adhesion to most ECM proteins and reduced migration in a chemotaxis assay. Several chromatin remodeling factors altered by *PHF10* knockdown such as *PCGF5* exhibited the same trend in the *PHF10* mutant tumors. Mutations in *PHF10* have not been described in tumors before, although mutations in other PBAF components are found in other cancer types. *PHF10* lies in a region of Chr 6q which harbors an unidentified tumor suppressor for a variety of epithelial cancers so besides contributing to tumor development in some cases of UM it should be considered as a candidate for this elusive tumor suppressor gene as well.

## PgmNr 2432: Next generation sequencing-based gene panel tests for the diagnosis of hereditary cancers.

Next generation sequencing-based gene panels are more efficient and cost effective in diagnosis of many cancer syndromes. Large number of variants can be identified by these panels due to the genetic heterogeneity of these cancers. Interpretation of the obtained genetic information becomes very substantial. In this study, 193 patients with BRCA1/2 negative Hereditary Breast/Ovarian Cancer (HBOC) or different hereditary cancer syndromes admitted to our clinic were screened for 27 genes related with Hereditary Cancers. All exons and exon-intron boundaries of 27 genes were amplified using Hereditary Cancer Solution (Sophia) (156 cases) and BRCA Hereditary Cancer Mstr plus (Multiplicon) (37 cases) kits and sequenced with MiSeq (Illumina) system. Sophia DDM platform and Sophia Genetics' MOKA software was used for variant analysis and annotations. Pathogenicity of variants was analyzed using online tools (HGMD Professional, ClinVAR, MutationTaster, SIFT, Polyphen) and ACMG criteria. We identified the total of 146 variant; of these variants pathogenic (11), likely pathogenic (8), variant of uncertain significance (VUS)(112) and conflicting interpretation of pathogenicity (15) seen in Hereditary Cancer patients. Additionally in 60 BRCA1/2 negative HBOC patient, we found 3 pathogenic, 3 likely pathogenic, 34 VUS and 5 conflicting variants. Implementations of targeted next generation sequencing based panels for hereditary cancers give us many variations that need to be carefully reviewed. They provide clinically critical informations in the diagnosis of BRCA1/2 negative HBOC patients in addition to other familial cancer syndromes.

## PgmNr 2433: Amplification of *BCR-ABL1* fusion gene in acute leukemia: Report of three new cases.

The Philadelphia chromosome (Ph) resulting from a reciprocal translocation t(9;22)(q34;q11) is a characteristic finding in chronic myeloid leukemia (CML) and in a subset of acute lymphoblastic leukemia (ALL) as well as rarely in acute myeloid leukemia (AML). The derivative chromosome contains the BCR-ABL1 fusion gene that encodes for a protein with constitutive protein kinase activity. Amplification of BCR-ABL1 and mutations in the ABL1 kinase domain have been described in Ph+ leukemia cases that were resistant to tyrosine kinase inhibitor (TKI). Here we report three new Ph+ acute leukemia cases with amplification of the BCR-ABL1 fusion. Case 1 is a 35 year-old male with Ph+ ALL who underwent two allogeneic stem cell transplantations and treatment with multiple TKIs, and upon his second relapse demonstrated complex karyotype (50-51,XY,add(4)(q35),+8,t(9;22)(q34;q11),del(10)(q24),del(12)(q24.1),+17,+18,+20,der(22)t(9;22)(q34;q11)x1-2,+1-4mar[cp20]), amplification of Ph+ by fluorescence in situ hybridization (FISH), and multiple ABL1 kinase mutations. This patient was TKI-refractory and succumbed to his disease 7 years after diagnosis. Case 2 is a 77 year-old female with newly diagnosed AML had a complex karyotype (44~46,XX,t(1;3)(p36;p21),-4,-5,add(10)(p11.2),der(22)t(9;22)(q34;q11.2),+mar[20]), BCR/ABL1 translocation with both Ph and MLL amplification and TP53 deletion. This is the first documented case of AML with t(1;3) in conjunction with t(9;22) and Ph amplification. Case 3 is 60 years old male with newly diagnosed AML. Complex karyotype 51-69,XY,+Y,+1,+2,+3,+6,i(6)(p10),+8,t(9;22)(q34;q11.2),+10,+11,+12,+13,del(13)(q12q14),+14,+15,+16,+18,+19,+20,+der(22)t(9;22)[cp4]/46,XY[10] was seen by cytogenetics and BCR/ABL1 translocation with Ph amplification seen by FISH. The patient was given induction chemotherapy but deceased two month late due to severe sepsis and cardiogenic shock. These three cases illustrate the genetic heterogeneity of Ph-positive leukemias. Numeric and/or structural cytogenetic aberrations, as well as ABL1 kinase mutations, may be present at initial diagnosis or acquired with disease progression, and they are associated with an aggressive disease course and resistance to TKI therapy. Understanding the underlying molecular pathogenesis and appropriate of such cases would help to provide more effective clinical management.

## PgmNr 2434: Next-generation cytogenetics: High-resolution optical mapping to replace FISH, karyotyping and CNV-microarrays.

Structural variants (SVs) are an important source of genetic variation in the human genome and they are involved in a multitude of human diseases. Somatic SVs are important for cancer development and progression while constitutional SVs are involved in many developmental disorders. In a diagnostic set-up, comprehensive analysis of all molecular cytogenetic aberrations in a given sample still requires a combination of techniques, such as CNV-microarrays, karyotyping and fluorescence *in situ* hybridization. We hypothesize that the combination of classical approaches could be largely replaced by high-resolution optical mapping.

Leukemia bone marrow aspirates and blood samples were analyzed using standard of care workflow and the residual samples were processed for Bionano Saphyr optical mapping to detect chromosomal aberrations. We generated up to 400-fold genome coverage by imaging long chromosomal fragments and detected chromosomal aberrations by comparing optical maps to a reference and control dataset.

In the first leukemia samples we compared the results with those obtained using standard methods. In each sample, all previously known clinically relevant aberrations were identified. This held true for deletions, insertions, inversions and translocations, including a 3-way Philadelphia chromosome (t(9;14;22)(q34;q11;q11.2)) and even chromothripsis structures were resolved. We were also able to identify aberrations in samples with cancer cell content less than 40% using Bionano's latest single-molecule SV detection tool. Importantly, optical mapping additionally identified multiple novel events, e.g. an inversion of chromosome 11 (chr11:24,875,044-26,299,641) and a translocation (t(5;14)(q35.2;q32.2)), both validated afterwards. These novel events are now followed-up to identify possible fusion genes as novel leukemia drivers.

We are now conducting a study to systematically compare the sensitivity and specificity of optical mapping in 100 leukemia samples and 50 samples with known germline cytogenetic aberrations against the standard of care workflow. Of these, 17 with constitutional aberrations and 19 leukemia samples have been processed successfully so far.

Optical mapping may have the potential to replace most classical cytogenetic tests. In addition this

holds the potential to map new fusion genes as novel leukemia drivers rapidly.

## PgmNr 2435: Acute myeloid leukemia with iAMP21.

**Authors:**

G. Tang; W. Xie

[View Session](#) [Add to Schedule](#)

**Affiliation:** Hematopathology, U.T. MD Anderson Cancer Ctr, Houston, Texas.

---

**Background:** iAMP21 is defined as amplification of a portion of chromosome 21, typically detected by FISH with  $\geq 5$  copies of *RUNX1* gene in a cell or  $\geq 4$  copies on a single abnormal chromosome 21. B-lymphoblastic leukemia with iAMP21 has been well studied and recognized as a provisional entity by the current WHO classification, it is often associated with poor prognosis and requires more intensive therapy. Acute myeloid leukemia (AML) with iAMP21 is rare and its clinicopathologic features and outcomes remain largely unknown.

**Methods:** We searched our database in the past 10 years for cases with iAMP21 confirmed by FISH, then narrowed down to the patients with AML. Clinicopathologic features, molecular and cytogenetic information were collected from the charts.

**Results:** we identified 9 patients with AML and iAMP21, four women and five men, with a median age of 64 years (range, 34 to 75 years). Five patients had iAMP21 detected at the initial diagnosis of de novo AML, 1 at relapsed AML, 2 at the AML progressed from myelodysplastic syndrome, and 1 therapy-related AML. All patients showed pancytopenia and various degrees of myelofibrosis; 8 patients had a complex karyotype; 4 patients harbored a *TP53* mutation. Eight patients received induction chemotherapy or hypomethylating agents, one patient also received allogeneic stem cell transplant (SCT). By the end of follow-up, 5 patients died, 3 alive with persistent disease and 1 alive in complete remission (who received SCT), with a median overall survival of 1 month.

**Conclusion:** We conclude that AML with iAMP21 is often associated with pancytopenia, myelofibrosis, *TP53* mutation, and a complex karyotype. Patients with AML-iAMP21 are often refractory to conventional AML therapy and have very poor outcomes. SCT at the first remission as well as novel therapies may improve the outcome.

## PgmNr 2436: Next generation sequencing of *BRCA1* and *BRCA2* genes among women with breast cancer in Burkina Faso.

Breast cancer is the most commonly diagnosed cancer in Africa, including sub-Saharan Africa (SSA) and the leading cause of cancer mortality in women. To date, knowledge of the etiological factors of breast cancer in Africa has been poorly studied.

The early-onset and the aggressive clinical features of breast cancer in patients of African ancestry suggest that the hereditary predisposition may have an important function, but the absence of extensive studies, specially for Sub-Saharan Africa (SSA), greatly reduces the understanding of the impact of germline mutations in breast cancer patients and its effects in terms of prevention, diagnosis and patient management.

The aim of this study is to define the impact of germline mutations in *BRCA1* and *BRCA2* genes in breast cancer among young women in Burkina Faso and determine their implication in clinics perspectives.

Fifty-two women with early-onset breast cancer ( $\leq 40$  years), eleven of them with a family history were analyzed by Next Generation Sequencing (NGS).

Six different pathogenic mutations (3 in *BRCA1*, 3 in *BRCA2*), two of which recurrent in more than one patient, were identified in eight unrelated patients.

Moreover, three variants of uncertain clinical significance (VUS) and three novel unclassified variants were identified in six other patients with no family history of the disease.

The present study is the first one in which the entire coding sequence of both *BRCA* genes is analyzed in Burkinabe women with breast cancer. Our data suggest that hereditary predisposition is responsible for a significant proportion of breast cancer in Burkina Faso women that should undergo genetic cancer risk assessment. The identification of the most common mutations of *BRCA1* and *BRCA2* genes in the Burkina Faso population will allow the development of a cost-effective genetic test for the early detection of these mutations contributing to the medical treatment of women with breast cancer, with important consequences in society and economy of this country.

## PgmNr 2437: *BRCA1* and *BRCA2* germline mutational spectrum in Algerian population: What we know now.

### Authors:

F. Cherbal <sup>1</sup>; C. Mehemmai <sup>1</sup>; L.L. Saada <sup>1</sup>; M. Nehari <sup>1</sup>; K. Yatta <sup>1</sup>; H. Gaceb <sup>1</sup>; H. Mahfouf <sup>2</sup>; W. Benbrahim <sup>3</sup>; K. Boualga <sup>4</sup>

1) Unit of Genetics, LMCB, Faculty of Biological Sciences, USTHB, Algiers, Algeria; 2) Mohamed El Kolli Public Hospital, Academic Medical Oncology Services, School of Medicine, University of Algiers, Rouiba, Algeria; 3) Anti Cancer Center, Batna, Algeria; 4) Anti Cancer Center, Blida, Algeria

---

**Background:** BRCA genetic testing can reduce incidence and mortality of BRCA-linked cancers. There are limited data regarding BRCA genetic testing in Algerian population. Between 2008 and 2018, we screened 288 breast/ovarian cancer families for *BRCA1* and *BRCA2* germline mutations. Here, we present the experience of our research laboratory and some unpublished results.

**Methods:** 100 index cases and relatives were screened for complete *BRCA1* and *BRCA2* germline mutations using HRM-direct sequencing (86 individuals) or NGS using a cancer panel of 30 hereditary cancer genes or *BRCA1/2* genetic test in 14 probands (Color Genomics, Burlingame, California, USA). In addition, 215 index cases and relatives were tested for *BRCA1* and *BRCA2* recurrent mutations previously found in Algerian HBOC patients using PCR-direct sequencing. Screening for large genomic rearrangements (LGR) in *BRCA1* and *BRCA2* genes was performed in 79 patients tested negative for small point mutations using MLPA technique. To confirm the genomic rearrangement and its genomic breakpoints, long-range PCR of genomic DNA was performed.

**Results:** The analysis of DNA samples of 315 individuals revealed that 42 patients and relatives carried pathogenic germline mutations: 32 within *BRCA1* and 10 within *BRCA2*. 10 distinct pathogenic mutations have been identified in *BRCA1* gene: c.19\_47del, c.83\_84delTG, c.181T>G, c.505C>T, c.798\_799delTT, c.2125\_2126insA, c.5332 + 1G > A and 3 LGR (exon 2 del, exon 7 del and exon 15del). Six distinct pathogenic mutations have been identified in *BRCA2* gene: c.1310\_1313delAAGA, c.1813dupA, c.5722\_5723delCT, c.7654dupA, c.8485C>T and c.8940delA. The following recurrent *BRCA1* mutations have been identified in 12 unrelated families: c.83\_84delTG (4 families), c.181T>G (2 families), c.798\_799delTT (3 families) and c.2125\_2126insA (3 families). *BRCA1* exon 7 del and *BRCA1* exon 15 del have been identified within four different new genomic breakpoints :3,135bp and 4,200bp; 3,341bp and 4,112bp, respectively (each deletion/2 unrelated families). The *BRCA2* c.1310\_1313delAAGA mutation has been detected in two unrelated families. Interestingly, our study showed differences in the distribution of the mutation spectrum of *BRCA* genes between the Eastern region and the North central region of Algeria.

**Conclusions:** Our study will help to implement affordable genetic testing and to improve the clinical management and better risk assessment of hereditary breast and ovarian cancer in Algerian population.

## PgmNr 2438: Development of an expanded hereditary breast and ovarian cancer next-generation sequencing panel; experience of collaboration between the CHEO Genetics Diagnostic Laboratory and clinical Hereditary Cancer Program.

### Authors:

P.E. Harper; R. Potter; E. Smith; E. Tomiak; A. Rusnak; L. Huang; L. Bronicki; O. Jarinova; E. Sinclair-Bourque; J. McGowan-Jordan; A. Smith

[View Session](#) [Add to Schedule](#)

**Affiliation:** Genetics Department, CHEO, Ottawa, ON, Canada

---

Expanding next-generation sequencing (NGS) panels for hereditary breast and ovarian cancer syndrome (HBOC) beyond *BRCA1/2* testing increases the diagnostic yield of clinically actionable genes. Over the past years, NGS-based panels have been expanding to include many more genes, some with limited clinical utility that do not necessarily translate to higher quality clinical care. In some cases, genes with limited information or no clear guidelines for screening and management are included. Furthermore, expanding NGS-based panels comes with limitations of resource management for smaller laboratories operating in a publically funded health care setting. With the goal of expanding our HBOC panel, the CHEO Genetics Diagnostics Laboratory and clinical Hereditary Cancer Program collaborated to implement an expanded hereditary cancer panel, with a strong consideration to the clinical utility of the genes included and the limited resources available in the laboratory. The implementation of the expanded panel involved developing a new workflow, updating result report formats and requisitions to ensure timely and high quality results. An expedited surgical panel (*BRCA1/2*, *PALB2* and *TP53*), including sequence variant and copy number detection, is followed by one of two expanded panels, a 9 gene breast cancer panel (*ATM*, *CDH1*, *CHEK2*, *PTEN*, *STK11*) or a 17 gene breast and ovarian cancer panel (*ATM*, *BRIP1*, *CDH1*, *CHEK2*, *EPCAM*, *MLH1*, *MSH2*, *MSH6*, *PMS2*, *PTEN*, *RAD51C/D*, *STK11*). In addition, ongoing collaboration between clinical team and laboratory staff provides the opportunity for feedback including improved variant interpretations supported by clinical information. Developing multi-gene panel testing raises resource challenges for laboratories in publically funded health care settings. Our joint laboratory and clinical department approach implemented an expanded HBOC cancer panel under limited resources while maintaining a high quality of patient care.

## PgmNr 2439: DNA-depleted plasma-based extraction controls enable effective assessment of specificity and sensitivity of liquid biopsy assays.

### Authors:

Y. Lu; K. Ooi; K. Shi; T. Fu; E. Chan

[View Session](#) [Add to Schedule](#)

**Affiliation:** Anchor Molecular Inc, Pleasanton, California.

The usage of PCR-based or NGS-based liquid biopsy assays for circulating tumor DNA (ctDNA) detection is growing rapidly in clinical labs. However, inconsistent results are often observed especially when assays from different developers are compared. One reason might be due to lack of thorough understanding of the role of plasma factors on cfDNA extraction since the extraction step contributes significantly to assay variation. To address this issue, Anchor Molecular has developed a proprietary technology that specifically removes DNA from plasma without affecting the composition of the plasma. The DNA content in the treated plasma was measured to be less than 0.01ng/mL. The composition of all other components such as proteins and lipids remain the same as in normal patient plasma. Extraction Quality control samples based on this DNA-depleted plasma were used to evaluate the effect of plasma factors on extraction and sensitivity and specificity of cfDNA assay.

These controls are made by either synthetic DNA or native DNA fragments derived from cell lines spiked into DNA-depleted plasma. The recovery and stability of these DNAs were studied by extractions followed by quantitative PCR (qPCR). Specificity of cfDNA extraction was studied by spiking both low- and high-molecular-weight DNA fragments into DNA-depleted plasma followed by extraction by five different cfDNA extraction kits. The purified DNAs were analyzed using Bioanalyzer 2100. The sensitivity of cfDNA extraction was examined by extractions of the spiked low concentration of target DNA fragments with different commercial kits followed by qPCR. The observed and expected concentrations of extracted DNA-depleted, plasma-spiked DNAs were shown to be linearly correlated, mimicking the spiked DNAs in normal plasma.

Both synthetic DNA and fragmented genomic DNA showed at least 125 days of real-time stability at 2-8°C. The specificity study showed that different kits exhibited varying preferences in extracting DNAs of different sizes. In the sensitivity study, differences in extraction efficiency and precision were observed among different kits.

The data demonstrated that plasma factors influence cfDNA extraction. Quality controls samples based on DNA-free plasma can be effectively used for monitoring the entire ctDNA assay process including the extraction step.

## **PgmNr 2440: Three way t(8;14;22)(q24;q24;q32;q11.2) characterized by molecular cytogenetics with involvement of *MYC/IGH/IGL* in a case of a diffuse large B-cell lymphoma (DLBCL).**

A 48 year old male presented with palpable right inguinal lymphadenopathy. CT scan revealed a 3 cm enlarged lymph node and several adjacent smaller lymph nodes measuring up to 1.2 cm. No additional lymphadenopathy was detected. Past medical history was significant for right testicular seminoma treated by radical orchiectomy at 27 years of age, and remote history of Hodgkin lymphoma diagnosed at 15 years of age treated with right upper neck lymph node resection, radiation therapy and splenectomy. Excisional right inguinal lymph node biopsy revealed diffuse large B-cell lymphoma (DLBCL), NOS with a germinal center B-cell subtype (CD10+/BCL6+/MUM1-). The lymphoma cells were *BCL2*-negative and showed >95% proliferation index by MIB1 (Ki-67) immunohistochemical stain. The lymphoma cells lacked surface and cytoplasmic light chain expression by flow cytometry. Chromosome analysis revealed an abnormal clone with t(8;14;22)(q24;q32;q11.2) within the context of a complex karyotype. Metaphase FISH analysis detected a *MYC/IGH* rearrangement on the derivative chromosome 14 and also an *IGL* (22q11.21-q11.23) rearrangement. A signal of the distal portion of *IGL* (BCR) was present on the derivative chromosome 8. Metaphase FISH using the *IGH* break-apart probe showed intact fusion signal on the normal copy of chromosome 14 and in the derivative chromosome 14 as well as an 5' *IGH* signal on the derivative chromosome 22. FISH for 14q subtelomere showed 14q subtelomere signal on the derivative chromosome 22.

Herein we pinpoint the involvement of *MYC/IGH/IGL* in a three-way translocation in a DLBCL case characterized by FISH. The t(8;14)(q24;q32) is a recurrent chromosome abnormality described in non-Hodgkin lymphomas (NHL), especially in 60-70% of Burkitt lymphoma (BL) and diffuse large B-cell lymphomas. The variant t(8;22)(q24;q11) is also seen in these cases. *MYC* rearrangements have been observed in up to 10% of cases of Diffuse Large B Cell Lymphomas (DLBCL) and is usually associated with a complex pattern of genetic alterations. This particular pattern with *IGH-MYC* rearrangements within the context of complex karyotypes is seen in diffuse large B-cell lymphomas. Complex karyotypes are associated with genomic instability and a poor prognosis. Clinical correlation was recommended.

## PgmNr 2441: Cytogenetic findings in a case of blastic plasmacytoid dendritic cell neoplasm (BPDCN).

### Authors:

---

The patient is a 67-year-old female with a recent peripheral blood morphology revealing a hematopoietic leukemia process. Flow cytometry revealed an atypical cell population without B-cell or T-cell lineage expression. It was positive for CD45 and CD123 and negative for CD34. She undergoes a bone marrow biopsy. Bone marrow and peripheral blood showed a blastic plasmacytoid dendritic cell neoplasm (BPDCN), Hypercellular marrow (estimated 95%) with 90.4% blasts (aspirate smear). The peripheral blood showed blastic plasmacytoid dendritic cell neoplasm, macrocytic anemia, and moderate thrombocytopenia.

Chromosome analysis of twenty G-banded metaphases revealed an abnormal karyotype with i(7)(q10) and monosomies of 13 and 15 in 10 metaphase cells examined . The karyotype was described as 46,XX,i(7)(q10),-13,-15[10]/46,XX[10].

Loss/deletions of 7p [i(7)(q10)], 13q and 15q have been reported as recurrent chromosome abnormalities in blastic plasmacytoid dendritic cell neoplasm (BPDCN). Clinicopathologic correlation of these results was recommended.

---

Breast cancer diagnosed at ages of adolescent and young adults (AYA; 15 to 39 years old) consists approximately 5% of all breast, waiting for developing therapeutic options. Homologous recombination deficiency (HRD) phenotype often observed in tumors with *BRCA1/2* deficiency is considered to be associated with efficacy of PARP inhibitor and platinum agent-based therapies. In this study, HRD score was calculated for 47 Japanese AYA breast cancers using their whole exome sequencing data. The HRD-high phenotype was defined as HRD scores  $\geq 42$ . Genetic and pathological factors in HRD-high cases were determined by analyzing the sequencing data and DNA methylation chip analysis data as well as clinicopathological information of the cohort. The HRD-high phenotype was observed in 13/47 (27.7%) cases and was preferentially observed in cases with germline *BRCA1/2* and somatic *TP53* mutations, triple negative subtype and higher nuclear grades. Two “pathogenic” *BRCA1/2* germline mutations were observed in the 13 HRD-high cases, while a case with a “likely pathogenic” *BRCA1* germline mutation was judged as HRD-low. Three *BRCA1* hypermethylated and a *RAD51C* hypermethylated cases were also included in the 13 HRD-high cases. A predictive model for the HRD-high phenotype was developed using a TCGA data set of all breast cancers ( $n = 744$ ; Area under the curve [AUC] = 0.86) based on *BRCA1/2* and *TP53* mutations, hypermethylation status, triple negative subtype and higher nuclear grades. This prediction model was generated from coefficients of a logistic regression analysis and these five factors were statistically significant in a TCGA data set ( $P < 0.01$ ). Its prediction power was validated in Japanese ( $n = 46$ ; AUC = 0.90) and European ( $n = 58$ ; AUC = 0.95) AYA cohorts. After excluding a factor of methylation status, the prediction model derived from four factors still showed high AUC (AUC = 0.85). Its prediction power was validated in Japanese ( $n = 46$ ; AUC = 0.90) and European ( $n = 58$ ; AUC = 0.96) AYA cohorts. These four factors can be assessed by gene panel tests and daily pathological analyses. Thus, this study clarified genomic and pathological factors associated with HRD phenotype of AYA breast cancers. The present predictive model would be a tool to identify AYA breast cancer patients who would benefit from PARP and/or platinum therapies in the clinical setting.

## PgmNr 2443: Role of calreticulin gene (*CALR*) in changing the WHO diagnostic criteria of myeloproliferative neoplasms.

### Authors:

Calreticulin gene (*CALR*) encodes a calcium binding multifunctional protein localized primarily in the endoplasmic reticulum but is also found in the nucleus, cell membranes and extracellular matrix. *CALR* binds to mis-folded proteins and prevent their exported from the endoplasmic reticulum to the golgi apparatus. Outside the endoplasmic reticulum it has been implicated in diverse processes including proliferation, apoptosis, phagocytosis and immunogenic cell death. Until December 2013 *CALR* had never previously been reported mutated in cancer or to be associated with hematological disorders particularly Myeloproliferative neoplasms (MPN). The discovery of *CALR* mutations further assisted the diagnosis of *BCR-ABL1* negative MPNs and in response to this milestone and continuous research studies in favour of this finding, the World Health Organization (WHO) in 2016 eventually included *CALR* in the ET and PMF diagnostic criteria. All *CALR* mutations are majorly somatic heterozygous insertions or deletions resulting in a frame shift and cluster in exon 9 which is the last exon of the gene. Thus far, more than 50 different types of mutations in *CALR* have been reported. Two specific mutations, Type I (52bp deletion) and Type II (5bp insertion), are the most prevalent. Overall, these two mutation types are found in more than 80% of patients with mutant *CALR*.

**Methods:** Clinical and hematological features were obtained from 128 MPN patients. We studied 35 PV patients, 44 ET patients, 39 MF patients and 10 patients with Undifferentiated MPN (UMPN).

**Results:** In our cohort, *CALR* mutations were detected in 23 patients (17.9%; 23/128) of which one patients was positive for *JAK2* V617F as well. *CALR* mutations were found in 17 (13.2%; 17/128) ET patients and 6 (4.6%; 6/128) MF patients. Among ET patients *CALR* mutation frequency was 38.6% (17/44) and among MF patients it was 15.3% (6/39). *JAK2*V617F mutation was found in 74.2% (26/35) patients of PV, 21.9% (9/41) of ET, 13.7% of MF (4/29) and 40% (2/5) of UNPM. None of the UMPN patients exhibited any *CALR* mutation. In ET type I mutation was found in 6 patients (35.3%; 6/17) and among them 2 had two new scattered point mutations (c.1081C>G and c.1086C>G) as well, type II in 8 patients (47.0%; 8/17), and others in 3 patients (17.6%; 3/17). In MF patients type I was found in 4 patients (66.6%; 4/6), type II in 1 patient (16.6%; 1/6) and one novel homozygous *CALR* mutation in 1 patient (16.6%; 1/6).

## PgmNr 2444: Development of MethylArray for classifying tumors of the central nervous system.

---

DNA methylation patterns have demonstrated clinical significance in classification, diagnosis, progression monitoring, and predicting treatment response in numerous cancer types. Recent studies have shown methylation patterns to be useful for classifying tumors of the central nervous system (CNS), many of which have poor prognosis and limited treatment success. Capper et al. (2018) developed a free online classifier tool (MNP v11b4, [www.molecularneuropathology.org](http://www.molecularneuropathology.org)) for classifying CNS tumors into one of 82 categories based on DNA methylation profiles. The classifier allows for a more robust, reproducible diagnosis of CNS tumors over traditional histopathology, which can be subject to pathologist-dependent variation. We have developed a diagnostic assay, MethylArray, which uses the Illumina Infinium HD Methylation EPIC array and the MNP classifier tool to categorize adult and pediatric CNS tumors from FFPE or fresh frozen specimens. We processed 76 CNS tumor samples, both adult and pediatric, through the Illumina Infinium HD Methylation EPIC protocol. Sample quality was assessed using the Infinium FFPE QC Kit, and bisulfite conversion was performed using the Zymo EZ DNA Methylation Kit. While the protocol suggested a minimum of 250 ng of input DNA, we were able to obtain reliable results at 50 ng of input DNA. Converted DNA was then processed through the Illumina Infinium FFPE Restore protocol to repair low-quality DNA from FFPE samples. Other workflow conditions, such as incubation temperatures and reagent volumes, were optimized for processing FFPE samples. The prepared BeadChips were scanned on the Illumina iScan, and the results were run through the MNP classifier tool. Of the 76 samples processed, 7 samples failed due to insufficient DNA or tissue. For the remaining samples, a specific CNS tumor classification was identified for 57 of 69 samples (83%), with 12 samples not matching to any of the 82 categories. The “No Match” classification indicates insufficient calibrated scores needed for a valid classification or that the case may represent a novel tumor entity. Based on our results, the Methylation EPIC array, in conjunction with the MNP classifier tool, has shown to be a reliable assay for classifying both adult and pediatric CNS tumors from FFPE or fresh frozen tissue. Our MethylArray assay will be a valuable tool for providing oncologists with an accurate and reliable diagnosis of CNS tumors leading to more informed treatment decisions for patients.

## PgmNr 2445: High accuracy NGS platform based on electrical impedance detection: Applications for oncology research.

---

Next Generation Sequencing (NGS) technologies have made rapid strides in the throughput and accuracy of DNA sequencing in recent years. These advances have revolutionized biomedical and clinical research, especially in oncology. NGS cancer panels are used to determine cancer predisposition, detect early cancer, identify tumor mutations, and develop personalized therapies. Here, Genapsys presents a novel, scalable, low cost, and high accuracy NGS platform, and demonstrates its applications to oncology research.

The GenapSys NGS platform is based on accurate detection of electrical impedance changes resulting from single base incorporations during sequencing-by-synthesis. We show that impedance changes measure a steady state dNTP incorporation signal, leading to higher accuracy. The core of the technology is a CMOS-based electronic chip that enables scalability and low instrument and consumable costs. Chips with 1M, 16M and 144M sensors can be run on the same GenapSys instrument, giving a lab flexibility in NGS assay design and sample multiplexing. We demonstrate that a single run with a 16M sensor chip generates 1.5 Gb of data, with greater than 99% raw accuracy and up to 175 bp read lengths.

We tested hybrid-capture and amplicon-based cancer panels on a range of DNA sources, including oncology reference standards derived from cell line DNA, as well as clinical FFPE and blood sample DNA. Reference DNA standards from Horizon Discovery included the Quantitative Multiplex (HD701), EGFR Gene-Specific Multiplex (HD802) and Oncospan (HD827). For hybrid-capture libraries, we tested the IDT xGen Pan Cancer Panel v1.5 (800 Kb target region, 127 genes) and the IDT xGen Exome Research panel (39 Mb target region, 19,396 genes). We detected low frequency mutations in the range of 1%-24.5% across multiple standards with the Cancer panel, with mean coverage of >600x in a single run. Whole exome sequencing of clinical FFPE and blood samples showed high concordance (F1 score > 95%) of SNV mutation calling with industry standard technology. For amplicon panels, we used the Ion AmpliSeq Cancer Hotspot Panel v2 (207 amplicon pairs, 50 genes) with Horizon reference standards. We demonstrate detection of low frequency mutations (>1%) and a high correlation (R squared > 0.99) with expected allele frequencies. Thus, we demonstrate that the GenapSys NGS platform is an accurate, scalable, and low cost solution for oncology research on a wide range of sample types and NGS assays.

# PgmNr 2446: Novel triadic fusions among *ZNF384*, *EWSR1* and *EHMT1* genes in pediatric B-cell precursor acute lymphoblastic leukemia with translocations resembling Philadelphia chromosome.

## Authors:

Chen <sup>1</sup>; F. Wang <sup>1</sup>; P. Cao <sup>1</sup>; Y. Zhang <sup>1</sup>; X. Ma <sup>1</sup>; M. Liu <sup>1</sup>; W. Teng <sup>1</sup>; J. Yang <sup>1</sup>; J. Zhang <sup>1</sup>; T. Wang <sup>1,2</sup>; H. Liu <sup>1,2,3</sup>

## Affiliations:

1) Hebei Yanda Lu Daopei Hospital, Langfang, Hebei, China; 2) Beijing Lu Daopei Hospital, Beijing, China; 3) Beijing Lu Daopei Institute of Hematology, Beijing, China

**Aims** We report triadic fusions among *ZNF384*, *EWSR1* and *EHMT1* genes in a 5-year-old girl who relapsed with Ph like chromosome after initial diagnosis of normal karyotype BCP-ALL.

**Methods** Conventional laboratory tests were performed for the diagnosis of BCP-ALL. Whole transcriptome sequencing (WTS) and whole genome sequencing (WGS) were performed to clarify the gene rearrangements in transcriptional and genomic levels.

**Results** The patient was diagnosed with BCP-ALL and the blast cells were partially positive for CD13 and CD33, but negative for CD10. The karyotype was normal and 36 fusion genes frequently reported in hematological malignancies were negative. She achieved a complete remission (CR) after induction chemotherapy but relapsed 17 months later. t(9;22)(q34;q11.2) translocation was identified by karyotyping with the ratio of 50% but *BCR-ABL1* fusion was not detected by RT-PCR. FISH testing using *BCR-ABL1* dual color, dual fusion probe showed fusion signals with a lower percentage (6%). WTS revealed triadic fusions among 3 genes: *EWSR1* exon 7-*ZNF384* exon 7 in-frame fusion; *ZNF384* exon 6-*EHMT1* exon 2 out-frame fusion; *EHMT1* exon1-*EWSR1* exon 8 out-frame fusion. *EWSR1-ZNF384* is deemed to be the pathogenic fusion. RT-PCR and Sanger sequencing confirmed the 3 fusion transcripts both in relapsed and diagnostic BM. WGS revealed breakpoints in *EWSR1* intron 7, *ZNF384* intron 6, and *EHMT1* intron 1 in both relapsed and diagnostic BM. Structural variations detected by WGS were further analyzed to decipher the *BCR-ABL1* FISH fusion signals. A breakpoint in 9q34.11 located upstream of *ABL1* and a breakpoint in 22q11.23 located between *BCR* and *EWSR1* were found in both diagnostic and relapsed BM. The secondary translocation caused by these two breakpoints resulted in a subclone with seemingly normal karyotype and FISH fusion signals due to ectopically proximity of *BCR* and *ABL1*. The patient underwent allo-HSCT after chemotherapy and CD19 CAR-T cell therapy and has survived for more than 13 months.

**Conclusion** we deciphered a novel pathogenetic *EWSR1-ZNF384* fusion isoform and the complicated chromosomal translocations resembling Ph chromosome in a pediatric BCP-ALL patient. Integrated genomic analysis is crucial in elucidating the pathogenic and rare fusion pattern. Further investigation is needed to elucidate the oncogenic properties of *EWSR1-ZNF384* and confirm the clinical and biological features of patients harboring this fusion.

# PgmNr 2447: Optical mapping for chromosomal abnormalities: A pilot feasibility study for clinical use.

## Authors:

G.A. Toruner; Z. Tang; G. Tang

[View Session](#) [Add to Schedule](#)

**Affiliation:** Hematopathology, UT MD Anderson Cancer Center, Houston, TX.

**BACKGROUND:** Chromosome analysis, FISH and microarrays are three major methods used in clinical cytogenetics labs. Each method has its own limitations. Optical mapping (OM) is a technique which uses fluorescence- labeling (with a site-specific DNA binding protein) large genomic DNA fragments, then pass through nano channels for linearization and get imaged. The fluorescent tags provide a bar code that allows subsequent assembly of individual molecules into larger contiguous maps, which are compared to a reference genome to identify numerical and structural chromosomal abnormalities with high resolution.

**METHODS:** OM was performed with Saphyr™ system from Bionano Genomics on five bone marrow specimens with hematological malignancies. We compared the results from OM and the clinically reported results from karyotyping (4 cases), FISH (4 cases) and microarray analysis (1 case). (Table 1).

**RESULTS:** Overall, clinically reported results and OM results were concordant (Table 1). In addition, several novel structural and copy number changes were detected by OM. .

**CONCLUSION:** OM is a powerful technology that enables us to “scan” the whole genome for both numerical changes and balanced rearrangements with high resolution by one assay. Besides, it detects additional chromosomal abnormalities which could be of clinically significance. Confirmation of additional abnormalities detected by OM and further testing with larger cohorts for validation is warranted before it could be utilized in clinical service.

---

PCR and NGS based technologies are being developed for mutation detection in cfDNA or ctDNA from liquid biopsies. However, they are often not sensitive or specific enough for early detection of cancer and other applications, where a minimum amount of template with specific nucleotide variants, such as single base substitutions, insertions, and deletions, are present in great excess of wildtype genome.

The Pyrophosphorolysis-activated polymerization (PAP) methodology is a more affordable, next-generation nucleic acid amplification technology beyond PCR that possesses ultrahigh sensitivity and selectivity in detection of such mutations without false positives in non-invasive liquid biopsies from patients. The high specificity of PAP derives from the serial coupling of activation of a 3' blocked pyrophosphorolysis-activable oligonucleotide with extension of the unblocked, activated oligonucleotide.

Here we demonstrate the detection of specific cancer mutations in KRAS, EGFR, and BRAF at very low frequencies and down to just one molecule of mutated DNA without detection of false positives.

## PgmNr 2449: RNA-seq identifies structural variants in hereditary cancer genes.

### Authors:

B. Conner <sup>1</sup>; M. Richardson <sup>2</sup>; F. Hernandez <sup>2</sup>; T. Landrith <sup>1</sup>; T. McBride <sup>2</sup>; B. Tippin-Davis <sup>1</sup>; R. Karam <sup>1</sup>

### Affiliations:

1) Research & Development, Ambry Genetics, Aliso Viejo, CA; 2) Clinical Diagnostics, Ambry Genetics, Aliso Viejo, CA

**Introduction:** Massively parallel RNA sequencing (RNA-seq) is able to identify structural variants (SV) in *MSH2*, a frequent site for this type of alteration due to its enrichment with intronic Alu elements<sup>1,2</sup>. We have expanded upon this previously reported *MSH2* cohort to investigate, by RNA-seq, other SV in additional Lynch Syndrome (LS) and hereditary breast and ovarian cancer (HBOC) genes.

**Methods:** RNA-seq was performed as described previously in the whole blood of patients identified with germline SV<sup>1</sup>. Reads supporting aberrant splicing of the involved exons were used as one line of evidence for variant classification using ACMG/AMP guidelines<sup>3</sup>. All study participants consented to RNA genetic testing on a research basis.

**Results:** A set of 15 SV were reclassified from variant of unknown significance (VUS) to clinically actionable pathogenic/likely pathogenic variants (LP) or likely benign (LB). RNA genetic testing provided evidence for reclassification of SV in the following HBOC genes: *BARD1* (n=1), *BRCA1* (n=3), *BRIP1* (n=1), *CHEK2* (n=2), *PTEN* (n=1), *PALB2* (n=1), *RAD50* (n=1). Nine exonic duplications had reads supporting aberrant splicing and were determined to be in-tandem, resulting in their reclassification from VUS to LP. *RAD50* EX8dup was found to have a mid exonic breakpoint and there was no evidence of aberrant splicing by RNA-seq. This evidence was used to reclassify the variant from VUS to LB.

The previously reported *MSH2* duplication cohort was expanded upon by adding *MSH2* EX3\_6dup. SV in the following LS genes were also analyzed: *MLH1* (n=3), *PMS2* (n=1). RNA genetic testing identified aberrant splicing in all five LS SV, leading to their reclassification from VUS to LP.

**Discussion:** RNA-seq has clinical utility as RNA evidence carries strong weight in the ACMG/AMP variant classification guidelines<sup>3</sup>. This proves to be a high-throughput approach by which variants can be reclassified from VUS to either benign or pathogenic/likely pathogenic. Such reclassifications empower clinicians to offer the appropriate clinical management to LS and HBOC patients.

---

There is an important need to understand the functional consequence of a specific genomic change to a gene or protein when interpreting a variant in the context of pathogenicity determination. The joint guidelines of the American College of Medical Genetics and Genomics (ACMG) and the Association for Molecular Pathology (AMP) requires the assessment of well established in vivo or in vitro functional studies showing no damaging effect (BS3) or supportive of damaging effect (PS3) on protein function or splicing.

The Clinical Genome Resource (ClinGen)'s Familial Hypercholesterolemia (FH) Variant Curation Expert Panel manually curated a comprehensive list of 128 peer-reviewed publications describing functional studies of variants identified in FH patients. This body of literature identified 305 variants in three genes: APOB (19 variants), LDLR (263 variants), and PCSK9 (23 variants). We reviewed the diversity of biochemical experiments, and heterogeneity of results with the goal to find a pattern that could promote consistency across the aggregated results.

We propose the use of structured narratives with the structure of 1) method, 2) material, and 3) effect (with or without a quantifier), using standardized terminology from BioAssay Ontology (BAO), Methods and Materials Ontology (MMO), Cell Line Ontology (CLO), and Gene Ontology (GO). For example, a given publication could refer to the use of the luciferase reporter gene assay (method assigned to BAO:0002661) with Hep G2 cells (material assigned to CLO:0003704) finding 12% gene expression (effect assigned to GO:0010467, with a quantifier of 12%). For qualitative findings (i.e. abnormal transcript length), the quantifier would not be used.

We found that only 13 terms were used to describe methods, 17 for materials, and 22 for effects. For a panel of experts, like the ClinGen's FH-VCEP, deliberating about the correct assignment of a reduced number of terms is far less challenging than being familiar with all available literature.

Our structured narrative have the potential to be used by other expert panels and working groups in the ClinGen ecosystem. With the proper validation and expansion of existing ontologies, we believe that our framework can accelerate the curation of functional data in accordance with the BS3/PS3 criteria of the ACMG/AMP guidelines. In the future, with defined rules for numerical thresholds, this framework could pave the way for automated scoring of BS3/PS3.

## PgmNr 2451: Next generation sequencing to identify novel genetic variants of possible familial hypercholesterolemia patients in Taiwan.

### Authors:

T. Hsiao <sup>1</sup>; Y.M. Chen <sup>2</sup>; C.H. Lin <sup>1</sup>; W.W. Lin <sup>3</sup>

---

**Background:** Familial hypercholesterolemia (FH) is an autosomal dominant inheritable disease characterized with premature cardiovascular disease and high levels of low-density lipoprotein (LDL) despite intensive statin therapy. This study aimed to interrogate novel genetic variants of possible FH patients in Taiwan using a next-generation sequencing (NGS) platform.

**Methods:** We enrolled 89 possible FH participants (age  $50.9 \pm 13.8$  years, 45 female, 44 male) with Dutch Lipid Clinic Network score 3-5. A customized targeted amplification panel of the coding region of LDLR, PCSK-9 and APOB genes were performed with the Illumina iSeq 100 platform.

**Results:** In total, we identified 14 pathogenic (12 LDLR, 2 APOB) and 6 likely pathogenic variants (5 LDLR, 1 APOB & LDLR). Three variant of unknown significance (VUS) were also categorized. The mean LDL levels were  $137.6 \pm 69.2$  mg/dl after maximum dose of statin therapies. We found that LDL levels were significantly different among participants of pathogenic, likely pathogenic, benign or VUS groups ( $p = 0.045$  by Kruskal-Wallis test).

**Conclusions:** NGS-based methods can be used to identify heterozygous FH patients of Chinese Han ancestry in the possible FH patients by Dutch Lipid Clinic Network score. However, subjects with VUS deserve further investigations.

## PgmNr 2452: Dilated cardiomyopathy: Genomic and diagnostic approach.

---

Cardiomyopathy is a disease of the heart muscle associated with a disorder of its function. This is a heterogeneous group of diseases with various clinical signs that can ultimately lead to heart failure. Subset of cardiomyopathies are genetically conditioned. In this group can be found congenital heart defects, muscular dystrophy and congenital myopathy, hereditary disorders of metabolism (e.g., diseases of the lysosomal and mitochondrial diseases,  $\beta$ -oxidation disorders of fatty acids, glycogenosis, etc.) and genetic syndromes, e.g., Rasopathies.

Paediatric cardiomyopathies are known for their high phenotypic and genetic variability and causal mutations are very rare in the population. The use of the whole exome sequencing is currently one of the most effective tools for elucidating the genotype of individual patients.

We have successfully used this method for studying of genetic architecture of dilated cardiomyopathy cohort where in about 80% of the 460 examined patients we have found probably causal variant for DCM. At present, we are also focusing on paediatrics forms of cardiomyopathy which are more complex and the clarification is below 50%.

Successful molecular biology diagnostic and helps to identify the risk of occurrence of the disease in the family and to ensure prenatal diagnosis. In selected cases, the phenotype can also be studied on cell models, which contributes to the understanding of the molecular mechanism of the disease and allows a more accurate interpretation of border clinical or laboratory findings.

## PgmNr 2453: Identifying causal genes from abnormal clinical microarray results in patients with heterotaxy-spectrum congenital heart defects.

---

Heterotaxy is a rare congenital anomaly syndrome caused by abnormal left-right patterning in the developing embryo. Patients with heterotaxy exhibit a wide range of phenotypic features including abdominal situs anomalies and congenital heart defects (CHD). However, the genetic basis of heterotaxy is rarely identified clinically. We previously showed that 16% of heterotaxy patients carry damaging copy number variants (CNVs). To further identify candidate genetic loci, we used the Cytogenomics of Cardiovascular Malformation (CCVM) Registry, an ongoing multi-site study that prospectively enrolls participants with abnormal cytogenetic and echocardiogram findings. Of 1827 CHD cases in the registry, we identified 69 patients with heterotaxy-spectrum CHDs using a modified Botto cardiac classification system. A total 137 genetic alterations were detected in heterotaxy patients, including 44.9% gains, 40.6% losses, 2.9% complex losses+gains. Regions of homozygosity (ROH) are identified in 11.6% of patients (7.3% with multiple segments due to consanguinity; 4.3% with segmental uniparental disomy [UPD]). Ten well-known genomic disorders such as 22q11.2 deletion were found in 14.5% patients. CNVs spanning cilia or laterality genes, such as *DNAI2* and *NPHP1*, occurred in multiple unrelated patients, affecting 20.3% of participants; 8.7% of patients carry ROHs spanning known laterality genes including multiple occurrences of *DNAH5*, *DNAI1* and *PKHD1*. CNVs in 6 genetic regions suggested as novel candidate loci in previous studies were present in our cohort. In order to identify novel candidate genes in the unsolved cases, we utilized 32 clinically established heterotaxy genes as the training set for a ToppGene bioinformatics gene prioritization approach. We identified 18 candidate genes enriched for heterotaxy-related Gene-Ontology and Phenotype-Ontology terms including *LIFR*, *KIF26B* and *MSX1* ( $p < 0.01$ ). Taken together, these data demonstrate the spectrum of submicroscopic chromosome abnormalities causing heterotaxy: known genomic disorders, novel damaging CNVs, and ROH. We replicate previous associated novel loci and identify that CNVs encompassing genes known to cause laterality defects or cilia dysfunction may be important etiologic contributors. ROH resulting from UPD may be a previously unappreciated mechanism of heterotaxy. Finally, novel candidate genes for heterotaxy CHD can be identified using bioinformatics approaches to interrogate heterotaxy-associated CNVs.

---

**Introduction:** Williams-Beuren syndrome (WBS), caused by the loss of 23 genes including elastin (*ELN*) on chromosome 7q11.23, is associated with heart malformations, developmental delay, hypercalcaemia and characteristic facies. Genetic testing enables confirmation of diagnosis, improves management and genetic counselling. Sri Lanka (average household income \$115/month) has a free health service but genetic testing costs are borne by parents, making it mostly unaffordable.

**Materials and Methods:** Suspected WBS cases (n=24) were recruited following ethical clearance and informed consent. Molecular diagnosis was performed using semi quantitative polymerase chain reaction (semi-qPCR) (target *ELN*; control *CFTR*), quantitative PCR (qPCR) (target *ELN*; control *TES*) using dyes SYBR green and EvaGreen; 10 results (n=10) validated by fluorescent *in-situ* hybridization.

**Results:** Among 19/24 (79%) clinically typical cases, an *ELN* deletion was identified by semi-qPCR and qPCR. Nine cases had their diagnosis confirmed by FISH. Five clinically atypical cases were not found to have a deletion (2 familial cases, one isolated SVAS, two unknown) on semi-qPCR and qPCR (EvaGreen dye). There was a discrepancy for two patients with qPCR (SYBR green dye): one duplication (FISH negative); one deletion (parents declined FISH). The cost of consumables for semi-qPCR, qPCR and FISH was around \$6, \$7 and \$225 respectively.

**Conclusion:** The semi-q and qPCR using EvaGreen, although not the gold standard, appear to offer a molecular diagnostic test that is more affordable for Sri Lankan families and when used with clinical data, is a useful diagnostic tool in a resource limited healthcare setting.

---

A genetic diagnosis aids clinical management of families with inherited heart disease and sudden cardiac death. Although exome sequencing has revolutionised the genetic testing of these diseases, for many families the genetic cause is not found. Computational tools can detect copy number variants, such as large deletions and duplications, by examining exome sequencing read depth. We sought to look for clinically actionable copy number variants in a large cohort of patients with inherited heart disease and sudden cardiac death. We performed exome sequencing on DNA isolated from patients with inherited cardiomyopathy, arrhythmia syndromes, or sudden cardiac death. We used eXome-Hidden Markov Model (XHMM) to detect copy number variants from exomes that were batched according to the enrichment kit. We focused on copy number variants located within a panel of 369 cardiac genes. Breakpoints were mapped by 1) viewing exome read alignments at the predicted breakpoint junctions, 2) confirming and resolving the extent of the variants with quantitative-PCR, and 3) performing PCR and Sanger sequencing to define the precise breakpoint junction. Segregation analysis was performed on affected family members, where available. Analysis of exome data of 701 patients revealed 10 (1.4%) potentially relevant copy number variants in 4/56 with left ventricular noncompaction, 1/257 with hypertrophic cardiomyopathy, 1/48 with dilated cardiomyopathy, 1/20 with long QT syndrome, 1/14 with arrhythmogenic cardiomyopathy, 1/141 with sudden cardiac death, and 1/1 with unicuspid aortic valve. Of significance, a 9.3 kb deletion spanning exons three to six of *ACTN2* was found in a female with LVNC, and in an unrelated male with HCM. Sequencing revealed that the breakpoint junction was identical in both families and likely resulted from non-homologous end joining. A female with sudden unexplained death at age 17 years had a 1.1 Mb deletion spanning 24 genes, including the long QT syndrome gene *KCNH2*. Finally, a male with HCM has a 29.4 kb duplication involving part of *MYH6* and *MYH7*, which likely occurred by non-allelic homologous recombination between a duplicated segment within the two genes. Copy number variants are a rare cause of inherited heart disease. Characterising the precise breakpoints of copy number variants enables cascade genetic testing of family members and improves our understanding of the molecular mechanisms leading to large deletions and duplications.

Around 10% of natural death cases remain unexplained each year and are subsequently classified as sudden unexpected deaths (SUD). The use of exome sequencing-based (WES) molecular autopsy protocol has recently proven its potential to improve this yield. As genomic sequencing expands and knowledge of gene?disease and variant?disease associations increase, reanalysis of initial WES data may facilitate new discovery and maximize the accuracy of clinical sequencing.

We tested this hypothesis in the Scripps Molecular Autopsy study, where in 2017 we reported a diagnostic yield of 16% through WES of 50 sudden-death cases. We re-assessed these post-mortem genetic data ~2 years later using an improved variant classification methodology and updated variant annotation pipeline.

Reanalysis yielded one pathogenic variant that was not initially reported in one individual, comprising an 18% increase in P/LP yield. We also reclassified variants of uncertain significance (VUS) to benign due to updated population frequency data. Explanatory variants have been discovered in 9 of 50 previously SUD cases. Our re-annotation efforts also classified another 30 (60%) cases with uncertain clinical significance finding (VUS), an almost 10% increase from our original study. These new genetic diagnoses are mainly due to improved variant prioritization, newly available clinical information since our original publication and highly accurate annotation database.

Iterative reanalysis of negative WES data may prove useful, as knowledge of genetic etiologies grows. In addition, these findings underline the importance of systematic molecular autopsy to cases with an undetermined manner of death, with implications for screening of relatives.

---

Hypertrophic cardiomyopathy (HCM) is an inherited disease of the myocardium characterised by unexplained left ventricular hypertrophy. Recent expert curation has classified 23 HCM disease genes as having moderate, definitive, or strong evidence of causing isolated left ventricular hypertrophy. Consequently, previously reported pathogenic variants in genes with lower, or no, evidence of association with HCM are now considered unlikely to be responsible for disease causation. We sought to reassess the genetic testing diagnostic yield of familial HCM in expert curated genes using stringent variant classification criteria.

We re-evaluated genetic testing results in unrelated probands with a family history of HCM who had undergone cardiac gene panel, exome or genome sequencing. Variants were evaluated in genes with definitive or moderate association with HCM (*MYBPC3*, *MYH7*, *TNNT2*, *TNNI3*, *TPM1*, *ACTC1*, *MYL2*, *MYL3*, *CSRP3*, *TNNC1*, *JPH2*), and in syndromic genes where isolated left ventricular hypertrophy may be seen (*ALPK3*, *CACNA1C*, *DES*, *FHL1*, *FLNC*, *GLA*, *LAMP2*, *PRKAG2*, *PTPN11*, *RAF1*, *RIT1*, *TTR*). Variants with frequency < 0.004% in the Genome Aggregate Database of population controls were classified for pathogenicity using American College of Medical Genetics guidelines.

Amongst 229 familial HCM probands, 147 (64%) had a pathogenic or likely pathogenic variant, of which all but 5 variants were in definitive HCM genes. 33 (15%) probands harboured only a variant of uncertain significance, of which 24 were in definitive genes and 9 were in syndromic genes. 49 (21%) probands had no rare variants and were classified as having an indeterminate genetic test. When compared to familial HCM probands with a pathogenic or likely pathogenic variant, those with an indeterminate test were older at diagnosis (mean age 44 versus 33 years;  $p < 0.001$ ), had fewer affected family members (mean 2.4 versus 3.5;  $p < 0.001$ ) and a lower maximal left ventricular wall thickness (mean 18 mm versus 21 mm;  $p < 0.001$ ). There were no differences between the two groups with respect to a family history of sudden cardiac death or sex.

Patients with familial HCM and an indeterminate genetic test are older at diagnosis and have less hypertrophy than those with a clinically actionable variant. While a non-familial HCM sub-group is already known, further sub-classification of familial HCM may be warranted. Future research should focus on resolving the pathogenicity of variants of uncertain significance.

Sudden death is a traumatic event, often leaving surviving family members with unanswered questions regarding the cause of death and their personal risks for cardiac events. We performed multigene cardiac genetic testing in nearly 800 postmortem cases. Positive diagnostic results were obtained in 14%. To highlight the clinical utility of postmortem genetic testing (PMGT), we present three case examples, in which sudden death precipitated familial genetic testing and provided critical information for family members. **Case 1:** A teen female with a history of prolonged QTc interval and family history of syncope died suddenly in her sleep. A living sibling was later diagnosed with LQTS, and genetic testing identified a novel *KCNH2* missense variant, which segregated with LQTS in several affected relatives, including the deceased proband. **Case 2:** An adult male with DCM died suddenly in his early 40s, and his sister passed way in her 30s while sleeping. PMGT identified a pathogenic *LMNA* nonsense variant. Familial testing revealed that the proband's affected mother is mosaic for the variant. Multiple siblings of the proband are pre-symptomatic carriers and are at risk to develop and transmit an *LMNA*-related cardiomyopathy. **Case 3:** A male infant presenting with dyspnea, hypotonia, and metabolic acidosis shortly after birth was found to also have moderate biventricular dilatation with markedly reduced function, ultimately dying from cardiac arrest. Autopsy findings were consistent with DCM. PMGT revealed a maternally inherited pathogenic *TAZ* missense variant associated with X-linked Barth syndrome. In conclusion, PMGT may establish or confirm a clinical diagnosis in the proband, which allows for testing of at-risk family members and determine recurrence. Genetics professionals complement the medical examiner's services by facilitating genetic testing to obtain answers for family members. They also play a vital role in providing counseling and medical management options for surviving relatives. As state laws begin to mandate protocols for PMGT as part of the standard investigation when sudden death occurs under age 50 years, it will become increasingly important for genetics health care providers to stay abreast of both common and unique findings that may arise during these investigations.

---

Autosomal recessive congenital ichthyosis (ARCI) is a phenotypically and genetically heterogeneous skin disease. It is an ultra-rare disease with less than one patient in 50,000 people and can be caused by mutations in more than twelve different genes, with approximately 20% of the cases without mutations in a currently known candidate gene. The main pathophysiological feature is an impaired skin permeability barrier function, which leads to a disturbance of the cutaneous water homeostasis. A clear correlation between genetic causes and clinical picture has not been described to date, in part because of pronounced allelic heterogeneity and a vast majority of compound heterozygous cases. We have therefore collected cases from populations with a large percentage of consanguineous families, mainly from Saudi Arabia, Yemen, and Pakistan. We have assessed various approaches to identify candidate genes and mutations, including SNP-based homozygosity mapping, gene panel sequencing and whole exome sequencing. Interestingly, we found likely pathogenic variants in known candidate genes in all 19 families studied here, and these variants were identified in only five different genes, namely *TGM1*, *ABCA12*, *CYP4F22*, *NIPAL4*, and *ALOXE3*. Variants included both known and previously unknown mutations and nonsense, splice site, and missense variants. Patients from Saudi Arabia and Pakistan were assigned to potential founder mutations in *TGM1*, *ALOXE3*, and especially *NIPAL4*, respectively. Importantly, based on detailed clinical data including recent treatment information, we defined clear genotype/phenotype correlations. We attributed *TGM1* and *ABCA12* mutations to the most severe forms of lamellar and erythematous ichthyoses, respectively, almost regardless of treatment, and identified the phenotypic spectrum of ARCI associated with variants in each of the other genes. A detailed clinical analysis will be completed and specified. Our results contribute to the mutational spectrum of ARCI and revealed significant insights into genotype/phenotype correlations. The findings are instrumental for defining a fast and convenient procedure to make a diagnosis considering the patient background and the laboratory facilities available.

## PgmNr 2461: Somatic mutation spectrum of segmental overgrowth.

### Authors:

S.H. Heo <sup>1</sup>; Y.M. Kim <sup>2</sup>; A. Oh <sup>3</sup>; Y. Lee <sup>3</sup>; G.H. Kim <sup>4</sup>; T. Kim <sup>1</sup>; I.H. Choi <sup>4</sup>; J.H. Jang <sup>5</sup>; H.W. Yoo <sup>3</sup>; B.H. Lee <sup>3</sup>

### Affiliations:

1) Asan Institute for Life Sciences, Asan Medical Center, College of Medicine, University of Ulsan, Seoul, Korea; 2) Department of Pediatrics, Gangneung Asan Medical Center, Gangneung, Korea; 3) Department of Pediatrics, Asan Medical Center Children's Hospital, College of Medicine, University of Ulsan, Seoul, Korea; 4) Medical Genetics Center, Asan Medical Center, College of Medicine, University of Ulsan, Seoul, Korea; 5) Green Cross Genome, Yongin, Korea

Congenital overgrowth of body segment is noted in several genetic syndromes such as Klippel-Trenaunay (KT) syndrome, Cowden syndrome, Megalencephaly-capillary malformation (MCAP) syndrome, CLOVES (or CLOVE) syndrome and fibroadipose hyperplasia, and Parker-Weber syndrome. These syndromes share the common phenotypic findings, somatic segmental overgrowth (brain, limb or visera), fibro-adipose, lymphatic, vascular or muscular proliferation, and cutaneous nevi. Recently, PIK3CA-related signaling pathway has been suggested as the main molecular pathogenic pathway of these syndromes; The somatic mutations of the PIK3CA or its related genes have been identified and its target agent improved the segmental overgrowth in the affected patients.

In the current study, we designed the customized panel of 145 genes (372 kbps) related to PI3K/AKT/mTOR pathway, in order to identify the somatic mutations in the 12 patients suspicious of PIK3CA-related segmental overgrowth syndrome. DNA was identified both in the affected tissues (cutaneous vascular or lymphatic proliferative tissue) and normal blood leukocytes. The Mean depth of the 145 genes was 711X and 97.5% of the target genes were read >100X. PIK3CA mutations were found in 6 patients (MAF=2-18% of the affected tissues and 0% in the leukocytes). In addition, KRAS, MAP2K3, TBC1D4 and GNAQ somatic mutations were found in single cases (MAF=4%). One patient had a germline PTEN mutation. All of these variants were not found in normal population (MAF <0.002%).

With our customized panel, we identified somatic genetic alteration in a total 10 patients (83%). This genetic information would help to apply therapeutic target agent in select cases and understand the molecular pathology more in detail.

## PgmNr 2462: Exome-sequencing identifies a novel 3.6 Kb deletion from PYGL as the cause of glycogen storage disease type VI.

### Background:

Glycogen storage diseases type VI (GSD VI) is an autosomal recessive condition that presents in infancy/early childhood with hepatomegaly and hypoglycemia. Because of its wide spectrum of clinical manifestations, it is difficult to distinguish GSD VI from other liver GSDs. By now, several pathogenic single nucleotide variants (SNVs) and large size copy number variations (CNVs) on the glycogen phosphorylase L (PYGL), the only gene known to be associated with GSD VI, were identified. However, due to the limitations of detection methods and the rarity of the variations, the detection of some pathogenic point mutations can be missed, and pathogenic structure variants (SVs) have not been reported yet.

### Purpose:

In this study, we investigated whether there exist SVs on the PYGL gene that cause GSD6 by means of a new exome sequencing analysis.

### Methods:

Based on exome sequencing data, a rapid bioinformatics method of SAM file analysis searching for potential SVs was constructed. This method was applied in 16,247 unrelated samples for SV screening, including 9,708 samples performed clinical exome sequencing (CES) and 6,539 samples performed whole exome sequencing (WES). Detected potential SVs were validated by long-rang PCR.

### Results:

A novel 3.6 Kb deletion variant which involved the exons 14-17 of PYGL was identified. The deletion variant was detected in six samples, which suggested a potential mutation hotspot, with an estimated allele frequency of 0.018%. Three samples of them each had another different pathogenic SNV on the PYGL gene and clinical symptoms of hepatomegaly and high level of liver glycogen. The other three samples, due to no clinical phenotypes of GSD VI and undetected pathogenic mutations in the PYGL exon regions, were considered as carriers.

### Conclusions:

The identification of the novel PYGL exons deletion broaden the understanding of the genetic factors of GSD VI pathogenesis. In addition, this paper was also demonstrated the feasibility of exome sequencing data analysis in the search for SV. The three samples with clinical symptoms of GSD VI and identified SV suggested the limitations of SNV-alone analysis with exome sequencing detection.

## PgmNr 2463: Exonic duplication of the *OTC* gene by a complex rearrangement that likely occurred via a replication-based mechanism: A case report.

**Background:** Ornithine transcarbamylase deficiency (OTCD) is an X-linked recessive disorder involving a defect in the urea cycle caused by *OTC* gene mutations. Although a total of 417 disease-causing mutations in *OTC* have been reported, structural abnormalities in this gene are rare. We here describe a female OTCD case caused by an exonic duplication of the *OTC* gene (exons 1-6).

**Case presentation:** A 23-year-old woman with late-onset OTCD diagnosed by biochemical testing was subjected to subsequent genetic testing. Sanger sequencing revealed no pathogenic mutation throughout the coding exons of the *OTC* gene, but multiplex ligation-dependent probe amplification (MLPA) revealed duplication of exons 1-6. Further genetic analyses revealed an inversion of duplicated exon 1 and a tandem duplication of exons 2-6. Each of the junctions of the inversion harbored a microhomology and non-templated microinsertion, respectively, suggesting a replication-based mechanism. The duplication was also of *de novo* origin but segregation analysis indicated that it took place in the paternal chromosome.

**Conclusion:** We report the first OTCD case harboring an exonic duplication in the *OTC* gene. The functional defects caused by this anomaly were determined via structural analysis of its complex rearrangements.

# PgmNr 2464: Molecular diagnosis of autoimmune polyendocrine syndrome type 1 (APS1) and systemic literature review.

## Authors:

## Background

Autoimmune polyendocrine syndrome, type 1 (APS1), also called APECED (autoimmune polyendocrinopathy, candidiasis, ectodermal dystrophy) syndrome, is rare. The clinical diagnosis of APS1 requires the presence of two of the three cardinal components: chronic mucocutaneous candidiasis, autoimmune hypoparathyroidism, and autoimmune adrenal insufficiency. We reported a girl with APS1 with molecular diagnosis and systemic review of the literature.

## Case Presentation

A 15-year-old girl presented to the pediatric endocrinology clinic because of hyperpigmentation of the oral mucosa, gingiva, lips, skin, and knuckles. Physical examination showed she also had oral candidiasis and onychomycosis of the fingernails and toenails. Her morning serum cortisol was 5.39 µg/dL and ACTH >1390 pg/mL. Pathological examination of the nail of the big toenail revealed fungal infections. Her calcium was 10 mg/dL, phosphorus 4.5 mg/dL, total cholesterol 204 mg/dL, triglyceride 57 mg/dL, uric acid 4.5 mg/dL, creatinine 0.9 mg/dL, ALT 19 U/L, and AST 24 U/L. She was treated with cortisone acetate. At the age of 20 she had cramps of extremities with a serum calcium of 7.9 mg/dL and phosphorus of 7.1 mg/dL and began to take calcitriol and calcium carbonate.

## Methods

Molecular genetic analysis of her genomic DNA was performed on the autoimmune regulator (*AIRE*) gene using PCR and sequencing.

## Literature review

We searched PubMed using MeSH terms 'Autoimmune polyendocrine syndrome, type 1' and 'polyendocrinopathies, autoimmune'. We also screened for relevant references from all original and review articles by hand, Online Mendelian Inheritance in Man (OMIM), and Human Genetic Variation Database.

## Results

We found that the patient was a compound heterozygote with mutations c.32T>G (p.Leu11Arg) and c.483\_484delC (p.Lys164Argfs\*214). The two mutations were not found in 50 healthy individuals. C.32T is conserved in *Mus musculus*, *Macaca nemestrina*, *Gorilla gorilla*, *Pan troglodytes*, and *Homo sapiens*. Mutation c.32T>G is pathogenic by PolyPhen-2, SIFT, and LoFTool. Mutation c.483\_484delC is probably damaging by LoFTool.

Systemic literature review showed mutations are specific in ethnicity and of genotype-phenotype correlation.

**Conclusion**

Although APS1 is rare, alertness for early diagnosis is beneficial to patients for appropriate treatment to various symptoms. Molecular genetic diagnosis provides proper genetic counseling. Mutations show ethnic specificity and genotype-phenotype correlation.

## PgmNr 2465: Diagnostic yield for multi-gene testing in patients with a clinical diagnosis of nephrotic syndrome/focal segmental glomerulosclerosis.

### Authors:

P. Celestino Soper; E. Williams; L. Goodell

[View Session](#) [Add to Schedule](#)

**Affiliation:** GeneDx, Gaithersburg, Maryland, USA

---

Nephrotic syndrome (NS) is a clinically heterogeneous group of disorders characterized by proteinuria, hypertension, hypercholesterolemia and edema. The most prevalent disorder is focal segmental glomerulosclerosis (FSGS), which is characterized by scarring in a limited number of glomeruli of the kidneys. Multiple genes have been linked to NS, which may be inherited in an autosomal dominant (AD), recessive (AR) or X-linked manner. Currently, there are no clear guidelines for genetic testing of patients with NS/FSGS. Published studies estimate the diagnostic yield of genetic testing in patients with well-defined steroid resistant NS to be about 15-30%, however the yield in a broader/less defined phenotype has not been evaluated thoroughly. The purpose of this study was to review the results from clinician-built multi-gene NGS tests based on exome capture (XomeDxSlice) to determine the yield and validity of panel testing for NS/FSGS. Probands were selected based on the presence of NS, FSGS, glomerular disease and/or proteinuria, whose test included at least one gene from a list of 25 known to be strongly associated with NS/FSGS (tests reviewed had an average of 84 genes, range of 2 to 340 genes). Approximately 21% (18/85) of individuals had a positive diagnostic result. Of these, the majority (55.6%; 10/18) had pathogenic or likely pathogenic variant(s) (PV) in a gene for Alport syndrome (*COL4A3*, *COL4A4*, *COL4A5*). Two affected individuals had biallelic PV in AR genes (*NPHS1*, *SMARCAL1*), while the remaining 6 cases had PV in AD genes (*WT1*, *INF2*, *TRPC6* and *PAX2*). Another 48% (41/85) of individuals had a result of possible clinical importance, such as a single PV in an AR gene or variant(s) of uncertain significance in an AD or AR gene, where additional follow-up was recommended. Of these, 54% (22/41) had a result in at least one of the 25 strongly associated genes. The high number of probands with a molecular diagnosis of Alport syndrome in this study may indicate a considerable clinical overlap with NS/FSGS, thus illustrating the benefits of multi-gene testing for accurate diagnosis, appropriate management and follow-up. Genetic diagnosis may guide decisions regarding steroid therapy and kidney transplant candidacy, and assist with prognostic predictions. Additionally, increased utilization of genetic testing may, over time, allow for an expanded understanding of the genetic factors that cause NS/FSGS.

## PgmNr 2466: First report of late-onset Peutz-Jegher Syndrome (PJS) with APC gene mutation, and no alteration of PJS-related STK11 gene.

### Authors:

M. Ibrahim <sup>1</sup>; A. Ibrahim <sup>2</sup>; M.J. Hajianpour <sup>3</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

Peutz-Jegher syndrome (PJS) is a rare autosomal dominant syndrome usually due to a germline mutation in STK11 gene. It is characterized by multiple hamartomatous polyps in the gastrointestinal tract with mucocutaneous pigmentation and has an increased risk of cancer. Currently only mutations in STK11 (AKA LKB1) have been identified as causative of PJS. The STK11 gene sequencing detects 55% of cases when the family history is positive for PJS, and 70% of sporadic cases.

Deletion/duplication analysis detects 45% of familial cases and 21% of sporadic cases. High penetrance rate by the age of 30 years, but 10-20% of the cases result from de novo mutations<sup>1</sup>. To our knowledge this is the first report of association of APC gene alteration and Peutz-Jegher syndrome (PJS).

A 56-year-old who presented to the emergency department with abdominal pain and rectal bleeding. No family history of PJS, but breast and colon cancer found in first degree relatives. He had dysphagia, nausea, vomiting and fatigue at presentation with pallor, multiple nevi/brown spots over the arms and legs and right palm, superficial tenderness in the right side of the abdomen on physical examination. Rectal examination revealed no masses or active bleeding at the time. Patient has renal cyst, iron- deficiency anemia and a history of recurrent rectal bleeding over the past four years. Upper GI endoscopy showed duodenal hamartomatous polyps; histologically P-J polyps with a stricture at the distal esophagus.

Colonoscopies performed over the past 8-10 years showed 2-10 polyps which were histologically confirmed to be benign tumors with atypical hyperplasia. Molecular studies showed a variant of uncertain significance (VUS) of APC gene: c2297C>T (p. Ala766Val) (aka A766V (2297C>T)). The APC gene is associated with familial adenomatous polyposis (FAP). The sequencing and deletion/duplication analysis of STK11 gene was normal.

A clinical diagnosis with PJS requires the presence of any one of the following:

Two or more histologically confirmed Peutz-Jeghers (PJ) polyps, any number of PJ polyps detected in an individual who has a family history of PJS in a close relative, characteristic mucocutaneous pigmentation in an individual who has a family history of PJS in a close relative, any number of PJ polyps in an individual who also has characteristic mucocutaneous pigmentation.

## PgmNr 2467: Cost-effectiveness analysis of using *TBX6*-associated congenital scoliosis risk score in genetic diagnosis of congenital scoliosis.

### Affiliations:

1) Department of Orthopedic Surgery, Peking Union Medical College Hospital, Peking Union Medical College and Chinese Academy of Medical Sciences, Beijing 100730, China.; 2) Beijing Key Laboratory for Genetic Research of Skeletal Deformity, Beijing 100730, China.; 3) Graduate School of Peking Union Medical College, Beijing 100005, China.; 4) Medical Research Center of Orthopedics, Chinese Academy of Medical Sciences, Beijing 100730, China.; 5) Department of Central Laboratory, Peking Union Medical College Hospital, Peking Union Medical College and Chinese Academy of Medical Sciences, Beijing 100730, China.; 6) Department of Breast Surgical Oncology, National Cancer Center/Cancer Hospital, Chinese Academy of Medical Sciences and Peking Union Medical College, Beijing, China.

### Background

This study tested whether using *TBX6*-associated congenital scoliosis risk score (TACScore) as a screening method is more cost-effective compared to using Whole Exome Sequencing (WES) as a first-line genetic testing for congenital scoliosis.

### Method

Molecular diagnosis of 416 patients in the DISCO (Deciphering disorders Involving Scoliosis and COMorbidities) cohort were collected retrospectively. A decision tree was constructed to estimate the money and time costs of two alternative strategies (TACScore versus WES). Bootstrapping simulations and sensitivity analyses were performed to examine distributions and the robustness of estimates. The economic evaluation adopted both health care payer and personal budget perspective.

### Result

The strategy of using 'TACScore' for primary screen resulted in a cost of \$1074.2 and diagnostic time of 38.7d in average to gain a molecular diagnosis or an uninformative ES report for each patient compared with \$1169.6 and 41.4d for the 'ES as a first-line test' method (incremental cost, -\$95.4, 95%CI: -\$124.9 to -\$66.0,  $P < 0.001$ ). Patients predicted by TACScore received a result within \$715.1 and 30.4d, significantly lower than \$1193.4 and 44.0d when ES served as a first-line test (incremental cost, -\$478.3, 95%CI: \$-599.1 to \$-357.5,  $P < 0.001$ ). In 100% of bootstrapping simulations, the strategy using TACScore was less costly and time-saving. The sensitivity analyses revealed that the strategy using TACScore remained cost-effective even the cost of per ES decreased to \$8.8.

### Conclusion

From both health care payer and personal budget perspectives, using TACScore as a screening test is more cost-effective than using ES as a first-line test, for pursuing a molecular diagnosis in patients with congenital scoliosis.

## PgmNr 2468: Establishment of next-generation sequencing based polydactyly gene panel.

### Authors:

J. Hong; K. Park; H. Kim; W. Lee; S. Chun; W. Min

[View Session](#) [Add to Schedule](#)

**Affiliation:** Department of Laboratory Medicine, University of Ulsan College of Medicine and Asan Medical Center, Seoul, Korea, Republic of

---

### Introduction

Polydactyly is a congenital condition characterized by extra digits, though its phenotype varies from skin tag to complex duplication. Polydactyly is an anomaly observed right after birth, and it can occur either alone or as a sign of various syndromes. The main etiology of polydactyly is known to be genetic. However, genetic testing for polydactyly is not routinely performed. We established a gene panel for polydactyly using next-generation sequencing (NGS), a method that can analyze many genes simultaneously.

### Method

We reviewed literatures and searched databases such as Human Gene Mutation Database and Online Mendelian Inheritance in Man to list up and select genes associated with polydactyly. BED file including exons and part of introns of selected genes was created and probes were designed. The reagents used were DxSeq Library Preparation Reagent and DxSeq Target Capture Reagent. Illumina Miseq DX was used for sequencing. Bioinformatics software employed were Illumina VariantStudio and DxSeq Gene Analysis System. Reporting methods followed standards and guidelines of the American College of Medical Genetics and Genomics. Designed panel was applied to NA12878 reference genome to validate and the result was compared to databases such as Genetic Testing Reference Materials Coordination Program and The Genome in a Bottle Consortium hosted by NIST.

### Result

Overall, 167 genes and ZRS, a region in intron of *LMBR1* gene, were included in the polydactyly panel. 503,063 base pairs of target region were assigned. Several regions that repeatedly generate low coverage due to deletion and GC bias were excluded from target and left to manual review and Sanger sequencing if needed. Sequencing and analyzing of NA12878 were performed according to the established panel and protocol. 205 previously reported variants in the target region were detected in all duplicated samples of NA12878, yielding analytical sensitivity of 100%. The match rate was calculated for the detected sequence and the high-confidence region of NIST, and the analytical specificity and accuracy were over 99.9%.

### Conclusion

To test many genes related to polydactyly at once, NGS is a suitable method. Some regions showed low coverage and made QC workflow difficult. We excluded the regions from target and prepared manual review process and Sanger sequencing to solve the problem. In conclusion, polydactyly NGS panel can be used for detecting causal genes of polydactyly and benefit patient management.

## PgmNr 2469: Validation study of the integration of next-generation phenotyping in exome analysis.

**Background:** The expanding use of next-generation sequencing technologies will increase the challenges in interpretation and prioritization of resulting genomic variants. Variant prioritization and clinical correlation require the integration of rich phenotypic data, which can be accomplished through the use of next-generation phenotyping (NGP) technologies. The Face2Gene platform (F2G) leverages NGP analysis of various phenotypic signals, including DeepGestalt for facial analysis. The PEDIA algorithm is the first framework to integrate F2G-generated phenotypic scores along with molecular data to enable variant prioritization based on phenotypic relevance.

**Methods:** Using F2G and the PEDIA algorithm, we analyzed facial photos, HPO features, and VCFs from 126 real-world cases sent for exome sequencing at the Greenwood Genetic Center (GGC). Cases were segmented by diagnosis status and difficulty level. For each diagnosed case, we generated a PEDIA score for each variant and gene. Using these scores, we defined the PEDIA rank for the known causative gene in each case. This PEDIA rank was compared to the original GGC variant rank and a molecular rank based on the CADD score.

**Results:** Integration of NGP into the variant prioritization process dramatically increased diagnostic efficiency, as demonstrated by the increase in top-ranked causative genes and the overall improvement in gene ranking. PEDIA ranked the causative variant first in 27.5% of cases, compared to 2.5% based on GGC rank and 7.5% based on CADD rank. Compared to GGC and CADD ranks, PEDIA resulted in a significantly improved rank ( $\geq 15$  positions) in 17.5% and 33% of cases, respectively. For cases originally solved only with analysis of parental data, PEDIA showed improved ranking in 25% of cases (average improvement 27.7 positions) and successfully placed the causative gene in the top 5 in 33%. In cases diagnosed with a syndrome supported by a facial model in F2G, PEDIA ranks the causative gene in the top 5 for 67% of cases, compared to 11% based on either GGC or CADD ranks.

**Conclusion:** Integrating NGP into the molecular diagnostic process increases diagnostic efficiency and yield. Further work may demonstrate this method's effectiveness as an alternative to trio analysis. As more NGP technologies are developed, the impact of NGP on the molecular diagnostic process will increase substantially.

## PgmNr 2470: 3q26.1-q29 microduplication: A case report.

### Authors:

Microdeletion and microduplication syndromes involving many different chromosomal segments are significant factors implicated in mental retardation and dysmorphism. Overall, the detection rate of chromosomal aberrations in patients with ID and/or congenital malformations using conventional karyotyping is approximately 9.5%. The use of array comparative genomic hybridization (array CGH) as a diagnostic tool in molecular genetics has facilitated the identification of many new microdeletion/microduplication syndromes (MMSs).

We report a case of an 9-month-old child who was referred to our genetic consultation by prenatal suspicion of malformation of the central nervous system and neurodevelopmental disorder. Physical examination revealed dolicocephaly, dysmorphic ears, wide nasal bridge, anteverted nostrils, nasal tip bifid, long philtrum, micrognathia, malformed auricles, short, webbed neck, no visual contact and generalized hyperreflexia. The child underwent genetic karyotype reported duplication interstitial of 3q, this duplication was confirmed with comparative genomic hybridization that it reported interstitial duplication of approximately 30 Mb at chromosome 3 bands q26.1-29.

The duplicated segment overlaps with Dup(3q) syndrome, 3q26 microduplication syndrome and recently described 3q29 microduplication syndrome (MIM 611936). Clinically, the patient's phenotype is congruent with some anomalies described in all syndromes that compromised of 3q. We suggest that 3q26.1-q29 microduplication identified is a novel genomic spectrum of Dup(3q) syndrome.

## PgmNr 2471: Copy number variation (CNV) identification, interpretation and database from a Brazilian cohort.

### Authors:

M.I. Melaragno <sup>1</sup>; V. Cabral <sup>1</sup>; F.T. Bellucco <sup>1</sup>; M. Colovati <sup>1</sup>; H.R. Oliveira-Junior <sup>1</sup>; M. Moysés-Oliveira <sup>2</sup>

Copy number variations (CNVs) constitute an important class of variation in the human genome and the interpretation of their pathogenicity considering different frequencies across populations is still a challenge for geneticists. Since the CNV databases are predominantly composed of Caucasian and/or non-mixed-race individuals, and Brazilian genetic constitution is admixed and ethnically diverse, diagnostic screenings on Brazilian variants are greatly confounded by the lack of populational references. We analyzed a clinical cohort of 268 Brazilian individuals, including patients with neurodevelopment disorders and/or congenital malformations. We used Affymetrix's arrays, considering a minimum size of 150 kb for losses and 200 kb for gains. The pathogenicity of CNVs was classified according to their gene content and overlap with known benign and pathogenic variants. A total of 1,504 autosomal CNVs (1,207 gains and 297 losses) were classified as benign (92.9%), likely benign (1.6%), VUS (2.6%), likely pathogenic (0.2%) and pathogenic (2.7%). The mean size of the CNVs was ~763 kb, being ~704 kb for gains and ~1.0 Mb for losses. The mean sizes of benign, likely benign, VUS, likely pathogenic and pathogenic CNVs were 586 kb, 522 kb, 621 kb, 1.0 Mb and 7.2 Mb, respectively. Some of the CNVs were recurrent and with frequency increased in our cohort, when compared to open resources of structural variants: 14q32.33 gain (96.6% patients), 22q11.22 gain (32.1%), 1q21.1 gain (4.5%), and 1p36.32 gain (7.5%). Then, CNV's pathogenicity interpretation was reevaluated according to their frequency. Highly recurrent CNVs classified as likely benign or VUS were considered non-pathogenic in our Brazilian sample. This study shows the relevance of introducing CNV data from diverse cohorts to improve on the interpretation of clinical impact of genomic variations. Financial support: FAPESP, Brazil

## PgmNr 2472: *EP300* related Rubinstein-Taybi syndrome: Expanding the phenotype and genotype spectrum.

### Authors:

R. Kosaki <sup>1</sup>; H. Okuno <sup>2</sup>; K. Kosaki <sup>3</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Div Med Genet, Natl Ctr Child Hlth & Dev, Tokyo, Japan; 2) Department of Physiology, Keio University School of Medicine; 3) Center for Medical Genetics, Keio University School of Medicine

**Background?** Rubinstein-Taybi syndrome (RSTS) is a multiple malformation syndrome characterized by typical facial appearance, broad thumbs and toes, and developmental delay. RSTS is an extremely rare autosomal dominant genetic disease. An estimated prevalence of one case per 125,000 live births.

The diagnosis of RSTS is primarily based on clinical features with distinctive facial features and hand and foot abnormalities. RSTS is caused by heterozygous mutations in *CREBBP* and in *EP300* genes in fifty to sixty percent and eight to ten percent. *EP300* is responsible for a minority case of RSTS, the phenotype has been shown various spectrum. Some do not have characteristic facies nor hand and foot abnormalities. Intellectual disability also appears to be affected mildly.

**Purpose?**

The purpose is to describe three unrelated RSTS patients without classic manifestations who have *EP300* mutations.

**Method?**

We examined three intellectual disability /developmental delay with congenital multiple malformations.

Genomic DNA was extracted from a peripheral blood sample. Medical exome sequencing was performed using the TruSight One Sequencing Panel (Illumina San Diego, CA) running on a MiSeq platform (Illumina, San Diego, CA). The bioinformatics analysis was performed. The mutation was confirmed using Sanger sequencing.

**Result?**

Case1: A 5-months old boy with developmental delay, large VSD and broad thumbs. We identified with *EP300* nonsense mutation.

Case2: A 2-years old girl with intellectual disability, downslanting palpebral fissures, and slightly big toes. We identified with *EP300* missense mutation.

Case3: A 11-months old girl with DORV, TR, myelomeningocele, hydrocephalus, imperforate anus, coloboma and hearing impairment. We identified de novo *EP300* frameshift mutation and de novo *SOS1* mutation.

Case4: A 6-years old girl with PDA, PS, coloboma and hearing impairment. We identified de novo *EP300* frameshift mutation.

**Discussion?**

We showed the clinical variability of RSTS with *EP300* mutations which provided the expansion of RSTS spectrum. It will contribute the genotype-phenotype correlation in RSTS. We also showed the clinical utility of medical exome analysis as a diagnostic test in patients with congenital multiple malformations.

Informed consent from the parents and approval from the local institutional review board were obtained prior to the molecular studies.

There are no conflicts of interest to declare.

## PgmNr 2473: A 3.99 MB interstitial deletions of 8q12.1q12.2 in a girl with CHARGE syndrome.

### Authors:

---

CHARGE syndrome is a genetic syndrome characterized by a specific and recognizable pattern of features. Mutations or deletions of the gene encoding chromodomain helicase DNA binding protein 7 (CHD7) cause this syndrome.

A girl was born after 40 weeks and 4 days of gestation. Apgar scores at 1 and 5 min were 8 and 8, respectively. Her birth weight was 2386 g (-2.19 SD), height 48.0 cm (-0.97 SD), and head circumference 31.0 cm (-1.96 SD). She was transferred to our hospital because of right preaxial polydactyly, bilateral ear deformations, and low oxygen saturation (70% in room air).

Echocardiography revealed patent ductus arteriosus (PDA), and patent foramen ovale (PFO). Hearing loss was also noted.

The initial G-banding karyotyping showed 46,XX. Whole-genome SNP microarray analysis revealed a 3.99 MB interstitial deletion of chromosome 8q. arr[hg19] 8q12.1q12.2(58,009,323-61,994,781)x1. The Online Mendelian Inheritance in Man database includes two morbid genes in this interval. *CA8* gene is an autosomal recessive causative gene of cerebellar ataxia and mental retardation with or without quadrupedal locomotion 3. *CHD7* is an autosomal dominant causative gene of CHARGE syndrome.

CHARGE syndrome caused by the microdeletion of 8q is rare (5 cases in ClinVar). In 2013, Palumbo O. et al. reported the 8q12.1q12.3 de novo microdeletion involving the *CHD7* gene in a patient without the major features of CHARGE syndrome.

## PgmNr 2474: Clinical and genetic variant spectrum of 23 Chinese Fanconi anemia patients.

---

Fanconi anemia (FA) is the most common inherited bone marrow failure syndrome with 22 causal genes identified to date. Main clinical features of FA include congenital malformations, bone marrow failure onset at pre-school age, and predisposition to hematological and solid malignancies. *FANCA* gene variants contribute to over 60% of all cases followed by variants in *FANCC* and *FANCG*, which both account for 10% of cases. We identified 24 Chinese FA patients via clinical manifestations combined with Chromosome breakage tests and whole genomic sequencing (WGS) and described their phenotype and genetic aberrations here. There were 17 males and six females. The media age of the onset of bone marrow failure was 5 years old. two patients had family history of anemia. 20/23 (87%) patients manifested malformations, including skin pigmentation (10/23), polydactyly (8/23), growth retardation (6/23), café au lait spots (6/23), flat nose bridge (5/23), hypertelorism (5/23), microcephalus (5/23), adduction deformity thumbs (4/23), blepharoptosis (3/23), patent ductus arteriosus (3/23), absent of thumbs (2/23), renal ectopia (1/23), unilateral ovary absent (1/23), delayed puberty (1/23), thenar dysplasia (1/23), indirect inguinal hernia (1/23), and hydronephrosis (1/23). 19 patients had significantly increased chromosome breakage rates induced by mitomycin C. 40 variants were identified including 28 in *FANCA* gene, 4 in *FANCD2*, 3 in *FANCB*, 2 in *FANCE*, 2 in *SLX4*, and 1 in *FANCC*. Two homozygous mutations (*FANCC* c.545C>A and *FANCA* c.1867C>T) were discovered in two patients came from consanguineous families. Variants composed by 13 missense mutations, 10 large deletions, 7 nonsense mutations, 7 frameshift mutations, 2 splicing mutations, and one deep intron mutation. Most variants were novo and private, and no overlaps harbored by different patients except one CNV (*FANVA* chr16:89780001-89822000del) shared by two. The only efficient therapeutic strategy of FA is hematopoietic stem cell transplantations (HSCTs) up to now, which were performed on 19 patients in this cohort. In the patients who accepted HSCTs, 14 patients have achieved complete remission, while five patients died from thrombotic microangiopathy or sever infections. Although this cohort is relatively small, data obtained are still informative. Nationwide multicenter study on this disease entity is expected for its rarity.

## PgmNr 2475: Skewed X-chromosome inactivation in symptomatic female carriers of hemophilia A and B.

---

Hemophilia A (HA) and B (HB) are X-linked recessive bleeding disorders caused by defects in the factor VIII and factor IX. Patients of HA and HB are typically hemizygous males and females homozygous or compound heterozygous for mutant *F8* or *F9*. Symptomatic female carriers are relatively rare. Here, we report three families afflicted with female hemophilia, one with severe HA, another with moderate HA and the other with severe HB. Cytogenetics, molecular analyses on *F8* and *F9*, and X-skewed inactivation assay were performed to determine the genetic defects of diseases. All the three female patients are demonstrated to carry a heterozygous mutation for the *F8* or *F9* (one mutation is inherited and the remaining two mutations are sporadic). In one HA and one HB patients, highly skewed inactivation of the wild-type X-chromosome (100%) was noted, which are thought to be responsible for the HA and HB. Our result highlight the importance of X-chromosome inactivation analysis to explore the underlying cause of affected females with X-linked recessive diseases (e.g. HA and HB) when only one mutant allele was determined.

## PgmNr 2476: A newborn with novel mutation in the hematopoietic-specific RAC2 GTPase identified by targeted exome analysis.

---

The Rac subfamily belongs to the Rho family of GTPases. Unlike the widely-expressed RAC1 and RAC3, RAC2 is restricted to hematopoietic cell lineages. Germline alterations in RAC2 have recently been linked to immunodeficiency syndromes. To date, only 3 RAC2 germline mutations were reported in patients affected with primary immunodeficiency but distinct clinical features (W56\*, D57N, and E62K). Interestingly, all of them occur in the region between switch I and switch II, a region critical in defining major conformational differences between the GTP- and GDP-bound forms. Mouse models have recently revealed the essential role of Rac2 in neutrophil functions. However, these different mutations apparently cause distinct immunodeficiency, which warrants further systematic investigations.

The patient reported herein was a full-term newborn with no remarkable prenatal findings. At ~24 hours of life his CBC differential showed total WBC of 0.2K, and 0.07K at 3 days of age. He had normal IgG, but low IgM/A. Screening showed no detectable TRECs. His lymphocyte studies showed essentially absent B/NK cells, minimal T cells, and low response to mitogen stimulation. At 45 days of age, the patient underwent allogeneic bone marrow transplantation with an HLA-matched sibling. An assessment of post-transplantation chimerism showed full T-cell engraftment with normal proliferation to PHA, and normal diversity of the T-cell repertoire.

Targeted exome analysis was performed on the patient's DNA. A novel missense variant in RAC2 (p.Q61R) was identified. Parental studies confirmed this change is *de novo*. Interestingly, this variant also occurs at the highly conserved N-terminal region of switch II and closely approximates all 3 previously published germline mutations. Structural modelling predicted this mutant [R61] may disrupt the hydrogen bond between the residue D39 and Y64. Additionally, this mutant might also obstruct Mg<sup>2+</sup> cofactor to achieve high catalytic efficiency and specificity.

Although all patients with RAC2 mutations exhibited profound lymphopenia, these individuals presented with distinct phenotypic features, presumably due to varying pathogenic mechanisms. The *de novo* RAC2 mutation (p.Q61R) identified by our targeted exome analysis has not been observed previously. To fully understand the disease mechanism, we aim to further examine its biological pathways in hematopoiesis, which may help us better understand its pathogenic roles during T-cell development in humans.

## PgmNr 2477: Characterization of causal variants associated with hereditary thrombocytopenias.

### Authors:

Inherited thrombocytopenias (IT) are a heterogeneous group of 33 different forms of monogenic disorders caused by molecular defects affecting at least 40 genes. Pathogenic variants in these genes usually lead to the disruption of megakaryopoietic and thrombopoietic processes and present as the thrombocytopenia phenotype (low platelet count, blood-examination). However, patients are occasionally misdiagnosed with the immune thrombocytopenia and unsuccessfully treated with steroid therapy and splenectomy. In some patients, accurate diagnosis of IT can only be established based on the results of molecular genetic testing.

In our patient cohort, we have identified novel variants in three IT families. First, a rare variant in a proband with Wiskott-Aldrich syndrome who was originally misdiagnosed as Bernard-Soulier syndrome. Second, the both family members carried a variant for *TRPM7*-related thrombocytopenia and one of them had hematological disease in their medical history. We detected in the third family rare variants of autosomal recessive Glanzmann thrombasthenia which was caused by mutations in the *ITGA2B* gene. Germline DNA analysis was performed on all available samples and somatic DNA analysis was done for the oncological patient. Sequencing libraries were prepared according to the SeqCap EZ Human Exome Probes v3 protocol and sequencing was performed on NextSeq500. Within each family, the obtained variants were compared between the individuals with thrombocytopenia phenotype and their disease-free relatives.

Using whole exome sequencing (WES), we characterized a unique variant segregating with thrombocytopenia phenotype for each of the three families: *WAS*: NM\_000377: exon 10:c.998G>C:p.Gly333Ala, *TRPM7*: NM\_017672: exon4:c.223A>G:p.I75V, and *ITGA2B*: NM\_000419: exon29:c.2965G>A:p.A989T; exon29:c.2944G>A:p.V982M. *In silico* analysis revealed a structural defect of amino acid changes found in the protein structures, indicating that all of the variants are pathogenic. We identified a causal variant for each of the families analysed. These results helped the clinicians determine the correct diagnosis to patients. Besides that, accurate diagnosis of IT allow clinicians to conduct further examinations if the identified variant poses additional risk to the carrier, i.e., a higher risk of oncological disorders.

The research was done according to the Declaration of Helsinki.

Supported by Ministry of Health of the Czech Republic, grant No 16-29447A.

## PgmNr 2478: New case of Fanconi anemia complementation group T caused by a pathogenic missense variant in *UBE2T*.

### Authors:

A. Ferrer<sup>1</sup>; L. Schultz-Rogers<sup>1</sup>; A. Mangaonkar<sup>2</sup>; N. Jacobi<sup>3</sup>; M. Litzow<sup>2</sup>; E. Klee<sup>1,4</sup>; M. Patnaik<sup>2</sup>

---

Fanconi Anemia (FA) is characterized by genomic instability, bone marrow failure and skeletal abnormalities. Several subtypes of FA have been described and associated with variants in different genes. The FA complementation group T (FA-T) is caused by variants in *UBE2T*. Only 3 patients with (FA-T) have been reported to date, all carrying at least one loss-of-function (LoF) variant. Here we report a fourth FA-T case and the first one caused by a homozygous missense variant in *UBE2T*.

A 21-year-old Ecuadorian female presented to the Bone Marrow Failure Precision Medicine Clinic (Mayo Clinic, MN) for assessment. She reported periodic fevers, persistent macrocytosis and intermittent cytopenias since 8 years of age. Her last complete blood count (October 2018) indicated anemia, thrombocytopenia and increased MCV. Her bone marrow was moderately hypocellular (40% to 50%) without evidence of dysplasia or lymphoproliferation. Other phenotypes included urticaria, discoloration of hands with cold and intermittent ulcers on lips. Previous genetic testing including cytogenetics and a periodic fever gene panel were negative, as well as testings for autoimmunity and infectious diseases. No related family history or consanguinity was described.

The patient underwent a custom-designed XomeDSlice panel through GeneDX that uncovered a homozygous variant in *UBE2T* (c.196C>T; p.P66T) not reported in gnomAD or associated with disease (ClinVar and HGMD). The encoded proline is highly conserved across species and located in the UBC fold domain, critical for protein function. *In silico* tools (SIFT, MutationTaster, PolyPhen2, MCAP and PredictSNP2) agreed on a deleterious effect. To confirm this, a chromosomal breakage assay was performed and resulted positive (58% and 36% breakage positive cells with MMC and DEB, respectively) in line with previous FA-T reported. Complementation testing is currently underway. With these results we classified the variant as likely pathogenic by ACMG criteria.

This is the first FA-T patient reported with a homozygous missense likely pathogenic variant in *UBE2T*. This variant may cause a milder effect in the *UBE2T* function compared to the other three reported patients harboring one loss of function variant, possibly explaining the lack of skeletal finding in the proband. However, more research is needed to confirm this hypothesis. This case adds to our knowledge of FA-T causal variants and highlights the relevance of including *UBE2T* in FA evaluations.

## PgmNr 2479: Survivors of childhood cancer are at high risk for clonal hematopoiesis.

### Authors:

With aging, hematopoietic stem cells acquire somatic mutations and undergo clonal expansion, a process called clonal hematopoiesis (CH). CH is associated with an increased risk of hematologic cancers, coronary artery disease, and all-cause mortality. As survivors of childhood cancer (SCC) experience these same complications as late-effects of cancer treatment at younger ages than the general population, we hypothesized that SCC have a higher prevalence of CH relative to sex and age matched peers. As such, CH may represent a genomic biomarker for the premature aging phenotype seen in survivors.

82 consecutive SCC (46 females and 36 males) who were  $\geq 18$  years old,  $\geq 5$  years from cancer treatment completion, and who had not undergone a bone marrow transplantation were recruited and consented from a structured long-term follow-up program. Age and sex matched controls were pulled in a 3:1 ratio from healthy parents of probands referred for clinical exome sequencing who had no personal or family history of cancer (N=246). Whole exome sequencing was performed using DNA extracted from whole blood (100X median coverage), with somatic variant detection for 309 previously published CH SNVs in 56 genes. A variant allele fraction cutoff of  $>5\%$  was used to call CH. Stratified analysis was conducted to test clinical factors for association with CH.

Survivors had a mean age of 26.45 years (range: 18.1-50), and 13.4 years off therapy (range: 6.6-34.8) at the time of sample collection. All survivors were treated with chemotherapy, and 48.8% were exposed to therapeutic radiation. 18.3% of survivors had at least 1 CH variant, compared with 6.5% of controls ( $p=0.0036$ , two-tailed Fisher's exact test). Among SCC, individuals with CH had multiple CH variants whereas the controls with CH tended to have 1 variant (mean CH count 0.256 for SCC and 0.0732 for controls;  $p=0.0014$ , Wilcoxon rank sum). Among genes analyzed, SCC had the most CH variants in DNMT3A (7 variants from 7 individuals), while controls had the most CH variants in RAD21 (7 variants from 7 individuals). We did not observe an association between CH and primary cancer type, treatment modality, time from therapy, or outcome, although this study was not powered to detect such associations.

In summary, SCC are at greater risk for CH, and have more CH variants than age and gender-matched controls. Future studies are needed to examine the association of CH with exposures, risk of chronic disease and mortality.

## PgmNr 2480: Lymphocyte abnormalities in patients with 22q11.2 deletion syndrome.

**Background and aims:** 22q11.2 deletion syndrome (22q11.2DS) is the most common human microdeletion. It is known to have a heterogeneous presentation that includes multiple congenital anomalies and immunodeficiency one of the most striking features. Usually it is characterized by T cell lymphopenia, B cell dysfunction and autoimmunity.

**Methods:** Peripheral blood mononuclear cells were isolated from heparinized venous blood from 15 healthy individuals and 15 22q11.2DS patients. Patient history and medications were also collected. We performed immunophenotyping of T cells in patients and controls by flow-cytometry, through incubating peripheral blood mononuclear cells with a specific panel of antibodies.

**Results:** Patients presented low levels of TCD3<sup>+</sup> lymphocytes and elevated relative values of double-negative T cells (TCD3<sup>+</sup>/CD4<sup>-</sup>/CD8<sup>-</sup>) when compared to healthy controls (p=0.01 e p=0.03, respectively). The TCD4<sup>+</sup> and TCD8<sup>+</sup> lymphocyte values were slightly lower in the patients when compared to the healthy controls (without statistical significance).

**Conclusions:** 22q11.2DS patients present not only T-cell lymphopenia but also high levels of double-negative T cells that may be one of the signs of an immune dysregulation observed in these patients.

**Support:** FAPESP and CNPq.

## PgmNr 2481: Clinical significance of reinterpreting previously reported immunologic disease genomic tests.

---

**Introduction:** Next-generation sequencing (NGS) testing has become a common diagnostic tool for evaluating pediatric patients with immune disorders. NGS testing can comprehensively identify gene variants of interest; however, determining the clinical significance of novel variants is challenging. Advances in publicly available databases and standardized interpretation criteria have improved the clinical interpretation of variants. However, the utility of re-interpreting previously reported NGS immune tests has not been systematically evaluated. In this study, we identify the frequency and significance of variant reclassification from previously reported NGS immune gene panels.

**Methods:** All NGS immune gene panel reports sent out from a tertiary-care pediatric hospital were retrospectively reviewed (July 2012 to July 2018). Reports were from multiple reference laboratories, and included genes for severe combined immunodeficiency, primary ciliary dyskinesia, and autoimmune and lymphoproliferative syndrome. Previously reported variants were first screened using population (gnomAD, 1000 Genomes phase 3) and clinical (ClinVar) databases. Any variant marked for having a high population frequency (>1%) or a conflicting report in ClinVar was 1) flagged then 2) reinterpreted using ACMG variant classification criteria.

**Results:** 120 patients were previously tested yielding 110 variants in 62 patients. Of the 110 variants, 36% were pathogenic or likely-pathogenic (P-LP n=40), and 64% were variants of uncertain significance (VUS n=71). 15% (n=6) of the P-LP variants were reclassified; variants were downgraded to VUS (n=5, CYBB, DOCK8, FOXP1, MBD5), or B-LB (n=1, CFTR). Of the 71 VUS, 27% (n=19) were reclassified downward in significance (B-LB), and none were upgraded to clinically significant (P-LP). Overall, 23 of 120 patients (19%) were impacted by variant reclassification.

**Conclusions:** Based on our single institution experience, a large proportion of variant classifications were revised (21%; 25/120). These reclassifications impacted 19% of patients (23/120). A clinically significant reclassification (P-LP to VUS or benign) occurred in 15% of patients with a diagnostic variant. In addition, many reclassified VUS were downgraded. Overall, these findings indicate that all P-LP and VUS variants from previously reported NGS tests should be routinely reviewed and reanalyzed.

## PgmNr 2482: Companion genetic aberrations in CEBPA double mutated AML and their clinical significance.

### Authors:

Background: Acute myeloid leukemia (AML) with double mutant CEBPA (CEBPAdm) is a new entity in the 2016 WHO classification with favorable prognostic implications, but still have some patients relapsed. This retrospective analysis aimed to thoroughly analyzed the molecular abnormalities of AML patients with CEBPAdm, explored the pathogenesis and prognostic factors, and provided guidance for clinical diagnosis and treatment. Methods: Amplicon-targeted, next-generation sequencing was performed on 609 patients who were diagnosed of de novo AML. Results: CEBPA mutation were detected in 15.9% of patients (97/609), of which 76 cases were CEBPAdm and 21 cases were CEBPA single mutation (CEBPAsm). A total of 88.2% of CEBPAdm patient concomitant with other gene mutations and 39 kinds of mutation combinations were detected. The frequency of GATA2 mutation in CEBPAdm group was significantly higher than that in CEBPAsm group (31.6% vs 0%,  $P=0.003$ ), and the GATA2, CSF3R, JAK3 and KIT mutations were exclusively occurred with CEBPAdm. The proportion of epigenetic modifiers mutations in CEBPAsm group was significantly higher than that in CEBPAdm group (47.6% vs 15.8%,  $P=0.005$ ). In patients with normal karyotype, CEBPAdm patients with activated signaling mutations had poorer OS and DFS than patients without activated signaling mutations ( $P=0.035$ ;  $P=0.023$ ), with FLT3-ITD mutations showed significantly poor OS than patients with FLT3-ITD wild-type ( $P=0.012$ ), and with KIT mutations showed significantly poor DFS than patients with KIT wild-type ( $P = 0.015$ ). The incidence of germline mutations in this cohort was 5.3% (4/76), including one C-terminal mutation. Conclusions: A comprehensive analysis of the mutation profile of CEBPAdm patients will help us to better understand the pathogenesis and identify prognostic factors. Therefore, it is helpful for early identification of patients with poor prognosis, thus better guiding treatment and improving prognosis.

## PgmNr 2483: Genotyping in regions of high homology.

Many SNP and indel variants of particular interest occur in genes with very high homology to pseudogenes, paralogs, and other gene family members. *CYP2D6*, a gene critical to the metabolism of 25% of drugs, has two highly homologous pseudogenes, *CYP2D7* and *CYP2D8P*. Genotyping many critical variants in *CYP2D6* is complicated by variation at or near the equivalent site in the pseudogenes, or by variable background signal arising from the frequent deletion of the pseudogenes. Similarly, variants in the *RHCE* gene determine critical antigens of the Rh blood group system, the most important blood group system after ABO for transfusion medicine, can be complicated by SNP or copy number variation in the paralogous *RHD* gene, the other gene determining Rh blood type.

Here we demonstrate accurate genotyping of *CYP2D6* and *RHCE* polymorphisms on the Applied Biosystems™ Axiom™ PMD Array, a microarray that includes pharmacogenomic and blood-typing research variants as well as genome-wide coverage for global populations. We demonstrate accuracy for 96 samples from the 1000 Genomes Project with two very different approaches. For *CYP2D6* and other drug metabolism genes, we employ a target enrichment approach in the assay, combining mPCR of the target variants with whole genome amplification for other genotyping. For *RHCE*, we use an algorithmic approach, producing accurate genotype calls with no enrichment step required. In particular we show accurate genotyping of the *RHCE* exon 2 T307C variant determining Rh C/c alleles, historically an especially challenging target due to the 100% homology of the C allele to *RHD* exon2.

The ability to genotype these variants, both specifically and in the context of genome-wide tests, supports both targeted and broad research in precision medicine. In contrast to assays for a relatively small number of SNPs, target enrichment in combination with whole genome amplification in the same microarray assay enables efficient data collection on *CYP2D6* and other variants of research interest in pharmacogenomics as well as genome wide markers for discovery of novel associations. The success of an algorithmic approach for the *RHCE* gene suggests that the simpler assay, without target enrichment, might suffice for other difficult target variants as well.

## PgmNr 2484: Functional analysis of a novel splice site variant in *GLI3* gene causing Greig cephalopolysyndactyly syndrome.

---

**BACKGROUND:** Preaxial polydactyly type IV (MIM 174700; ORPHA 93338), also referred as polysyndactyly, has been described in a few syndromes including Greig cephalopolysyndactyly syndrome (GCPS; MIM 175700; ORPHA 380). GCPS is caused by heterozygous mutation in the *GLI3* gene (MIM 165240), which is located in the cytoband 7p14. In this study, we present the functional analysis of a novel *GLI3* splice site variant, which cosegregates in three generations of a family with preaxial polydactyly type IV and other clinical features of GCPS.

**METHODS & RESULTS:** Sequencing analysis of the *GLI3* coding region identified a novel donor splice site variant NC\_000007.14(NM\_000168.6):c.473+3A>T in the proband and the same variant was subsequently identified in other affected family members. In order to elucidate the pathogenicity of the detected variant in *GLI3* gene, proband's RNA was isolated from fibroblast culture and template cDNA was synthesized. Further Sanger sequencing of the proband's cDNA sample revealed that the splice site variant disrupts the original donor splice site, thus leading to exon 4 skipping. Based on *in silico* analysis, the pathogenic splice site variant consequently results in a truncated protein NP\_000159.3:p.(His123Argfs\*57), which lacks functionally important domains: zinc finger domain, proteolytic cleavage site, transactivation domain 2, transactivation domain 1 as well as part of repressor domain.

**CONCLUSION:** The functional cDNA analysis revealed that NC\_000007.14(NM\_000168.6):c.473+3A>T led to the haploinsufficiency of *GLI3* that causes GCPS in the affected family members. This analysis provides a unique possibility to identify the molecular basis of GCPS as well as many other hereditary diseases and conditions. The work was funded by the Research Council of Lithuania (No. S-MIP-17-19/LSS-150000-1179, Ingenes project).

## PgmNr 2485: Chromosomal microarray analysis uncovers pathogenic copy number variations in neurodevelopmental disorders and congenital anomalies.

Neurodevelopmental disorders (NDDs) represent broad spectrum of cognitive, neurological, and/or psychiatric dysfunction caused by impairment of the brain during development. We used chromosomal microarray (CMA) to study NDDs in patients with unexplained developmental delay/intellectual disability (DD/ID) accompanying dysmorphism and/or congenital anomalies. Of all the 102 patients identified with DD/ID, 48 patients had a normal profile (46XX/XY), 53 showed pathogenic CNVs along with an exceptional case (case 199) encompassing high levels of homozygosity (approx. 17.5%). The size of the CNVs in affected patients ranged from 36 kb to 15.5 MB. The most common variant in cases with ASD and developmental delay was duplication 22q11.2 involving 400Kb region, which was validated using karyotyping and FISH. Five of 53 sporadic patients had known microdeletion syndromes. It is envisaged that the application of microarray will expand the spectrum of cytogenomic abnormalities by including complex and cryptic structural variants. Further, delineation of molecular mechanisms of these cytogenomic abnormalities coupled with development of novel therapeutic approaches will ultimately lead to disease-specific personalized management and precision treatment.

## PgmNr 2486: Revealing a familial atypical deletion in 5p using checklist directing and correct indication of molecular tests.

---

Deletions in the short arm of chromosome 5 (5p) are usually diagnosed when the patients present cat-like cry and typical phenotype involving microcephaly and intellectual disability. The most used molecular test to detect this syndrome is karyotype but it is only useful for deletions greater than 10 Mb. In the cases of patients with smaller deletions, the diagnosis may be delayed due to the availability of the molecular testing and correct indication. With the assistance of specialized physicians and our research group, we developed a checklist for patients with 5p deletion suspicion and confirmation using cytogenomic tests (karyotype, MLPA and array). The checklist evaluated familiar background, physical and intellectual development of the patient. Two siblings, a 6-years-old boy and 8-years-old girl, were referred to genetic investigation due to the moderate to severe intellectual disability and speech delay. During the appointment, we discovered both presented the high-pitched cry at birth although did not present any of the typical physical features of 5p-syndrome. Karyotype did not show any alteration. P064 MLPA kit, with five probes for 5p region, showed that the patients and the mother presented an atypical deletion with four probes deleted (*TERT\_ex2*; *TERT\_ex13*; *CLPTM1L*; *IRX4*) but one was still present (*CTNND2*). Using array, we were able to determine that the siblings presented a 6,2 Mb deletion, inherited from their mother who presented similar features. *CTNND2*, the gene that was not deleted, is associated to cerebral development and neurons migration. The presence of this gene may explain why the patients were still able to communicate, learn and understand other people, some of the features that patients with larger 5p deletions are not able to do. Our results indicate that a complete evaluation and different investigations tools, as checklists, can lead to the correct cytogenomic investigation without delays to clarify the genetic cause for intellectual disability. Also, be engaged with research projects may be the only opportunity for patients to have access to molecular tests that are expensive and not available in the Brazilian public healthcare.

## **PgmNr 2487: An international collaboration between a high- and low-resource country leads to the identification of a novel chromosome 18 deletion, chromosome 5 duplication with translocation causing facial dysmorphism and global developmental delay.**

### **Authors:**

S. Upadhyaya<sup>1</sup>; G. Verdi<sup>1</sup>; J.L. Smith<sup>2</sup>; S.H. Elsea<sup>2</sup>; B. Nelson<sup>4,5</sup>; K. Yearwood<sup>5</sup>; H. Hakonarson<sup>3</sup>; D. Li<sup>3</sup>; E.J. Bhoj<sup>3</sup>; A.K. Sobering<sup>1</sup>

### **Affiliations:**

1) Department of Biochemistry, St. George's University School of Medicine, Grenada; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, USA; 3) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA, USA; 4) Grenada General Hospital, Pediatrics Ward, Grenada; 5) Clinical Teaching Unit, St. George's University School of Medicine, Grenada

The experience for families of children born with developmental delay in low- and middle-income nations is in stark contrast to high-income nations. In resource-limited countries, barriers to obtaining genetic diagnosis might involve economic disparities, geographical isolation, and inadequate access to genetic medicine. As part of a combined teaching, research, and community outreach effort, we provided genetic testing for a child with global developmental delay (GDD), dysmorphism, and intellectual disability (ID). Deletions involving the terminal region of 18q may lead to a variable phenotype including short stature, developmental delay (DD), hypotonia, hearing impairment and foot deformities (OMIM 601808). Duplications of the 5p terminal region cause DD, ID, and variable facial dysmorphism (OMIM 613174).

We present a 5-year-old Afro-Caribbean boy who has GDD, ID, hypotonia, feeding difficulties, facial dysmorphism and bilateral club feet. Speech development is limited to less than 5 words. He can walk for a short distance with an unstable gait. He has a high frontal hairline with a prominent widow's peak, frontal bossing, a flat and broad nasal bridge, up-slanting palpebral fissures, hypertelorism, and camptodactyly. His feet are internally rotated, and the right foot is worse than the left. Both of his parents are healthy. The family described a now deceased maternal aunt who they thought had Down syndrome, but to our knowledge, she was never medically evaluated. He has two maternal aunts who have primary infertility. Conventional karyotyping showed additional chromatin of unknown origin on the long arm of chromosome 18. Cytogenomic microarray analysis showed a 6.4 Mb deletion (chr18:71518518-77943115) on chromosome 18 and a 24 Mb duplication (chr5:8097721-32062984) of material from chromosome 5. We postulate that the combined clinical features of our patient are due to deletions of regions of chromosome 18 and the partial duplication of chromosome 5. We are now in the process of offering a karyotype to both parents. A definitive diagnosis is beneficial to these families and can assist in providing answers with reassurance, and allows for informed genetic counseling and recurrence risk assessment, especially if a balanced translocation is found in a parent as suspected.

## **PgmNr 2488: *FMR1* methylation and sizing PCR assays improve sensitivity and efficiency in clinical testing for fragile X syndrome, revealing some uncommon and unexpected results.**

### **Authors:**

J.A. Lee; R.C. Caylor; W. Hall; J.A.C. Coleman; R.J. Louie; M.J. Friez

[View Session](#)[Add to Schedule](#)

---

Fragile X syndrome is the most common cause of autism worldwide, affecting 1 in 4000 males and 1 in 6000 females, and is caused by a CGG triplet repeat expansion in the *FMR1* gene. *FMR1*-related disorders also include fragile X-associated tremor ataxia syndrome and *FMR1*-related primary ovarian insufficiency. The disease mechanism involves aberrant methylation and expression of *FMR1*. A repeat size of 200 CGG repeats or greater is considered a full mutation, causing hyper-methylation of the *FMR1* promoter and transcriptional silencing. Premutations are between 55 and 200 CGG repeats and are generally not associated with abnormal methylation; they typically result in an unmethylated allele in males and partially methylated alleles in females due to X-inactivation, and are associated with increased expression. In our molecular diagnostic laboratory, we have implemented a more sensitive methylation PCR since July 2017, as well as a sizing PCR since November 2015, replacing the traditional Southern blotting and homebrew PCRs, respectively. By implementing these assays, we have been able to improve the efficiency of our workflow, as well as detect size and methylation mosaicism with a greater accuracy than was possible by traditional methods. We have also detected some uncommon and unexpected results, including males and females with size and methylation mosaicism as well as with fully-methylated premutations. Here we describe our experience to date, share some unusual findings, and reaffirm that methylation analysis be performed for any patient with a premutation-sized allele or greater.

## PgmNr 2489: CNV/SNV analysis of 844 ID genes vs. virtual panel testing based on HPO terms in singleton NGS referrals.

Trio analysis of WES data represents the gold standard genetic test for complex referrals. It is costly and not always possible. Our clinical exome pipeline has been modified and validated for detection of SNV, CNV and AOH and utilised diagnostically for 844 gene panel testing of singleton referrals using NxClinical software. The average time for classification of roughly 50 SNV events per case and whole genome CNV analysis was 30 minutes per case. No variants of possible clinical relevance were detected in roughly 50% of cases. All CNVs previously detected by CMA were also detected using this pipeline, providing the CNV regions contained at least one sequenced gene. Furthermore, pathogenic SNVs and CNVs, which had not been identified from previous more targeted analysis, were detected in more than 10% of cases. An additional re-analysis of the clinical exome data was completed for all cases using the variant prioritisation based on HPO terms within NxClinical environment. All SNVs and CNVs reported by the diagnostic panel testing were also detected by HPO variant prioritisation. Several additional findings were also detected and classified as pathogenic and relevant to the reason for referral. Our approach clearly demonstrates that even in the instances where trio WES is not possible, our single assay approach can efficiently detect pathogenic and likely pathogenic variants, and copy number abnormalities involving known OMIM morbid genes with no significant additional analysis time.

## PgmNr 2490: Low-pass whole genome sequencing identified a single exon deletion in RPS6KA3 causing Coffin-Lowry syndrome.

Low-pass WGS has recently been reported to be able to detect CNVs at the resolution comparable with that of chromosomal microarray analysis (CMA). In the meantime, the coverage of CMA is variable across the genome depending on the probes included in the assay, low-pass WGS has much more uniform coverage and can potentially detect CNVs encompassing any genes. While low-pass WGS has been shown to effectively detect large CNVs, its utility in detecting smaller events is relatively unknown. Here we report the identification of a single exon deletion in RPS6KA3 gene by low-pass WGS in a male patient with global developmental delay, hypertelorism, hearing impairment, and hypotonia. At the mean coverage of 3X (paired end reads), WGS detected the hemizygous deletion encompassing exon 1 of RPS6KA3. The size of the deletion is about ~42 kb (chrX:20257168-20299113, hg19). RPS6KA3 is associated with X-linked Coffin-Lowry syndrome [MIM: 303600] or mental retardation X-linked 19 [MIM: 300844]. Coffin-Lowry syndrome typically presents with dysmorphic facial features including hypertelorism, sensorineural hearing loss, skeletal abnormalities, hypotonia, and neurologic problems, which are consistent with the clinical features of this patient. Interestingly whole exome sequencing (WES) was ordered concurrently for this patient. CNV analysis based on the WES depth of coverage revealed no reads aligned to exon 1 of RPS6KA3 in this patient, consistent with the WGS findings. Our results showed that low-pass WGS, which is usually used to detect gross deletions and duplications, can also detect smaller, intra-genic CNVs.

## PgmNr 2491: Whole exome sequencing identifies two novel de novo truncating mutations in UPF3B and NLGN3 in patients with intellectual disability.

Three families with idiopathic intellectual disability has been recruited to identify their genetic causes. The families were non-consanguineous and had a single affected patient each. All had an uneventful pregnancy and delivery. Informed consent was obtained and all procedures followed were in accordance with the ethical standards of the Institutional Review Board. Whole exome sequencing was carried out for the patients and their parents. Whole exome capture and sequencing were performed at Centogene Laboratory. Approximately 60 MB of human exons were enriched from 1 µg of fragmented genomic DNA using the SureSelect Human All Exon V6 Kit followed by processing on NextSeq platform to obtain an average coverage of ~100X. Approximately 97% of targeted bases are covered > 10X. An in-house bioinformatics pipeline was applied including base-pair calling, alignment of reads to genome assembly GRCh37/hg19, filtering out low-quality reads, and variants annotation. All disease-causing variants in CentoMD, ClinVar, and HMGD were considered. Additionally, all variants in gnomAD database with a minor allele frequency of <1% were considered. Evaluation of identified variants was focused on coding exons and their flanking intronic bases with consideration of multiple inheritance patterns. Further, clinical data and family history were considered for evaluating identified variants. Sanger sequencing was performed to confirm identified variants. Only variations in genes potentially related to the patient's clinical phenotype were reported. Two of the families showed two novel de novo nonsense mutations, one in UPF3B gene (NM\_080632.2: c.724C>T, p.Arg242\*) in first family and in NLGN3 gene (NM\_181303.1:c.2525C>A, p.Ser842\*) in second family. Both of these mutations were not found in ExAC, Kaviar, 1000G, and Gnomad databases. The third family showed a known mutation in SYNGAP1 (NM\_006772.2: c.1735C>T, p.Arg579\*). All three genes are already implicated in the etiology of intellectual disability. In summary, we identified two novel de novo nonsense mutations in two genes and one known mutation in a third gene in three families with singleton patients with intellectual disability.

## **PgmNr 2492: A novel *de novo* RAC1 frameshift likely pathogenic variant in a patient with developmental delay and epilepsy suggests haplo-insufficiency as a new mechanism of disease in RAC1-related disorders.**

Rac family small GTPase 1(*RAC1*) is a ubiquitously expressed gene involved through its interaction with different genes in numerous cellular functions, including motility, invasion, migration, apoptosis, proliferation, growth, cell-cycle regulation, morphology, adhesion, neuronal polarization with axonal growth, and differentiation. Although *RAC1* is an extensively studied gene, only seven patients with distinct *de novo* missense pathogenic variants and developmental disorders with diverse phenotypes have been reported.[PMID: 28886345] Functional studies were compatible with either a dominant-negative or gain-of-function mechanism.

Here we report a 16 month-old female with global developmental delay and epilepsy, normal head circumference, hypotonia, Duane syndrome, bilateral fourth toe clinodactyly, difficulty feeding, horseshoe kidney, and recurrent ear infections. On exam she had dysmorphic facies with broad forehead, deep-set eyes, hypertelorism, down-slanting palpebral features, and mild micrognathia. Brain MRI identified a mildly decreased white matter volume with thinning of the corpus callosum. Chromosomal microarray was normal, and trio whole exome sequencing revealed a novel *de novo* *RAC1* likely pathogenic frameshift, denoted c.383\_384insGT; p.I129SfsX4 (NM\_018890.3). *RAC1* deletion/duplication analysis was negative.

*RAC1* is associated with autosomal dominant intellectual disability. The seven cases described in 2017 by Reijnders et al. presented with global developmental delay/intellectual disability, and either macrocephaly or microcephaly. However, other features were variably present, such as hypotonia, dysmorphic features, cardiac abnormalities, behavioral problems, stereotypic movements, epilepsy, cerebellar abnormalities and corpus callosum hypoplasia. Therefore, the disruption of the complex signaling pathway between *RAC1* and different proteins might result in complex and diverse clinical presentations. Contrary to previous reports, our patient was found to have a frameshift variant, which is expected to result in loss of function. This suggests that haplo-insufficiency is the most likely pathogenic mechanism in our patient. To our knowledge, this is the first report of a patient with a *RAC1*-related disorder due to a heterozygous loss-of-function variant.

Background: Fragile X Syndrome (FXS) is the second leading cause of intellectual disability (ID), affecting 1: 5000-7000 men and 1: 4000-6000 women. An alteration of the *FMR1* gene at Xq27.3 cause the FXS. Most of patients present CGG expansion (> 200 triplets) in the 5'UTR of the gene, the other patients present *FMR1* mutations and duplication / deletion in the same genomic region. Diagnostic detection using commercial kits allows the unambiguous identification of patients and carriers, while prenatal and neonatal diagnoses are a challenge. Clinical features comprise global developmental delay, anxiety and hyperactive behavior. Characteristic facies include large ears, a long face, a prominent jaw and forehead and flat feet. Material and Methods: We evaluated 63 patients with intellectual disability associated with neuropsychomotor developmental delay and / or other (FXS) clinical features, both sexes and without age restriction, using FragilEase® kits (Perkin Elmer, Massachusetts, USA) or Amplidex® (Asuragen, Texas, USA). The results show four evils with full CGG expansion (> 200 repeats), two patients with intermediate alterations, ranging from 45 to 54 repeats and one patient with pre mutation (range from 55 to 200 repeats). Four females showed alleles in heterozygosis. Discussion: Our study revealed the prevalence of 6.3% of complete mutations, and for non-complete mutations, we identified a percentage of 11.1%. The obtained results corroborated data reported in the literature, but the overall detection rate was higher than the rates previously reported, highlighted the importance of the criteria used to select patients.

## PgmNr 2494: Detection of CGG repeats in Fragile X syndrome using CRISPR Cas 9 combined with single molecule sequencing.

Fragile X Syndrome is caused by CGG expansion in the 5' untranslated region (5'UTR) of the fragile X mental retardation 1 (*FMR1*) gene. These alterations range from a permutation state (55-200 repeats) to a full mutation allele (>200 repeats). It is the most common cause of X-related inherited intellectual disability. Patients with fragile X syndrome present an hypermethylation of the CGG triplets leading to an epigenetic gene silencing of *FMR1* that induces the loss of the encoded fragile X mental retardation 1 protein, FMRP.

Current diagnostic techniques are primarily based on costly and time-consuming PCR reactions that are specific to either repeat detection or promoter methylation. Using third-generation high throughput sequencing, one can fully sequence single molecules without fluorescent labelling and PCR amplification, thus significantly reducing turnaround time and reagent costs. Single molecule sequencing enables real-time sequencing of DNA which facilitates the detection of structural variants (copy number variants, gene duplications, deletions, insertions, inversions, and translocations) or base modifications (methylation). Combined with the emergence of CRISPR-Cas 9 genome editing, selection and subsequent sequencing of these genomic regions of interest is now possible.

We present a new methodology that uses targeted read, single molecule sequencing to simultaneously identify and count CGG repeats, detect interrupting AGG sequences and provide insight into the methylation status of the *FMR1* gene with a single analysis. Moreover, the technique demonstrates high sensitivity to detecting mosaic alleles. The method was validated based on DNA samples with genotyped CGG repeats and specific cuts using CRISPR Cas 9. We further demonstrate that the identification of CGG repetitions using MinION (Oxford Nanopore Technologies) is as precise as conventional techniques based on PCR amplification. We have also been able to observe DNA methylation patterns found on mutated alleles with more than 200 CGG repeats.

The validation and implementation of this new methodology for Fragile X Syndrome diagnostic will be detailed. The application of the approach in diseases involving repeat-expansions, such as ataxic syndromes, muscle atrophy, Steinert's myotonic dystrophy or Huntington's chorea will also be discussed.

## PgmNr 2495: *ZNF407* variants: A new cause of autosomal recessive syndromic intellectual disability?

Kambouris et al. (2014) described a consanguineous Arab family with a homozygous damaging *ZNF407*-p.S1685W variant and affected by an apparently novel autosomal recessive disorder characterized by cognitive impairment, failure-to-thrive, hypotonia and dysmorphic features including bilateral ptosis and epicanthic folds, synophrys, midface hypoplasia, downturned mouth corners, thin upper vermillion border and prominent ears, bilateral 5th finger camptodactyly, bilateral short 4th metatarsal bones, and limited knee mobility bilaterally. Here, we describe a 7-year-old Brazilian female, born to a consanguineous couple. She presented with cognitive impairment, microcephaly, strabismus, thick lips, abnormal implantation of her fingers, radio-ulnar synostosis and poor weight gain. As part of the Baylor-Hopkins Center for Mendelian Genomics we performed whole exome sequencing on the proband, her mother and father. Using the PhenoDB Variant Filtering tool we identified a rare, missense, homozygous variant on exon 1 of the *ZNF407* gene (c.G2405T; p.Gly802Val) in the proband that was heterozygous in her mother and father. In gnomAD, there are 20 alleles described with this variant but no description of a homozygous sample. This variant was not described in the Brazilian database, ABraOM (Online Archive of Brazilian Mutations), that contains genomic variants of 609 elderly Brazilian individuals from a census-based sample from the city of São Paulo. This variant's CADD score is 14.5, it is predicted to be damaging by DANN (0.9935), and SIFT (0.005, 0.022), and, its GERP score is 5.84. The *ZNF407* PLi score is 1 and its missense Z-score is 0,86. Based on these findings, we suggest that the homozygous *ZNF407*-p.Gly802Val variant identified in our patient is responsible for her phenotype and that together with the family described by Kambouris et al. (2014), our patient have a novel autosomal recessive syndromic intellectual disability disorder caused by homozygous or compound heterozygous variants in *ZNF407*.

## PgmNr 2496: Diagnostic yield of array CGH and focused clinical exome sequencing in patients with developmental delay/intellectual disability disorders.

**Objective:** To determine the detection rate and diagnostic/clinical advantages of implementing Array (aCGH) followed by Focused Clinical Exome Sequencing (CES) in individuals with unexplained developmental delay/intellectual disability (DD/ID).

**Methods:** Retrospective case series of individuals evaluated from 2016 until May 2019 by the Genetics and Neurology areas of our laboratory, in which diagnostic yield was performed after aCGH testing and followed by Focused CES in those who were negative. All of them have been proven negative by conventional cytogenetical analyses. Inclusion criteria: Studies that used aCGH and Focused CES to identify genetic abnormalities or pathogenic variants in patients with DD/ID and dysmorphia/congenital anomalies, in whom conventional cytogenetic analysis proved negative. Exclusion criteria: patients in whom genetic diagnostic had been carried out by other molecular studies.

**Results:** One hundred and ninety-five patients with DD/ID and dysmorphia were included. All of them were evaluated by karyotyping, aCGH and Focused CES on genes associated to DD/ID. Conventional cytogenetic analysis detected seven structural chromosomal rearrangements, of which only one was a balanced translocation. In forty-seven cases (24,10%) a pathogenic copy number variant was detected by aCGH and only eleven (5,60%) patients resulted in a variant of uncertain significance (VOUS). Otherwise, Focused CES on DD/ID genes yielded forty-eight cases (24,61%) with a pathogenic variant and eleven cases (5,60%) with a VOUS variant.

**Conclusion:** The combined diagnostic yield of causal genetic anomalies detected by aCGH or Focused CES on DD/ID genes in our case series was 60%. In order to improve this result, we are considering switching to clinical Whole Genome Sequencing with which, in addition to detecting CNVs and variants in coding sequences, could also identify intronic genetic variants and/or regulatory elements that we are not currently targeting due to both the intrinsic limitations of the techniques used and the enormous complexity implied in genetic counseling for WGS.

Copy number variant discovery from clinical NGS data is an essential diagnostic tool. Traditional variant callers, such as GATK, are tuned to detect smaller indel events, but are limited by read length. Read-depth based callers perform better with larger events. Single-exon or sub-exonic deletions are of clinical importance, but can be missed by such variant callers. We, therefore, developed a custom structural variant discovery tool, SCRAMble (Soft Clipped Read Alignment Mapper, [github.com/genedx/scramble](https://github.com/genedx/scramble)) that detects breakpoints from clusters of clipped reads.

We applied breakpoint deletion detection prospectively to our clinical exome diagnostic pipeline for 6385 cases, of which 1301 (20.4%) had a positive molecular diagnosis. Among the positive cases were 60 (4.6%) causative deletions. From this cohort, we confirmed and reported 10 breakpoint deletions, 4 of which were considered causative, 3 were considered possibly causative, and 3 were found in candidate genes. Altogether, causative breakpoint deletions accounted for 4/1301 (0.3%) positive diagnoses and 4/60 (6.7%) positive diagnoses resulting from deletions.

SCRAMble can detect deletions too large to be called as sequence indels and too small to be called by read depth as copy number variants. In fact, we found that 5/10 of the reported breakpoint deletions detected by SCRAMble were not called by an orthogonal NGS method. Among the 5 breakpoint-only deletions were 3 partial-exon deletions, 1 deletion fully encompassing 2 small (<150 bp) exons, and a partial deletion of each of 2 adjacent exons. We note that clinically reportable breakpoint deletions have a median size of 1.6 kb, while clinically reportable read depth deletions have a median size of 185 kb (Wilcox  $p < 0.005$ ).

In one case, an adult female presented with developmental regression in early childhood. Rett syndrome was suspected, but prior targeted sequencing of the *MECP2* gene yielded negative results by both Sanger and NGS panel testing. However, SCRAMble analysis of exome capture data identified a pathogenic, partial exon 4 deletion in *MECP2*, which was confirmed by targeted Sanger sequencing across the breakpoints.

Clipped read calling of deletions is a useful addition to clinical diagnostic NGS capture pipelines and can detect causative variants missed by typical sequence and copy number variant callers. SCRAMble increases the yield of causative deletions by 7.1% (4/56), thus leading to diagnoses, which were not previously evident.

## PgmNr 2498: Angelman like spectrum: Molecular diagnostic performance when the phenotype is evocative of an Angelman syndrome, but methylation is negative.

### Authors:

I. Canonero; G. Méjico; M.F. Gosso; M.F. Madeira; C. Rohr; B. Brun; A. Ruggieri; F. Fay; M. Vázquez

[View Session](#) [Add to Schedule](#)

**Affiliation:** HERITAS, Ocampo Bis 210, Rosario, Argentina

**Introduction:** Angelman syndrome(AS) is characterized by severe developmental delay/intellectual disability(DD/ID), speech impairment, gait ataxia, inappropriate happy demeanor that includes laughing, smiling, excitability, postnatal microcephaly and seizures. Diagnosis is established in patients with clinical diagnostic and molecular genetic testing with deficient expression of the maternally inherited *UBE3A* allele by the methylation study in the 15q11.2-q13 region (80%). *UBE3A* sequencing detects mutations in an additional of 11%. Therefore, molecular genetic testing identifies alterations in approximately 90% of cases. The remaining 10% with AS phenotype are associated with microdeletions /microduplications (CNVs) and point mutations constituting of spectrum Angelman Like Syndrome (ALS).

**Objective:** to determine the diagnostic performance of array Comparative Genomic Hybridization (aCGH) and Focused CES in patients with AS phenotype and negative methylation, and to identify the different entities that make up the spectrum(ALS).

**Methods:** Observational, retrospective, descriptive study of the implementation of molecular techniques and assessment of their diagnostic capacity, which included patients with AS phenotype, evaluated in Medical Genetics, and molecularly studied in the Héritas laboratory during 2016-2019. Molecular studies included methylation study, aCGH and Focused CES. We excluded patients with DD/ID without AS phenotype, and patients with clinical criteria but lacking molecular studies.

**Results:** 46 patients with AS phenotype were included. 21 cases (45,6%) were positive for methylation test (typical AS). By NGS ALS was identified in 14 cases (30.4%): 5 cases of typical Rett syndrome(*MECP2* gene), 2 FOXP1 related-syndromes, 2 GRIN2B related-syndromes, 2 Mowat Wilson syndromes(*ZEB2* gene), 1 Pitt Hopkins syndrome (*CNTNAP2* gene), 1 Phelan McDermid syndrome(PHMDs) and 1 case of epileptic encephalopathy (*STXBP1* gene). aCGH identified 4 pathogenic deletions (8.6%): 1 Kleeftstra syndrome and 3 PHMDs. Only in 7 cases (15%) the molecular diagnostic not be identified.

**Conclusion:** In patients with AS phenotype but with negative methylation test we have been able identify CNVs or pathogenic point mutations in 72% of cases, with a wide diagnostic spectrum of rare syndromes that we can currently diagnose, advise, and perform genetic counseling on thanks to diagnosis techniques based on aCGH testing followed by Focused CES.

## PgmNr 2499: Partial 5p duplication and 15q deletion in a family with a t(5;15)(p13.3;q26.3) translocation.

### Authors:

F.T. Bellucco; B. Favilla; E. Perrone; M.I. Melaragno

[View Session](#) [Add to Schedule](#)

**Affiliation:** Department of Morphology and Genetics, UNIFESP - Universidade Federal de São Paulo, São Paulo, Brazil

---

Several patients with 5p duplication and 15q deletion have been reported in the literature, involving different chromosome regions and great variations in their clinical features. To the best of our knowledge, partial trisomy 5p associated with monosomy 15q was never reported. Here, we describe a family, characterized by G-banding karyotype and array technique, in which we identified a 30 Mb 5p15.33p13.3 duplication and a 2.5 Mb 15q26.3 deletion in three individuals (two siblings and their paternal uncle), due to a balanced familial translocation between 5p and 15q (found in the father and in the paternal grandmother). The siblings present neurodevelopment delay, intellectual disability, short stature, facial dysmorphisms (such as downslanting palpebral fissures, retrognathia and downturned corners of mouth), short neck, and brachydactyly with 5th finger clinodactyly. Although the boy presents obesity and hyperphagia, like his uncle, the girl does not present these phenotypes. Instead, she presents convergent strabismus and ocular hypertelorism, which were not identified in her brother. Duplications at 5p13.3-5p15.33 region result in mild and relatively indistinct phenotypes, in comparison with duplication at 5p10-5p13.1 segment including the *NIPBL* gene, which results in a more severe phenotype. Chromosome rearrangements involving 15q26, on the other hand, are often related to multiple congenital anomalies, such as growth delay, learning disabilities, unusual facial features and anomalies of the hands and feet. One of the most important genes that seems to be responsible for 15q26 deletion phenotype is the *IGF1R* gene, which has already been associated with growth retardation, developmental delay, clinodactyly, and brachydactyly. Despite presenting such phenotypes, our patients' deletion does not include *IGF1R* gene. They show a combination of phenotypic findings of both 5p duplication and 15q deletions described in the literature thus far. However, the genotype-phenotype correlation is still challenging, since there is no phenotype concordance among the patients, even between both siblings, who have the exact same rearrangement. These data emphasize the importance of detailed cytogenomic and clinical analyses for an accurate diagnosis, prognosis, and genetic counseling and provide an opportunity to improve genotype-phenotype correlations of partial 5p duplication and 15q deletion syndrome patients. Financial Support: FAPESP, Brazil.

## PgmNr 2500: Missense variants in the histone acetyltransferase complex component gene *TRRAP* cause autism and syndromic intellectual disability.

---

Acetylation of the lysine residues in histones and other DNA-binding proteins plays a major role in regulation of eukaryotic gene expression. This process is controlled by histone acetyltransferases (HATs) found in multiprotein complexes that are recruited to chromatin by the scaffolding subunit transformation/transcription domain-associated protein (TRRAP). *TRRAP* is evolutionarily conserved and is among the top five genes intolerant to missense variation. Through an international collaboration, 17 distinct de novo or apparently de novo variants were identified in *TRRAP* in 24 individuals.

A strong genotype-phenotype correlation was observed with two distinct clinical spectra. The first is a complex, multi-systemic syndrome associated with various malformations of the brain, heart, kidneys, and genitourinary system and characterized by a wide range of intellectual functioning; a number of affected individuals have intellectual disability (ID) and markedly impaired basic life functions. Thirteen individuals with this phenotype had missense variants between amino acids 1031 and 1159, clustering around the c.3127G>A p.(Ala1043Thr) variant identified in five unrelated individuals. The second spectrum manifested with autism spectrum disorder (ASD) and/or ID and epilepsy and was particularly associated for 7 individuals with missense variants clustering between amino acids 1859 and 1932. Facial dysmorphism was seen in both groups and included upslanted palpebral fissures, epicanthus, telecanthus, a wide nasal bridge and ridge, a broad and smooth philtrum, and a thin upper lip.

RNA sequencing analysis of skin fibroblasts derived from affected individuals skin fibroblasts showed significant changes in the expression of several genes implicated in neuronal function and ion transport. Thus, we describe here the clinical spectrum associated with *TRRAP* pathogenic missense variants, and we suggest a genotype-phenotype correlation useful for clinical evaluation of the pathogenicity of the variants. We will discuss new variants identified in a follow-up study and pathomechanistic perspectives.

## PgmNr 2501: Phasing heterozygous *NPC1* mutations by long range amplicon sequencing.

---

The Niemann-Pick type C1 (NPC1) protein is an intracellular cholesterol transporter which plays an essential role in the maintenance of lipid homeostasis. *NPC1* genetic defects cause NPC1 disease, a fatal autosomal-recessive lipid-storage disorder characterized by progressive neurodegeneration. However, the highly variable disease phenotypes, including the wide range in age of onset, the challenges of annotation of new genetic variants, and the complexity of biochemical and cytologic lab tests to detect the compromised lipid trafficking have all contributed to the current inefficient ascertainment of genotype and phenotype association and the NP-C diagnosis. We report a child with two rare variants in *NPC1* (parents unavailable for testing). Marked behavioral and emotional dysregulation were noted at 18 months. Abilities in using verbal information and spatial and logic-based reasoning have decreased significantly since her previous testing (2.5 years previously). Hallucinations and delusions are partially suppressed on clozapine. To confirm the diagnosis, we established methods to phase the two variants of 16,474 bp apart on chromosome 18, without relying on trio analysis or statistical inference. The first variant, c.547G>A (p.Ala183Thr), has a reported allele frequency <0.001 in public databases (gnomAD, TopMed and 1000 Genomes Project) and is cataloged as of 'uncertain significance' by ClinVar. The second variant, c.1937G>A (p.Arg646His), may be benign as it is a conservative substitution and represented in ExAc 13 times. Despite the lack of functional evidence to support the pathogenicity of both variants, it is still of profound interest to determine if both affected *NPC1* alleles of the patient are in cis position so that the existence of one functional copy of *NPC1* gene can be confirmed. We selected PrimeSTAR GXL Polymerase to amplify the 17.8 kb amplicon from the patient sample. Purified PCR product was sequenced on the Pacbio Sequel with a yield of 19.2 Gb and a mean read length of 23.7 kb, providing a coverage of 28,938x for this genomic region. Using the Whatsap program we showed the two SNVs were on the same haplotype and the patient was not a compound heterozygote for this disorder. The treatment mode has been adjusted appropriately and the study highlights the importance of phase information in clinical diagnostic genetics. Long range amplification and long read sequencing can be used as an efficient and valuable option for this phasing.

## PgmNr 2502: Variability of average relative telomere length measurement using multiplex Luminex assay in DNA from different cell types and blood collection tube.

### Authors:

M.G. Kibriya; F. Jasmine; A. Shaikh; H. Ahsan; B.L. Pierce

[View Session](#) [Add to Schedule](#)

**Affiliation:** Institute for Population and Precision Health, Public Health Sciences, Univ Chicago, Chicago, Illinois.

**Background:** Relative Telomere Length (RTL) is a potential biomarker of aging and chronic disease. Previously we developed a non-PCR, probe-based high throughput RTL assay on Luminex platform suitable for large-scale studies. This multiplexed assay (measuring the telomere and the reference gene from the same DNA sample in a single well) requires ~50ng of DNA. We use branched DNA technology of QuantiGene chemistry for signal amplification. The “telomere length” is measured against a standard or reference DNA sample (hence the term “relative”). In this study we examined if different source of DNA from same individual’s blood sample could affect the RTL measurement in this Luminex based assay.

**Material Methods:** Blood from 11 individuals were collected in different tubes - (a) K2-EDTA tube, (b) Trace element tube with EDTA, (c) Heparinized tube, and (d) serum separator SST tube with gel and clot activator. The blood in K2-EDTA tube was used to separate (1) Peripheral Blood Mononuclear Cell (PBMC) and (2) granulocyte cell population using standard Ficoll gradient for DNA extraction. DNA from Whole blood (WB) was derived from (i) trace element EDTA tube, (ii) heparinized tube and (iii) the serum separating tube (SST) with clot activator. DNA was extracted using Flexigene DNA kit (5 samples/person). Quantification was done by Nanodrop spectrophotometry. We tested a total of 55 different DNA samples from the 11 individuals. RTL assay was performed using Luminex method - each was assayed in quadruplicate in four different plates simultaneously in a single batch by same individual.

**Result:** The RTL measurement in DNA from PBMC or Granulocyte was not different (1.039 SD 0.169 vs 1.047 SD 0.167, ANOVA  $p=0.911$ ). RTL measurements of Whole Blood DNA from EDTA, Heparin or SST tubes did not show any difference (0.976 SD 0.125, 0.999 SD 0.188 and 1.011 SD 0.136;  $p=0.857$ ). Regression using General Linear Model (GLM) showed that the variation in RTL measures was mainly attributed to “person-to-person” variation (69%) and the “tube-to-tube” variation contributed only 3.3% of the total variation. The precision of the assay was good to excellent with the Intraclass correlation coefficient (ICC) of 0.896 (95%CI 0.842 - 0.935) among the replicates.

**Conclusion:** The Luminex based multiplex assay for RTL yields similar RTL measures from an individual whole blood sample irrespective of blood collection tube (EDTA, Heparin or SST) or white blood cell type (PBMC or Granulocyte).

## PgmNr 2503: Biallelic variants in *COX4I1* associated with a novel phenotype of developmental regression, intellectual disability and seizures.

### Authors:

N. Pillai <sup>1,2</sup>; N. AlDhaherri <sup>1,2,3</sup>; R. Gosh <sup>1</sup>; J. Lim <sup>2,4</sup>; H. Streff <sup>1,2</sup>; A. Nayak <sup>2,4</sup>; B. Graham <sup>5</sup>; N. Hanchard <sup>1,2</sup>; S. Elsea <sup>1,2</sup>; F. Scaglia <sup>1,2,6</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

### Background:

Biallelic variants in *COX4I1* (OMIM: 123864) have been previously described in a single patient who presented with short stature, poor weight gain, dysmorphic features and features of Fanconi anemia. *COX4I1*, located at 16q24.1, encodes the subunit IV isoform 1, COX-IV subunit of cytochrome c oxidase (COX/Complex IV) in humans and other vertebrates. COX plays an important role in oxidative phosphorylation by transferring electrons from cytochrome c to molecular oxygen and contributes to a proton electrochemical gradient and formation of ATP. Here, we describe a novel *COX4I1* variant in two siblings who presented with developmental regression, seizures and pathognomonic changes in brain imaging resembling Leigh syndrome phenotype.

### Case reports:

First sibling is a 3 year old Iraqi male, born at 37 weeks of gestation to consanguineous parents. After initial normal growth and development, his motor skills regressed at 8 months of age. Brain MRI findings were suggestive of Leigh syndrome. He developed seizures at 2 years of age. A trio WES done as a part of his diagnostic evaluation showed a homozygous novel variant in *COX4I1*, c.454C>A (p.P152T). Untargeted metabolomics profile was done on plasma and CSF, which showed elevated lactate along with fumarate suggesting mitochondrial dysfunction.

His older brother, 11 years of age had the same phenotype with regression of skills at 11 months of age followed by seizures at one year of life. He had known familial mutation testing for *COX4I1*, which identified the same variant. A mitochondrial respiratory chain enzyme analysis done on the muscle biopsy specimen showed reduction in complex IV activity to 16% compared to normal controls, meeting modified Walker criteria further confirming the diagnosis of mitochondrial disease. Chromosome breakage studies done on both siblings were normal.

**Conclusions:** Here, we describe siblings with a novel homozygous variant on *COX4I1* presenting with encephalopathy, developmental regression, hypotonia, pathognomonic brain imaging findings resembling Leigh-like syndrome, expanding the known clinical phenotype associated with pathogenic variants *COX4I1*. We also emphasize the importance of using untargeted metabolomics analysis that

could provide functional evidence for pathogenicity of variants in mitochondrial syndromes.

## PgmNr 2504: Unexpected levels of benign heteroplasmic variation: A case of possible biparental inheritance of mtDNA?

### Authors:

---

Strict maternal inheritance of mitochondrial DNA and subsequent homoplasmy is a well-established tenant of human genetics. On average 24% of individuals contain at least one heteroplasmic position (MAF $\geq$  10%), with generally no more than two heteroplasmic positions observed in a single individual. Multiple heteroplasmic variants are usually explained by sample degradation, contamination, or recent blood transfusion. We report on a 19 year old female with a complex phenotype raising suspicion for a mitochondrial disorder. From 2014 to 2019 the patient had mitochondrial sequencing performed 4 times by 3 different institutions. All 4 tests reported the presence of multiple heteroplasmic positions. The most recent sequencing done at our institution revealed 6 benign homoplasmic and 21 benign heteroplasmic variants observed at levels ranging from 10-20%. While the patient's primary haplogroup is X2, 8 of the heteroplasmic variants are associated with the haplogroup R or with H, J, or U which are all branches off of R. Another 10 variants aren't part of a specific haplogroup but are reported in individuals who are primarily Eurasian and in some cases African. This evidence led us to hypothesize that the heteroplasmic variants are likely derived from the same Middle Eastern haplogroup. As the patient is adopted we don't have data on the parents, however we do know that her mother is Syrian and her father is Iraqi which appears to fit with the two observed haplogroups. We believe these results are unlikely due to contamination as the results were confirmed in a separate urine specimen, neither specimen was run with other samples with the same haplotype, and testing of an independently collected specimen at another institution reported the same results. Neither of these specimens were collected within 4 months of a blood transfusion. Finally, two custom long-range PCR reactions were performed prior to sequencing to exclude interference from any nuclear genes or pseudogenes. Therefore, we propose that one possible explanation for this patient's unusual sequencing results is biparental inheritance of mtDNA. Recent work by Luo et al. provided convincing evidence of paternally inherited mitochondrial DNA in several unrelated families. Whether the unexplained excessive heteroplasmic positions in our patient are caused by biparental inheritance, a technical issue, or some other anomaly, it is a phenomenon worth investigating for its implications in clinical testing.

# PgmNr 2505: A novel liquid chromatography-tandem mass spectrometric method reveals decreased levels of guanidino compounds in the plasma of patients with arginase 1 deficiency treated with pegzilarginase.

## Background

Arginine and guanidino compounds (GCs) accumulate in the plasma of patients with arginase 1 deficiency (ARG1-D) and may contribute to the neurologic phenotype of the disease. Pegzilarginase (PZA) treatment has been shown to sustainably reduce arginine levels in a phase 1/2 study of patients with ARG1-D. To date, determination of GC levels has been challenging due to inadequately sensitive methodologies. We assessed plasma GC levels in patients with ARG1-D treated with PZA using a novel liquid chromatography-tandem mass spectrometric (LC-MS/MS) method.

## Methods

Blood samples for GC ( $\alpha$ -keto- $\delta$ -guanidinovaleric acid [GVA]; N $\alpha$ -acetyl-L-arginine [NAAArg]; R,S-argininic acid [ArgA]; guanidinoacetic acid [GAA]) analyses were collected from patients with ARG1-D receiving up to 7 single ascending doses of PZA every 2 weeks followed by a weekly repeat dose for up to 8 weeks before entering into a long-term extension study. Samples were collected in a tube containing dipotassium ethylenediaminetetraacetic acid (K<sub>2</sub>EDTA), N<sup>w</sup>-hydroxy-nor-arginine (nor-NOHA) and mannitol, and processed to plasma. Various concentrations of GCs were added to calibration standards prepared in a surrogate matrix, and quality control samples were prepared in pooled K<sub>2</sub>EDTA human plasma containing nor-NOHA, PZA, and mannitol. Fifty microliters of plasma were treated with 100  $\mu$ L of 1N hydrochloric acid containing internal standards, followed by 400  $\mu$ L of ice-cold 10% trichloroacetic acid. Supernatant derived from vortex-mix and centrifugation was analyzed by LC-MS/MS using Shimadzu Nexera UHPLC-Applied Biosystems/MDS Sciex API 5500.

## Results

Sixteen patients were recruited for the study; 69.0% were females and median age (range) was 15 (5–31) years. Baseline mean GVA, NAAArg, ArgA, and GAA levels (standard deviation) were 5.1 (1.67), 1.1 (0.48), 2.8 (1.21), and 3.1 (1.11)  $\mu$ mol/L, respectively, which decreased to 2.7 (1.26), 0.7 (0.46), 1.8 (0.87), and 2.0 (1.21)  $\mu$ mol/L, respectively, 2 weeks after the last repeat dose. The concentration range for validation of this method was 0.03–10  $\mu$ M for GVA, NAAArg, and ArgA, and 0.300–100  $\mu$ M for

GAA.

### *Conclusions*

Treatment with PZA was associated with marked reduction in plasma GC levels in patients with ARG1-D. Further studies are needed to confirm the relationship between GC levels and patients' outcomes. This LC-MS/MS method was effective in measuring GCs in this patient group and could represent a useful tool in conditions with altered GC levels.

## PgmNr 2506: Mitochondrial DNA mutations in Leigh syndrome: Our experience.

---

**Background:** Leigh syndrome (LS) is severe neurological disorder characterised by progressive loss of mental and movement abilities i.e. psycho-motor regression. First symptoms of LS become apparent in the early childhood with lethal outcome within two to three years. LS has heterogeneous genetic aetiology and could be associated with mutations in more than 75 genes. About 20% of LS cases are caused by mitochondrial DNA (mtDNA) mutations, in which the mutated or impaired mitochondria show defective mitochondrial protein synthesis with sequentially reduced activity of respiratory chain complex I.

**Objective:** The aim of this study was to perform mutational screening of entire mtDNA in Serbian patients clinically diagnosed with Leigh syndrome.

**Material and Methods:** Five patients included in this study were recruited from the child neurology hospitals in Belgrade, Serbia. All examined individuals had characteristic clinical presentation suggesting the presence of LS. Molecular genetic analysis of entire mtDNA was performed by Sanger sequencing.

**Results:** We have detected mtDNA mutation in one out of five LS patients. In that case sequence analysis showed homoplasmic m.8993 T>G substitution in *ATP6* gene. The T>G transition of the mitochondrial nucleotide pair 8993 causing change amino acid Leucine to Arginine is one of the most frequent mtDNA mutations in LS. Numbers of other variants were detected in various fragments of mitochondrial genome.

**Conclusion:** This is the first case of mtDNA mutation in LS in Serbia. Understanding of the genetic background of mitochondriopathies may further facilitate the diagnostic approach and open perspectives to future, possibly therapies.

## PgmNr 2507: Identification of an insertional duplication of the *AMT* gene in a patient with glycine encephalopathy.

---

Glycine encephalopathy, an inborn error of glycine metabolism, is defined by the deficiency in the activity of the mitochondrial glycine cleavage enzyme system and the aberrant accumulation of the undegraded glycine. It can be caused by the mutations in the genes encoding the protein components of the glycine cleavage system with an autosomal recessive inheritance pattern. Most patients have elevated glycine in plasma and CSF, and present with phenotypes such as lethargy, seizures, hypotonia, abnormal EEG and mental retardation. Death in infancy can be common for patients with the classic neonatal form of the disorder. Mutations in the *AMT* (aminomethyltransferase) gene, which encodes the T protein of the glycine cleavage system, account for approximately 20% of the affected patients. Here we report one newborn female with symptoms reminiscent of glycine encephalopathy. Whole exome sequencing only detected one novel missense variant c.665G>T (p.R222L) in the *AMT* gene which was inherited from the patient's mother. Follow-up array CGH using the MitoMet v3.3 oligonucleotide microarray identified a 0.7 Kb duplication including exon 5 and partial exon 6 of the *AMT* gene. Further gap-PCR and Sanger sequencing analysis at junction breakpoints confirmed that this duplication was inserted into intron 3 of the same gene. This intragenic duplication in the *AMT* gene reshuffles the exons and probably results in an absent or truncated protein. Based on the whole exome data, the duplication is in trans configuration with the missense variant. Copy number changes involving the *AMT* gene are very rare. To our knowledge, this is the first report of duplication of this gene ever identified in patients with glycine encephalopathy.

## PgmNr 2508: The correlation study between phenotypes and genotypes of 174 cases of mitochondrial diseases caused by mitochondrial DNA variations in children.

### Authors:

Y. Shi; F. Fang; Z. Liu; D. Shen; L. Dai; W. Zhang; J. Li; X. Ren; T. Han; C. Ding

[View Session](#) [Add to Schedule](#)

**Affiliation:** Department of Neurology, Beijing Children's hospital, Capital Medical University, National Center for Children's Health, China, Beijing, China

**Objective:** To delineate the phenotypes and genotypes of children with mitochondrial DNA (mtDNA) variations, and analyze the correlation between them.

**Method:** The clinical and genetic data of patients with mitochondrial diseases caused by mtDNA variations in the department of Neurology, Beijing Children's Hospital from Jan 2001 to Feb 2019 was collected retrospectively. Pathogenicity analysis was performed in the three cases with variants of uncertain significance.

**Results:** There were total 174 diagnosed cases with mtDNA variations collected in our study. Male: Female=1.3:1. The average age of presentation was  $(5.67 \pm 4.07)$  years old, ranging from the neonatal to 15.1 years old. Twelve phenotypes were discovered in our study, including MELAS (n=82), MILS (n=64), MM (n=6), MERRF (n=5), LHON (n=3), KSS (n=5), MELAS and LS overlap syndrome (n=3), MERRF and LS overlap syndrome (n=2), RIRCD, DEAF, DMDF and Mitochondrial encephalomyopathy with deafness, epilepsy and developmental delay in 1 case respectively.

In our study, there were two kinds of mtDNA variations, including large-scale deletions and point mutations. The five deletions were all KSS. Among the point mutations, there were 13 genotypes and 29 allele changes. tRNA was the most common. The mutation ratios of Co<sub>2</sub> were higher than Co<sub>1</sub> and tRNA.

In MELAS and MELAS/LS, m.3243A>G was the "hot point", accounting for 92.7%. In MILS and LS/MERRF, *MT-ATP6* and m.9176T>C was the most common. MM were all caused by m.3243A>G; MERRF were all caused by m.8344A>G. The most common phenotype of tRNA variations was MELAS. The most common phenotype of Co<sub>2</sub> variations was MILS. And the only phenotype of Co<sub>1</sub> variations was MILS. The three cases with variants uncertain significance in our study were respectively m.9396G>A (MELAS), m.3955G>A (MILS), m.10407A>G (Mitochondrial encephalomyopathy with deafness, epilepsy and developmental delay).

### Conclusions:

MELAS and MILS were the most common phenotypes, accounting for 83%. tRNA was the most common in which the most common phenotype was MELAS. The most common phenotype of Co<sub>2</sub> variations was MILS. Moreover, the only phenotype of Co<sub>1</sub> variations was MILS. In MELAS and MELAS/LS, m.3243A>G was the "hot point". The mutation threshold was calculated into 35.63%. The most common pathogenic variations of MILS were Co<sub>2</sub> variations. The most common phenotype and allele change was *MT-ATP6* and m.9176T>C, only accounting for 14.1%.

## PgmNr 2509: Detection of succinic semialdehyde dehydrogenase deficiency in newborn dried blood spots.

### Authors:

**BACKGROUND & RATIONALE** – Succinic semialdehyde dehydrogenase deficiency (SSADHD) is a rare inborn error of  $\gamma$ -aminobutyric acid (GABA) metabolism, originating from inherited mutations in *ALDH5A1*, which manifests global developmental delays, motor dysfunction, intellectual disability, seizures and other behavioral abnormalities (Attri, 2017). Biomarkers for the disease include elevated GABA and its derivative  $\gamma$ -hydroxybutyric acid (GHB) in biological fluids. With the GHB-lowering antiepileptic vigabatrin being the only targeted therapeutic available, treatment is primarily symptomatic. Although there is no defined life expectancy of patients with SSADHD, there has been an increasing number of reports of sudden unexpected death in epilepsy (Pearl, 2011; Horino, 2016).

To date, SSADHD is not included in newborn screening (NBS) panels, as GABA and GHB are not routinely measured in newborn dried bloodspots (DBSs). As a result, families experience an approximate 2-year diagnostic delay resulting in profound stress, anxiety, and delayed treatment. **SPECIFIC AIMS** – We sought to determine whether SSADHD can be detected in the newborn period with novel metabolic analyses and biomarkers. Our objectives were two-fold: 1) to determine if SSADHD is associated with a unique metabolic profile in the newborn and post-newborn periods, and 2) to determine if GHB can reliably be detected in SSADHD patient DBSs.

**METHODS/DESIGN** – We obtained historical newborn DBSs from 7 SSADHD patients including 1<sup>st</sup> and 2<sup>nd</sup> screens from 3 of the 7 patients (age at collection between 48 and 340 hrs), and collected 17 post-newborn DBSs (0.8-38 years of age; median, 8.2 years) from patients with confirmed diagnosis of SSADHD. DBS amino acids, acylcarnitines and creatine were determined using currently available NBS methodology and compared to archival age-matched control data points (CLIR, Mayo Clinic). DBS GHB was determined using UPLC-MS/MS (Forni, 2013).

**RESULTS** – In newborn DBSs, GHB was 111-767 mM, exceeding the 99.99%-tile (78 mM). In contrast, C2-, C3-, C4- and C4-OH carnitines, creatine and ornithine concentrations were below normal. Low levels of C2- and C4-OH carnitines, ornithine, histidine and creatine were also observed in post-newborn DBSs.

**CONCLUSION** – Early detection of SSADHD in newborn DBS now appears plausible with quantitation of short-chain acylcarnitines, creatine and ornithine used as potential 1<sup>st</sup> tier screening tool and GHB as a 2<sup>nd</sup> tier method.

---

Chromosomal constitutional imbalances are frequently associated with learning disabilities, deterioration, congenital anomalies and deterioration of growth. Chromosomal aneuploidies, particularly those that involve chromosome 21, are one of the alterations most prevalent human chromosomes, and occur in approximately 1 of every 700 births. We present the case of a two-year-old boy with facial dysmorphism, deterioration of growth and developmental disorder. A karyotype in G banding and chromosomal analysis was performed using a comparative genomic hybridization matrix to make its correct diagnosis. The karyotype was performed in 15 metaphases, which reported a masculine 46, XY, r (21); Ring chromosome 21, which leads to the loss of genetic material. CGH evidenced the deletion of a region of approximately 4.5Mb on chromosome 21q22.3 with pathogenic classification; this alteration affects approximately 119 genes. This is a rare deletion in the long arm of chromosome 21. These types of deletions have been reported with clinical variability, but common features include craniofacial, skeletal malformations, cardiac and genitals with cognitive impairment. It is reported that under normal conditions there is a high interaction between genes product of the terminal deletion on chromosome 21q22.3. The condition in genes of the KRTAP family, characterized as a class of human genes that promote proliferation in epithelial cells in mammals, lead to significant damage to necessary biological functions such as keratinization, cell and epithelial cell differentiation, tissue and epithelial development, in the same way that the genes of the TFF family act. Also, the genes of collagen play important roles in maintaining the structure and function of the extracellular matrix. The members of the family of Collagen VI, such as COL6A1, COL6A2, form distinct networks of microfibrils in the connective tissue and are responsible for interacting with other components of the extracellular matrix; these last genes are closely related to POFUT2, ADARB1, SLC19A1 and PCBP3 in charge of processes mesenchymal and epithelial. The present analysis will help to determine a better phenotype-genotype correlation analysis in cases with partial monosomy 21. The future implementation of exome and RNA sequencing techniques, and analysis of their proteomic expression in a clinical context could lead to better analysis and interpretation of the genotype-phenotype correlation in cases similar to that described.

## PgmNr 2511: Phasing of genomic rearrangements reveal involvement of both homologous chromosomes in pre- and post-zygotic events.

---

Copy number variation (CNV), including duplications and triplications formed by microhomology-mediated break-induced replication (MMBIR) has been shown to be generated mainly by intrachromosomal events, i.e. only segments originating from the same homologue are part of the end product. The hypothesized reason is that template-switches (TS) within the same chromosome are thought to be facilitated by the physical proximity in the nucleus due to linkage as well as to *cis* intrachromosomal interactions. Autosomal triplications followed by runs of homozygosity (ROH) are clinically relevant exceptions: they are generated post-zygotically due to interhomolog TS which can lead to imprinting perturbations and associated diseases. To gain mechanistic insights into the formation of *de novo* autosomal copy number gains and complex rearrangements, we studied 11 trios (patient + parents) in which probands were referred with congenital malformations carrying rearrangements involving 17p11.2. Trios were studied by combining array comparative genomic hybridization (aCGH), long-and short-reads DNA sequencing technologies including a targeted 7Mb Illumina short read spanning the 17p interval and Pacific Biosciences SMRT sequencing approach. Phasing of the copy number gains were obtained by B-allele frequency analysis provided by trio joint-calling, whereas array data and PacBio were used to resolve CNV breakpoint junctions. Intrachromosomal rearrangements were observed in 6 out of 11 cases and interchromosomal events in 1 out of 11, confirming that a majority of events occurred within the same homolog. Surprisingly, though, in 4 out of 11 (36%) cases the CNVs constitute a mix of both intra- and inter-homologue amplified segments rather than originating from only one ancestral chromosome, all of them formed by pre-zygotic mutagenesis. Intriguingly, only a subgroup of the template-switching events led to CNVs, similar to what was previously observed for post-zygotic autosomal triplications. Our results indicate that high-resolution B-allele frequency analysis is a helpful tool to uncover CNV formation and reveal TS events that can result in increased rearrangement complexity. Importantly, DNA segments originating from two distinct parental chromosomes contributing to the formation of the same rearrangement strongly support a TS model of generating amplifications and have further implications for human diseases, including those resulting from perturbations of imprinting.

## **PgmNr 2512: Cousins with 4p- syndrome mosaicism and parents with balanced translocation: The importance of the family history in cases of structural chromosomal disorders.**

### **Authors:**

---

4p- syndrome or Wolf-Hirschhorn syndrome (WHS) arises from a contiguous gene deletion of the distal short arm of chromosome 4 and is characterized by craniofacial features, growth impairment, intellectual disability, and seizures. Usually cases of chromosomal mosaicism occur due to post-zygotic error, for this reason a negligible risk of recurrence of that condition in the future offspring of the parents during their genetic counseling is reported. We present here the case of two cousins, a girl born in 2014 and a boy born in 2013, both presenting WHS in mosaic [46, XY, del (4) (p15.3) / 46, XY] with 20% of normal cells. They came for evaluation separately when they were about one year old and without identifying their kinship. The girl's father and the boy's mother are siblings and have balanced translocation. These cases illustrate the importance of the good anamnesis carried out with the deepening of the family history for similar cases as bases to a adequate genetic counseling.

## PgmNr 2513: Diagnostic approaches and yields following the detection of long continuous stretches of homozygosity (LCSH) in SNP microarrays.

### Authors:

Y. Fan; L. Wang; Y. Sun; W. Qiu; H. Zhang; B. Xiao; L. Han; R. Xu; F. Lin; X. Gu; Y. Yu

[View Session](#) [Add to Schedule](#)

**Affiliation:** Xinhua Hospital affiliated to Shanghai Jiaotong University School of Medicine, shanghai, Shanghai, China

**Purpose:** Single-nucleotide polymorphism (SNP) microarrays can identify long continuous stretches of homozygosity (LCSH). LCSH is associated with risk of recessive disorders and uniparental disomy (UPD). However, the diagnostic utility of LCSH warrants further clinical investigation. The goal of this study is to evaluate the diagnostic yields of different approaches following LCSH detection, and recommend optimal reporting thresholds.

**Methods:** A cohort of 2226 index cases (mostly pediatric patients) with SNP microarray results were recruited. LCSH was defined as uninterrupted copy-number neutral homozygosity above 3Mb. A total of 1944 cases harboring at least one LCSH were further divided to three groups: 1) "Suspected consanguinity" group (total LCSH covered over 1.5% of autosomal region, n=18), followed by whole-exome sequencing (WES); 2) "Imprinting related" group (cases with LCSH on chr 6,7,11,14,15 and 20, n=26), followed by either methylation-specific MLPA or STR linkage analysis for UPD testing; 3) "Not-imprinting related" group (cases with LCSH on single chromosome not involving imprinting disorders, n=17), followed by WES. The diagnostic yields in these three groups and the LCSH pattern in the cases with confirmed diagnosis were analyzed. Potential reporting thresholds and corresponding missed diagnosis and false negative rates were presented.

**Results:** In suspected consanguinity group, WES revealed diagnostic variants on LCSH in 11.1% cases, and another 22.2% cases were diagnosed with LCSH-irrelevant variants, including de novo and autosomal dominantly transmitted variants. For cases harboring LCSH on single chromosome, similar yields after WES were found - 11.8% diagnosed with variants on prior detected LCSH, 17.6% diagnosed with variants irrelevant to LCSH. For cases with LCSH on imprinting related chromosomes, subsequent analysis confirmed UPD diagnosis in 48% cases, and the most prevalent diagnosis is maternal UPD of chr15 associated with Prader-Willi syndrome. Pattern analysis suggested a threshold of ~5Mb for terminal LCSH and ~15Mb for interstitial LCSH was associated with maximal UPD yield and minimal false positives.

**Conclusion:** WES following the detection of LCSH may identify diagnostic variants, but the yield is low and possibly not related to the original LCSH finding. UPD analysis following LCSH detection on imprinting-related chromosomes is highly recommended after setting optimal reporting thresholds.

## PgmNr 2514: Whole genome sequencing (WGS) as a first-line diagnostic test: Its success is in the details.

### Authors:

A. Kaplun; N. Neerman; C. Stanley; G. Faust

[View Session](#) [Add to Schedule](#)

**Affiliation:** Variantyx Inc., Framingham, Massachusetts.

---

### Background:

WGS is well positioned to become the clinical diagnostic standard for rare genetic disorders due to the benefits inherent in PCR-free, genome-wide sequencing combined with its continually decreasing cost. Initial published reports are supportive of this paradigm shift, yet all WGS assays are not created equal. We've undertaken the challenge to develop and validate a clinical WGS pipeline that supports simultaneous analysis and interpretation of multiple variant types, resulting in a clinically available alternative to sequential testing.

### Methods:

Clinical grade whole genome sequencing (WGS) is conducted on an Illumina platform using the Illumina TruSeq DNA PCR-Free Library Preparation Kit. With the PCR-free protocol, significantly less average coverage is required compared to panels and exomes. Specifically, we find that 30X mean mappable coverage provides a highly uniform sequencing depth with 97.3% of nucleotides covered at  $\geq 8X$  and 99.4% of HGMD and ClinVar annotated variants covered at  $\geq 8X$  - a depth that is sufficient for specific and sensitive variant calling. Following alignment of reads, a combination of open source and proprietary algorithms call small sequence change variants, structural variants, mitochondrial variants and tandem repeat expansions. Variants are subjected to annotation and filtering before being presented to our clinicians for interpretation within the context of the patient's clinical symptoms and medical history.

### Results:

In 2018, we obtained full CLIA accreditation and CAP certification for all four components of our WGS pipeline: small sequence changes, structural variants, mitochondrial variants and short tandem repeats. We will present a combination of secondary and tertiary validation results which demonstrate >99% sensitivity, specificity and PPV for single nucleotide variants; >95% sensitivity and specificity for indels up to 50 nucleotides; >96% clinical sensitivity for structural variants; the ability to detect mitochondrial heteroplasmy levels down to 5%; and >99% sensitivity for tandem repeat expansions spanning >20 known pathogenic loci. We will additionally present cases representative of those processed in the first 18 months that the full Genomic Unity™ test has been available for clinical use.

## PgmNr 2515: Genetic variants in a cohort of Colombian patients with VACTER/VACTERL association.

### Authors:

---

**Introduction:** VACTER-L association comprises different multisystem congenital malformations including vertebral anomalies, anal atresia, cardiac defects, trachea-oesophageal fistula with or without oesophageal atresia, renal malformations and limb defects. Prevalence has been estimated in 1:7000 to 1:40000 individuals. This heterogeneous condition has many overlapping defects with other malformation syndromes and it is usually considered as a diagnosis of exclusion. Fanconi anemia (FA) patients often exhibit birth defects suggesting VACTERL association. Because of this, FA must be considered among one of the first differential diagnosis. **Objective:** The aim of this study was to determine genetic abnormalities through banding-cytogenetics analysis, molecular cytogenetics (aCGH), and chromosomal breakage test for FA in patients with diagnostic criteria of VACTER/VACTER-L association and establish the relationship with the phenotype. **Methods:** This was a prospective study. Data regarding clinical features was obtained by physical examination or from clinical reports, and then it was analyzed to describe all clinical aspects. Complete cytogenetic investigation based on chromosomes with G-band staining was performed in all patients, as well as chromosome breakage studies for FA using standard procedures. **Results:** We evaluated 18 patients who met criteria for VACTER/VACTER-L association, 11 were female and 7 were male. Age range between 1 month and 16 years. 13(72.2%) patients presented with vertebral anomalies, 8(44.4%) anal atresia, 14(77.8%) congenital heart defects, 8(44.4%) oesophageal atresia, six of them having TE fistula, 10(55.6%) renal anomalies, and 10(55.6%) limb defects. Karyotypes were normal for all patients and chromosomal breakage tests were negative for FA. aCGH was performed in 15 patients, eight of them had alterations classified as Variants of Unknown Significance (VUS), and in one patient dup(17)(q12) classified as pathogenic and in other patient del(15)(q11.2) classified with variable effect.

**Conclusion:** All patients in our study exhibit a wide clinical spectrum. Chromosome aberrations and FA were ruled out in all of the patients. aCGH revealed microalterations that in two cases could explain the phenotype, while the VUS variants have not yet been described in patients VACTER/VACTER-L; these VUS affect some genes important in cell function and could be involved in embryonic development.

## PgmNr 2516: A quantitative, sensitive method for the confirmation of low-level chimeric RNAs identified by RNA-fusion detection in inherited conditions.

### Authors:

N. Vidal-Folch <sup>1</sup>; L. Schultz-Rogers <sup>3,4</sup>; G.R. Oliver <sup>3,4</sup>; E.W. Klee <sup>1,3,4,5</sup>; D. Oglesbee <sup>1,2</sup>

---

**Introduction:** Chimeric RNAs (fusion transcripts) are frequently found in cancer tissues where their oncogenic, diagnostic and therapeutic relevance is widely recognized. Recently, fusion transcripts have also been reported in sporadic cases of developmental and neurological phenotypes including brain malformation, intellectual disability, schizophrenia, spastic paraplegia and autism spectrum disorder, as well as in normal physiology. When using fusion-detection methodology, confirmation of candidate hits with an orthogonal method is critical to elucidate true transcripts from false positive events. Traditional techniques, such as targeted PCR and Sanger sequencing, are often used for hit validation, but these platforms lack sufficient sensitivity and specificity for low-level chimerism. Here, we describe our droplet digital PCR (ddPCR) approach to RNA fusions that provides unsurpassed analytical sensitivity down to 4 supporting reads per 100 million total reads.

**Methods:** Chimeric RNAs were identified by a modified fusion-transcript detection algorithm coupled with a categorization workflow. A total of 11 candidate fusion transcripts with strong phenotypic relevance were discovered from 9 undiagnosed patients suspected of inherited disease. For fusion confirmation, G-block constructs for each candidate were synthesized. Each fusion transcript was amplified from patient cDNA. DdPCR was performed using EvaGreen Supermix, QX100 droplet generator and QX200 droplet reader (Bio-Rad).

**Results:** G-blocks showed positive amplification of all candidate RNA-fusion constructs. Five fusion transcripts (with 10, 11, 15, 31 and 32 supporting reads) were confirmed by both traditional PCR and ddPCR, providing the clinical diagnosis for two previously unsolved cases. Three fusion transcripts (with 4, 7 and 13 supporting reads) were confirmed only by ddPCR. Three fusion transcripts (with 5, 12 and 15 supporting reads) were not confirmed by either methodology. While the latter species appear to be artefactual hits, all three candidates contained reads across exon-exon boundaries consistent with RNA splicing products.

**Conclusion:** This ddPCR approach is a highly sensitive and specific method for confirming chimeric RNAs discovered in rare inherited disorders.

## PgmNr 2517: The VetSeq Study: Follow-up results from a feasibility study of expanded exome sequencing in the Veterans Health Administration.

---

### Background

Although exome sequencing (ES) has demonstrated utility in many diagnostic contexts, the range of secondary results that should be returned from ES is an open question. We are conducting a feasibility study of ES in the VA Boston Healthcare System (VABHS), returning indication-based and secondary results.

### Methods

In the VetSeq Study, providers refer patients for indication-based ES from a CLIA-certified lab through a research protocol. The report includes indication-related results, secondary pathogenic or likely pathogenic variants in >4600 genes associated with monogenic disease risk, carrier status variants, and pharmacogenomic results. Patients complete surveys and interviews before ES and 3 months after receiving results from their referring providers.

### Results

Two patients have completed the study. P1 is a 72-year-old man with decades of sensory neuropathy and myalgias. ES identified a pathogenic p.Arg298Cys variant in *LMNA* associated with Charcot-Marie-Tooth hereditary neuropathy type 2. Though some *LMNA* variants are associated with dominantly inherited neuromuscular disease, P1's variant is typically associated with autosomal recessive inheritance and was thus inconclusive for his presentation. Family testing determined the variant was absent in a daughter and grandson with similar symptoms. In his baseline interview, P1 had hoped ES would identify a diagnosis and possible treatment not for himself but possibly for his family or for other patients. In his follow-up interview, he was uncertain ES met these expectations, given the apparent lack of definitive familial benefits or scientific advancement. P2 is a 33-year-old woman with a history of severe thrombocytopenia in her and 1 of 2 sons. In her baseline interview, she hoped that ES would suggest a treatment to stabilize their platelet counts. ES identified a p.Tyr346Cys variant in *ETV6* that was present in her affected son but not her unaffected son. *ETV6* has been associated with autosomal dominant thrombocytopenia, but this variant was classified as uncertain significance due to insufficient evidence of pathogenicity. In her follow-up interview, P2 said that although ES did not conclusively identify a cause for the family's thrombocytopenia, learning she carries a pathogenic *HFE* variant associated with hereditary hemochromatosis was useful.

### Conclusions

It is feasible to introduce ES to VABHS clinical care. Patients might find value in outcomes unrelated to their own diagnosis and treatment.

## PgmNr 2518: Hepatic hemangioma in a patient with *de novo* mutation in NF1 gen.

Neurofibromatosis type 1 is a neurocutaneous disorder caused by mutation in the suppressor gene of neurofibromin 1 - NF1 located in the chromosome 17q11.2. This disease is of autosomal dominant inheritance with very variable expressivity and with progressive multisystemic commitment. Exist de novo mutations, these are generally related to alleles inherited from parents of very advanced age. More than 1289 mutations have been found in this gene but few have been related to the disease phenotype. The diagnosis is characterized by presence of more than 6 café-au-lait macules greater than 5 mm in pre-patients pubescent and 15 mm in diameter in post pubescent patients, axillary freckles or inguinal, 2 or more neurofibromas of any type or 1 or more neurofibromas plexiform, optic gliomas, 2 or more Lish nodules, bony dysplasias and presence of tumors malignancies of the peripheral nerve sheath. The most frequent neoplasms in the pediatric age are intracranial gliomas (20%), and other high and low grade gliomas, followed by malignant tumors of the peripheral nervous sheath, and rhabdomyosarcomas. With the objective of to determine the molecular etiology of a patient with hepatic hemangioma and neurofibromatosis through exomic studies. We studied the clinical case of a 3-year-old male patient with multiple café-au-lait spots throughout the body, of different sizes, freckles in the armpits and inguinal area, broad forehead, eyebrows arched, palpebral fissures down, hypertelorism and anteverted ears. With history of respiratory distress at birth, dermatitis, rhinitis, asthma, alteration in psychomotor development, with no family history of the disease and finding of Hepatic hemangioma in abdominal magnetic resonance. Clinical exome was requested where a de novo mutation is detected, with variant pathogenic in the NF-1 gene: c1381C>T; p.Arg461Ter in heterozygous, autosomal state dominant. The use of imaging techniques is essential to assess the

extension and progression of subcutaneous and plexiform neurofibromas, but not used routinely and there is no consensus on which patients should be monitored. the early presentation of hepatoblastoma without neurofibromas or hemangiomas cutaneous lesions have not been previously described; only one case has been described in the literature of cutaneous hemangioma associated with hepatic hemangioma in a patient with neurofibromatosis type 1 with this same mutation.

## PgmNr 2519: De novo KAT6B mutation identified with whole-exome sequencing in a boy with Say-Barber-Biesecker-Young-Simpson syndrome.

Say-Barber / Biesecker / Young-Simpson syndrome (SBBYSS; OMIM 603736), variant of Ohdo syndrome is a rare syndrome with multiple congenital anomalies. The clinical diagnosis is usually based on a phenotype with a mask-like face severe blepharophimosis a bulbous nasal tip, feeding problems, long thumbs and big toes, and dislocated or hypoplastic patellae. . this disease is also associated with delayed development and intellectual disability, which are often severe. Many affected infants have weak muscle tone (hypotonia) that leads to breathing and feeding difficulties. We present the clinical case of a Colombian boy of 4 years with dysmorphic features, short stature, suction and swallowing disorder, bilateral hearing loss, bilateral cryptorchidism, and developmental delay. The boy has normal echocardiogram and echocardiogram results. Previous genetic testing (array-CGH, PTPN11 FOXL2 mutation analysis) gave normal results. We performed whole-exome sequencing and identified on chromosome 10 a heterozygous nonsense mutation in the KAT6B gene, NM\_012330.3 : c.3349 C>T (p.Gln1117\*). The mutation led to a premature stop codon. The analysis carried out in the parents confirms that the variant is *de novo* in the patient. To our knowledge, this mutation has not been reported before. Being a stop codon, this mutation is classified as probably pathogenic. several aspects found support for the causal relationship between the mutation in KAT6B and the correct diagnosis of our patient. KAT6B mutations have been described in other patients with SBBYSS. This disease is not found in the updated list of orphan diseases in Colombia. In the literature it is reported that typically the syndrome is caused by *de novo* pathogenic variants. The disease manifests in childhood with severe hypotonia and feeding difficulties. Skeletal problems such as hypoplasia are associated and in 50% of patients structural heart defects and dental anomalies are reported. In many cases it is also associated with intellectual disability and severe developmental delay. If a patient is suspected of SBBYSS, its recommend sequencing the KAT6B gene to find the correct diagnosis. In these cases where the CGH does not provide enough information, the complete sequencing of exome allows to provide a diagnosis correct, genetic counseling and personalized therapy.

## PgmNr 2520: Evaluation of clinically relevant CNVs from WES data in the cytogenomic routine.

---

**Introduction:** Detection of single nucleotide variants (SNVs) and copy number variations (CNVs) is essential for patient genotyping in cytogenomic diagnostic. Recently the screening of CNVs from whole exome sequencing (WES) data has become a common practice for routine diagnostic and allowed improving the accuracy of CNVs detection associated with phenotypes. **Methods:** In this study, we evaluated 38 patients with developmental delay and/or multiple congenital malformations and negative WES (Nextera Rapid Capture Exomes - Illumina) results for pathogenic SNVs. The WES data were submitted to ExomeDepth software in order to identify potential relevant CNVs. We performed genomic array using Infinium CytoSNP850K BeadChip (Illumina) and BlueFuse Multi v4.3 (BlueGnome - Illumina) software in all samples for comparison and confirmation of the CNVs. Those were classified as benign, VUS or pathogenic, and only the pathogenic CNVs were evaluated. **Results:** We identified 44.7% of the patients with pathogenic CNVs detected by both techniques including deletions and duplications in different chromosomal regions. Only one patient showed pathogenic CNV detected by array and missed by WES. Also, only the genomic array technique revealed cases with regions of homozygosity (8%) that led to correct diagnostic conclusion. Additionally, we performed a reevaluation and reanalysis of WES for normal results in attempt to reclassify variants originally classified as VUS based in relevant literature, updated available mutation/variant databases, and the latest research. The reanalysis improved the detection and cytogenomic diagnostic and showed 29.4% of the patients with SNV in a specific gene/region related to clinical phenotype. The extraction of CNVs information from WES data is an advantageous approach since it can improve the cost-effectiveness and reduces the number of genomic tests required in routine diagnostic. **Grants:** FINEP-CT INFRA0160/12-SP8; CAPES-Finance Code 001.

## PgmNr 2521: A comprehensive genome analysis approach using whole exome sequencing and microarrays reveals novel diagnoses in autopsy negative patients.

---

**Background** Thousands of deceased patients do not receive genetic testing and the underlying molecular etiology, despite a comprehensive autopsy, remains unknown. In the pediatric setting, a post-mortem molecular diagnosis can help families determine recurrence risk and support the development of management strategies for similarly affected relatives. This study aims to leverage a comprehensive genomics strategy including chromosomal microarray (CMA) and/or whole exome sequencing (WES) to determine the utility of this strategy in identifying pathogenic variants in a deceased pediatric cohort. **Methods** Subjects were enrolled in the research biorepository at the Center for Applied Genomics at Children's Hospital of Philadelphia. Eighty-one patients with unexplained death were selected based on pre-determined criteria related to phenotype and family history (55.6% male, 44.4% female). We performed CMA and WES analysis using a series of custom bioinformatics pipelines and algorithms. **Results** The cohort's phenotypic spectrum included multiple congenital anomalies (85.2%), neurodevelopmental disorders (45.7%) and craniofacial disorders (7.4%); 38/81 (46.9%) presented with overlapping features. CMA was performed on 81 patients and a pathogenic/likely pathogenic copy number change was found in 16% (13/81). A molecular diagnosis was identified using WES in 2/11 subjects initially sequenced. Results on WES analysis for the remaining 57 undiagnosed individuals will be presented. One patient, with prenatal findings of polycystic kidneys, oligohydramnios, pulmonary hypoplasia, mild increased NT and ventriculomegaly, had findings in 2 potentially relevant genes: a homozygous variant in *GLYCTK* (D-glyceric aciduria, AR) and a homozygous variant in *CEP290* (Meckel syndrome/Bardet-Biedl syndrome/Joubert syndrome, AR). The other patient, with renal dysplasia, gastroesophageal reflux, severe intellectual disability, focal epilepsy, microcephaly, small optic nerves and facial dysmorphism, carried a pathogenic variant in *DYRK1A* (Mental retardation 7, AD). **Conclusion** A comprehensive post-mortem genomics approach can help establish a molecular diagnosis for patients with uninformative autopsy results. We will provide the molecular diagnostic yield in this cohort and describe the unique challenges associated with performing accurate interpretation on a deceased patient cohort.

## PgmNr 2522: The spectrum of pathogenic variants and clinical features of individuals undergoing *IRF6* gene testing.

### Authors:

H. Cox; J. Dong

[View Session](#) [Add to Schedule](#)

**Affiliation:** Geneticists, PreventionGenetics, Marshfield, WI

---

**Background:** Pathogenic variants in the *IRF6* gene are associated with autosomal dominant isolated orofacial clefting, Van der Woude Syndrome (VWS) and Popliteal Pterygium Syndrome (PPS). Features of VWS may include lower lip pits, cleft lip, cleft palate, cleft uvula, submucous cleft palate and hypodontia. The PPS phenotype is more severe and may include orofacial clefting, abnormal external genitalia, syndactyly, ankyloblepharon, syngnathia, and pyramidal skin on the hallux. To date, over 300 pathogenic variants have been reported in the *IRF6* gene. This study reports the clinical features and spectrum of pathogenic variants in individuals referred for clinical *IRF6* gene testing. **Methods:** This study included 126 individuals who underwent *IRF6*-gene testing at a single clinical laboratory. Clinical information was obtained from provider-completed test request forms. Of the tested individuals, 54% (68/126) were male and 46% (58/126) were female with a median age at testing of 2.7 years of age (range 0.01-51 years). The majority of individuals (64%, 81/126) were ascertained based on a personal history of orofacial clefting. Clinical suspicion of VWS or PPS was reported for 13% (16/126) and 4% (5/126) of individuals, respectively. A positive family history of orofacial clefting was reported in 33% (42/126) of individuals. The *IRF6* gene was analyzed using Sanger sequencing and Next Generation Sequencing methods. Copy Number Variation (CNV) analysis was performed for 29% (37/126) of tested individuals. **Results:** Overall, 40 unique *IRF6* pathogenic variants were identified in 51 individuals (41%, 51/126) during the course of clinical testing. Pathogenic variants were detected in 37% (38/94) of individuals with a personal history of orofacial clefting, VWS or PPS. Of the pathogenic variants detected, 35% (14/40) localized to the winged-helix DNA-binding domain and 22.50% (9/40) localized to the SMIR/IAD protein-binding domain. Pathogenic missense (13/40), nonsense (12/40), frameshift (11/40) and splicing (4/40) were observed. No pathogenic CNV events were detected. **Conclusion:** The phenotype of individuals with an *IRF6* pathogenic variant was consistent with previous reports, with the majority of individuals presenting with a personal history of orofacial clefting. The overall positive rate was 41% with a clinical sensitivity of 37% for individuals with a personal history of orofacial clefting, VWS or PPS.

## PgmNr 2523: Heterozygous double gross deletions in *JAG1* in a patient with Alagille syndrome.

---

Alagille syndrome (ALGS; OMIM 118450) is an autosomal-dominant multisystem disorder affecting the liver, heart, face, eyes, skeleton, and other organs. The prevalence is estimated to be approximately 1 in 30,000 live birth. ALGS is caused by a mutation in one of two genes in the Notch signaling pathway, *JAG1* or, rarely, *NOTCH2*. *JAG1* is located in 20p12 and consists of 26 exons. A mutation in *JAG1* can be identified in approximately 90% of clinically diagnosed patients with ALGS. To date, over 500 *JAG1* mutations have been reported, and approximately 10% of the mutations were gross deletions. Here, we present a patient with clinically diagnosed ALGS and with novel heterozygous double gross deletions in *JAG1*. The patient was a Japanese male from nonconsanguineous parents. He represented intrahepatic cholestasis and was introduced to our institution at 3 years in order to test molecular genetic analyses. His clinical features showed as follows; intrahepatic cholestasis with elevated serum liver enzyme, characteristic facial features including a high broad forehead and a triangular face, and dysplastic kidney. These features fulfilled clinical diagnostic criteria of ALGS. We carried out our targeted next-generation sequencing using the AmpliSeq and Ion Torrent Personal Genome Machine (ThermoFisher Scientific) system as we previously established. Sequenced reads were analyzed through Ion Reporter software (IR, ThermoFisher Scientific). Consequently, the IR called 2 heterozygous gross deletions in *JAG1*; 1616bp deletion in exon10 and 659bp deletion in exon 25 encompassing to exon 26. To eliminate false-positive mutations, we ascertained those by multiplex ligation-dependent probe amplification (MLPA) analysis using the SALSA MLPA probemix P184-C2 *JAG1* (MRC-Holland), and we successfully validated those two regions. Next, we validated the origin of the two deletions with the same method using gDNA from his parents. The examination revealed that his mother carried the both deletions. Thus, we confirmed that the double gross deletions were on the same allele which was transmitted from his mother. After the molecular testing, we carefully checked his mother, and she showed slightly elevated liver enzyme, agenesis of one kidney, and hypertension. These were compatible with clinical aspects of ALGS. In conclusion, this is the first report that a patient with clinically diagnosed ALGS had doubly mutated allele, including 2 gross deletions, in *JAG1*.

## PgmNr 2524: When a SV anomaly can hide another.

---

**Introduction:** Structural variations (SVs) such as apparently balanced translocations, insertions and inversions are evidenced by karyotype. Some publications showed the potential role of whole genome sequencing (WGS) to characterize SVs (Redin et al. 2017, Schluth-Bolard et al. 2018).

**Methods :** The goal is to use WGS to characterize SVs in 10 patients with SVs and an abnormal phenotype, but also with the potential to identify other hits. Whole genome analyses were performed using short reads with 40X depth. Bioinformatic analysis of the raw data was performed with Lumpy algorithms for translocations and inversions and ControlFreeC for CNVs.

**Results:** The WGS short-read identified the 10/10 SVs and allowed to propose a diagnosis for two cases. In one case, the translocation breakpoint interrupted the *GRIN2B* gene. In the second case, the *NBEA* gene was interrupted by the same mechanism. The disruption of these two genes was compatible with the phenotype of these two patients. Five cases had translocations that disrupted unknown genes and one without gene. For two cases, WGS analysis found no gene disruption or effect position, but found rare variants of *FBN1* and *CD151* genes respectively responsible for the phenotypic features. The first one suffered of marfanoid syndrome with cardiac complications associated with *de novo* t(1;5)(q25;q11). The second one presented with epidermolysis bullosa associated with an maternal inv(3)(p14.3p24.2).

**Conclusion:** The use of the WGS is therefore particularly effective in characterizing the breakpoints of the SVs. We report two rare cases of SVs associated with pathogenic SNV which explain the clinical presentation. These SNVs hidden by SVs will be more frequently discovered with the increased use of WGS in France thanks to the generalization of pangenomic NGS.

## PgmNr 2525: Emerging value of rapid whole genome sequencing in complex congenital heart disease with multisystem involvement.

### Authors:

S. Girgis; J. Sasaki; B. Totapally; M. Diaz-Barbosa; K. Schain; J. Runyon; S. Lala Kana; P. Jayakar

[View Session](#) [Add to Schedule](#)

**Affiliation:** Nicklaus Children's Hospital, Miami, Florida

---

**Background:** The utilization of rapid whole genome sequencing (rWGS) can provide a diagnosis in the setting of multisystem involvement of unclear etiology. However, at this time, the cost-benefit ratio of this test must be weighed in the diagnostic decision-making process. We present a patient with complex congenital heart disease, pulmonary hypoplasia and diaphragm abnormality, lacking a unifying diagnosis. Whole genome sequencing revealed de novo likely pathogenic c.2042C>A variant in *MYRF* gene, consistent with the patient's presentation of cardiac-urogenital syndrome.

**Case Report:** The patient presented is a female born at 38 weeks, to a primigravid mother, with hypoplastic left heart syndrome (HLHS) diagnosed prenatally at 20 weeks gestation. Postnatally, she had findings consistent with hypoplastic right lung secondary to congenital diaphragmatic hernia (CDH). She was initially placed on hospice care and discharged home at 4 days of age, then transferred to our facility at 10 days of age. Physical exam was unremarkable. Brain MRI, newborn screen, karyotype and microarray were normal. Given multisystem involvement, rWGS was ordered, which was significant for a de novo, likely pathogenic, heterozygous c.2042C>A (p.Ala681Asp) variant in the myelin regulatory factor (*MYRF*) gene.

**Discussion:** The *MYRF* gene encodes a precursor of the transcription factor which mediates autocatalytic cleavage of myelin regulatory factor, leading to activation of the transcription of central nervous system myelin genes. Variants in the *MYRF* gene lead to multisystem involvement including the cardiac, pulmonary and urogenital systems, namely cardiac-urogenital syndrome. With congenital heart disease being linked to many syndromes as in this case, to suspect an underlying genetic defect in the setting of negative microarray and karyotype is not unfounded. Further pursuit with rWGS may be of benefit when a unifying diagnosis is suspected. The utilization of rWGS earlier in the diagnosis process of a multisystem disease, as opposed to after non-diagnostic subsequent serial testing and panels, may provide a potential cost and time-saving alternative for early treatment modalities including appropriate genetic counseling and management of care.

**Conclusion:** The utilization of rWGS can be of benefit when presentation does not readily conform to a specific syndrome or disease but is suggestive of an underlying genetic etiology.

## PgmNr 2526: Pathogenic variants in 77 individuals with Coffin-Siris syndrome.

Coffin-Siris syndrome (CSS, MIM#135900) is a congenital disorder characterized by coarse facial features, intellectual disability, and hypoplasia of fifth fingers and nails. Pathogenic variants were found in genes encoding BRG1- or HBRM-associated factors (BAF) complex. To date, more than 120 patients with pathogenic variants in 9 BAF-related genes have been reported. We previously reported 71 patients of whom 39 had pathogenic variants. We newly recruited 182 CSS-suspected patients. In 182 patients together with previously unresolved 32 patients, we found 77 pathogenic variants in 77 patients. Pathogenic variants in *ARID1B*, *SMARCB1*, *SMARCA4*, *ARID1A*, *SOX11*, *SMARCE1* and *PHF6* were found in 47, 8, 7, 6, 4, 1 and 1 patients, respectively. In addition, pathogenic CNVs including duplication of *SMARCA2* were found in 3 patients. No novel genes with pathogenic variants have been identified. Of note, we first found a partial deletion of *SMARCB1* in a CSS patient.

SouthSeq is a Clinical Sequencing Evidence-Generating Research (CSER2) effort to perform genome sequencing (GS) for infants with congenital anomalies or other signs of a genetic disorder. We aim to provide genomic testing across rural/minority populations that are historically under-represented in clinical and genomic research. Recruitment sites are located at hospitals in Louisiana, Mississippi and Alabama. The primary goals are to provide early diagnoses, demonstrate the utility of GS as a frontline test with potential to improve outcomes, and equip non-genetics providers to return GS results.

Sequencing and analysis of the infant's DNA is conducted at HudsonAlpha. When genetic variation associated with the child's symptoms is identified, clinical Sanger confirmation of the variant in the child and available parental DNA is conducted to determine inheritance. Also, families have the option to receive pathogenic/likely pathogenic (P/LP) secondary findings, which focus on medically actionable genes.

To date, 106 newborns have received sequencing and analysis. The average age of enrolled newborns is 39 days and 57% are male. 50% of enrollees are from minority populations. 60% of newborns were enrolled along with both biological parents. Genetic variation associated or potentially linked to the congenital phenotype has been observed in 49 newborns (46%); 35 newborns have received a result that is likely diagnostic (33%), 26 of which harbor variation in an autosomal dominant disease. Notably, four babies harbored variation in *CHD7* associated with CHARGE syndrome. The remaining nine likely diagnostic cases have recessive disease. Fourteen infants harbored variants leading to uncertain diagnosis (13%). Interestingly, we detected heterozygous genetic variation in recessive disease genes (*PALB2*, *TMCO1*, *TAPT1*, *MUT*, *ATPAF2*, and *PMM2*) in five newborns in which their phenotypes match well with those previously associated with the gene; however, no variation in the other allele could be identified. Eighty-eight percent of families elected to receive secondary findings. Three families (1.9%) received P/LP variation across four genes, including *APOB*, *MSH6*, *ACTC1*, and *LDLR*.

Preliminary results suggest that we have successfully deployed GS in NICU settings to obtain early genetic diagnosis for babies born with multiple congenital anomalies. We hope and expect that early genetic diagnosis will improve long-term outcomes for newborns with rare disease.

## PgmNr 2528: CNVs as genetic modifiers for congenital heart disease in a Brazilian 22q11.2 deletion syndrome cohort.

---

The clinical heterogeneity found in patients with the 22q11.2 deletion syndrome is not directly correlated to the different classes of deletion sizes related to this locus (3 Mb, 1.5 Mb and atypical deletions). Congenital heart disease represents one of the most clinically relevant phenotypes and the etiology of its variability among patients is not fully understood. Although the dose-sensitive genes mapped in the deleted region are the most important candidates for the phenotype, it has been suggested that more complex molecular mechanisms are involved in the phenotypic variability of the syndrome, including variants in the 22q11.2 intact region and genetic modifiers in other regions of the genome, i.e. structural and single nucleotide variants. Previous work in the literature has shown that both rare and common copy number variants (CNVs), outside of the 22q11.2 deleted region, could play a role in this variability. Even though some candidate genes and regions have been described as modifiers for the cardiac phenotype, they account for only a small proportion of this incomplete penetrance. This suggests that existence of other modifiers for this condition and, therefore, studies in new cohorts are important to identify them. To identify new CNVs modifiers of the cardiac phenotype, in this study, we generated SNP-array data from 215 individuals, being 99 22q11.2 deletion patients (65% with congenital heart disease and 35% with normal cardiac phenotype) and 116 controls using the CytoScan HD platform (Affymetrix). Modifying CNVs, outside of the 22q11.2 region, were detected using two different tools (PennCNV and CNV Workshop). Only the CNVs detected by both algorithms were considered for subsequent analysis. The genetic content of the CNVs revealed candidate genes that could be associated with the risk or protection for cardiac malformations in the patients, potentially acting as genetic modifiers for congenital heart disease in the 22q11.2 deletion. To our knowledge, this is the first comprehensive study in a Brazilian 22q11.2 deletion syndrome cohort. This study will leverage valuable knowledge for the better understanding of the role of genetic modifiers involved in the expressivity of cardiac alterations in the 22q11.2 deletion syndrome.

---

Genome analyses that generate very long haplotypes may facilitate diagnostic testing, particularly through the detection of structural variants. In this study, we probed the ability of *de novo* genome assemblies to improve identification of genetic lesions responsible for undiagnosed conditions. We hypothesized that a single genetic test could detect all types of genetic variants, including coding, noncoding, and structural variants. We used a hybrid linked read/optical mapping approach on undiagnosed cases, using a trio design. Potential diagnostic candidate variants were verified using secondary testing and reviewed by a multidisciplinary team. Clinically significant structural rearrangement and copy number variants were detected, and we were able to determine novel phasing data that discerns allele-specific mutations. We conclude that *de novo* genome assemblies can provide detailed diagnostic information beyond that provided by typical clinical sequencing technologies.

## PgmNr 2530: Diagnostic yield of array-CGH in Colombian patients: Beyond the American College of Medical Genetics recommendations.

### Authors:

**Introduction:** Array-based comparative genomic hybridization (aCGH) is a method for high-resolution evaluation of chromosomal copy number variants (CNVs). In the clinical setting, the American College of Medical Genetics (ACMG) recommends aCGH as a first-tier test in patients with global development delay (DD), intellectual disability (ID), autism spectrum disorders (ASD), and congenital malformations (CM). This study evaluated the diagnostic yield of aCGH in a group of Colombian patients in relation to the ACMG indications. **Methods:** A retrospective study of postnatal aCGH cases evaluated in a Colombian genetic laboratory from April 2017 to March 2019 was performed. Clinical significance of CNVs was determined using open access databases (DGV, Decipher, SFARI, ClinGen). A medical record review was conducted to collect clinical patient's data. Frequency and clinical correlation analysis were carried out. **Results:** Of the 606 included patients (61,6% male, 38,4% female) 93,8% had one or more of the ACMG recommendations, being CM associated to DD/ID (41,2%) and CM only (23,5%), the most common. In the studied population, 124 pathogenic variants were identified in 106 patients (17,5%): 18,1% pathogenic variants among patients with one or more ACMG criteria (n=569) vs 8,1% within patients without ACMG indications (n=37). Interestingly, in this last group, 3,4% had short stature and/or epilepsy as a medical reason for aCGH, which showed a diagnostic yield of 17% and 24%, respectively, when associated to an ACMG recommendation. In patients with ASD, we found a 6% diagnostic performance, similarly to the 7-9% previously described. Among pathogenic variants, 69,4% were deletions and 30,6% duplications, contrary to VUS where 34,1% were deletions and 65,9% duplications, suggesting that deletions have a stronger and better studied deleterious effect than duplications. Most frequently affected chromosomes were 1, 7, 17, 22 and X, corresponding to the main known chromosomal syndromes (e.g. del-22q11). **Conclusions:** The aCGH diagnostic yield was 17,5% in this study, similar to the 18% previously reported. Patients following ACMG recommendations have a higher probability to have pathogenic findings than patients without any of those indications. Based on the high yield identified in epilepsy and short stature, we recommend that aCGH should be also considered as a first-tier test for patients with these clinical findings.

## PgmNr 2531: Importance of cytogenomic investigation of pigmentary mosaicism associated a global developmental delay in patients with blood karyotype normal result.

---

Pigmentary mosaicism is associated with different cutaneous patterns of pigmentation in skin cells. Most of the cases present additional extracutaneous abnormalities including global developmental delay usually affecting the central nervous system and/or the musculoskeletal system. Usually, patients with those clinical manifestations begin the genetic investigation using peripheral blood karyotype. But recent studies showed that despite a karyotype from peripheral blood without alterations, genetic investigation in other tissues, as fibroblasts and saliva, may demonstrate a pigmentary mosaicism that explains the phenotype. We report four patients with global developmental delay and hyperchromic and/or hypochromic cutaneous spots. Cytogenetic analysis was performed in fibroblasts obtained from spots and peripheral blood. All patients analyzed showed normal karyotyping results from peripheral blood, but presented mosaicism in skin fibroblasts, either in hyperchromic and/or hypochromic cutaneous spots. G-banding karyotype analysis revealed one patient with 12 trisomy mosaicism in hypochromic spots (46,XX[36]/47,XX,+12[14]) and in hyperchromic spots (46,XX[34]/47,XX,+12[16]); one with 8 trisomy (47,XY,+8[25]) in all spots; one with triploidy (69,XXX[20]) in all spots; one with Mosaic Variegated Aneuploidy Syndrome (46,XY[33]/random losses[9]/hyperdiploidies[3]/premature separation of chromatids[4]/47,XY,+7[1]); and one case of hermaphroditism in a male patient with (46,XX[15]) in all spots. Array in the DNA extracted from skin fibroblasts, peripheral blood and saliva may reveal if those patients present a genomic mosaicism besides the chromosomal mosaicism present in the cutaneous spots. Our results highlight that although mosaicism is a relatively frequent phenomenon in the population it is not usually detected in peripheral blood but in other tissues. The cytogenomic investigation in different tissues for patients with global developmental delay and cutaneous spots is essential since it has allowed conclusive diagnosis as well as genetic counseling for the families.

## PgmNr 2532: High usability of NGS diagnostic in Slovenian children with neurodevelopmental disorders.

---

### Introduction:

Since the implementation of molecular karyotyping in diagnostics of neurodevelopmental disorders (NDDs), the understanding of the genetic causes of these diseases has significantly improved. However, with the introduction of the Next Generation Sequencing (NGS), the setting of the genotype-phenotype correlations has become even more straightforward. By determining causative mutations in individual genes, it enabled us to understand the role of individual genes in the aetiology of the disease, and significantly increased the diagnostic yield for genetic diagnostic of NDDs in Slovenian children.

### Methods:

In this study, we present a small series of paediatric patients with various NDDs where molecular karyotyping as the first-tier diagnostic test in our laboratory did not show the presence of microdeletion or microduplication, which could explain the patients' clinical picture. By using the panel sequencing of 4813 genes (TruSight One Illumina Kit) and focusing on phenotype driven analysis, we were able to identify the genetic origin of the disorder (pathogenic Single Nucleotide Variant – pSNV) in 29% (N 13/45) of screened patients. In 24% (N 11/45) of patients, a SNV classified as variant of unknown significance (VOUS) has been determined within the disease-associated genes.

### Discussion:

Although a small series of Slovenian paediatric patients were analysed using target NGS sequencing, our study illustrates the high usability of this method in diagnostic of NDDs. With phenotype-genotype driven analysis, we were able to identify rare and clinically poorly defined syndromes in previously undiagnosed patients. Among them, disorders such as Kabuki and Noonan syndrome, Menkes disease, mutations in *IQSEC2* gene causing the Rett-like phenotype etc. were identified. A high percent of pSNV are also partly due to the selection of suitable patients for NGS testing based on their good clinical characterization. Our study confirmed a high efficiency of NGS in diagnostic of NDDs and enabled the diagnosis of rarely described cases which will be presented.

---

FSHD has a prevalence of 1:8,000-20,000 in the general population and is recognized as one of the most common forms of neuromuscular disorders. FSHD is primarily (95% of cases) caused by a deletion of the D4Z4 macrosatellite repeats (each unit 3.3 kb long) on chromosome 4p35, resulting in 1-10 D4Z4 repeats (healthy range 11-100). The D4Z4 region in healthy individuals has been shown to be transcriptionally repressed. Studies have shown the region becomes transcriptionally de-repressed and DNA demethylated when the number of D4Z4 repeats is shortened to 10 units or less. Current standard genetic testing for FSHD is to detect contracted D4Z4 array using Pulsed-Field Gel Electrophoresis (PFGE) in combination with Southern Blotting, which is time consuming, labor intensive and in some cases not precise enough for FSHD diagnosis. To address these diagnostic limitations, we used a novel optical genome mapping approach that combines both genetic and epigenetic variations in the telomeric region of chromosome 4q35 for FSHD diagnosis. Optical mapping captures a pattern of fluorescent labels in long DNA molecules (>150kb), in nanochannel arrays for *de novo* genome assembly and structural variant (SV) calling. This technology offers substantial advantages over the current clinical diagnostic practice as it has been successfully used for identification of SVs in Duchenne muscular dystrophy and more recently in FSHD cases. However, these tests were focused only on genotypic diagnosis of FSHD based on D4Z4 repeat array. Here, we incorporated dual high molecular weight DNA labeling for both assessment of D4Z4 repeat array as well as its methylome based epigenetic profiling. In the protocol, long DNA molecules are first nicked/labeled with BspQI/BssSI endonucleases and labeled with red fluorescent nucleotides. Second, the same DNA molecules undergo treatment with M.TaqI methyltransferase that attaches green fluorescent cofactor onto non-methylated CpGs in ATCG sequences throughout the genome. Imaging and analysis of the sample library revealed the methylation pattern as well as the number of D4Z4 repeat units. We successfully identified the molecular diagnosis in all tested cases (i.e. constriction of D4Z4 array) and show that dually labeled optical mapping for genetic/epigenetic markers in FSHD provides the underlying disease-causing mechanistic information that can be used to identify disease onset, severity and prognosis.

## PgmNr 2534: Toward comprehensive interpretation of *RYR1* variants associated with malignant hyperthermia susceptibility.

*RYR1* is one of the 59 genes recommended by the American College of Medical Genetics and Genomics (ACMG) for opportunistic screening, it is recommended that only known pathogenic (KP) variants be returned. Nearly all malignant hyperthermia (MH) associated variants are rare amino acid substitutions making interpretation challenging. To address this challenge, we set out to work toward a complete interpretation of known *RYR1* variants, which could be made available to the genetics community. We set out to do this through review by a ClinGen expert panel including medical geneticists, clinical molecular geneticists, physiologists, and anesthesiologists. Variants associated with malignant hyperthermia susceptibility (MHS), and other *RYR1*-associated dominant phenotypes were identified from the European Malignant Hyperthermia Group's (EMHG) list of "diagnostic mutations", the Human Gene Mutation Database (DM), GeneReviews, and ClinVar (likely pathogenic/pathogenic), (n=302). The ACMG-AMP criteria for variant interpretation were modified based on the biology and genetics of *RYR1* and MHS. Proposed *RYR1* specific rules were applied to 48 variants from the EMHG list of "diagnostic mutations". Resulting classifications were discussed by the *RYR1*-MHS expert panel to reach a consensus classification and refine the rules. Further revision of *RYR1*-specific rules included reducing PM2 to supporting and re-evaluating PS4, BA1, and BS1. The prevalence of MHS has been estimated to be 1 in 2-3,000 based on genetic studies. Using allele counts in the non-Finnish European (NFE) population in gnomAD for EMHG variants assessed as pathogenic (30 variants, total of 54 alleles) or likely pathogenic (15 variants, total of 22 alleles) a prevalence of MHS due to variants in *RYR1* in the NFE population was predicted to be 1 in 849 (maf=0.0007, 95% CI). As only EMHG variants were included, we considered this a minimum prevalence, we therefore set BA1 to be twice this value at 0.0014. The maximum reported allele contribution for any single allele is 21%, BS1 was set to 0.0003. Finalized assessments will be made available to the genetics community through ClinVar. Access to variants curated by this process will allow more efficient review of secondary variants and support improved interpretation of *RYR1*/MHS

genomic testing results and improve the ability to implement opportunistic screening for *RYR1*.

## **PgmNr 2535: High throughput analysis of tandem repeat contraction associated with facioscapulohumeral muscular dystrophy (FSHD) by optical mapping.**

### **Authors:**

J. Wang; E.T. Lam; A.W.C. Pang; T. Wang; H.B. Sadowski; A.R. Hastie; M. Borodkin

---

Facioscapulohumeral Muscular Dystrophy (FSHD) is one of the most common forms of muscular dystrophy. FSHD symptoms include progressive muscular degeneration, weakness, and atrophy. A genetic disease, FSHD could be inherited and could impact multiple members of a family. Non-inherited FSHD also occurs. Genetic testing is the most reliable way to confirm a diagnosis. Contraction of D4Z4, a tandem repeat region on chromosome 4q35, is diagnostic, when present on a permissive haplotype, for FSHD and can be assayed for by Southern blot.

We have developed a new workflow based on optical mapping on the Bionano Genomics Saphyr platform, which offers several advantages. Based on specific labeling and mapping of ultra-high molecular weight DNA in nanochannel arrays, optical mapping provides a higher resolution determination of D4Z4 and other tandem repeat expansions and contractions, even those which span more than 100 kilobase pairs. Analyses showed that molecules could span and be uniquely mapped to this region, and the repeat region could be accurately sized while also defining permissive and non-permissive alleles (4qA and 4qB). Because of the single-molecule nature of the platform, it is even possible to detect and quantify mosaicism in the repeat length. Also, the data could help resolve borderline or indeterminate Southern blot results. To better define outliers, we have developed a database of typical D4Z4 lengths based on control samples. The data can be imported into a graphical user interface tool for visualization and curation.

Bionano offers sample preparation, DNA imaging and genomic data analysis technologies combined into one streamlined workflow that enables high-throughput analysis of tandem repeat regions of interest. Together, these components allows for efficient analysis of diseases associated with repeat expansion and contraction.

## PgmNr 2537: Whole exome study of early onset Alzheimer's disease.

**Authors:**

J.H. Kim

[View Session](#) [Add to Schedule](#)**Affiliation:** Ilsan hospital, Koyang, KyungKi, Select a Country

---

**Background :** Alzheimer disease (AD) is the most common cause of dementia and heritability is about 70%. The development of genetic research techniques has revealed a number of related genes, but it still cannot explain all of the heritability of AD. Early onset AD (EOAD) accounts for about 5% of all AD patients. The heritability of EOAD is as much as 100%. Thus, genetic studies for EOAD can reveal important genetic factors for AD.

**Methods :** DNA was extracted from the blood of 17 EOAD or mild cognitive impairment with age < 65. Exome sequencing was performed in TheragenEtex Bio Institute. The data was analyzed by GATK version 3.8. We also analyzed copy number variations (CNV) using xhmm. The results were filtered out according to mutation frequencies reported in gnomAD. Gene functions were predicted by SNPEFF and ANNOVAR.

**Results :** Among genes related with AD, two nonsynonymous mutations in *ABCA7* (Glu316Lys and Pro1396Leu), one in *SORL1* (Ile2033Leu) and one in *TREM2* (Ser183Cys) were found. As far as genes related with frontotemporal lobar degeneration, mutations in *TBK1* (Arg724Cys) and *GRN* (Asn537Lys) were found. We checked CNV of genes related with cognitive impairments. Duplications or deletion of *ABCD1* gene causing adrenoleukodystrophy were found. Duplication was found in the *MECP2* gene causing angelman syndrome.

**Conclusions :** There were no *APP*, *PSEN1* or *PSEN2* mutations in WES in 17 EOAD patients. For *ABCA7*, *SORL1*, *TREM2*, *TBK1*, and *GRN* mutations found in patients, further functional studies are needed to reveal their association with disease. In addition, large-scale studies are required for the CNVs of the *ABCD1* and *MECP2* genes.

## PgmNr 2538: Revealing repeats: Toward a PCR-based test for autosomal dominant spinocerebellar ataxias 1, 2, 3, 6, & 7.

### Authors:

---

Spinocerebellar ataxias (SCAs) belong to a family of neurological diseases that lead to progressive cerebellar atrophy and eventual loss of peripheral motor functions. Of the roughly 40 hereditary SCAs described to date, the subtypes SCA1 [MIM 164400], SCA2 [MIM 183090], Machado-Joseph disease/SCA3 [MIM 109150], SCA6 [MIM 183086], and SCA7 [MIM 164500] are the most common autosomal dominant ataxias worldwide and are caused by pathogenic expansion of exonic CAG repeats in SCA-associated genes. Symptoms of these five subtypes are clinically heterogeneous, and de novo mutations are known to arise, so molecular genetic testing is required for differentiation. Here, we describe the development of a test for the quantification of CAG repeats in the SCA-associated genes *ATAXIN1* (SCA1), *ATAXIN2* (SCA2), *ATAXIN3* (SCA3), *CACNA1A* (SCA6), and *ATAXIN7* (SCA7). Quantification of CAG repeats was performed using a chimeric triplet repeat-primed PCR method, which was originally developed at ARUP Laboratories for detection of repeat expansions in Fragile X, Huntington disease, and myotonic dystrophy-1. Forward primers were designed with HEX, NED, and FAM fluorescent dyes to facilitate multiplexing, and reverse primers were designed with a CAG<sub>n</sub> repeat region and flanking region. The amplicons were separated by capillary electrophoresis, and the characteristic ladder of peaks counted to determine the number of CAG repeats in each allele. Repeats in all five SCA-associated genes can be quantified in just two multiplex PCR reactions, an improvement over previously published methods. Our method also allows detection of CAT interruptions in *ATAXIN1* and CAA interruptions in *ATAXIN2*, both of which have clinical utility for patients. We have detected CAG expansions with as many as 60 (SCA1), 44 (SCA2), 72 (SCA3), 22 (SCA6), and 62 repeats (SCA7) in patient samples, but our method is expected to reveal even larger pathogenic expansions. To verify correct repeat allele sizing, deidentified normal patient samples with homozygous alleles were confirmed by Sanger sequencing. Nine samples from the Coriell Institute and three CAP proficiency testing samples were also tested to verify correct repeat allele sizing. These results indicate that the triplet repeat-primed PCR technique is a robust and flexible method that allows for accurate quantification of CAG repeats and CAA/CAT interruptions in SCA-associated genes.

## **PgmNr 2539: Pulse-field capillary electrophoresis of repeat-primed PCR amplicons for analysis of large repeat in spinocerebellar ataxia type 10.**

### **Authors:**

---

Large expansions of microsatellite DNA cause several neurological diseases. In Spinocerebellar ataxia type 10 (SCA10), the repeat interruptions change disease phenotype; an (ATTCC)<sub>n</sub> or a (ATCCT)<sub>n</sub>/(ATCCC)<sub>n</sub> interruption within the (ATTCT)<sub>n</sub> repeat is associated with the robust phenotype of ataxia and epilepsy while pure (ATTCT)<sub>n</sub> may have reduced penetrance. Large repeat expansions of SCA10, and many other microsatellite expansions, can exceed 10,000 base pairs in size. Conventional next generation sequencing (NGS) technologies are ineffective in determining internal sequence contents or size of these expanded repeats. Using repeat primed PCR (RP-PCR) in conjunction with a high-sensitivity pulsed-field capillary electrophoresis fragment analyzer (FEMTO-Pulse, Agilent, Santa Clara, CA), we successfully determined sequence content of large expansion repeats in genomic DNA of SCA10 patients and transformed yeast artificial chromosomes containing SCA10 repeats. This RP-FEMTO is a simple and economical methodology which could complement emerging NGS for very long sequence reads such as SMRT sequencing (PACBio) and Nanopore sequencing technologies.

## PgmNr 2540: Molecular testing of ataxia-related conditions: Experience from the University of Chicago Genetic Services Laboratories.

Ataxias represent a clinically and genetically complex group of neurological disorders and may be hereditary or sporadic. The ataxia symptom can be isolated or part of a multisystemic neurological disorder, presenting at ages ranging from infancy to adulthood, and can be dominant, recessive, X-linked or mitochondrial. Genetic testing for hereditary ataxias remains challenging mostly due to the significant clinical overlap and genetic heterogeneity with more than 500 genes reported to be associated with ataxia or ataxia-like presentation. Targeted exome sequencing is regarded as a powerful diagnostic tool for heterogeneous neurological disorders such as ataxia, but limited in its ability to detect repeat expansions which are estimated to account for over 50% of dominant hereditary ataxias. In 2014, we developed a targeted exome panel consisting of a predefined and regularly updated set of genes known to be associated with ataxia and ataxia-related conditions. In 2017, we implemented repeat expansion testing to allow for more comprehensive testing and enhancement of our diagnostic yield. Here, we present the results of 411 patients with ataxia and ataxia-like conditions, referred for genetic testing between April 2014 and May 2019. Overall, 53% of patients were female, 47% were male, and patient age ranged from 1 to 88 years. Of the 411, 68% (279) were referred for exome sequencing, 25% (102) for repeat expansion testing, and 7% (30) for both. Clearly pathogenic and suspected diagnostic variants were identified in 167 patients (41%), an impressive yield given the heterogeneity of our cohort. A total of 80 different genes were implicated in our cohort. 14 of the 167 patients had pathogenic repeat expansions in either spinocerebellar ataxia genes or the *FXN* gene. The 7 most common genes with abnormalities detected were *CACNA1A* (14), *SPG7* (13), *SYNE1* (10), *ADCK3* (6), *ATXN2* (6), and *ATP1A3* (5). Together, these genes accounted for 38% of positive cases.

With new gene discoveries and consequent updates to our exome panel, re-analysis of negative cases can be performed and was instrumental in the identification of pathogenic variants in *EBF3* in three patients with early onset ataxia. The ongoing discovery of novel gene-disease associations are expected to increase the diagnostic yield of targeted clinical exomes. Our lab is in the process of updating our bioinformatic pipeline to implement an automated reanalysis process for negative ataxia exomes.

## **PgmNr 2541: Phenotype influences the likelihood of a diagnostic result in a sequencing test of 2,300+ genes associated with autism spectrum disorders and/or intellectual disability.**

### **Authors:**

T. Brandt; A. Shanmugham; J. Scuffins; J. Juusola; D. McKnight

[View Session](#) [Add to Schedule](#)

**Affiliation:** Gene Dx, Gaithersburg, Maryland.

---

Autism spectrum disorders (ASD) and intellectual disability (ID) are common and frequently co-morbid disorders with a high degree of genetic heterogeneity. Exome sequencing is reported to have a positive diagnostic result (PDR) of ~14-33% for ASD/ID cohorts. However, studies demonstrating the utility of genetic testing for subgroups of patients within this wide phenotypic spectrum are rare. The objective of this study was to determine the utility of genetic testing for patients with ASD and/or ID. This is a retrospective study of genetic testing results of 2,497 patients with ASD/ID/developmental delay referred to our clinical laboratory. For each of these patients, 2,300+ genes associated with ASD and/or ID were sequenced and analyzed. The PDR for all cases was ~16%; however, the PDR varied depending on the clinical information provided. Patients with ID and multiple additional malformations or other significant medical issues (e.g. dysmorphic features, seizures, hypotonia), but not autistic features, had the highest PDR (~36%, 46/128), whereas patients with autistic features and multiple additional medical issues in the absence of ID had a significantly lower PDR (~15%, 57/386,  $p < 0.0001$ ). Patients with isolated ID or ASD had a PDR of ~23% (10/44) and ~4% (19/492), respectively. The PDR for patients <2 years old with developmental delays was ~27% (27/99). High genetic heterogeneity was observed among positive cases; however, 22 different genes were responsible for >40% of positive cases. In summary, genetic testing for patients with ID and additional major medical issues revealed a genetic etiology of disease in over one-third of cases. A genetic etiology was less likely to be identified in patients with ASD. The presence of additional phenotypic findings did correlate with an increased PDR. Therefore, this study supports the hypothesis that monogenic etiologies are relatively uncommon findings in patients with isolated ASD. In addition, although there is vast genetic heterogeneity for ID and ASD, findings in just over 20 genes accounted for a significant portion of positive cases, suggesting a minimum number of genes that should be tested for these patients.

## PgmNr 2542: Ten years of experience in molecular genetic diagnostics of Rett syndrome in Bulgaria.

---

Rett syndrome (RTT) is caused by pathogenic variants in the methyl-CpG-binding protein 2 (*MECP2*) gene. The *MECP2* gene has some unique characteristics: 1) it is mainly affected by de novo pathogenic variants, due to recurrent independent mutational events in a defined "hot spot" regions or positions; 2) complex mutational events along a single allele are frequently found in this gene; 3) most pathogenic variants arise on paternal X chromosome. The recurrent point mutations involve mainly CpG dinucleotides, where C>T transitions are explained by methylation-mediated deamination. The complex mutational events might be explained by the genomic architecture of the region involving the *MECP2* gene. The finding that most spontaneous mutations arise on paternal X-chromosome supports the higher contribution of replication-mediated mechanism of mutagenesis.

Here we present our ten years of experience in the molecular genetic diagnostics of RTT. Altogether 131 unrelated families with clinical suspicion of RTT were screened for mutations in the *MECP2* gene by Sanger sequencing, MLPA or NGS. The diagnosis was confirmed in 55 families (42%). The detected pathogenic variants were distributed in the following categories: 46 point mutations, small deletions, small duplications; 1 indel and 3 large deletions within *MECP2* gene; 1 large duplication covering *MECP2* gene; 1 Xp deletion involving the genes *ARX* and *CDKL5*. From the *MECP2* negative cohort, 2 patients turned out to carry pathogenic variants in the *CDKL5* gene and 1 patient was positive for pathogenic variant in the *FOXG1* gene. A male patient with RTT-like features was screened by whole exome sequencing and pathogenic variant in the *MECP2* gene was found; inherited from asymptomatic mother. A large pedigree with more than 5 affected males (severe mentally retarded) turned out to be positive for large duplication, covering the genes *SLC6A8*, *L1CAM*, *MECP2*, *TKTL1*, *FLNA*, *GDI1*. Although the clinical diagnosis of RTT is rather uniform, the genetic verification of RTT and RTT-like cases (both female and male) requires different diagnostic approaches due to the large spectrum of pathogenic variants associated with the disease.

## PgmNr 2543: Design and validation of a single customized next-generation sequencing capture library for neurodevelopmental, cardiac, immune, and inflammatory bowel diseases.

Edelman<sup>1,2</sup>; F. Suer<sup>1,2</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Sema4, a Mount Sinai venture, Stamford, CT, 06902; 2) Department of Genetic and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY, 10029

**Background:** Cost-effectiveness of next-generation sequencing (NGS) libraries has increased as sequencing costs continue to decline. Neurodevelopmental, cardiac and immunodeficiency diseases share overlapping genes and phenotypes that facilitate consolidation into a single sequencing library. Locus heterogeneity and phenotypic overlap make NGS ideal for diagnostic testing of such disorders. Targeted NGS captures relevant coding, intergenic, intronic and problematic regions to increase diagnostic yield. Genomic diagnosis enables personalized care.

**Methods/Results:** Primary literature, public database, expert opinion and commercially-available panel review provided potential genes. These genes and HGMD known/potential disease-causing mutations/phenotypes were split into subgroups based on gene/mutation/HPO relationships. Genes, source lists and mutations were then consolidated into preliminary lists with total and filtered P/LP variants, variant type and detectability by NGS, and CNV detection availability. Genes were computationally scored for actionability by tallying filtered variants and commercial availability. These data and published rules for clinical utility assessment guided laboratory directors and fellows in manually scoring the preliminary gene list; 885 had sufficient clinical actionability.

Agilent SureSelectQXT libraries were sequenced on Illumina NovaSeq 6000 instruments. Saliva, peripheral blood, prenatal, and Coriell cell line samples (576) were assessed for performance. Reproducibility, intra and inter-run genotyping concordance were >99%. All known P/LP small insertion/deletions and single nucleotide variants (SNVs) in 115 samples were successfully detected. The estimated analytical test sensitivity was 99% for SNVs and 95% for small insertions/deletions; the overall detection rate was >97%. CNV detection using an eXome Hidden Markov Model (XHMM) with a baseline of 346 negative samples was validated with 174 positive (variants ≥ two probes) samples. The sensitivity of XHMM was >94%, specificity was >99%, and accuracy was >99%.

**Conclusion:** Test orders change frequently during the diagnostic odyssey. A single panel library allows pivoting on changed orders. A larger library broadens the sensitivity, specificity, and accuracy. As the number of genes increases in large diagnostic panels, addressing variants of uncertain clinical significance remains an important area of development that will benefit from public efforts such as ClinVar/ClinGen.

## PgmNr 2544: When less is more: A novel whole gene deletion of *DHX30* confers an apparent smaller-effect relative to typical missense, which results in NEDMIAL-associated phenotypes.

University Medical Center Hamburg-Eppendorf. Hamburg, Germany; 3) Dept. of Neurology, David Geffen School of Medicine, University of California Los Angeles; 4) Dept. of Physiology, David Geffen School of Medicine, University of California Los Angeles; 5) Dept. of Pediatrics, University of California San Francisco; 6) Dept. of Human Genetics, University of California Los Angeles; 7) UCLA Clinical Genomics Center, David Geffen School of Medicine, University of California Los Angeles

The RNA helicase *DHX30*, of the DExH-box protein family, is predicted to mediate ATP dependent unwinding of RNA secondary structure and is highly expressed during brain neurogenesis. Five unique *de novo* missense *DHX30* variants have been described in patients with Neurodevelopmental Disorder with Severe Motor Impairment and Absent Language (NEDMIAL syndrome, MIM: 617804), conferring impaired ATPase activity or RNA binding, implicating the helicase domain of its encoded protein, suggesting that accumulated mutant protein leads to a global decrease in protein synthesis (Lessel et al 2017). However, the consequences of *DHX30* deletion in humans are unknown. Chromosomal microarray analysis detected a *de novo* 1.1 Mb loss of 3p21.31 in a 3-year-old with hypotonia, developmental delay (DD), and speech delay with motor impairment, experiencing difficulty climbing stairs, and falling frequently. Brain MRI detected Chiari malformation and hypomyelination. Of the deleted genes, *DHX30* was associated with NEDMIAL, whose phenotype partially overlapped with our patient's, and was predicted to be dosage-sensitive. This is the first report of full gene deletion and a milder presentation compared to others with missense variants in *DHX30*.

In parallel, clinical exome sequencing found novel missense *DHX30* variants in two patients with intellectual disability, DD and NEDMIAL spectrum. Both, a *de novo* p.R782Q and p.T739A localize to the helicase domain. 3D-Protein modeling for both supports helicase localization, predicting ATPase deficiency. Functional analysis of the missense mutations will be presented. Helicase-inactivating missense variants may exert a spectrum of dominant negative phenotypes and could suggest that over-expression of the mutant helicase protein potentially interferes with normal RNA metabolism, and may be one way in which dominant-negative missense variants may lead to a greater defect compared to that of a heterozygous deletion allele with  $\leq 50\%$  protein activity. We report 1) the first complete null *DHX30* allele conferring a milder phenotype than the severity associated with missense SNVs in patients who are non-verbal have no independent walking, and present with delayed myelination with cerebellar or cerebral atrophy, and dilated ventricles; 2) Two novel missense

variants associated with NEDMIAL. All three patients add to the limited phenotypes of patients with NEDMIAL and spectrum, guiding clinical interpretation for these and other novel *DHX30* variants.

## PgmNr 2545: Age-related molecular diagnosis of 539 patients with hereditary spastic paraplegia using next generation sequencing gene panel.

### Authors:

H.Z. Elloumi; R. Brandon; T. Brandt

[View Session](#) [Add to Schedule](#)

**Affiliation:** GeneDx, Gaithersburg, MD

Hereditary spastic paraplegia (HSP) comprises a diverse group of neurodegenerative motor neuron disorders characterized by progressive lower limb spasticity and weakness. Age of onset can range from early childhood to late adulthood. The genetic basis of HSPs is heterogeneous.

We performed a retrospective study to evaluate the diagnostic yield of HSP genetic testing. Data represent an unselected cohort of 539 individuals sent to our clinical diagnostic laboratory for HSP genetic testing using a next-generation sequencing plus deletion/duplication analysis panel including up to 42 genes. The average age at testing was 39 y.o. (range 1-85).

We obtained a positive diagnostic rate (PDR) of ~24% (128/539). The PDR based on age at testing is as follows: 22% (38/172) for children (1-17 y.o.), 28% (40/142) for younger adults (18-50 y.o.), and 22% (50/225) for older adults (51-85 y.o.). Of positive findings, 73% were identified in genes associated with autosomal dominant disorders and 45% were found in the *SPAST* gene. Autosomal recessive (AR) disorders accounted for 24% of positive cases and X-linked disorders represented only 3%. It is interesting to note that *SPG7* mutations were the most frequent etiology of AR-HSP in our cohort (13/31), followed by *SPG11* (9/31). The most common molecular diagnoses in children were in the following genes (from most to least prevalent): *SPAST*, *ATL1*, and *KIF1A*. For younger adult patients, common causative genes were *SPAST*, *SPG11*, *SPG7*, and *KIF5A*. The most likely causative genes were *SPAST*, *SPG7*, *REEP1*, and *BSCL2* for adults age 51+. Other interesting age-related trends were observed. For instance, this panel only identified *ATL1*-related diagnoses in children (n=11), *SPG11* or *CYP7B1*-related diagnoses in younger adults (n=9 and 3, respectively), *BSCL2* positive cases in older adults (n=3), and *SPG7*-related diagnoses in adults (n=13). Diagnostic pathogenic/likely pathogenic variants in *SPAST*, *REEP1*, *KIF1A* and *KIF5A* were identified in all age groups.

Amongst diagnostic variants, missense variants were the most frequent (~43%), followed by Indels (~20%), copy number variations (CNVs) (~15%, with the vast majority involving *SPAST*), nonsense variants (~12%), and splice site variants (~9%).

In summary, this data showed the utility of genetic testing for HSP, a complex disorder with a challenging diagnosis, and how positive findings vary with patient age.

## PgmNr 2546: *SMN1* and *SMN2* copy number quantification using a novel digital PCR platform.

### Authors:

L. Jiang; M. Dueck; R. Lin; S. Gallagher; A. Zayac; P. Hung

[View Session](#) [Add to Schedule](#)

**Affiliation:** COMBiNATi, Burlingame, California.

---

Spinal muscular atrophy (SMA), a genetic neuromuscular disorder and the leading cause of infant mortality, is largely caused by the loss of the survival motor neuron gene 1 (*SMN1*). Survival motor neuron gene 2 (*SMN2*) has been found to produce partial function and can compensate for *SMN1* deletion. Accurate quantification of *SMN1* and *SMN2* copy numbers provides critical diagnostic and prognostic values for the disease. SMA has become an actionable disease with the advancement of treatments. Newborn screening of SMA is increasingly practiced in many states and other countries. Current screening methods are complex and time consuming. Here we present two duplex PCR assays capable of absolute quantification of *SMN1* and *SMN2* copy numbers on a novel digital PCR platform to meet the growing demand for SMA Newborn screening.

The duplex assays consist of *SMN1* or *SMN2* hydrolysis probe assay with a commercially available Rnase P TaqMan copy number reference assay. We simplified the assay workflow by eliminating the restriction digestion recommended for copy number assays. We also evaluated the assays using a DNA concentration (~2ng/ul) resembling newborn dried blood spots. Additionally, accuracy and repeatability studies were conducted on 10 human genomic DNA samples with characterized *SMN1/SMN2* copy numbers from the Coriell Institute Cell Repository. All the tests were conducted on a novel digital PCR platform with one-step walkaway workflow. Data were analyzed using platform-specific software that identifies positive dPCR partitions, applies Poisson Statistics for absolute quantification of copy numbers and can also display individual amplification curves to provide confidence in assay performance.

Both assays demonstrated accurate and consistent *SMN1/SMN2* quantification of all samples with a simple workflow and low DNA concentration. For *SMN1*, the assay correctly assessed the copy number of the 10 samples - zero (n=5), one (n=3), two copies (n=1) or three copies (n=1). For *SMN2*, the assay also exhibited robust performance for the 10 samples containing 2 zero copy, 1 one copy, 3 two copies, 3 three copies, and 1 five copies. *SMN1/SMN2* results were 100% consistent across 3 repeat experiments on the instrument. Additionally, the data were obtained in under 90 minutes.

We demonstrated two duplex SMA newborn screening assays that accurately and reliably quantify *SMN1* and *SMN2* copy numbers on a novel *digital PCR* within 90 minutes, *with a single-step and walkaway workflow*.

## PgmNr 2547: Full genome analysis for identification of single nucleotide and structural variants in genes that cause developmental delay.

---

Developmental delay caused by gene mutations are hard to identify due to phenotypic and genetic heterogeneity. While whole exome sequencing (WES) has been used to identify causal mutations, the majority of cases remain unsolved. In this study, we test the hypothesis that full genome analysis (phased whole genome sequencing with assembly based on linked-read sequencing and mapping technologies) of trios provides the best chance of identifying gene mutations, and especially structural variations, that cause developmental delay.

Eight trios with negative finding by WES were subjected to (1) whole genome sequenced (WGS) to 60X coverage on the 10x Genomics linked-read platform, and (2) mapped to 90X coverage on the Bionano Genomics optical mapping platform. The de novo, phased genome assemblies of the patient and his/her two biological parents were compared and the single nucleotide variants (SNVs) and structural variants (SVs), including de novo variants, were identified. After filtering out synonymous SNVs, and common SNVs/SVs against public databases, the remaining variants were further evaluated according to the three possible genetic models: autosomal recessive, autosomal dominant and X-linked recessive. In the autosomal dominant and X-linked recessive models, de novo variants were selected for careful analysis. In each instance, we examined genes affected by SNVs, SVs, or a combination of SNVs and SVs.

Candidate variants (both SNVs and SVs), predicted as deleterious by multiple tools in the web-based WANNONAR suite, were selected for genotype-phenotype correlation in consultation with the clinicians and a literature search of the candidate genes were performed. Three WES-negative cases that were successfully diagnosed by this full genome analysis approach will be presented.

## PgmNr 2548: Copy number variations contribute to neurodevelopmental disorders.

---

Copy Number Variants (CNVs) detection of by Chromosomal Microarray Analysis (CMA) testing is a powerful diagnostic tool is now well accepted as genetic diagnostic tests for various disorder including such as Developmental delay (DD), Intellectual disabilities(ID) and Autism Spectrum Disorders(ASD). CMA offers high resolution scan of whole genome which, significantly contribute to understand the etiology of these complex neurodevelopment impairments. Considering the detection efficiency of CMA and its impact on medical management, CMA is first-choice of test for in-depth analysis of children with these disorders.

In the present study, we have investigated 130 children (83 Males and 47 Females; Age ranges from: 2.0 yrs.-17yrs.) diagnosed with Developmental delay, Autism spectrum disorder or intellectual disabilities were recruited for the genetic analysis. The microarray platform utilized in this study was specifically designed to increase detection of CNVs in genomic regions of demonstrated relevance to DD/ID/ASD. Array CGH was performed on oligonucleotide microarray platform (G2565CA, Microarray Scanner System, Agilent (USA). Array data was analyzed using cytogenomics software (CytoGenomics v4.0.3, Agilent technologies).

CMA results revealed a total of 55 CNVs in 46 patients (35.38%). Among these, 32 (69.56%) signified as known diagnostic CNVs contributing to the clinical representation, 23 were non-diagnostic CNVs (variants of unknown significance (VOUS)). Fourteen patients (30%) with developmental delay showed 15 CNVs, 18 patients (40%) with intellectual disabilities showed 24 CNVs and 14 patients (30%) with Autism Spectrum Disorders (ASD) showed 16 CNVs. Imbalances of chromosome 2,15 and 22 were found to be most common. CNVs were detected more in males than females. The likelihood of an abnormal microarray results increased with the number of clinical abnormalities.

CMA has demonstrated great value in the clinical assessment of neurodevelopmental disorders. The optimized CMA platform can increase the diagnostic yield. Pathogenic findings give insights into the etiology of patients' neurodevelopmental conditions, and in many cases positively impact medical management decisions. The development of novel and accurate methods to interpret the potential pathogenicity of VOUS will further enable patients and their physicians to realize the maximum benefits of genetic testing for clinical care.

## PgmNr 2549: Utility of gene panel testing in children with seizure onset after 2 years of age: Results from a European and Middle Eastern epilepsy genetic testing program.

---

**Background:** Epilepsy is one of the most common childhood-onset neurological conditions with a genetic basis. Genetic diagnosis provides potential for etiologically-based management and treatment. Existing research has focused on early-onset (<2 years) epilepsies while data regarding later-onset epilepsies is limited. Program goals: Determine, in a selected pediatric epilepsy cohort, the overall and actionable molecular diagnostic (MDx) yield and the CLN2 disease MDx yield. CLN2 is a severe, rapidly progressive neurodegenerative disease with onset of seizures at/after 2 years and average age-of-diagnosis of 5 years.

**Methods:** Blueprint Genetics' next-generation sequencing (NGS)-based 283-gene epilepsy panel was used. Copy number variant (CNV) detection from NGS data was included. Variant interpretation was performed according to ACMG guidelines. Program results (Oct/2017-Nov/2018) are reported from 210 patients (Europe, Middle East) with inclusion criteria: Age 24-60 months, first seizure at/after 24 months, and at least one additional finding. The program was sponsored by BioMarin Pharmaceutical Inc.

**Results:** Median age-at-testing: 42 months; median age-of-first-seizure-onset: 30 months; average delay from first seizure to comprehensive genetic testing: 10.3 months. Genetic diagnosis was established in 42 patients; 20.0% MDx yield. CNVs were reported in 26.2% of diagnosed patients; 27.3% of CNVs identified were intragenic. MDx included 5 CLN2 (*TPP1* gene) diagnoses, 4 MECP2, 3 SCN1A, 3 Angelman syndrome, 2 each of CHD2, KCNA2, MFSD8, SCN2A and STXBP1.

**Conclusion:** This program demonstrates the clinical utility of a comprehensive epilepsy gene panel for patients with first seizures at/after 2 years for MDx of pediatric epilepsy and CLN2 disease to guide management and treatment.

## PgmNr 2550: Exome sequencing in neurogenetics solves challenging cases.

### Affiliations:

1) Inserm UMR1231 team GAD, University of Burgundy and Franche-Comté, F-21000 Dijon, France; 2) Genetics Center, FHU-TRANSLAD, Dijon Bourgogne University Hospital, F-21000 Dijon, France; 3) Neurology, Dijon Burgundy University Hospital, Dijon, Burgundy, France; 4) Functional Unity of innovative diagnosis for rare disease, Dijon Bourgogne University Hospital, F-21000 Dijon, France; 5) Service de Pathologies Inflammatoires du système nerveux central, Neurologie Général, Dijon University Hospital; 6) Dijon Stroke Registry, EA7460, Pathophysiology and Epidemiology of Cerebro-Cardiovascular Diseases (PEC2), University Hospital of Dijon, University of Burgundy, Dijon, France

Most neurogenetic pathologies share two major characteristics: first, within a given framework their clinical presentations are highly uniform and non-specific e.g. gait disorders and limb incoordination for cerebellar ataxias. Second, their molecular bases are quite vast with large genetic and multiple modes of inheritance, making them difficult for physicians to choose between countless syndromes and genes.

After years of clinical classifications, the last decades have been marked by the clinical implementation of massive parallel sequencing technologies including exome sequencing (ES). Its implementation in neurogenetics led to the discovery of numerous new genes, phenotypes expansion and markedly increased diagnostic yield.

We performed ES as a first- or second-tier test in a cohort of 52 patients with neurodegenerative diseases: 13 cerebellar ataxia, 12 neuromuscular disorders, 10 spinocerebellar ataxia, 8 spastic paraplegia, 2 movement disorders and 7 labelled “others” in regard of complex clinical features. This study revealed a 42% overall diagnostic yield with 6 interesting atypical findings.

In a 13 year-old girl, with suspicion of mitochondrial cytopathy for years because of isolated cerebellar ataxia subsequently associated with psychomotor regression, cerebellar atrophy, hearing impairment, extensive leukoencephalopathy and gradient-echo sequences hyposignal of the basal ganglia, ES identified a homozygous *CRAT* missense variant inherited from related parents in favor of Neurodegeneration with Brain Iron Accumulation.

In an 11 year-old girl referred for the diagnosis of a cerebellar ataxia with basal ganglia and midbrain hypersignal, ES with a dedicated pipeline analysis allowed to identify a mitochondrial DNA missense variant in the *MT-ATP6* gene.

In a family referred for familial gait disorder (spastic paresis of lower limbs in a 46 year-old man and hypotonic cerebellar ataxia in his daughter), ES identified a causal *BSCL2* missense variant in the father while his daughter, who inherited this variant, also carried an additional missense variant in the *MT-ATP6* gene leading to a mitochondrial defect explaining her current symptoms.

ES is a powerful tool for diagnosing neurodegenerative diseases, allowing not to be restricted to a given panel and thus to identify molecular bases of very interesting findings such as differential diagnosis, expansion of clinical spectrum, multiple diagnosis within a given family and even a given patient.

## PgmNr 2551: Detection of spinal muscular atrophy genotypes in a highly multiplexed test.

Spinal muscular atrophy is a debilitating disease causing lack of spinal muscle control and infant mortality in the most extreme cases. Normal spinal nerve-muscle connections require the presence of protein produced by the SMN1 gene (Spinal Muscle Neuron 1 Gene). Symptoms can be reduced in severity by the presence of extra copies of the SMN2 gene, which produces a protein with reduced activity. The SMN1 and SMN2 genes are nearly identical in sequence (99.6% identity). Accurate detection of the number of SMN1 and SMN2 genes in a sample is critical to the correct characterization of the SMA genotype. Approximately one in 6,000 babies are born with the disease and one in 40 individuals are carriers of a defective SMA1 gene.

For analytical verification, 386 DNA samples were characterized using two methods: the Applied Biosystems CarrierScan® Assay and droplet digital PCR (ddPCR). In this data set, 7 samples were identified as having SMA carrier status. 19 samples were identified as having the SMN1 g.27134T>G mutation that is in linkage-disequilibrium with the silent-carrier chromosome, a chromosome containing 2 copies of the SMN1 gene in cis in some populations.

The CarrierScan and ddPCR data were 100% concordant for SMA carrier state and g.27134T>G genotype. Concordance for SMN1 copy number was 94% and concordance for SMN2 copy number was 82%.

The results show that the highly-multiplexed CarrierScan assay is very effective and accurate for detecting SMA carrier genotypes.

## PgmNr 2552: The *c.1353C>G* (p.D451E) variant of *SLC6A1* gene is associated with myoclonic-atonic epilepsy and absence seizures in a family with autosomal dominant mode of inheritance.

**Myoclonic-atonic epilepsy (MAE)** is an autosomal dominant disorder characterized by onset of absence and myoclonic seizures in early childhood. Patients have delayed development before the onset of seizures and show varying degrees of intellectual disability following seizure onset. MAE is caused by heterozygous mutation in the *SLC6A1* gene on chromosome 3p25. We present a family with multiple affected individuals presenting with variable expression of MAE and with an autosomal dominant mode of inheritance; all carrying a variant of uncertain significance (VUS) of *SLC6A1* gene.

**Proband** is an 11-year-old female with intractable seizures, developmental delay, intellectual disability (IQ 45), ADHD, disruptive mood dysregulation, bicuspid aortic valve, SVT, joint hypermobility, and dysmorphic features (dolichocephaly, low-set ears, high nasal bridge, high-arched palate, retrognathia, pes planus). She was born at 32 weeks of gestation, to a 19 yo, G3, P2 mother. Birth weight was 5 lbs.

### Pertinent Family History:

- **Full brother;** 12 yo with seizures and ID (IQ 40)
  - **Maternal half-brother;** 14 yo with “drop-type absence seizures” and ID (IQ 48), autism spectrum disorder (ASD), ADHD, and bipolar disorder
  - **Full sister;** 9 yo with joint hypermobility, no seizures, IQ 80 (unaffected)
  - **Father** has ID
  - **Mother** has joint hypermobility, mild ID, and possible seizures
- All children are adopted by a single family (Parents unavailable for testing).

Molecular studies for ID panel of 140 genes (and Whole Exome Sequencing) showed a variant of uncertain significance (**VUS**) of *SLC6A1* gene: *c.1353C>G* (p.D451E), which is present in **two affected full-siblings**, their **affected maternal half-brother** and their **mother** (obligate carrier-not tested), but not present in their **unaffected sister**.

The affected family members show similar but **variable** clinical features, and all carry the *SLC6A1* gene variant p.D451E, which is most likely the cause of the phenotype in this family with an autosomal dominant mode of inheritance.

*SLC6A1* encodes a GABA transporter that removes GABA from the synaptic cleft. Pathogenic mutations of *SLC6A1* gene present with variable expression of **myoclonic-atonic epilepsy, absence seizures, developmental delay, and intellectual disabilities**, as seen in affected members of this family. The phenotype is segregating with the p.D451E variant indicating it is a likely pathogenic variant (VLP). To our knowledge, this variant has not previously been characterized as pathogenic, or benign.

## PgmNr 2553: Phenotypic expansion of TAF1-related syndrome: *TAF1* variants and clinical phenotypes.

**Purpose:** We recently described a new neurodevelopmental syndrome caused by mutations involving the X-linked gene, *TAF1*, in 11 families. These individuals with missense variants or a duplication involving *TAF1* - encoding a subunit of basal factor TFIID for RNA polymerase II transcription - were shown to present early in life with hypotonia, developmental delay, and characteristic facial features, followed by later diagnoses of intellectual disability (ID) and/or autism spectrum disorder (ASD). We investigated *TAF1* rare variant genotype/phenotype correlations, hypothesizing a broader clinical phenotypic spectrum for this disorder, by identifying additional families through a genotype-first approach.

**Methods:** Families were identified through an international collaboration and primarily clinically-based sequencing. Variants of interest were identified with a range of bioinformatic approaches, followed by molecular modelling for those variants falling within structurally characterized domains of *TAF1*. Phenotyping cluster analysis was also performed using Human Phenotype Ontology (HPO) terms.

**Results:** We studied a total of 27 families, each with a distinct variant in *TAF1*. We used familial segregation analysis, clinical phenotyping, bioinformatics, molecular modelling, and clustering approaches to determine whether these variants contribute to the clinical phenotypes. We determined that five of these variants are likely benign, ten of the *de novo* variants are likely pathogenic, and the remaining twelve maternally inherited variants remain of uncertain significance. Two of the *de novo* variants occurred in females with significant skewing of X-chromosome inactivation. Phenotypes associated with *TAF1* variants show considerable pleiotropy and clinical

variability in their presentation, including autism spectrum disorder, brain anomalies (e.g. ventriculomegaly and corpus callosum abnormalities), seizures, hearing loss, and cardiac malformations.

**Conclusion:** Our allelic series data reveal that likely damaging TAF1 variant alleles can result in a broad phenotypic spectrum for TAF1 syndrome, whilst also broadening the range of molecular defects in TAF1 observed in human neurodevelopmental disorders. It also illustrates the current difficulties in assigning pathogenicity to inherited missense variants.

## PgmNr 2554: Targeted resequencing identifies genes with recurrent variation in cerebral palsy.

---

A growing body of evidence points to a considerable and heterogeneous genetic aetiology of cerebral palsy (CP). To identify recurrently variant CP genes we designed a custom gene panel of 112 candidate genes. We tested 366 clinically unselected singleton cases with CP, including 271 cases not previously examined using next generation sequencing technologies. Overall, 5.2% of the naïve cases (14/271) harboured a genetic variant of clinical significance in a known disease gene, with a further 4.8% of individuals (13/271) having a variant in a candidate gene classified as intolerant to variation. In the aggregate cohort of individuals from this study and our previous genomic investigations, six recurrently hit genes contributed at least 4% of disease burden to CP: *COL4A1*, *TUBA1A*, *AGAP1*, *L1CAM*, *MAOB* and *KIF1A*. Significance of Rare VARIants (SORVA) burden analysis identified four genes with a genome-wide significant burden of variants, *AGAP1*, *ERLIN1*, *ZDHHC9* and *PROC*, of which we functionally assessed *AGAP1* using a zebrafish model. Our investigations reinforce that CP is a heterogeneous neurodevelopmental disorder with known as well as novel genetic determinants.

## PgmNr 2555: Spinal muscular atrophy screening workflow for rapid whole genome sequencing.

---

Spinal muscular atrophy (SMA) is a neuromuscular disorder that results in the loss of motor neurons and progressive muscle wasting. SMA is caused by a biallelic loss or mutations in *SMN1* gene, which encodes SMN, a protein necessary for survival of motor neurons. A gene paralog (*SMN2*) that differs in five non-protein-changing base pairs has mostly aberrant splicing and its copy number may dramatically modify disease severity. With the advent of new therapies for SMA, a rapid diagnosis of SMA is crucial to optimize patient outcomes.

Rapid Whole-Genome Sequencing (rWGS) technology has transformed medicine as a cost-effective approach to detecting pathogenic variants on a genomic scale in patients with genetic diseases. The ability to detect *SMN1* and *SMN2* copy numbers using rWGS in one test is highly desirable to increase the diagnostic yield, yet is typically hindered by inability to correctly map short reads by conventional alignment software due to high degree of sequence similarity. We present a computational workflow that robustly estimates *SMN1* and *SMN2* copy numbers from a standard Illumina short-read rWGS.

**Method:** Following the conventional short-read alignment, an estimate of the high-quality alignment read counts for two specific loci is performed. While the entire sequence of the two genes is essentially identical, the 270 base pair area near exon 7 with five conserved differences is useable for correct unambiguous assignment of the reads to the correct gene paralog (under the condition of now standard low sequencing error rate, <0.5%). The read count model has been trained on 900 normal and eight true positive samples and normalized to different read lengths (2x100, 2x150 bp). The read counts are stochastic by the nature of their generation by random shearing, but at the level of target average genomic coverage of  $\geq 40\times$  are statistically significantly robust to determine *SMN1* and *SMN2* ploidy levels of 0, 1, 2, and 3+.

**Results:** 31 clinically confirmed retrospective SMA samples with various ploidy (including 8 DNA samples purchased from Coriell) were used for validation. For clinical correlation, *SMN1* and *SMN2* copy numbers were analyzed using custom-designed MLPA reagents, according to the manufacturer's recommendations. The MLPA method was perfectly concordant with the computational estimates. The computational workflow robustly estimates *SMN1* and *SMN2* copy numbers and is validated and approved for all prospective clinical samples at RCIGM.

*IFIH1* encodes the protein interferon-induced helicase C domain-containing protein 1, otherwise known as melanoma differentiation-associated protein 5 (MDA5), which is a cytosolic sensor of double-stranded(ds) RNA as innate immune receptor. Enhanced type I interferon signaling secondary to gain-of-function mutations in *IFIH1* results in a range of neuroinflammatory phenotypes including Aicardi-Goutieres syndrome (AGS) and multi-system phenotypes like Singleton-Merten syndrome (SMS). Here we describe the clinical spectrum of three patients from three independent families with gain of function *IFIH1* mutations identified by exome sequencing.

All three probands have a typical AGS phenotype with various neurological and systemic manifestations, and brain imaging consistent with intracranial calcification. Probands 1 and 2, harboring heterozygous *IFIH1* variants (c.1009A>G;p.Arg337Gly and c.2342G>A;p.Gly781Glu, respectively) presented with an AGS and SMS overlapping phenotype, manifesting with abnormal dental findings (periodontitis and moderate enamel hypoplasia) and cutaneous findings (psoriasis and chilblain lesions). Atypical presentations were also noted; proband 1 had recurrent non-diabetic pancreatitis while proband 2 had axonal sensory motor neuropathy. Proband 3, with a heterozygous c.2335C>T;p.Arg779Cys variant, showed early-onset epileptic encephalopathy (EOEE) with severe global developmental delay.

To determine the cellular consequences of these variants, we measured the interferon activity in mammalian cells overexpressing the different mutations as compared to full length, wild-type *IFIH1*. Based upon this luciferase-based reporter assay, all three variants had increased interferon activities, confirming a gain-of-function mechanism. We hypothesize that these variants will lead to the upregulation of interferon-stimulated gene transcription.

Our results further delineate the spectrum of *IFIH1*-associated type 1 interferonopathy, ranging from neuroinflammation in SMS to an autoimmune phenotype.

---

Tay-Sachs disease (TSD) is an autosomal recessive storage disorder caused by impaired activity of the lysosomal enzyme hexosaminidase-A (EC3.2.1.52) due to the mutation in HEXA gene. As per HGMD database, ~190 mutations have been reported from different ethnic groups, although very few disease-causing mutations are known in Indian TSD patients. Hence, the present study was undertaken to identify more novel mutations in HEXA gene in Indian TSD patients to evaluate genotype-phenotype correlation and to establish the common disease-causing mutations that can be utilized for carrier screening in the mass population. The overall study detected 26 mutations belonging to 35 affected patients with infantile-onset TSD, through bidirectional sequencing of HEXA gene and MLPA-based approach (MRC-Holland, P199-B) were also applied to investigate for the potential occurrence of large HEXA deletions/duplications. The most common mutations detected in six individual [18%] was c.1278insTATC (p.Y427IfsX5) while p.E462V mutation was found in 5 individuals [14%]. Overall, 17 patients harbors 15 novel variants, including 7 missense variants [p.V206L, p.Y213H, p.R252C, p.F257S, p.C328G, p.G454R, p.P475R], 4 nonsense variant [p.S9X, p.E91X, p.W420X, p.W482X], 2 splice site variants [c.347-1G>A, c.460-1G>A] and 2 small deletion [c.1349delC (p.A450VfsX3) and c.52delG (p.G18Dfs\*82)]. While remaining 18 patients harbors 11 previously reported variants that includes 6 missense variants [p.M1T, p.R170Q, p.D322Y, p.D322N, p.E462V, p.R499C], 1 nonsense variant [p.Q106X], 2 splice site variants [c.1073+1G>A, c.459+4A>G], one 4bp insertion [c.1278insTATC (p.Y427IfsX5)] and one large deletion of exon 1. In silico analyses of all novel mutations of HEXA gene were shown to be probably damaging with a deleterious effect on protein function. Protein homology modeling studies further established the effects of novel mutations occurred at highly evolutionarily conserved and functionally active domain residues in the protein leading to conformational changes in HEXA protein. In conclusion, Indian infantile TSD patients provide newer insight into the molecular heterogeneity of the TSD. Combining present study and our earlier studies, we have observed that 67% genotypes found in Indian TSD patients are novel which are associated with severe infantile phenotypes. Present study again reconfirms that, 2 variants E462V and c.1277\_1278insTATC are most common in nearly 32% (11/35) of Indian TSD patients.

## PgmNr 2558: Massively parallel sequencing: A robust approach to genotyping the myotonic dystrophy type 2 locus in the general population.

### Authors:

T. Oyeniyi <sup>1</sup>; R. Krahe <sup>2</sup>; D. Monckton <sup>1</sup>

[View Session](#) [Add to Schedule](#)

Myotonic dystrophy type 2 (DM2) is an autosomal neuromuscular disorder caused by a microsatellite expansion in intron 1 of the *CNBP* gene. The DM2 locus is a compound microsatellite having a complex array of repeats with three motifs arranged as (TG)<sub>n</sub>(TCTG)<sub>n</sub>(CCTG)<sub>n</sub>. The mutation is an expansion of the CCTG motif from the non-disease associated <CCTG<sub>75</sub> into the pathogenic range of an average of CCTG<sub>500</sub>. The conventional molecular method of diagnosis is fragment length analysis by PCR, gel electrophoresis and/or Southern hybridization. However, these methods do not account for the highly polymorphic TG and TCTG motifs of the repeat array. This makes it hard to distinguish between two non-disease associated alleles that are identical by state (length) but are different by structural (sequence) arrangement. With this limitation, unaffected heterozygous individuals may falsely appear as homozygous requiring further analysis to confirm their true genotype. This fast and accurate method for genotyping non-disease associated alleles at the DM2 locus. Primers were barcoded such that individual samples were identified for analysis in a pool of many, up to 384 individuals of the general Scottish population were screened at one sequencing run. To evaluate the sensitivity of the assay, 15 individuals from Texas who had been previously genotyped by fragment length analysis, were screened.

Sequencing revealed a typical sequence arrangement of (TG)<sub>n</sub>(TCTG)<sub>n</sub>(CCTG)<sub>n</sub> and an 8-bp flanking sequence TCTGTCTC downstream of the last CCTG repeat. The allele range at the three motifs was (TG)<sub>10</sub> to (TG)<sub>30</sub>, (TCTG)<sub>2</sub> to (TCTG)<sub>13</sub> and (CCTG)<sub>8</sub> to (CCTG)<sub>27</sub>, the modal alleles being (TG)<sub>21</sub>, (TCTG)<sub>9</sub> and (CCTG)<sub>15</sub>, and together, these three constituted the most frequent haplotype. A 12-bp sequence interruption (GCTG)<sub>1</sub>(CCTG)<sub>1</sub>(TCTG)<sub>1</sub> was observed within the CCTG motif in most alleles, while a few alleles had none or more insertion(s) of the interrupting sequence. In terms of total allele length, a unimodal distribution was observed amongst the cohorts, within a range of 106 bp to 186 bp with the mode at 138 bp. Of the total population, 5.8 % was homozygous by sequence as opposed to the 9 % homozygous by length.

NGS as an approach to genotyping the DM2 locus is robust and accurate, it offers a resolution to the base pair and remarkably high throughput that cannot be attained with the traditional fragment length analysis methods.

## PgmNr 2559: Analysis of neuromuscular problems using NGS panels in Ecuadorian population.

**Authors:**

V. Espin

[View Session](#) [Add to Schedule](#)

**Affiliation:** Genetics, Hospital Carlos Andrade Marin, Quito, Pichincha, Ecuador

---

The study and analysis of neuro-muscular problems is a very complex task. There are many difficulties to get a precise diagnosis because clinical presentations are quite similar among these diseases. In many cases this has capital importance in order to be able to establish the natural history of the disease, recurrence risk and sometimes to take choices of reproductive medicine.

Molecular technology has made the diagnostic approach easier.

We analyzed 27 patients who presented with neuromuscular symptoms at the Genetics Service of the Hospital Carlos Andrade Marín (Quito) between in 2017-2018.

An NGS panel of 123 genes was used, finding a conclusive diagnosis in 16 patients (Detection rate 59.25%). If the probable ones (Variable Unknown Significance VUS) are added, the diagnosis rate would reach 88.8%.

Ecuador is not a wealthy country. The option of applying this technology to patients with suspected hereditary neuromuscular disorder becomes a feasible and accessible option to reach diagnosis in a large number of these cases.

---

Genetic malformations of cortical brain development, such as focal cortical dysplasia (FCD) and hemimegalencephaly (HME), are major causes of severe pediatric refractory epilepsies subjected to neurosurgery. Neuropathological hallmarks of FCDs include enlarged dysmorphic neurons (DNs) and balloon cells (BCs). Here we aim to provide a comprehensive assessment of the contribution of germline and somatic variants in a large cohort of FCD/HME patients.

We enrolled in a monocentric study 80 children with drug-resistant epilepsy and a postsurgical neuropathological diagnosis of FCD1, FCD2 or HME. We performed targeted gene sequencing ( $\geq 2000\times$  read depth) on matched blood-brain samples to search for low-allele frequency variants in mTOR pathway and FCD genes.

We were able to elucidate 29% of FCD1 patients and 63% of FCD2/HME patients. FCD1 cases carried somatic loss-of-function variants in the N-glycosylation pathway-associated *SLC35A2* gene. FCD2/HME cases carried somatic gain-of-function variants in *MTOR* and its activators (*AKT3*, *PIK3CA*, *RHEB*), as well as germline, somatic and two-hit loss-of-function variants in its repressors (*DEPDC5*, *TSC1*, *TSC2*). We show that panel-negative FCD2 cases display strong pS6-immunostaining, stressing that all FCD2 belong to mTORopathies. Analysis of microdissected cells demonstrated that DN and BCs carry the pathogenic variants. We further observed a correlation between the density of pathological cells and the variant detection likelihood. Single cell microdissection followed by sequencing of enriched pools of DN unveiled a second-hit somatic loss-of-heterozygosity in a *DEPDC5* germline case.

This study indicates that FCD1 and FCD2/HME are two distinct genetic entities: a subset of FCD1 are related to glycosylation defects, while all FCD2/HME are somatic mTORopathies. We provide a framework for efficient genetic testing in FCD/HME, linking neuropathology to genetic findings and emphasizing the relevance of molecular evaluation in the pediatric epileptic neurosurgical population.

## PgmNr 2561: A novel candidate gene for hereditary spastic paraplegia in a consanguineous Malian family.

### Authors:

Fischbeck <sup>1</sup>; The H3Africa Consortium

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Neurogenetics Branch, NIH, Bethesda, MD.; 2) Service de Neurologie, CHU du Point "G", Bamako, Mali; 3) Service de Neurologie, CHU de Gabriel Touré, Bamako, Mali; 4) Service de Chirurgie Pédiatrique, CHU de Gabriel Touré

**Introduction:** Hereditary spastic paraplegias (HSPs) are a heterogeneous group of neurodegenerative disorders characterized by lower extremity spasticity. At least 69 genes have been associated with the disease, but many other clinically characterized forms remain with no molecular diagnosis. In addition, very little data about HSPs exist in sub-Saharan Africa.

**Objective:** To characterize a Malian family with HSP and identify the underlying genetic defect.

**Methods:** After consent, patients went through a thorough neurological examination. Blood chemistries, brain and spinal imaging were done to exclude common causes. EEG was also performed to assess epileptiform activity. DNA was extracted for genetic analysis and fibroblasts were collected from patients and relatives for cell studies.

**Results:** We identified a consanguineous family in which three siblings presented with early onset HSP features. Symptoms started with toe walking followed by frequent falls, and worsened overtime. In addition, they presented generalized seizures. Neurological examination found brisk reflexes in four limbs with spastic gait, lower limb weakness, and equine feet. The oldest patient presented also problems with speech and behavioral disorder, and both had cognitive decline. Vitamin E levels and HTLV-1 serology, causing tropical paraplegia, were normal. Brain imaging showed thin corpus callosum with cortical and cerebellar atrophy, and EEG reported generalized spike-waves in the oldest patient, and slow background in the youngest. SPG gene panel testing (58 genes + *SPG4* del/dup + *mtDNA*) was negative. Exome sequencing in two affected individuals showed variants in two different genes. These variants segregated with the disease in this family. One of these variants, in the *AP2A2* gene, is not present in SNP databases including dbSNP, gnomAD, ExAc, and 1000Genomes. In addition, the gene has not been previously associated with any disease, but has a highest expression in spinal cord and fetal brain. Moreover, the protein product is a member of a complex known to be associated with other HSPs. The substituted amino acid lies in a critical part of a highly conserved domain and likely has a role in endocytosis.

**Conclusion:** Our findings suggests a novel candidate gene for HSP. Further studies are underway to evaluate this variant in the Malian population and its functional effects in cell culture.

## PgmNr 2562: Large pedigree subfamily's whole exome trio analyses from isolated South-Eastern Moravia (Czech Republic) population indicate heterogeneous genetic nature for Parkinsonism development.

### Authors:

R. Vodicka <sup>1</sup>; R. Vrtel <sup>1</sup>; K. Kolarikova <sup>1</sup>; K. Mensikova <sup>2</sup>; P. Kanovsky <sup>2</sup>; J. Stellmachova <sup>1</sup>; M. Prochazka <sup>1</sup>

---

We described higher prevalence of parkinsonism in the small isolated southeastern Moravian region in the Czech Republic and in addition with well assembled eleven generation large pedigree.

The study aims to set proper and accessible subfamily trios from the pedigree to find shared genetic variants potentially associated with parkinsonism using whole exome analyses.

We used NGS Ion AmpliSeq Exome method (IonTorrent) for five subfamily trios. Each trio comprised of two affected and one healthy person. DNA exome libraries were sequenced on IonPI chips. Variants were predicted using pipeline Torrent Suite/Ingenuity Variant Analysis/Two case/control analysis. Final filtering was done with respect to population frequency (Global MAF?1%), variant effects and biological context (Parkinsonism responsible genes). Last filter was done with respect to the segregation of the disease within particular subfamily.

Almost whole exome was sequenced with coverage 1-20 and 90 % of exome was covered more than 20x in all samples. Together more than 70.000 variants with average base coverage depth 75 were analyzable in all trios before filtering.

There were found no one founder pathogenic variant in the subfamilies through the pedigree. Each subfamily trio shows different set of suspected variants. Trio A shares 2 variants with trio D (novel variant NM\_002386.3:c.322G>A;p.A108T in the gene *MC1R/RP11-566K11.2* and rare variant NM\_015210.3:c.1445C>T;p.A482V in the gene *MTCL1* ), trio B shares 1 rare variant with trio C (NM\_001256864.1:c.1817A>C;p.H606P in the gene *DNAJC6*). In addition, in trios C and E there were found two novel gene *CSMD1* variants NM\_033225.5: c.3335A>G,p.E1112G and c.4071C>G; p.I1357M respectively.

It can be concluded that genetic contribution to the disease in our large pedigree could be heterogeneous. Detailed whole exome analyses in genetically isolated parkinsonism patients could contribute to further understanding of the molecular-genetic mechanism and background of the disease. This study was supported by MH CZ – DRO (FNOL, 00098892).

## PgmNr 2563: SMA screening in 10439 newborns with a novel capillary electrophoresis based method.

### Authors:

H. Zhu; L. Wang; Y. Chen

[View Session](#) [Add to Schedule](#)

**Affiliation:** Prenatal Diagnosis Center, The Sixth Medical Center of PLA General Hospital, Beijing, Beijing, China

---

**Objectives:** Spinal Muscular Atrophy (SMA) is a relatively common autosomal recessive disorder. It has a carrier frequency of 1/40 to 1/60 and an incidence rate of about 4 to 10 in 100,000 in newborns, which are basically the same among various population. Currently, there is no effective SMA neonatal screening method. To detect SMA, MLPA and qPCR are commonly used in clinical practice. However, both of them have their limitations. In this study, we have developed a novel rapid, simple and accurate method based on CE platform. To the best of our knowledge, no similar method has been previously reported.

**Methods:** Previous methods quantitatively detect the copy number of SMN genes by comparing results of targets and a control gene. We took Survival of Motor Neuron 1 telomeric Pseudogene (SMNP), which was highly homologous to SMN1/2, as the control. Using the same primer set, we could amplify the target and control with equivalent primer binding affinity, which greatly improved the stability and quantitative performance of the detection system. This new method was validated using 313 samples, which were all tested by qPCR in parallel. All SMA-positive samples were then confirmed by MLPA. After validation, we tested 10493 samples and compared the results from new method and qPCR. All SMA-positive samples were confirmed by MLPA. Incidence rate and carrier frequency of Chinese Han population were determined based on these results.

**Results:** In the validation of 313 samples, 5 SMA carriers and 308 normal samples were detected by CE method, which was consistent with the result given by qPCR. The 5 SMA carriers were confirmed by further MLPA method. In the test of 10493 samples, CE method successfully detected 98.3% (10315/10493) samples, with one SMA patient and 179 carriers. These 180 samples were then verified by MLPA method and showed highly concordant results, which were better than those results from qPCR method. According to the above data, the frequency of SMA carriers in Chinese Han population was 1.73%.

**Conclusions:** For the first time, we have established a method for quantitative detection of copy number of *SMN* gene based on CE platform. The accuracy of this new method was demonstrated by a developmental validation and a large population test, indicating our novel method was accurate, stable and affordable for SMA screening.

## PgmNr 2564: Clinical validation and implementation of a highly efficient and sensitive dual molecular diagnostic assay for myotonic dystrophy type 1.

### Authors:

J. Alaimo<sup>1,2,3</sup>; I. Thiffault<sup>1,2,3</sup>; M. Farooqi<sup>1,2,3</sup>; C. Saunders<sup>1,2,3</sup>

Myotonic dystrophy type 1 (DM1) is caused by a (CTG)<sub>n</sub> repeat expansion in the 3' UTR of *DMPK* and is an important and often overlooked consideration in the work up of a hypotonic infant. (CTG)<sub>n</sub> repeats are refractory to detection by short read sequencing and therefore, require other specialized methods for accurate quantification including PCR and Southern blot analysis. Current laboratory-developed PCR tests are limited to amplification of >100 repeats and require multiple reactions for either expansion detection or accurate sizing due to amplification dropouts. Furthermore, Southern blotting is labor-intensive, expensive, and has a significantly reduced turnaround time. Here, we describe the clinical validation and implementation of a new commercially available PCR assay that overcomes these significant hurdles. Triplet-primed PCR was performed on all samples and resolved using capillary electrophoresis. The assay generated numerical values for alleles up to and including 200 repeats and a categorical value for alleles >200 repeats to facilitate genotyping. Size estimation beyond 200 repeats were flagged by both an expanded stutter pattern and a corresponding pile-up peak. Larger expansions were resolved using an agarose gel electrophoresis method. A validation set of 23 samples was tested, including a subset obtained from previous CAP proficiency testing. Samples were selected to provide multiple representatives in each numerical category throughout the dynamic range which included the normal (5-34 repeats), premutation (35-49 repeats), and various disease ranges (>50 repeats). We observed 100% concordance between our results for this sample set and previously reported results with 100% sensitivity, specificity, accuracy, and precision. In addition, we were able to clearly resolve zygosity in all samples. Mosaicism of at least 10% was detectable. Another major advantage of this testing is a total hands-on time requirement of only 60 minutes, a significant improvement over dual PCR / Southern blot methods. Overall, this assay resulted in a faster, accurate, and cost-effective approach for reaching a DM1 molecular diagnosis and highlights the continuing advances in the molecular diagnostic testing space.

## PgmNr 2565: Beyond SNPs and INDELs: Identifying repeat expansions in an unresolved ataxia exome cohort.

### Authors:

H.P. Subramanian; S. Andani; D. del Gaudio; S. Das

[View Session](#) [Add to Schedule](#)

**Affiliation:** Department of Human Genetics, The University of Chicago, Chicago, Illinois.

Ataxias are a group of neurological disorders with tremendous genetic heterogeneity. Around 50-60% of dominant hereditary ataxias are estimated to be caused by repeat expansions while the majority of other ataxias are due to mutations in one of several hundred genes. The diagnostic yield in ataxia patients through exome sequencing has been shown to be around 40-50%, leaving a large number of patients with no diagnosis. The possibility exists of patients with repeat expansions that have not been detected by exome sequencing. With the advent of new bioinformatic algorithms to identify repeat expansions from sequencing data, we sought to identify the presence of such expansions in exome negative ataxia cases.

We re-analyzed exome sequencing data of 183 ataxia patients with no clear pathogenic variants in a curated set of ataxia genes. We utilized the exSTRA R package (Tankard *et al.* 2018, The American Journal of Human Genetics, 103(6), 858-873) to identify repeat expansions in coding regions of certain spinocerebellar ataxia genes (*ATN1*, *ATXN1*, *ATXN2*, *ATXN3*, *ATXN7*, *CACNA1A*, *TBP*). Repeat primed PCR (RP-PCR) was performed to confirm and size the repeat expansions.

exSTRA works by identifying outliers in the cohort. 16 such outliers were initially identified and 3 out of 16 outliers were confirmed to be a true repeat expansion by RP-PCR. Two samples had a full expansion repeat in *CACNA1A* (11,22 repeats) and *ATXN7* (11,76 repeats) respectively and one sample had a reduced penetrance repeat in *ATXN2* (31,32 repeats). We are in the process of performing similar analysis in additional 33 ataxia patients negative by exome sequencing. In addition, we performed a preliminary analysis to screen for the presence of the recently described intronic AAGGG repeat expansion in the *RFC1* gene in patients with cerebellar ataxia, neuropathy, vestibular areflexia syndrome (CANVAS). Analysis of off-target reads in 27 samples indicates the presence of the AAGGG repeat in 3 samples that needs to be confirmed by RP-PCR. Our results on these ongoing studies will be presented.

Reanalysis of exome sequencing data appears to be a promising screening tool for the detection of repeat expansions resulting in an increase in diagnostic yield. With the emergence of better detection algorithms, the ability to use exome data for both mutation detection as well as repeat expansions will be useful for diagnostic testing purposes and allow for more comprehensive and cost-effective testing.

## PgmNr 2566: Comparison of Stereocilin gene copy number detection by multiplex ligation-dependent PCR amplification (MLPA) and multiplexed droplet digital PCR (ddPCR).

### Authors:

R. Margraf<sup>1</sup>; R. Mao<sup>1,2</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) ARUP Institute for Clinical and Experimental Pathology, Salt Lake City, Utah.; 2) Department of Pathology, University of Utah School of Medicine, Salt Lake City, Utah

---

Stereocilin gene (*STRC*) mutations are a common cause of moderate autosomal recessive hearing loss. 11% of all individuals with isolated non-syndromic hearing loss have a large *STRC* deletion, ranging from partial to full gene. The *STRC* gene is 98% homologous with its pseudogene (*pSTRC*), which includes a 100% homologous region from exons 1 to 15. *STRC* deletions cannot be accurately detected using NGS or microarray due to the *pSTRC* pseudogene homology. This report compares two assays that could accurately and specifically detect *STRC* deletions even with the *pSTRC* homology: Multiplex Ligation-Dependent PCR Amplification (MLPA) and copy number droplet digital PCR (ddPCR) assays. The *STRC* MLPA uses the SALSA MLPA probemix P461-A1 DIS from MRC- Holland. The MLPA had 5 probes located within or near *STRC* exons 19 (2 probes), 23, 24, and 25; and included probes in flanking genes, *CKMT1B* and *CATSPER2*. A multiplex *STRC* copy number ddPCR assay was developed on the Bio-Rad QX200™ Droplet Digital™ PCR system. The ddPCR assay had four targets for copy number: three within *STRC* (exon 19, near exon 23, and intron 25) and *CATSPER2* gene exon 7. Each of the *STRC* ddPCR assays were nearby an MLPA probe location.

Fifty-two de-identified samples were tested for copy number by *STRC* MLPA and ddPCR and results were compared for all samples. The *STRC* copy number overall and also the copy number per similar targeted exon locations were in agreement for 51 of 52 samples. Thirty-three samples were wild type, 10 were heterozygous *STRC* deletion, 4 had homozygous deletion, and 4 had a duplication. The one discrepant sample was wild type by ddPCR but was heterozygous deletion for one MLPA probe at exon 19, and had the same respective results upon repeats. This MLPA exon 19 location overlaps by 3 nt to the ddPCR assay, so the discrepant result may be a real deletion present only under the MLPA probe or a polymorphism affecting the MLPA result only. To test for assay specificity to *STRC* versus *pSTRC*, the four homozygous *STRC* gene deletion samples were run at 2x the recommended DNA input, and these samples remained at 0 copies at all *STRC* probe locations in both assays. In conclusion, 98% of the samples had concordance in *STRC* copy number between MLPA and ddPCR assays, and both assays showed specificity to the *STRC* gene versus *pSTRC*.

## PgmNr 2567: The more the merrier? Comparison of the diagnostic yield between focused vs comprehensive panels for inherited retinal disorders.

### Authors:

M. Pantrangi <sup>1</sup>; M. Reeves <sup>2</sup>; K. Goetz <sup>2</sup>; J. Schroeder <sup>1</sup>; J. Rath <sup>1</sup>; G. Londre <sup>1</sup>; J. Weber <sup>1</sup>

---

Inherited retinal disorders (IRDs), such as Retinitis pigmentosa, Stargardt disease, and Leber congenital amaurosis (LCA), are the leading cause of blindness in the Western world, affecting ~1 in 3,000 individuals. IRDs have significant phenotypic overlap and molecular testing can help confirm a clinical diagnosis or achieve an accurate molecular diagnosis. In addition, an accurate diagnosis may be required to help guide treatment (e.g., *RPE65* gene therapy Luxturna<sup>TM</sup>). Identifying the genetic cause for IRDs is challenging due to genetic heterogeneity. To date, ~300 loci have been mapped and over 250 genes associated with IRDs have been identified (<https://sph.uth.edu/retnet/>).

PreventionGenetics (PG) offers a comprehensive IRD panel, which includes analysis of the mutational hotspot ORF15 region in *RPGR* and sequencing of over 300 genes with copy number variant (CNV) detection. This panel is an upgrade from our previous tier system of testing which included 107 common IRD genes in Tier 1 and 173 less common IRD genes in Tier 2. Tier 2 genes were tested only when Tier 1 was negative or indeterminate. Test outcomes were considered indeterminate if a single pathogenic variant was found in an autosomal recessive gene along with a variant of uncertain significance (VUS) or if only VUS were detected.

To date, we have tested ~530 individuals with IRDs. The positive rate between the Tier 1 testing (76 individuals) and the 300+ gene panel testing (455 individuals) was compared. Interestingly, the positive rate for Tier 1 testing alone was 47% and the indeterminate rate was 51%, while the positive rate for the 300+ gene panel was 42% and its indeterminate rate was 58%. The genes with the highest positive rates included *USH2A* (20%); *ABCA4* (15%); *EYS* (~6%); *RPGR*, *CEP290*, *CRB1*, and *PRPF31* (each ~4%); *RPE65*, *CERKL*, and *CLN3* (each ~3%); *BBS1* (2.5%); *CYP4V2*, *DHDDS*, *FAM161A*, *PCARE*, *PDE6B*, *RDH12*, and *RHO* (each ~2%); *CHM* and *NR2E3* (both ~1.5%); and *PROM1* and *TOPORS* (both ~1%). All of these genes had previously been included in the Tier 1 test, with the exception of *BBS1* and *CYP4V2*.

The current study suggests that including a larger number of genes increases the VUS burden. However, the positive rate is comparable between the focused panel with the most common IRD genes and a larger comprehensive panel. In summary, we present data to demonstrate the clinical validity of focused multigene panels for the diagnosis of clinically and genetically heterogeneous IRDs.

## PgmNr 2568: Large structural variants account for a substantial fraction of unsolved cases of inherited retinal disease.

---

**Background.** Inherited, degenerative retinal diseases (IRD's) affect more than 1.5 million people worldwide and are a major cause of legal blindness and loss of vision in young adults. Currently, there are a number of registered clinical trials and approved drugs for treating IRD patients with known disease-causing genes and mutations. Thus identifying the underlying cause of disease is not only of benefit to patients and families, but is a prerequisite for treatment. Panel testing of known IRD genes using next-generation sequencing (NGS) detects the cause in from 60% to 80% of cases, depending on the population tested. Among the remaining cases we have identified several large, complex, disease-causing structural variants not readily detected by conventional NGS.

**Results.** Our research focuses on families with autosomal dominant retinitis pigmentosa (adRP) and related dominant retinopathies. To date we have identified the cause in approximately 80% of cases. Our goal is to find the causes in the remaining 20%. Methods include linkage mapping, retinal targeted-capture NGS, whole-exome and whole-genome NGS, quantitative-PCR and quantitative-NGS, and Linked-Read 10X Genomics Chromium™ sequencing. Among the unsolved adRP cases one family was found to have a balanced translocation of the q terminus arms of chromosomes 2 and 4 involving 35 Mb and 73 Mb respectively. The likely cause of disease in this family is dysregulation of the *LRAT* gene on chromosome 4. The family also reports an increased incidence of miscarriages. In a second family, with dominant macular degeneration, we found a 60 kb tandem duplication of the *PRDM13* gene on chromosome 6q. The tandem copies of the *PRDM13* gene appear to be intact with unaltered flanking regulatory sequences. The likely cause of disease in the family is overexpression of the *PRDM13* gene. The family has clinical features of North Carolina Macular Dystrophy, with appearance of unique macular pits at birth, suggesting an *in utero* effect. Finally, we and other investigators have reported megabase deletions of the *PRPF31* gene on chromosome 19q as another cause of adRP.

**Conclusions.** These findings suggest that a substantial fraction of the unsolved IRD cases have structural mutations, in known disease-causing genes, not easily detected by conventional NGS. Further, large structural variants may have additional consequences such as increased miscarriages.

## PgmNr 2569: Detection, characterization, and breakpoint refinement of balanced rearrangements by optical mapping in clinical cases.

### Authors:

---

The current standard of care for molecular diagnosis of many constitutional syndromic disorders and reproductive disorders is often chromosomal karyotype analysis, fluorescence in situ hybridization (FISH), and chromosomal microarray (CMA). Each of these methodologies has shortcomings that whole genome optical mapping (Bionano Genomics) is able to alleviate. Studies have clearly shown that approximately 6% of fetuses with *de novo* balanced rearrangements have serious congenital anomalies. With the advent of CMA an associated deletion was identified in some patients, but in most cases no underlying cause for the anomalies was found. In this study we demonstrate the ability of Bionano optical mapping to detect balanced translocations in five samples, all of them corresponding to translocations found by karyotyping. However, because Bionano Optical mapping has much higher resolution compared to karyotyping, we were able to map translocation breakpoints within specific genes, which will ultimately allow for a more complete diagnostic test. While the optical mapping could molecularly localize breakpoints in all of the samples, one sample proved to be unique and complex. In this sample, a t(4;21) translocation was found by karyotype and a deletion found by CMA; however with optical mapping, we could determine that there were three breakpoints with a 107 kbp deletion on chromosome 4 next to one breakpoint and a 57 kbp deletion on chromosome 21 next to another junction. There was an additional breakpoint with no loss of material that resulted in a nested inversion in the der(4) translocation. In summary, optical mapping could find three breakpoints and two deletions, and define genes directly impacted – broken or deleted, while CMA and karyotyping could only find two breakpoints and one deletion together. In addition, optical mapping identified a balanced t(3;20) which broke genes on both chromosomes, a balanced t(4;9) which also broke two genes, and two additional balanced translocations in different samples. In addition to the ability for Bionano optical mapping to detect most or all variants detected by CMA and karyotyping, it can detect smaller structural variants (>500bp) very robustly, making it a great complement to whole genome sequencing to integrate SNP and Indel calling with structural variation calling.

## PgmNr 2570: Rare case of monocentric isochromosome Y with inversion-duplication of p arm in patient presenting with azoospermia.

### Authors:

B. Kar <sup>1</sup>; A. Afreen <sup>1</sup>; S. Kundavi <sup>2</sup>

### Affiliations:

1) Center for Genetic Studies & Research, The Madras Medical Mission, Chennai, Tamil Nadu, India; 2) Institute of Reproductive Medicine & Women's Health, The Madras Medical Mission, Chennai, Tamil Nadu, India

### Introduction

The occurrence of isochromosome Y along with mosaicism is relatively common in present literature but the presence of inversion duplication of the p arm of the Y chromosome has not been widely reported. The present study describes a 36-year-old male patient with azoospermia who had two cell lines – one cell line with rare isochromosome monocentric derivative Y and the other with a 45,X complement which is reported for the first time to the best of our knowledge

### Methods

Informed consent was taken to perform karyotyping for the proband and his wife as well as to test for Y chromosome microdeletion for the male patient. The cytogenetic analysis involved karyotyping and C banding. Y microdeletion study was performed to test for the presence or absence of selected AZF regions. Fluorescent in situ hybridization (FISH) test was performed using probes for SRY gene, heterochromatin region of the Y chromosome and centromeric region of the X chromosome.

### Results

Karyotyping of the proband revealed two cell lines – mos 46,X,ider(Y)(q10)inv(Y)(p11.3q11.1)/45,X. C banding and FISH revealed inversion-duplication of a segment of the p arm of the Y chromosome. The derivative chromosome contained two SRY genes but only one centromere. Y chromosome microdeletion studies were negative for the regions tested. The proband's wife had 46,XX genetic complement.

### Conclusion

Individuals containing such abnormalities have variable phenotypes. Since such structural chromosomal anomalies are known to be highly associated with increased risk of aneuploidy, the proband and his wife were advised to undergo artificial reproductive techniques using donor sperm in order to achieve conception.

## PgmNr 2571: Emanuel syndrome: A clinical case report.

### Authors:

---

Emanuel syndrome (ES) is an unbalanced translocation syndrome, an inheritable chromosomal abnormality also known by the names of: derived syndrome 22, derived syndrome 11:22, partial trisomy 11:22 or supernumerary syndrome or der (22) t (11; 22). It originates generally from an inadequate 3: 1 segregation process in meiosis I during gametogenesis, in a phenotypically normal carrier with a balanced translocation, which causes the presence of a supernumerary derived chromosome 22. Patients with Emmanuel syndrome are characterized by a characteristic phenotype, which consists of facial dysmorphism (broad forehead, epicanal folds, inferior palpebral fissures, wide and flat nasal bridge, filter and long nasolabial groove, micrognathia) microcephaly, mental retardation severe, delay in development milestones and other reported abnormalities especially in men: congenital heart defects, renal and genital anomalies.

The diagnosis should be suspected in those patients with characteristic phenotypic findings and associated symptoms. It is established karyotypically, when it is identified in the proband the duplication of 22q10-22q11 and the duplication of 11q23-qter in a chromosome 22 derived supernumerary. Its incidence is unknown and a little more than 200 cases have been described in the world literature.

We present the case of a male patient of 14 months of age, with Emanuel syndrome, confirmed by aCGH study where a pathogenic duplication detected in the 11q23.3q25 chromosomal region of a 18.21 Mb size and a second duplication of 22q11.1q11.21 with a size of 5.1 Mb and a G banded karyotype of 25 metaphases that presents a marker chromosome, indicating a probable microduplication syndrome

## PgmNr 2572: Frequency of deletions in the iduronate-2-sulfatase gene in patients with Hunter syndrome.

### Authors:

---

**INTRODUCTION:** Hunter syndrome (HS) or mucopolysaccharidosis type II (MPS II) (OMIM # 309900) is an X-linked recessive disease caused by deficiency of iduronate-2-sulfate-sulfatase lysosomal enzyme, which leads to progressive accumulation of heparan and dermatan sulfate in different organs and tissues. It has an approximate global incidence of 0.69 to 1.19 / 100,000 live births. The gene involved is IDS were wrong sense mutations, nonsense mutations and deletions have been described. Deletions are classified by size in large and small, being 14-20% and 4-10% of patients respectively. In some patients with more severe phenotypes, total deletions or rearrangements have been described between the IDS gene and the pseudogene IDS2.

**OBJECTIVE:** To determine the deletions frequency in IDS gene and IDS2 pseudogene in patients with HS.

**MATERIAL AND METHODS:** 12 DNA samples from patients with clinical diagnosis of HS between 4 and 12 years old were used. They were processed by multiplex ligation-dependent probe amplification (MLPA) with SALSA probemix P164-B2 specific for HS and finally analyzed by Coffalyser software.

**RESULTS:** 16.6% (2/12) of the samples from patients with HS present a complete deletion of IDS gene and pseudogene IDS2.

**CONCLUSIONS:** The frequency of deletions in IDS gene and IDS2 pseudogene of 16.6% observed in these patients agrees with the previous described in the literature. However, these deletions have been associated with severe phenotypes at the neurological level, which differs in the present study when observed in patients with moderate psychomotor delay.

## PgmNr 2573: Molecular cytogenetic characterization of a karyotype of a female patient with secondary amenorrhea.

---

Disorders of sex development (DSD) are congenital conditions characterized by atypical development of chromosomal, gonadal, and phenotypic sex. Herein we report a case of a 24 female patient who presented with secondary amenorrhea. Cytogenetic studies of her peripheral showed two abnormal cell lines. One cell-line (27 cells) had a normal copy of the X chromosome and an abnormal chromosome that needed further investigation.

FISH analysis was performed using Kallmanns, Xist, and X centromere probes. Only one signal was observed for each of these probes, and metaphase FISH analysis showed these signals were located on the one normal X. So this normal copy of the X chromosome is positive for KAL (ANOS1), DXZ1, and XIST.

Fluorescence in situ hybridization (FISH) analysis using the SRY, Yp11.1-q11 and the Yq12 probes was also performed and revealed two copies of the SRY, two copies of the heterochromatin Yq12, and two copies of the Y centromere Yp11.1-q11.1 on what resulted to be an isodicentric Y chromosome.

Therefore the karyotype was described as

45,X[3]/46,X,idic(Y)(p11.31)[27].ish idic(Y)(SRY+,DYZ3++,DYZ1++,ANOS1-,DXZ1-,XIST-).nuc  
ish(ANOS1,DXZ1)x1,(DXZ1,XIST)x1,(SRY,DYZ1)x2

Females with a 46,XY karyotype have gonadal dysgenesis and most of them are mosaic, with a 45,X cell line. Some of them showed small deletions of the short arm of the Y chromosome. Further studies based on the clinical picture, as well as possible prophylactic gonadectomy due to an increased risk of gonadal malignancy, (gonadoblastoma or dysgerminoma) are suggested. Genetic counseling was recommended.

## PgmNr 2574: PCR-free whole genome sequencing using isolates from dried blood spot.

---

**Background:** Polymerase Chain Reactions-free rapid Whole Genome Sequencing (PCR-free rWGS) using Illumina sequencing platforms has emerged as a powerful diagnostic tool within hospital intensive care units for children who are acutely ill. Current PCR-free WGS library construction kits utilize genomic DNA (gDNA) isolated from whole blood. Although dried blood spot (DBS) isolates can be used for WGS, whole genome amplification (WGA) or post-ligation PCR is required to ensure sufficient library yield for next generation sequencing. Recent publications have shown that WGA and PCR-based libraries result in downstream sequencing bias such as increased GC content. To demonstrate the application of DBS isolates to generate WGA free and PCR-free WGS, we report feasibility studies and initial results using the DBS isolates and KAPA HyperPlus kits. **Method:** DBS specimens were collected with Whatman FTA paper or Protein saver cards 903 (40 ul EDTA whole blood). Ten disks of 3x3 mm punches were lysed using proteinase K and lysis buffer. After 60 minutes incubation at 56°C, magnet KAPA Pure Beads were applied for purification purposes. DBS isolates were quantified with Picogreen assay and Nanodrop followed by 0.8% agarose electrophoresis to ensure the integrity of the DNA. KAPA HyperPlus PCR-free library construction kits (pair-end) were utilized following the manufacturer's protocol. Final libraries were measured using real time PCR assay and fragment analysis. Lastly five PCR-free libraries were pooled and sequenced on Illumina Novaseq6000 S2 flow cell with read length 101x2 format. **Results:** Around 100 ng to 600 ng gDNA were extracted from DBS without degradation from both Whatman FTA and Protein saver cards. Approximately 3 to 11 nM of PCR free WGS libraries were generated with peak insert size around 450 bp. Greater than 95% of OMIM genes had >10x coverage for all coding bases. All genome build metrics were equivalent to the data from the previously validated clinical workflow. **Discussion and conclusion:** DBS are routinely collected for newborn screening. Our approach allows researchers and clinical laboratories to utilize DBS specimens for PCR-free WGS. Additional validation will be performed to further improve sequencing outcomes at Rady Children's Institute for Genomic Medicine.

## PgmNr 2575: Diagnostic utility of whole genome sequencing in a clinically diverse, exome-negative patient population.

---

Since 2012, UCLA Clinical Genomics Center has performed clinical whole-exome sequencing (WES) on over 2,200 patients with a diagnosis rate of 25%. As sequencing costs continue to decline, a critical question moving forward is to what extent whole-genome sequencing (WGS) can improve diagnostic yield over WES. Here, we present preliminary results from a pilot study to evaluate the added value of performing WGS in a diverse cohort of patients with suspected rare Mendelian diseases. A total of 133 patients have been enrolled at UCLA in the study thus far, all of which have received no molecular diagnosis from WES. A significant portion of these have also received a negative result(s) from clinical microarray (CMA) and/or gene panel testing. 30x, PCR-free WGS sequencing was performed, with 90% of patients receiving trio or quad-based family testing. In addition to analysis of all coding and non-coding SNVs and indels, comprehensive analysis of structural variants (SVs) was also performed using three different detection methods aimed at targeting SVs of different sizes and types. Out of 85 cases that thus far have received in-depth genetic review, 13 cases (15%) have been given a molecular diagnosis from WGS data. Seven (8% of the original cohort) were solved by detection of a single nucleotide variants (SNV) or small insertions/deletions (indels) within coding regions. Although WGS allowed for the complete coverage of a substantially greater number of genes overall compared to WES (97 vs 90%, respectively), no additional diagnoses resulted from the increased gene coverage of WGS. Rather, all were due to the discovery of a novel disease gene since the initial WES and would have been resolved upon reanalysis of the original exome. An additional 6 cases (7% of the original cohort) were diagnosed on the basis of SVs, most of which were single-exon deletions (average size of 1.2kb) and were well below the resolution of traditional CMA testing. In one instance, WGS detected a large 350kb pathogenic deletion that was missed by CMA due to mosaicism. Although the diagnostic yield from variants not assayable by WES is modest (6 of 85 cases, 7%), an additional significant minority of patients have a strong candidate non-coding variant of uncertain significance that may be determined to be pathogenic when augmented by mRNA sequencing. Our findings indicate that WGS could replace CMA and WES as a single genetic test, and further augment SV detection at comparable cost.

## PgmNr 2576: Clinical whole genome sequencing: The New York Genome dxperience.

---

With the introduction of Whole Genome Sequencing (WGS), the ability to detect exonic and intronic single nucleotide, copy number, and complex structural variants in a single diagnostic test has become feasible. As cost decreases, WGS has the potential to become a first-tier test for individuals with suspected complex genetic disorders. Despite the increasing utility of WGS, few reports are available on the detection of variants which are undetectable by standard clinical diagnostic tests such as whole exome sequencing, NGS based panel testing, or microarray. Here we describe New York Genome Center's experiences in identifying these variants in cohorts of individuals with undiagnosed genetic disorders as well as healthy individuals referred for predisposition testing. In the course of our time performing more than 300 clinical WGS, we have identified causal pathogenic or likely pathogenic single nucleotide variants, mosaic variants, single and multi-exon deletions, mobile element insertions, rare deep intronic variants, mitochondrial variants, and copy number variants in disease genes associated with the individual's primary phenotype, as well as in genes recommended by the American College of Medical Genetics & Genomics (ACMG) for reporting medically actionable secondary findings. We discuss the various methods used to validate the variants identified in WGS, the challenges we have encountered in clinical interpretation, as well as our experience with cases previously reported negative by whole exome sequencing or microarray. The power of WGS to detect variants that were previously only detectable in single gene or specific targeted panel testing makes the clinical utility of WGS unparalleled in the current field of clinical diagnostics. Our data illustrates the power of WGS and its potential to redefine how we perform clinical genetic testing and what we know about the genetic basis of disease.

## PgmNr 2577: Analysis of products of conception (POC) by array-CGH and comparison to conventional USG findings.

Array Comparative Genomic Hybridization (aCGH) is a preferred technique for genetic analysis of abortus samples over conventional cytogenetic analysis, as it provides high resolution detection of the submicroscopic duplications and deletions. It was already known that aCGH showed increased detection rate of copy number variations (CNV) as compared to conventional cytogenetic analysis. Moreover, Ultra sound (USG) findings during fetal development also play a major role in detection of many anomalies. Correlation of USG findings and aCGH data can lead to understanding of the role of CNVs in disease manifestation and also give phenotypic to genotypic association which can be further used as diagnostic tools. In the present study, we categorized USG findings of the Product of Conception (POC) samples in five major classes. They are (A) Cardiac anomalies, (B) Central nervous system anomalies, (C) Skeletal anomalies, (D) Hygroma related anomalies, (E) Other types of anomalies, and we correlated it with aCGH data. Array CGH was performed on oligonucleotide microarray platform (G2565CA, Microarray Scanner System, Agilent, USA). Data of the array was analyzed using cytogenomics software (CytoGenomics v4.0.3, Agilent technologies). In the present study, we analyzed 103 POC samples for the genetic analysis. Among these samples 41.75% samples showed abnormal fetus USG. whereas, 33.01% of the samples had abnormal aCGH results. Results also revealed that 30.23% CNV detection rate in samples with abnormal USG findings. Among these, hygroma related anomalies showed highest (61.5%) CNVs followed by Cardiac anomalies (23.07%). Hence, we can conclude that CNVs detection is higher in POC samples having hygroma related anomalies and cardiac anomalies detected in USG findings.

## PgmNr 2578: Advanced structural analysis of CDH risk loci with optical genome mapping technology.

Recurrent microdeletions and microduplications have been reported in over 10% of patients with Congenital Diaphragmatic Hernia (CDH), a genetically heterogeneous condition associated with high mortality and severe long-term morbidity in survivors. We designed a pilot study to compare the output of Bionano optical genome mapping technology in different sample sources and across a variety of genomic events, such as balanced and unbalanced translocations, and Kb- and Mb-size copy number variants (CNVs) in a cohort of 5 trios and 4 singletons affected with CDH.

The expected high-confidence events originally detected by standard karyotyping and/or chromosomal microarrays were validated in all the samples using the Bionano platform, regardless of the type of source material, and additional variants of unknown significance were uncovered. Among the samples assayed:

A) Translocation breakpoints were mapped in one case of an apparently balanced t(1;6)(p22;q15) translocation, which was confirmed in the proband and absent in his parents suggesting a de novo event, and similarly in an unrelated case with a t(1;15)(q44;q26.3) unbalanced translocation.

B) 1.5 Mb *NR2F2* deletion at 15q26.2 was shown to contain the clustering of two separate events: the net deletion/loss of 1.3 Mbp with a nested inversion of 192.9 Kbp.

C) 2.4 Mb gain telomeric to the 16p11.2 duplication syndrome region (OMIM #614671) was previously proposed as a risk factor for CDH. A more complex structure with two smaller duplications collectively spanning approximately 1.8 Mb was identified in a carrier in our cohort.

Optical genome mapping using Direct Label and Stain (DLS) of DNA motifs is a non-sequencing technology allowing the assembly of chromosome-arm length maps for the detection of structural and copy number variants. The results of the pilot study presented here are informative for the design of a larger study cohort of CDH-affected individuals, who have recently undergone NGS and CNV analysis, for further discovery and refinement of their genomic events.

## PgmNr 2579: Copy number variants in the ClinGen Allele Registry.

Sharing genomic variant data is critical to improving our knowledge base for both sequence and copy number variant (CNV) interpretation. The ClinGen Allele Registry ([reg.clinicalgenome.org](http://reg.clinicalgenome.org)) supports genomic data sharing by providing stable, unique, and dereferenceable identifiers for over 910 million unique sequence variants, a critical step in aggregating knowledge. Various resources use these identifiers for interoperability. Representing CNVs, however, has been a challenge, due to limitations in the standardized systems of variant nomenclature. This limitation hampers the ability to accurately aggregate information and share knowledge about CNVs. Some of the main challenges in representation of CNV data arise due to the inherent imprecision in the determination of breakpoints, imprecise and inconsistent quantification of the number of copy number gains and copy number differences on the X and Y chromosomes as they relate to X-linked disorders in males and females. To address this problem, we first reviewed existing methods for representing CNV data in key databases, including ClinVar, DGV, dbVAR, and ExAC. We also compared commonly used CNV representations with nomenclatures proposed by ISCN and HGVS. We identified discrepancies or limitations in a few areas including differences between the HGVS expressions and preferred names in ClinVar, absence of exact copy numbers gains in ExAC, lack of nomenclature in DGV, and floating point representations of copy number in dbVAR. Through our review of existing resources, we identified key information to define CNVs and have incorporated updates to the ClinGen Allele Registry to support their registration and query. One of the services offered by the registry is variant registration: for CNVs, this service returns an existing identifier if present, or if the variant is not present in the registry, the service presents overlapping and nested CNVs, helping the user decide whether to use one of the existing identifiers or create a new variant entry for the specific CNV. Other registry services include query and retrieval using various combinations of CNV attributes to provide links to existing CNV entries. We show how these registry services support CNV data sharing by aggregating information about the same CNV across current CNV databases, detecting redundancy, and creating a refined map of recurrent copy number variations based on the combined databases.

## PgmNr 2580: Frequency and characteristics of copy number variants (CNVs) identified by a whole exome sequencing platform.

### Authors:

J. Schleit <sup>1</sup>; I. Saarinen <sup>2</sup>; K. Gall <sup>1</sup>; J. Hathaway <sup>1</sup>; E. Salminen <sup>2</sup>; J. Koskenvuo <sup>2</sup>; T.-P. Alastalo <sup>1</sup>

### Affiliations:

1) Blueprint Genetics, San Francisco; 2) Blueprint Genetics, Helsinki Finland

### Background:

Copy number variants (CNVs) are an important cause of hereditary disease. The prevalence of CNVs across various disease categories is only beginning to be understood as next generation sequencing (NGS) technologies have become more sensitive at detecting these. However, an NGS assay's ability to detect various sized CNVs is highly dependent upon the testing platform and bioinformatics pipeline.

### Objective:

We describe the frequency and characteristics of diagnostic CNVs identified on a whole exome sequencing platform across 15 medical specialties in patients referred for clinical genetic testing. We report on the proportion of diagnostic CNVs that contribute to the overall diagnostic yield in each disease category.

**Methods:** Next-generation sequencing (NGS) was performed using the IDT xGEN Exome Research Panel with added custom probes and the Illumina NovaSeq 6000 platform. We performed a retrospective review of all genetic tests run on this platform from April 2018 to April 2019. The type of CNV (deletion or duplication), size (in bp), genomic coordinates, impacted gene(s), classification and the presence of other variants (reported as primary findings) was extracted from our internal database.

### Results:

Overall, CNVs made up 9.8% of all diagnostic variants (401/4093) and were the primary diagnostic variant in 3.7% of all tests. The majority (91.5%) of diagnostic CNVs were deletions. The median size of all deletions was 10.7kb (range 122bp-154Mb), and 25.9% of deletions were  $\leq 500$ bp. The median size of all duplications was 1.2Mb (range 374bp-72Mb) and 5.9% of duplications were  $\leq 500$ bp. Diagnostic CNVs made up the highest proportion of all diagnostic findings in whole exome tests (45.3%), pulmonology tests (33.3%) and ear-nose-throat tests (20.1%). Diagnostic CNVs made up the smallest proportion of all diagnostic findings in ophthalmology, endocrinology and cardiology (6.9%, 6.9% and 6.0% respectively).

### Conclusions:

Diagnostic CNVs are identified in approximately 10% of all tests performed on this whole exome sequencing platform. CNVs ranging from one exon deletions/duplications to multiple gene deletions/duplications were identified in multiple genes across almost all medical specialties. Importantly, 24.2% of CNVs were less than or equal to two exons in size. These results highlight the importance of a comprehensive genetic testing approach with high sensitivity to detect CNVs less than 2 exons in size across all medical specialties.

## PgmNr 2581: A systematic evaluation of copy number variation detection based on capture sequencing data.

Capture sequencing (CS) is widely applied to detect small variations. Algorithms based on depth of coverage comparison enable CS to detect copy number variations (CNV). However, a systematic evaluation is lacking with a large sample size. We conducted a retrospective analysis of CS data to evaluate the efficiency of CS-based CNV detection in the clinical diagnosis. A total of 3010 samples referred to our diagnostic lab for the CS test were included in this study. They were divided into four subsets for using in different parts of the study: (i) to select the appropriate CNV calling algorithm, (ii) to setup a validated filtration step, and (iii) to select CNV algorithm and optimize filtration parameter to build a CS-CNV pipeline and apply it on the undiagnosed samples to improve the yield.

Concatenate CNV list fromXHMM and CNVKit shows highest sensitivity. Thus they were selected to identify the CNV. The raw sensitivity was high but the raw positive predictive value (PPV) was low. Filtration with in-house reference CNV database could increase the PPV significantly to 49.4%. The yield of CS-CNV pipeline was up to 6.8% for the undiagnosed samples. In conclusion, marked yield of CS-based CNV detection could benefit the molecular diagnosis as it enabled simultaneous evaluation of CNV and small variations.

## PgmNr 2582: Detection of copy number variations in blood typing research and ADME genes using Axiom™ assays.

Copy number variations (CNVs) in *CYP2D6* and other genes which are relevant for drug absorption, distribution, metabolism, and excretion (ADME) are difficult to detect because these genes are members of highly homologous gene families, or because of the high prevalence of deletions and duplications in the population. Genotyping blood type variants is complicated by the frequent deletion of the *RHD* gene and its high homology with *RHCE* which together encode for Rh factor antigens. Copy number aware genotyping of markers in these regions significantly improves the accuracy of variant calling.

Results from experiments run on the Applied Biosystems™ Axiom™ PMD Array are presented here. The platform has the dual ability to detect CNVs in targeted genomic regions and to genotype SNPs across the whole genome using a single assay. CNV analysis methods include (a) whole genome de novo analysis for discovery and (b) fixed region analysis when breakpoints of CNV regions of interest are known a priori and there is little breakpoint variability from sample to sample. In CNV discovery analysis, CN states are determined by a Hidden Markov Model implementation in single sample mode. Breakpoints are discovered and CN segments are labeled by states. Fixed region analysis uses an optimized multisample clustering algorithm to assign CN states to each region in each sample.

CNVs in *RHD*, *CYP2D6*, *CYP2A6*, *GSTT1*, *GSTM1*, and *UGT2B17* were identified on replicate runs of more than 90 HapMap samples. Discovery analysis detected CNVs with overall analytical reproducibility greater than 90% for losses and 70% for gains. It was less sensitive in detecting duplications in a small 150 bp region around exon 9 of *CYP2D6* which is important in predicting metabolic capability of individuals. However, using fixed region CNV analysis, duplications and deletions were detected with 100% concordance with known truth in this region in all samples and were reproducible in all but one sample. Across all defined fixed regions of interest, homozygous deletions were detected with 100% concordance, while single copy losses were detected with 100% analytical sensitivity and over 95% analytical specificity. In summary, the platform easily allows performing the analysis with both methods, which results in superior analytical sensitivity and specificity for known small regions, while enabling discovery for larger regions and across the whole genome.

Current standard-of-care for genetically heterogeneous phenotypes often employs serial targeted gene testing, chromosomal microarray analysis and/or whole exome sequencing (WES), resulting in a lengthy time to diagnosis. Whole genome sequencing (WGS) addresses many of the technical limitations of these methodologies and can detect most forms of variation in a single test. Our group and others have demonstrated the diagnostic superiority of WGS compared with conventional testing in pediatric patients and critically ill infants.

Although WGS is poised to become a first-tier test for diagnosis of patients with rare genetic disorders, technical challenges as well as a lack of standards in both defining and deploying a clinical WGS test remain. To address these challenges, the Medical Genome Initiative (<https://medgenomeinitiative.org/>) was formed as a consortium of leading health care and research organizations in the US and Canada with an overarching mission to expand access to high quality clinical WGS. The work presented here focuses on the analytical validation of a clinical WGS test and aims to provide practical recommendations based on the consensus of group members

An analytical validation working group was formed to share common challenges faced by laboratories during the implementation of clinical WGS which led to the identification of practical solutions employed by the group. A series of discussions and surveys yielded consensus on several important topics: 1) Intended use and composition of a clinical WGS test including recommendations for the types of variation that should be reported; 2) the types of controls required for analytical validation of a clinical WGS test including reference standards and either commercially available or laboratory held positive controls for each variant type; 3) measurement of genome completeness (coverage and uniformity) to define WGS performance (callability) that can be tied to variant calling sensitivity; 4) a validation framework that includes accounting for genome complexity and variant type since both will affect test accuracy; 5) use of a comprehensive set of performance metrics for ongoing monitoring of quality and periodic use of positive controls dependent on sample volume.

These consensus recommendations may reduce the burden on new-to-WGS laboratories who wish to introduce WGS into clinical practice, and more importantly may serve to support safe and effective WGS testing for genetic disease.

**Background:** Glycosaminoglycans (GAGs) are ubiquitous cell and matrix-resident complex sugars and substrates of specific lysosomal enzymes. Urine GAG excretion is characteristic to mucopolysaccharidoses (MPS) disorders. Liquid chromatography-tandem mass-spectrometry (LC-MS/MS)-based GAG methods are more sensitive and reliable to measure specific GAG elevations for MPS diagnosis, screening and patient management.

**Methods:** An international expert group of lab directors and clinicians gathered to discuss various LC-MS/MS-based GAG assays and best practices for clinical use. Results are reported.

**Results:** Following key considerations were discussed:

- 1) In MPS diagnostic work-up, LC-MS/MS-based GAG detection has greater sensitivity and identifies specific GAG elevation which may be missed by non-MS based assays. Urine is the most characterized sample matrix to detect specific GAGs. Experts recommend enzyme testing as gold standard to confirm an MPS diagnosis.
- 2) LC-MS/MS-based GAG measurement in MPS newborn screening has potential to decrease false positive rates and improve positive predictive value when introduced as a second-tier test after dried blood spot enzyme screening.
- 3) While relative GAG elevation may correlate with disease severity for the same MPS type, correlation of LC-MS/MS-based GAG levels with treatment efficacy and disease progression requires robust comparison to multiple baseline samples and demonstrate clinical utility of specific methods with diverse and substantial patient samples.

4) Current methods differ among laboratories regarding use of internal standards (IS), internal controls, results reporting, and validation sample sets. Standardization of different LC-MS/MS-based GAG methods is desirable, although challenging to achieve.

**Discussion:** To further validate, harmonize and expand clinical utility of LC-MS/MS-based GAG methods it is important to establish inter-laboratory sample exchanges and share information on IS, reagents, normalization protocols and methods comparison.

With the decrease in sequencing costs and increased potential for diagnostic yield over small panels, whole exome sequencing (WES) is rapidly being offered in the clinical testing space. However, there has not been a thorough evaluation of how different capture technologies and library preparations affect the quality of WES data. Here we show that not all exomes are the same. We selected the 4 most common exome panels, comprising 3 different technologies and combinatorially tested them with 4 different library preparation technologies. We used 3 clinical samples with challenging variants (a large CNV, an exon deletion, and an exon duplication) along with the gold standard NA12878 genome to produce a total of 96 exomes. As whole genome sequencing (WGS) data has reduced sequencing bias compared to targeted capture like WES, we also generated WGS data on the 3 clinical samples for comparison. For each exome, we considered several metrics concerning sequencing quality and variant discovery potential to determine which combination approached the same levels as WGS of the same sample. We also determined precision and recall comparing against the NIST NA12878 defined variants. To provide additional clinical relevance, we determined the performance of each technology in specific regions of interest with different sequence contexts and clinical features. These genomic loci included sites with high clinical significance, i.e. many known pathogenic variants and patient sample CNVs, technically challenging regions such as high GC content or segmental duplications, and less understood but likely important regions based on evolutionary conservation and constraint. In each of these regions we determined the overall error rate, read mismatch propensity, coverage uniformity, and compared across exome preparations and WGS data. With these results, we provide clinical laboratories and the molecular diagnostic community with information to make the most informed decision. We also highlight the importance of assessing performance in challenging genomic regions for optimizing variant discovery. By improving variant identification, including CNVs, we can enhance our understanding of the clinical significance of these loci and enable more accurate interpretation.

## **PgmNr 2586: Three-years' accomplishment of Initiative on Rare and Undiagnosed Diseases (IRUD): A nation-wide project in Japan for discovering causes, mechanisms and cures.**

Japan

---

### **Background**

IRUD was launched in 2015 as a nation-wide project in Japan to construct a comprehensive medical and research system for establishing diagnosis, discovering causes and ultimately providing cures for rare and undiagnosed diseases, supported by Agency for Medical Research and Development (AMED). IRUD covers the entire geographic areas and the whole fields of specialties, taking advantage of the health care system in Japan. IRUD has been motivated by a global trend to tackle undiagnosed diseases through international collaborative networks, leveraging the phenotypic and genetic data by extensive data-sharing to solve so-called 'N-of-1' problems.

### **Purpose**

To demonstrate the accomplishment of the three-years' effort of IRUD project illustrating the landscape of rare and undiagnosed diseases in Japan.

### **Methods**

IRUD consists of the four pillars: a coordinating center (IRUD-CC) to orchestrate the whole system and strengthen the governance, clinical centers?IRUD-C?to operate diagnostic committees which take charge of the process from the decision for recruitment to the establishment of final diagnosis, analysis centers?IRUD-AC? to conduct whole exome sequencing analysis and a data center (IRUD-DC) to implement data-sharing platform, IRUD Exchange. Phenotypic data described in Human Phenotype Ontology and candidate genes are registered in IRUD Exchange, which architecture is compatible to international data-sharing platform, MatchMaker Exchange. Resources including DNA samples and cell lines are deposited in a resource center (IRUD-RC) and prepared for further utilization.

### **Results**

Thirty-seven clinical centers, 5 analysis centers, 1 data center and 1 coordinating center have been established. Until the end of July 2018, 3356 pedigrees including 9524 individuals have been enrolled

in IRUD. WES has been completed in 2756 pedigrees and final diagnosis has been established in 1027 pedigrees (36.9%). Novel genes or new disease entities have been discovered in 18 pedigrees through extensive data-sharing.

#### Conclusion

IRUD has realized a nation-wide comprehensive diagnosis network for rare and undiagnosed diseases and succeeded in establishing diagnosis, identifying novel causative genes and new disease entities through extensive data-sharing and accomplishing resource repository. Extensive international collaboration would play an essential role in elucidating causes and ultimately providing cures for such rare and undiagnosed diseases.

## PgmNr 2587: Findings from the Diamond Blackfan Anaemia cohort in the 100K Genomes Project.

**Scope:** DBA is characterized by dominant inheritance, incomplete penetrance, anaemia and multiple congenital abnormalities where single gene tastings is able to diagnose only up to 25% of the cases.

**Methods:** The Hammersmith Hospital in the UK is the referral centre for DBA with a registry of over 200 families tested locally with a custom targeted panel comprising of 83 ribosomal genes. The centre has participated in the 100K Genomes Project with a cohort of 35 DBA families for Whole Genome Sequencing (WGS).

**Results:** together, the targeted NGS and WGS have identified 34 pathogenic variants in known genes, 44 variants of unknown clinical significance (VUS) in known genes, 47 VUSs in novel genes and 26 pathogenic CNVs. In a number of cases through WGS, the diagnosis of DBA was eliminated due to the identification of characteristic pathogenic variants of other disease leading to case referral to the appropriate clinic.

**Conclusion:** Using Whole Genome Sequencing (WGS) or at least Whole Exome Sequencing (WES) we were able to identify additional cases of DBA that have otherwise been difficult. These techniques are therefore the best way to diagnose heterogeneous disease such as DBA where the outcome of the test can not only explain the basis for the disease, but also assist in the accurate classification facilitating the appropriate treatment.

## PgmNr 2588: Considering potential secondary/incidental findings associated with off-target disease from targeted NGS panels.

### Authors:

---

Targeted NGS panels can either focus on a well-defined phenotype or be quite broad in scope. While recommendations exist on the use of secondary findings detected by genome-wide testing, a different type of secondary or incidental finding can arise in panel testing, as some panel genes can be associated with additional, unrelated disorders outside of the scope of the panel test. In this study, we evaluated our panel-based tests for potential unrelated findings due to an off-target disease. We performed an evidence-based curation of 592 genes present on 39 panels offered by our laboratory. These panels cover 19 unique disease groups ranging from well-defined disorders with few genes, to broader phenotype categories, such as hearing loss. We categorized each gene based on their associated disorders, inheritance patterns, and the relation of the associated phenotypes to the intended purpose of the panel. The genes were divided into three categories: Category 1 (n=461) are associated with a single disorder or phenotypic spectrum with consistent inheritance patterns; Category 2 (n=77) are associated with multiple disorders with at least one additional phenotype outside of the scope of the panel (e.g. *GJB2*); Category 3 (n=54) are associated with multiple disorders, with at least one disorder completely unrelated to the scope of the panel (e.g. *MARS*). Category 3 genes are the most worrisome, as the associated phenotypes can be completely unrelated to the reason for testing, and some conditions can be adult onset. We identified category 3 genes in 26 panels, covering 13 disease groups, with hearing loss panel having the most genes (16). So far, in >1800 panel tests, we have not identified an additional finding, suggesting the incidence is rare; however, as the panel test design and analysis strategy takes into consideration disease-specific variant types, inheritance, and prevalence, the off-target use of genes on panels is likely to miss pathogenic variants associated with secondary/incidental findings. Given the potential for unrelated findings, we propose that all potential outcomes should be considered when designing targeted NGS panels. Testing limitations should be included in the report, and upfront decisions should be made on how to deal with additional findings, and how to report them. Informed consent may be warranted and off-target use of the panel is generally not recommended due to the design limitations.

## PgmNr 2589: Development and validation of a 2-step PCR library preparation method for the detection of *GBA* variants by next generation sequencing.

### Authors:

R. Owen; S.H. Rosenthal; A. Gerasimova; A. Smolgovsky; A. Buller-Burckle; F. Lacbawan

[View Session](#) [Add to Schedule](#)

**Affiliation:** Quest Diagnostics, San Juan Capistrano, CA

---

**Background:** The *GBA* gene encodes glucocerebrosidase, a lysosomal enzyme that breaks down glucocerebroside into ceramide and glucose. Genetic variants in *GBA* can cause the autosomal recessive disorder Gaucher disease, the most common lysosomal storage disorder, and are strong risk factors for Parkinson's disease. *GBA* analysis is complicated by the presence of a pseudogene, *GBAP1*, located 16 kb downstream of the *GBA* gene. Sanger sequencing of gene specific PCR amplicons is the most commonly used method for variant detection. However, the method is not suitable to consolidation with other analytical methods, such as next generation sequencing (NGS) when used in carrier screening for inherited disorders. Here, we aimed to design and validate a new 2-step PCR NGS library preparation method for the sequencing of *GBA* using an Illumina Miseq.

**Method:** The 8 most common *GBA* variants included for detection were: p.N409S (N370S), c.84dupG (84GG), p.R535H (R496H), p.L483P (L444P), c.115+1G>A (IVS2+1G>A), p.V433L (V394L), p.D448H (D409H), and c.1263\_1317del (del55bp). The first PCR used conventional long-range PCR to specifically amplify targets in *GBA* but not in *GBAP1*. The second PCR used nested PCR with primers containing Illumina sequencing primer binding sites which enabled addition of specimen specific barcoded sequencing adapters via concomitant fusion PCR. Sequencing ultimately was performed on the Illumina MiSeq platform. Compatibility of the method within an expanded NGS carrier screening panel was evaluated in combination with 18 other inherited diseases. **Results:** Method validation using 159 samples (94 positives [17 *GBA* positives], 65 negatives) showed 100% sensitivity and specificity. Subsequent testing using 11,778 consecutive clinical samples submitted for the validated carrier screening test showed that 2.0% (232/11,778) of cases harbored a *GBA* variant: 174 cases positive for N370S, 29 cases with L444P, 9 cases with R496H, 6 cases with 84GG, 6 cases with D409H, 4 cases with V394L, 3 cases with IVS2+1G>A, and 1 case with del55bp. **Conclusion:** This study demonstrated that the 2-step PCR NGS library construction method successfully screens for common *GBA* variants and can be readily consolidated for use in a comprehensive carrier screening panel.

Whole genome sequencing (WGS) has been widely used in research studies, and evidence is accumulating to support its use in clinical diagnostics. A comprehensive validation is warranted to assess the standards, efficacy, and limitations of WGS in the clinical setting. Such an effort requires performing clinical sequencing and analysis in a CLIA and CAP certified environment using a large number of samples with diverse relevant mutations independently identified and confirmed with a separate technology.

We have performed a validation study to evaluate the detection of SNV/INDEL, CNV, SV, and UPD using a unique collection of samples with various types of mutations validated by assays such as WES, CMA and cytogenetics. Our goal was to characterize WGS in terms of variant detection of SNV, SV, CNV and other variant types. An additional goal was to characterize the impact of genome build on results.

Samples are sequenced by Illumina NovaSeq 6000 with a PCR-free protocol with minimum of 40X average coverage and 2X150bp read length with 550bp average insert size. Data are processed with the Illumina Dragen pipeline mapping to the GRCh38 reference, with haplotype, depth based CNV and Manta split read SV callers.

For our evaluations we selected the GIAB sample NA12878 as well as a large set of internal clinical samples with known pathogenic variants. High analytical precision (>99.97%) and recall (>99.84%) were achieved for SNV. INDEL detection also demonstrates high quality metrics with correlation to the INDEL sizes. For CNV, we selected >70 samples carrying clinically reported CNVs as well as manually curated benign or unknown significance CNVs, adding up to >200 individual events spanning losses or gains of hundreds of base pairs to megabases. The read depth method alone demonstrated 100% sensitivity for events larger than 3kb. For smaller events, joint analysis of the read depth and the Manta results increased the sensitivity. For SV and AOH/UPD, the analysis detected clinically reported inversions, translocations, insertions, hetero- or iso- disomies, and AOH in >25 samples. We also examined mosaic variations with positive results. In terms of regions of low sequencing coverage and sequencing depth uniformity, WGS provided data of higher quality than WES as expected.

This validation demonstrates that WGS applied to clinical molecular diagnostics can detect diverse mutation types with a comparable or superior robustness to traditional methods.

## PgmNr 2591: Targeted long-read sequencing of complex human duplicated regions.

Human-specific segmental duplications (“HSDs”; genomic regions >1 kbp in size with >98% identity), or loci existing exclusively in the human lineage, have the potential to contribute to traits and diseases unique to our species. Unfortunately, due to the high identity of these regions, they are technically challenging to study. Recent comparisons of great ape whole-genome shotgun sequences identified over 30 HSD gene families uniquely duplicated, including two genes previously characterized as potential drivers of human neocortex expansion (*SRGAP2C* and *ARHGAP11B* ).

To evaluate the potential evolutionary/disease impact of HSD genes, we surveyed genetic variants from human population controls using existing datasets and found less than 2% and 5% of HSD regions contain confidently mapping reads (1000 Genomes Project and Genomes in a Bottle (GIAB), respectively). As such, 78% of HSDs lack any common variants (dbSNP). To address this gap in variant discovery, we have established a high-confidence benchmark variant callset using BAC sequences from a haploid hydatidiform mole cell line (CHM1) across nearly 30 Mbp of the genome, including 22% of all annotated HSDs. We confirmed that Illumina CHM1 sequencing (>30X) underperforms in variant calling within HSDs due to inaccurate mapping of short reads. Sequencing CHM1 using Oxford Nanopore Promethion (>30X ) found that long reads map accurately within HSDs but high sequence error rates result in faulty variant calling. To address this, we combined target enrichment of select HSDs (>2 Mbp, 48 genes) using the new PacBio Sequel II sequencing platform. This approach uses single-molecule circular consensus correction to generate accurate long reads useful for variant calling. As proof of principle, we performed targeted sequencing of eight individuals (two haploid hydatidiform mole cell lines and two GIAB trios) generating, on average, 903 Mbp of sequences per sample with median polymerase read length 41.7 kbp and median circular consensus length 3.7 kb (14X coverage per 3 kbp fragment). Work is ongoing to confirm accurate variant calling. Once established, we will expand this approach to sequence HSDs in a larger cohort of modern humans to confidently survey genetic variants and shed light on the evolutionary impact of these complex regions within the human genome.

## PgmNr 2592: Assessment of sensitivity and specificity in a population genetic screen to identify medically relevant variation.

The Alabama Genomic Health Initiative (AGHI) is a state-wide effort to conduct genetic testing for ~10,000 individuals not ascertained for any phenotype. We are using an Illumina Global Screening Array (GSA) to detect pathogenic/likely pathogenic (P/LP) variation in medically actionable disease genes; predominantly associated with cancer/cardiac risk, that overlap largely the 59 actionable genes defined by the American College of Medical Genetics and Genomics.

To date, 4,355 participants have been analyzed. 63 (1.4%) harbor a P/LP variant deemed suitable for return, comprising 48 unique variants across 17 genes. P/LP variants were validated by CAP/CLIA-certified Sanger before return to participants.

Array-based genotyping is more efficient and cost-effective than sequencing, but does have limitations in terms of sensitivity and specificity. We found that ~60% of secondary P/LP variants found from sequencing ~1,000 healthy individuals are present on the array, indicative of a sensitivity upper limit. To assess sensitivity of P/LP variants on the array, we tested 24 individuals known to harbor a medically actionable variant targeted by the GSA; all expected variants were identified, suggesting high sensitivity to array-targeted variants.

We also assessed specificity. Hundreds of potential P/LP variants on the array are seen more frequently in AGHI than reported in databases, or is plausible given associated disease prevalence, suggesting false positives (FPs). After filtration to remove obvious FPs, the remaining P/LP variants in actionable genes were manually curated and Sanger tested. We found that 41 unique P/LP variants, in 39 individuals, detected by GSA were FPs; added to the 48 validated P/LP variants (above), these data indicate a false discovery rate among array-identified P/LP variants of ~46%, even after extensive automated filtration. In 28 of 39 individuals, Sanger detected benign missense/synonymous variation at, or nearby, the tested position, indicating that the array detected a non-targeted variant. For 11 individuals, no nearby alteration was identified by Sanger; reason for array detection is unknown.

Through AGHI, we have implemented an array-based process to screen a population of Alabamians to cost-effectively identify highly penetrant genetic variants in actionable disease genes. We demonstrate the need for clinical follow-up of array-identified variants, especially when considered in the context of direct-to-consumer genetic testing.

## **PgmNr 2593: Assessing clinical validity of genes of unknown significance in patients with undiagnosed diseases utilizing ClinGen's Clinical Validity Framework: Experience in the NIH Undiagnosed Diseases Program.**

### **Authors:**

---

The NIH Undiagnosed Diseases Program (UDP), a member site of the Undiagnosed Diseases Network (UDN), enrolls patients with diseases that remain undiagnosed despite extensive diagnostic evaluation and clinical testing. Clinical exome or genome sequence analysis is frequently non-diagnostic for our patients, therefore, the major work in the diagnostic odyssey for our patients is the assessment of candidate variants in genes of unknown significance (GUS). The major hurdle in this process is evaluating the level of evidence and establishing the clinical validity of these GUS in the context of our patients' clinical phenotypes. The UDP invests extensive resources to tackle this problem; one approach included reanalysis of 234 probands and their nuclear families, which was carried out over the span of 3 years from May 2015 to May 2018. Their variants of unknown significance (VUS) were triaged based on 3 principles: segregation with disease phenotypes, low population frequency consistent with a rare disease, and multifactorial prediction of molecular impact(s). The GUS are then further prioritized based on 3 broad evidence categories that either support or disqualify gene-disease relationship: clinical, genetics and experimental. The major outcome of this process is the prioritization of variants most likely to be the underpinning cause of the patients' diseases, and more importantly, designation of these variants to: (i) those deemed to be the diagnosis; (ii) those likely to be the diagnosis pending functional validation and/or accumulation of experimental evidence; and (iii) those needing additional evidence such as additional cases with similar genotypes and phenotypes for further actions. Over 750 candidate variants in 251 GUS were prioritized using this method, and to date, with the accumulation of evidence, 34 cases have reached a definitive diagnosis. To objectively evaluate the level of evidence supporting the gene-disease associations in these cases, a study was carried out using the ClinGen evidence based clinical validity framework. Gene-disease associations were scored through intervals before and after the diagnoses were made. Overall, the utilization of ClinGen's framework provides an objective assessment for the degree of evidence needed to reach a diagnosis for our patients, and how well the clinical validity of gene-disease associations has stood over time.

## PgmNr 2594: X chromosome haplotypization in the group of Turner syndrome patients.

### Authors:

---

Monosomy of chromosome X - Turner syndrome is the only monosomy postnatally compatible with life. The incidence of this chromosomal abnormality is 1 : 2 500 live female births. These patients are phenotypically characterized by lower stature compared with the general population, fertility disorders and other deviations from the physiological female genotype. Life expectancy could be affected by heart disorders that are present in almost 50 % of these females.

The origin of heart abnormalities and other phenotypical defects of these patients may correlate with maternal or paternal haplotype of chromosome X. We used molecular genetic analysis for detection microsatellite DNA markers on chromosome X for reveal of origin of these gonosome in Turner's syndrome patient's cases.

In the initial part of our study we selected cohort of 20 Turner syndrome patients with cytogenetically confirmed X monosomy and their parents. Results of another 22 families will be presented on the congress.

The biological material for DNA isolation was the peripheral blood of the patients and the cells of the buccal mucosa of the parents. We used the Argus X-12QS forensic kit for the X-chromosome analysis, which was optimized for our genetic testing. The method is based on detection of 12 STR markers from chromosome X. The variability of these STR markers allow to establish parental origin of haplotype.

Preliminary results suggest that 65 % of X chromosomes are of maternal origin and 35 % cases of paternal origin. We plan to extend the group of tested families and the next part of our project will be a specification of phenotypic deviations that will be compared with the origin of gonosome.

---

**Introduction:** Assisted reproductive technology (ART) *techniques* have become common practice in many countries today and has supported numerous infertile couples worldwide. Although, ART has evolved technologically in last few years resulting in increased success rate and low cost. Of all aspects of ART viz, gamete retrieval, in vitro fertilization, selection of embryo, cryopreservation, vitrification and embryo transfer, selection of embryo has significant impact on ART outcome. Advance genomic technologies like next generation sequencing and microarray can aid clinicians in selecting embryos with normal euploid and genomic content. Here, we present our experience with 1200 embryos from 280 females.

**Material and Method:** Subjects included in the study were both women and men who were then sub-grouped based on four major reasons viz. 1) advanced maternal age, 2) more than three IVF failures, 3) low sperm count and 4) genetic indications. Blastomere or Trophectoderm biopsy were performed in 1200 embryos from 280 females undergoing IVF treatment. These single cell (blastomere) or four to six cells (trophectoderm) biopsy were subjected to whole genome amplification (WGA) using a picoplex WGA kit (Takara). Amplified product was then taken up for customized microarray and NGS based chromosomal aneuploidy analysis where a lower mark of 10MB of deletion duplication was taken for reporting and a mosacisim of minimum 25% was reported.

**Results:** Combined NGS and microarray data revealed 272 (22.66%) embryo had segmental or whole chromosomal aneuploidy. From the pooled data of all aneuploid embryos, it is evident that chromosome 16 was involved in 4.33% of events and chromosome 8 showed the least (1.26%) incidence of deletion and duplication. Among the incidence of aneuploidy heterozygous deletion was a significantly frequent (18.7%) event as compared to homozygous deletion (8.42%), homozygous duplication (9.65%) and heterozygous duplication (12.4%).

**Conclusion:** A significant number of embryos showed chromosomal and/or segmental aneuploidy, thus requiring the genetic screening of potential embryos in couples undergoing IVF treatment. Chromosome 16 has maximum risk of deletion or duplication as compared to other chromosomes.

## PgmNr 2596: Unique dual indexing primers and universal blockers enable multiplexed target enrichment applications.

### Authors:

Target enrichment has been an enabling approach to sequencing specific regions of the genome and calling variants while reducing sequencing cost per sample. The ability to create customizable panels has been a key driver for increased utilization of target enrichment within various workflows and applications.

However, two important components, (1) unique dual-indexed (UDI) Y-adapters for library creation and (2) specific adapter blockers used to improve on-target rates during target enrichment, have seen few recent advancements and are fast becoming limiting factors in multiplexed target enrichment applications. Synthesis of UDI Y-adapters is challenging due to their relative long length (>65bp), 5'-phosphate chemical modification, and purity requirements that demand HPLC purification of two oligonucleotides for every desired index set. They also commonly generate significant amounts of undesired adapter dimer during ligation reactions. Some 'universal' adapter blockers are commercially available, but their application is limited to subsets of index lengths and artificially constrain experimental design.

To address these limitations, fundamental changes to (1) installation of UDI sequences during library creation and (2) adapter blockers were investigated and provided numerous benefits. Application of the Twist Universal Adapter System reduced undesired adapter dimer formation below the lower limit of detection under common reaction conditions, increased total gDNA library yield 2X with a 20% reduction of PCR amplification cycles, and enabled facile switching between index designs. In addition, facile synthesis allows for access to thousands of UDI pairs so the number of samples and amount of data generated during sequencing can be maximized. To complement this robust adapter system, Twist Universal Blockers eliminate any requirement for specific adapter blockers. This design functioned independently of index length, increased capture of on-target reads when compared to sequence-specific adapter blockers on a molar basis, was agnostic to target enrichment panel size, and remained functionality equivalent in singleplex and multiplex workflows.

Taken together, these advancements in the application of shared adapters for UDI sequence installation and universal adapter blockers eliminate numerous bottlenecks for target enrichment multiplexing applications.

# PgmNr 2597: Analytical validation of SNP arrays for clinical diagnostics: Multi-platform framework.

## Background

Clinical interpretation of genotype data requires high positive predictive value (PPV) and understanding of genotyping platform performance to minimize genotyping error. Single nucleotide variant (SNV) genotyping arrays, like the Global Screening Array (GSA), offer high-throughput, low-cost genotyping for actionable single nucleotide variants. Consequently, we hypothesize that analytical validation of GSA enables precision medicine.

## Methods

To validate the GSA, we generated whole genome sequence (WGS) data (30x, GenomeNext Churchill pipeline) for 263 1000 Genomes (1KG) project samples from Coriell. 236 of these were genotyped in triplicate with the GSA. Publicly available genotype and WGS data were downloaded and paired with GSA data. All WGS data were archived on Amazon S3. Following exclusion of low quality sample data and following stratification of the data by nucleotide type, change, allele frequency (AF), and DNA complexity at locus, we analyzed or are analyzing the GSA data performance metrics relative to the 1KG and the WGS data using two approaches: (1) GSA vs. 1KG, and (2) GSA vs. WGS. A random subset of discordant variants discovered by these analyses will be assessed using Sanger sequencing and performance of GSA relative to WGS and Sanger sequencing will be calculated.

## Results

Based on above analyses, we observed high concordance with the 1KG data across 612,341 GSA assays in the 236 sample triplicate dataset (avg. concordance range [0.991 – 0.994]; std-dev range [0 - 0.001]). Additionally, we observed the following for a single replicate dataset: PPV (0.989 ±0.0009), sensitivity (0.993 ±0.0006) and specificity (0.996 ±0.0003). Limiting the data to high-quality samples (call rate > 0.98) and high genotype call rate assays (assay call rate >0.997; 602,371 assays) improved the average overall concordance (0.9936 vs. 0.9937) and sensitivity (0.9929 vs. 0.993). Stratifying SNVs by various genomic features showed a reduced PPV if the alternate allele is rare (AF < 1%) and a reduction in all performance metrics if the SNV mapped to low-complexity regions. We also present additional performance metrics and discuss their role in analytical validation.

## Conclusion

Our systematic evaluation shows that SNV genotyping arrays, such as the GSA, can achieve analytical validity. This framework for analytical validation of genotyping arrays is a step toward their clinical use.

## **PgmNr 2598: Bionano Prep SP isolates high quality ultra-high molecular weight (UHMW) genomic DNA to improve research of cancer and undiagnosed disorders.**

---

Optical mapping of genomic DNA on the Bionano Genomics Saphyr® system for genome assembly or structural variation detection relies on starting with UHMW DNA. To achieve this, protocols using agarose plugs have been the gold standard. The “plug lysis” method is extremely robust, but it is also labor intensive, difficult to automate, lengthy and expensive. To address these shortcomings, we coupled solution-based lysis with a purification step that leverages a novel process to bind, wash and elute UHMW genomic DNA. This entire protocol can be conducted in less than 4 hours on a batch of 6 samples, allowing 12 samples to be processed in one day. The eluted material is ready to use by day 2 and contains high quality DNA that is clean enough for the direct label and stain (DLS) protocol. The resulting single molecule quality metrics of this labeled DNA on a Saphyr Chip® are comparable or exceed the metrics for labeled DNA isolated by the traditional plug lysis protocol. We have previously validated protocols for fresh/frozen human blood (EDTA) and cultured cells and released the Bionano Prep SP kit that provides virtually all of the required reagents and consumables. For many samples, the addition of DNA stabilizer has allowed us to achieve average labeled DNA centers of mass (COM) N50s of  $\geq 280$  kbp, with a significant proportion of Mbp-sized molecules. Unlike plug lysis, the SP protocols are clearly automatable, providing a solution for researchers needing to purify DNA from hundreds to thousands of individuals per year.

We have continued to expand the number of validated SP protocols for new sample types including fresh/frozen heparinized human blood and bone marrow aspirates (BMA)s. The new protocols also include; the addition of DNA stabilizer to the heparinized bloods/BMAs before they are frozen, to increase the size of isolated DNA (COM N50s  $\geq 300$  kbp), and cell straining upon thawing, to avoid clots and insoluble aggregates before cell counting. We have also developed working SP protocols for small amounts (5-15 mg) of animal and human tissues including tumor biopsies. These SP protocols are significantly shorter and less labor intensive than our previously released plug lysis protocols, while QC metrics of the SP isolated genomic DNA are comparable or exceed the metrics of genomic DNA isolated by the plug lysis protocols.

## PgmNr 2599: Monitoring the impact of pre-analytical parameters on cfDNA quality.

---

Cell-free DNA (cfDNA) has become an important source for potential new biomarkers. However, it represents a challenging sample type due to its low yield and complex fragment size distribution. Pre-analytical parameters have a major impact on the quality of cfDNA samples. Controlling and monitoring pre-analytical parameters, including cfDNA extraction, is crucial for experimental success. A new automated electrophoresis assay was used to compare nine different kits tailored for cfDNA extraction. Three independent plasma samples were processed with each kit in parallel and subsequently analyzed with the new electrophoretic assay in six replicates. The assay offers total DNA quantification, and automatically assigns a region for cfDNA separately from high molecular weight DNA by size. Using region analysis, the concentration of cfDNA apart from high molecular weight (HMW) DNA is evaluated by the software. The quality score %cfDNA is provided as additional quality parameter, determining the percent cfDNA of total DNA in presence of HWM. This set of quality parameters adjusted to the needs of cfDNA characterization was applied to compare the kits. The extraction kits varied in rate of yield and their size selection capacity to remove HMW DNA. In general, each kit afforded either superior yield or high selectivity towards cfDNA. High yield may be crucial for plasma with low cfDNA content, yet if the plasma is expected to contain considerable amounts of HMW DNA, the selectivity towards cfDNA might be favored. Therefore, the choice for the most suitable cfDNA extraction kit depends on the requirements for downstream analyses as well as the expected cfDNA concentration and occurrence of HMW DNA. Even if no preference for a single kit could be established, the results present a straightforward way to monitor the impact of pre-analytical parameters on cfDNA concentration and quality.

---

Genomic inversions are a class of DNA structural variation (SV) that usually presents with two breakpoints that occur in *cis* and a subsequent 180-degree longitudinal turn of DNA. Copy-number neutral inversions are challenging to resolve using classical methods for SV detection as there may be no immediately obvious genomic alteration to infer orientation of the copy number neutral event. Inversions are often flanked by inverted repeats and have breakpoints embedded within repeat regions further complicating analysis. Detection methods for inversions, such as fosmid clone sequencing (PMID: 18451855, 17901297) and paired-end (PE) sequencing (15895083), have limited ability to resolve/map breakpoint junctions of inversions larger than 100 kb in size. Optical mapping (OM) involves tagging sequence motifs along unbroken DNA strands >100 kb in length preserving the architecture of SVs harboring more than one breakpoint junction *incis*. Given the mounting evidence for inversion rearrangements contributing to disease pathogenesis we sought to compare different SV detection methods on a well characterized control genome.

We performed OM on a female lymphoblastoid cell line (NA15510) using BioNano direct label stain (DSL) technology. Given that inversions can be mediated by repeats, we incorporated a custom database, Highly Similar Intrachromosomal Repeats (HSIRs), allowing for the visualization of inverted repeat regions genome-wide. To allow for a direct comparison of OM versus both fosmid and PE sequencing the genomic location of inversions detected by these methods were also considered as part of our analysis. In total, 90 inversion events were detected by OM and/or other methods. Of the 46 inversion events detected by OM, 36% were not detected by other methods while 15% were detected by at least one other genomic sequencing-based technique. Only 1% of inversions were detected by both OM and all other methods analyzed. Only 19% of inversions studied involved HSIRs while 35% involved segmental duplications. The precise genomic location of all previously documented inversions was further refined due to the uncertainty inherent to previous methods versus that of OM.

The visualization of long lengths of unbroken DNA through OM is critical in properly studying an SV with two breakpoints in *cis*. As the role of SVs in human disease becomes more clear new methods like OM may be required to study a structural aberration in its totality.

---

Next generation sequencing technologies provide a means to detect vast quantities of rare variation in clinical subjects. With this opportunity comes the challenge of distinguishing reportable, clinically-relevant variation from thousands of non-reportable variants. Clinical laboratories have developed a variety of methods for prioritizing variants for manual review, including the use of patient phenotype information to create targeted gene lists that prioritize variants within genes potentially related to patient disease phenotypes. Using patient medical records and HPO terms listed by ordering providers, Stanford Medicine Clinical Genomics Program (CGP) generates a unique, phenotype-driven, target gene list (TGL) for patients referred to CGP for clinical exome analysis. This phenotype-driven prioritization approach is run upstream of broader variant prioritization strategies to maximize the chances of identifying clinically-relevant variation. Here, we retrospectively investigate the value of a phenotype-driven variant prioritization strategy on a cohort of proband-only and trio samples referred to CGP for clinical exome sequencing and analysis.

Gene, variant and prioritization data were collected from each case, including: number of genes on each patient's TGL, number of variants prioritized through the TGL, total number of prioritized variants, report result, and reported variant info. We investigated whether reported variants were identified via target gene strategies or broader strategies, whether variants identified by TGLs would have been identified by broader strategies had TGLs not been used, and which filters were most useful to prioritize variants when TGLs were not used.

Of the variants reported to clinicians, a majority were identified via the TGL, despite comprising a small quantity of the total prioritized variant list. For positive cases, about half of the reported variants were identified via the TGL. We observed that nearly all of our reported variants would have been identified by broader variant prioritization strategies had we not created a TGL. When TGLs were not used, inheritance and canonical loss of function filters were most useful in identifying reportable variants. Variants not detected in the absence of a TGL included rare, not previously reported, missense variation. These results demonstrate additional disease-gene association resources may help to improve phenotype-driven analysis.

## PgmNr 2602: Clinically ambiguous cases screened by NGS: VUS interpretation in the light of the clinical manifestation.

### Affiliations:

1) Human genetics, GMDL Genica1. Genetic Medico-Diagnostic Laboratory Genica, Sofia, Bulgaria, Sofia, Bulgaria; 2) Department of Medical Chemistry and Biochemistry, Medical University, Sofia, Bulgaria; 3) Department of Neurosurgery, University Hospital "Saint Ivan Rilski", Sofia, Bulgaria; 4) Department of Clinical Genetics, University Pediatric Hospital Sofia, Sofia, Bulgaria; 5) Department of Pediatrics and Medical Genetics, Medical University - Plovdiv, Plovdiv, Bulgaria; 6) Clinical Institute of Medical Genetics, UMC Ljubljana, Šljamerjeva 4, SI-1000 Ljubljana, Slovenia

Here we report 3 clinically ambiguous Bulgarian cases screened for genetic verification by NGS. Case 1: 2 years old boy with horizontal nystagmus, muscular hypotonia, retinopathy, neck hyperkinesia without teeth and epilepsy at the moment of genetic testing. Compound heterozygous variants in the *ROGDI* gene were detected: c.432+1\_432+2insG, likely pathogenic and c.727C>G, VUS. Pathogenic homozygous and compound heterozygous variants in this gene represent an established cause of Kohlschütter-Tonz syndrome, epilepsy, psychomotor regression and amelogenesis imperfecta, however development may be normal until the onset of seizures in infancy. Both variants are not detected among the healthy control population. Based on the previous reports of other pathogenic loss-of-function variants and the compatibility with the symptoms the variants are classified as probably pathogenic and disease causing.

Case 2: 1 year old girl with cerebellar atrophy, neonatal hypotonia and seizures. The NGS data indicated two heterozygous missense variants in the *GFM1* gene: c.881C>T and c.6607A>G, classified as VUS. Pathogenic biallelic variants in this gene represent an established cause for Combined oxidative phosphorylation deficiency 1 with generalized brain atrophy, hypotonia and seizures as it is in our patient. The mutations in this gene are associated with neonatal liver failure and lactic acidosis which are not manifested in our case. The variants are novel and we cannot conclude in favor of their pathogenicity.

Case 3: 3 years old boy with autism, neonatal epilepsy, encephalopathy and muscle hypotonia. A heterozygous variant was detected in the *CLCN1* gene c.1437\_1450del, reported to be associated with Myotonia congenita AR. The variant was detected in asymptomatic father. Later, the NGS data were reevaluated and two heterozygous missense variants were detected in the *SYNE1* gene: c.24569A>C and c.17650C>T, classified as VUS. Pathogenic variants in this gene were reported in association with Emery-Dreifuss muscular dystrophy 4 AD and Spinocerebellar ataxia AR8. Genetic variants in the *SYNE1* gene have been reported in patients with autism.

The detected variants in these 3 families segregated in terms of the expected mode of inheritance. The question is how positive we could be that the genetic diagnosis is clarified in these cases? Can we consider these genes as the only and definite cause of the diseases in the tested patients?

## PgmNr 2603: Broad genomic screening of active-duty Air Force members: Findings from the MilSeq study.

Keesler AFB, MS; 9) The Broad Institute of MIT and Harvard, Cambridge, MA

### Introduction:

Within the framework of the MilSeq Project, a pilot study examining the process of incorporating genomic testing into the United States Air Force Military Health System, 75 active-duty participants underwent genomic screening via exome sequencing.

### Methods:

Five main categories of genomic findings were returned to participants: 1) monogenic and 2) carrier status findings from >5000 genes, 3) 18 established or likely risk alleles with odds ratios >3 for 8 common diseases, 4) 230 pharmacogenomic (PGx) variants with CPIC and PharmGKB recommendations affecting the metabolism of >12 drugs, and 5) blood and platelet antigen typing results. Variants from categories 1 and 2 were assessed according to the 2015 ACMG/AMP guidelines, and pathogenic or likely pathogenic variants in genes with a strong level of evidence for association with disease were reported. Risk variants were assessed according to a novel framework developed by the laboratory and were an expansion in report content from our previous MedSeq and BabySeq studies.

### Results:

We identified monogenic findings in 12% (9/75) of participants and carrier status in 87% (65/75; average of 2 and range of 0-6 variants), consistent with previous studies. In 9 individuals, no variants associated with monogenic or carrier status findings were detected. We also identified risk alleles for 4 diseases in 37 participants, 29 of which had 1 reportable risk allele and 8 of which had 2 risk alleles. The most commonly identified risk allele was heterozygosity for the *APOE* e4 variant for Alzheimer's disease (22 participants), followed by heterozygosity for *MUC5B* c.-3133G>T for pulmonary fibrosis variant (17 participants). Only 1 participant was heterozygous for the frequent Factor V Leiden variant, which is associated with a risk for venous thromboembolism. Warfarin genotyping was provided for every individual due to incorporation of non-genetic factors in dosing guidelines. Additional PGx diplotypes prompting a potential change in drug management were identified in 92% of participants (average of 4 and range of 0-8 drugs). The most frequently affected drugs were PEG-IFN-alpha/ribavirin and tamoxifen.

#### Conclusions:

The findings from the genomic screening within the MilSeq project highlight the broad range – and potentially high impact – of genetic information that can be attained through systematic analysis of genomic sequencing data, particularly in a more diverse population.

## PgmNr 2604: Affordable trio-genome sequencing as first tier genetic test in critically ill infants: Practice in China.

### Authors:

H. Wang <sup>1</sup>; Y. Lu <sup>1</sup>; X. Dong <sup>1</sup>; G. Lu <sup>2</sup>; G. Cheng <sup>3</sup>; Y. Qian <sup>1</sup>; Q. Ni <sup>1</sup>; P. Zhang <sup>1</sup>; L. Yang <sup>1</sup>; B. Wu. <sup>1</sup>; W. Zhou <sup>1,3</sup>

---

**Background** Genome sequencing was feasible to provide genetic diagnoses in critically ill infants with rapid turn around time (TAT). Herein, to delineate the value of genetic diagnosis, we provide the results from 130 pediatric patients in the hospital in China.

**Methods** This study was performed with an affordable trio genome sequencing (ATGS) test. The sequencing depth of patients were 40-50 X, and of their parents were 8-10 X. Patients from PICU/NICU with complicated clinical features were enrolled from June 2018 to Dec. 2018, each with phenotypes suggesting of an underlying genetic disorder.

**Results** The ATGS testing identified diagnostic variants in 47.7% (62/130) individuals. The TAT was 3-5 work days and the cost was 2500\$ per family. Of the sixty-two infants with diagnoses, 48 (77.4%) patients were found with pathogenic single-nucleotide variants (SNVs), 12 (19.4%) patients were detected with pathogenic copy number variations (CNVs) or structure variants (SVs), 2 (3.2%) patients were found small deletions plus pathogenic variants in another allele of autosomal recessive gene. Therapeutic strategies of 48.4% (30/62) diagnosed patients were modified, including transplantation, dietary recommendation or change of drugs, which obviously avoided morbidity and improved prognosis.

**Conclusions** This study provided a powerful capacity of ATGS testing in detecting of SNVs and chromosome abnormalities with fast response, higher diagnostic yield and lower cost. ATGS shows the potential to be the first tier genetic test in critically ill infants in developmental country.

## PgmNr 2605: Detection of structural variations in monozygotic twins using Nanopore long-read sequencing technology.

### Authors:

H. Mishima <sup>1</sup>; S. Yoshida <sup>2</sup>; Y. Morimoto <sup>2</sup>; S. Ono <sup>3</sup>; A. Kinoshita <sup>1</sup>; A. Imamura <sup>2</sup>; H. Ozawa <sup>2</sup>; K.-I. Yoshiura <sup>1</sup>

---

**Purpose:** Recently Oxford Nanopore Technologies (ONT) released the MinION sequencer and its multiplex model the GridION sequencer. Although ONT's single molecule long-read sequencing technology has disadvantages in its lower base-call accuracy and high false-positive ratio in short insertion-deletions (indels) detection compared to Illumina's short-read technology, it is expected to have advantages in detecting genomic structural variations (SVs), including large indels, inversion, translocation, copy-number variation and tandem-repeat variation. The aim of this report is to assess and evaluate ONT whole genome sequencing data quality to detect SVs.

**Materials and methods:** We collected a pair of monozygotic twins and an unrelated control. Genomes from twins were previously analyzed serially by using G-banding, DNA microarrays, and whole-exome sequencing and concluded having only small genetic difference. All participants provided informed consent to undergo genetic research being approved by concerned ethics committees.

**Results:** We performed genome-wide sequencing by GridION on these three participants. Mean coverage depth was >15x, >15x, and >10x, respectively. To detect SVs for following validation, we integrated combinations of long-read genome mapping and SV detection software packages: NGM-LR + Sniffles, LAST + NanoSV, and LAST + Picky. We picked up called SVs which are shared in the twins and not shared in the control. We successfully and validated polymorphic SVs which had never been detected in our previous studies.

**Conclusions:** We performed genome-wide sequencing of human genomes using ONT long-read sequencing. Integrating SV detection workflows successfully found polymorphic SVs. Our report discussed only specificity of the method. Thus, future directions of study could discuss sensitivity of the method.

## PgmNr 2606: Complexities of exome reporting practices: Balancing the emphasis of phenotype and genotype.

Clinical diagnostic criteria have been used as a gold standard for clinical diagnosis in order to guide medical management and reproductive counseling. However, this approach may artificially define the phenotypes for a clinical entity based on the limited ascertainment of patient cohorts and a bias towards including patients who exhibit the most consistent phenotypic pattern. With the advent of robust molecular diagnostic tools, including exome sequencing, the definition of various disorders is now evolving, sometimes contracting, but often times expanding to include additional findings and a range of severity. It can be particularly demanding to strike a balance between phenotype driven and genotype driven analysis, as sometimes the molecular findings, patient features, and the understanding of the disease spectrum are not consistent. Approximately 8-10% of reports issued by our lab disclose a novel variant with strong molecular evidence for pathogenicity in an individual with limited or absent features of the characteristic phenotype. These may be due to 1) age-dependent penetrance, 2) gender-specific presentation, 3) nonsyndromic presentations of classically-reported syndromic disorders, or 4) mosaicism. For example, we detected a *de novo* *NSD1* missense variant of uncertain clinical significance. Heterozygous pathogenic variants in *NSD1* cause autosomal dominant Sotos syndrome with most pathogenic variants occurring within the SET domain. Despite the variant location within the SET domain, the proband did not exhibit the typical overgrowth but did express expected facial features and developmental delay. While the *NSD1* case *may* represent the potential to report phenotypic expansion or early presentation of a disorder, we must consider the risk to cause undue worry or harm from reporting a variant that may *not* cause the expected disorder, such as those associated with specific screening protocols or later-onset conditions. For example, an inherited loss-of-function variant in *NF2* was initially reported as pathogenic. After detailed evaluation and imaging of the proband and carrier parent revealed normal results, the classification of this variant was downgraded. By extrapolating from the lessons learned in these cases, we propose the implementation of an evidence-based approach to the reporting of these variants in an attempt to increase consistency, reduce time spent in decision-making, and improve the patient's and family's experience.

## PgmNr 2607: Challenges in returning actionable genomic results: The Mayo Return of Actionable Variants Empirical (RAVE) study.

---

**Background:** To inform best practices for returning actionable results to participants in genome sequencing studies, we describe challenges encountered and lessons learned from the Mayo Return of Actionable Variants Empiric (RAVE) study.

**Methods:** Participants (n = 2535, mean age 63±7, 57% female) ascertained based on hypercholesterolemia and/or colon polyps were sequenced for actionable genes (n=68) and single nucleotide variants (n=14). To participate, individuals had to consent to receive results related to hypercholesterolemia and colorectal cancer, but could opt out of receiving secondary findings. Participants with actionable results (n=121) were invited to schedule an appointment with a genetic counselor (GC). Neutral results (n=2414) were disclosed via mail. Results were placed in the electronic health record (EHR) following disclosure.

**Results:** Of those with actionable results, two opted out of receiving secondary findings and one participant died; 84 of 118 returnable results were returned in-person by a GC and 12 were returned via phone. Challenges in RoR could be categorized as: a) *sequencing report-phenotype mismatch*. These included three reports that were revised after review of the clinical record, and two reports requiring corrections. No gender mismatch was detected in those with actionable results (four were detected in those with neutral results). Three actionable results were probably mosaic requiring alternative DNA samples for confirmation. b) *contacting participants*: 16 participants were non-responders after four mailed letters. Of these five had previously identified clinically and were already documented in the EHR. In all 23 actionable results were already documented in the EHR. c) *EHR integration of results*. Ten results were disclosed to care providers prior to inviting the participant for a GC appointment, following an EHR workflow error. Five reports were reclassified due to modified informatics pipelines, four of which required participant re-contact and correction of the sequencing result in the EHR.

**Conclusion:** With the increasing number of large scale genome sequencing projects, there is a need

for greater awareness of potential challenges in RoR. In our study, such challenges were encountered in a significant proportion (24%) of participants.

## PgmNr 2608: Game of exomes: Comparing sequencing of commercial laboratories in the Undiagnosed Diseases Network.

### Authors:

The Undiagnosed Diseases Network (UDN) uses diagnostic tools including exome and genome sequencing (ES/GS) to solve complex medical cases. With the greater uptake of genetic testing, many patients have already undergone clinical ES before UDN evaluation. We sought to compare ES quality metrics among three major commercial laboratories alongside GS obtained through the UDN.

For patients with prior ES accepted to the Baylor College of Medicine UDN clinical site, we obtained and reprocessed sequencing data using a common analysis pipeline. We generated coverage and uniformity statistics for different gene classes including RefSeq, OMIM disease, and ACMG Secondary Findings (SF) genes. We paid close attention to first coding exons as well as non-coding regions such as introns and UTRs. We examined coverage at known pathogenic non-coding variant sites from ClinVar and the UDN. For comparison, we analyzed 50X GS data obtained through the UDN alongside these cases using the same methods. Importantly, we only addressed the quality of the sequencing, not the downstream processing or interpretation for clinical reporting.

We analyzed a total of 112 ES and 20 GS cases sequenced between 2013 and 2018. Among the three laboratories there was a significant difference in average coverage across all RefSeq genes (143X vs 116X vs 113X,  $P=0.00015$ ), a disparity that persisted ( $P=0.00049$ ) even in recent years (2016-2018). This difference was even greater for OMIM disease and ACMG SF genes, suggesting an enrichment for these clinically-relevant genes in some ES designs. Uniformity of coverage differed as well; some laboratories provided better sequencing homogeneity overall and in specific genes or regions (e.g., first exons, UTRs). While GS provided lower average coverage ( $\sim 50X$ ) compared to ES, it resulted in superior uniformity across all genes and regions. On average, 30.6/140 (21.8%) known pathogenic non-coding variant sites were missed by all laboratories due to low coverage ( $\leq 5X$ ), in contrast to GS where all sites were well covered.

Clinical ES remains an important tool in the diagnosis of patients with complex genetic cases. Our analysis suggests there are measurable differences in the sequencing quality of different commercial laboratories, in part related to the underlying ES design. Furthermore, with improving understanding of the role of non-coding variation in disease mechanisms, GS should be increasingly considered in the context of gene discovery and investigation.

# PgmNr 2610: Robust targeted sequencing approach for low input and variable quality DNA.

**Introduction:** Sequencing DNA extracted from dry blood spots and formalin-fixed and paraffin-embedded specimens (FFPE) can frequently provide limited amount of degraded, poor quality DNA. The inconsistent input volume and DNA damage, such as inter and intra strand crosslinks, accumulation of single-stranded DNA, and single-strand DNA breaks, prevalent in these types of samples can both negatively affect sequencing results. The effects can range from simple library failures to generating libraries that produce unauthentic data, leading to misinterpretation of the results. To overcome these issues, we evaluated the performance of the Twist Library Preparation Kit in poor quality samples.

**Methods:** We tested a total of fifty-two challenging samples. Amongst the cohort, there were two poor quality gDNA (saliva), four FFPE, and forty-six dry blood spots. Samples were manually processed to test the Twist Library Preparation Kit that used enzymatic fragmentation and Y-shaped adapters to generate dual indexed libraries, followed by target enrichment using Twist capture probes and hybridization reagents. Sequencing was performed on an Illumina HiSeq 2500 sequencer in Rapid Run mode and the bioinformatics analysis was completed using Illumina DRAGEN Bio-IT Software. We targeted 60X mean coverage for the two poor quality gDNA and four FFPE samples using the Twist Human Core Exome kit. In addition, we targeted 200X mean coverage for the forty-six dry blood spots using an in-house designed Twist custom epilepsy panel.

**Results:** Captured libraries were successfully generated according to the Center for Applied Genomics (CAG) quality standards/metrics for all the samples in question. The assay performance was evaluated by checking the quality of sequencing (passing filters), duplicate rates, on target, and coverage at bases on 20x; particularly by looking at the number of reads and the amount of data generated and by determining the presence of good coverage and high uniformity across the curated genes of interest.

**Conclusions:** The kit tested was able to overcome challenges in DNA purification, including low yields, poor quality, and difficult sample types. Following the initial tests, the Center for Applied Genomics NGS unit established the Twist Core Exome pipeline, and we are now optimizing the procedures on PerkinElmer Sciclone instruments for high-throughput use of the kit. Further improvements are still in development.

## PgmNr 2611: Is likely pathogenic really 90% likely? A look at the data.

The 2015 ACMG/AMP guideline for variant interpretation proposed that the term likely pathogenic (LP) be used to mean greater than 90% certainty of a variant being pathogenic. However, no study has analyzed the outcomes of LP variants to determine if the 90% certainty threshold is valid. Understanding LP classification confidence is necessary as many clinicians treat LP and P classifications equally, meaning reclassifications to VUS/LB/B are likely unanticipated. We sought to determine the true certainty threshold by calculating the reclassification rates of variants submitted to ClinVar, choosing variants assessed after Jan 2016 in hopes of restricting to variants classified with the 2015 ACMG/AMP guideline.

Between Jan 2016 and May 2019, there were 552,134 classifications submitted to ClinVar. By May 2019, 4,445 of these classifications had been reclassified, of which 92.5% moved to a classification category of more certainty and only 7.5% moved to a less certain (7.2%) or opposing (0.3%) category.

Of the five classification terms, LP variants had the highest reclassification rate (2.1%; 739/35731); comparatively, benign classifications had the lowest reclassification rate (0.03%; 17/56273). Of the 739 LP reclassifications, 5 were reclassified to LB/B, 145 reclassified to VUS, and 589 reclassified to P. If only including LP reclassifications to a more definitive category (LP to P or LP to LB/B), LP reclassification rates suggest a 99% (589/594) certainty of being P compared to B. However, 0.4% (145/35731) of LPs dropped to VUS suggesting that some may eventually move to LB/B and the rate may be lower than 99%.

Variants were further interrogated to determine if certain variant types were more likely to be upgraded (LP to P) or downgraded (LP to VUS/LB/B). We found that 48% (281) of LP variants reclassified to P were LOFs and 52% (308) were missense or intronic. In contrast, 18% (18) of LP variants downgraded to VUS/LB/B were LOFs versus 82% (81) were missense or intronic.

In summary, current reclassification data from ClinVar shows that 99% of LP classifications move to P compared to LB/B, suggesting that application of the term is consistent with the intended confidence level. However, the vast majority of LPs still remain as LP within a three year window and a small subset (0.4%) dropped to VUS suggesting that more data and a longer time of analysis will be needed to more robustly evaluate the rate of LP reclassification.

## PgmNr 2612: Whole genome sequencing versus standard-of-care genetic testing in patients with a suspected genetic disorder.

Current standard-of-care (SOC) diagnostic genetic testing typically relies upon high-coverage sequencing of a disease-specific set of candidate genes. This approach has two key limitations: first, it requires that a set of genes be prespecified for each disease area, limiting the ability to reanalyze after new genetic discovery data becomes available; and second, it requires provider awareness and commercial availability of numerous testing options. Clinical whole genome sequencing (cWGS) has the potential to allow use of a single genetic test regardless of disease area. Here, we set out to explore two key unanswered questions: first, does cWGS -- which provides lower coverage across the entire genome -- have adequate technical sensitivity to identify pathogenic variants across a spectrum of disease areas? Second, does the increased scope of cWGS permit identification of variants in genes not on the SOC gene panel that might nonetheless contribute to the patient's observed phenotype? We explored these questions among patients in whom a SOC diagnostic genetic test was being ordered within genetic clinics at Massachusetts General Hospital (MGH). Of 76 patients who underwent both SOC and cWGS, a pathogenic or likely pathogenic variant felt to explain the patient's phenotype was identified by SOC testing in 9 (12%) of the enrolled patients. Each of these 9 variants was also identified by cWGS (technical sensitivity 100%). Moreover, cWGS identified a potentially causal variant in 2 additional patients -- one in whom a variant detected by both SOC and cWGS was classified as likely pathogenic by our team but a variant of uncertain significance by the SOC test, and a second in whom a likely pathogenic variant was identified in a gene not covered in the SOC candidate gene panel. cWGS did not identify pathogenic or likely pathogenic secondary findings in the 59 genes recommended for return by the American College of Medical Genetics and Genomics (ACMG) in any of the 76 participants. In summary, these results suggest that cWGS may enable genetic diagnoses across a full range of patient phenotypes using a single test -- providing adequate technical sensitivity and allowing for analysis beyond a prespecified set of genes on a SOC testing panel.

## PgmNr 2613: Assessing for extreme polygenic risk burden in patients with presumed monogenic disease.

**Introduction.** Many research initiatives, such as the Undiagnosed Disease Network (UDN), undertake exploratory analyses of genomic sequencing data to identify novel monogenic etiologies for rare disease. Key questions typically unexplored by these analyses, however, include whether the patient's phenotype can be explained by an extreme polygenic risk burden of a related common disease and whether extreme polygenic risk burden to a common disorder can impact the expressivity of an underlying monogenic disorder. Here, we utilize genetic findings of well-characterized common diseases to identify patients with extreme polygenic risk burdens in a cohort of patients with suspected monogenic disease. **Methods.** Patients enrolled in Brigham Genomic Medicine/UDN Harvard Clinical Site received whole-genome sequencing for the affected proband and unaffected relatives. We generated genetic risk scores (GRSs) across multiple phenotypes and specifically focused on each proband's most analogous common phenotype (e.g. multiple sclerosis for CNS white matter disease) based on statistically significant variants from recent GWAS meta-analyses. We further leveraged genome-wide data to calculate polygenic risk scores (PRS). GRS and PRS were corrected for the underlying ancestry leveraging reference population data. **Results.** Generally, the affected probands and their unaffected relatives did not have high values either GRS or PRS for the respective common diseases (z-score < 2 for any comparison), suggesting that picking analogous diseases is error-prone in such complex patients and/or that there may be an undiscovered monogenic or oligogenic etiology for probands. However, samples with high GRS or PRS for common diseases often had phenotypic characteristics suggestive of the respective disease. For example, two probands and families with early onset multiple sclerosis (MS) had GRS and PRS near the underlying ancestral population mean, z-scores < |1|. When we surveyed the entire cohort for MS polygenic risk burden, the two patients with the highest burden for MS (z-score >2) had MRI-evident delayed myelination and T cell mediated central nervous disorder. **Conclusion.** We outline here a nascent methodology and report on initial results for evaluating extremes of polygenic risk in rare disease cohorts. Additional data will be presented from our broader rare disease cohort (>200 affected individuals) including summary statistics and illustrative examples.

## PgmNr 2614: Assessment of pathogenic structural variants in medically actionable genes in 982 healthy individuals.

---

**Background:** The clinical utility of whole-genome sequencing (WGS) has been primarily studied in the context of suspected heritable disorders and cancer. However, there is an increasing interest of its use for preventative medicine. Currently, limited statistics exist on the prevalence and penetrance of pathogenic alterations in actionable genetic conditions in the general population. Additionally, most studies have focused on single nucleotide variants (SNVs) and indels, with data lacking on the contribution of pathogenic structural variation (SV), including copy number variants (CNV) in the general population.

**Methods / Results:** We processed WGS data (median of 20X) generated for 982 unrelated individuals of primarily European ancestry in the Mayo Clinic Biobank. Subjects had no personal history of hematological malignancy or bone marrow transplant at the time of recruitment and an average length of electronic health record (EHR) data of 19 years. Sequencing data was analyzed using GenomeGPS v4.0.1 with BWA-MEM alignment to GRCh38 reference. SV calling was done with 4 algorithms: Lumpy, Delly, Cnvnator and Wandy (an internally developed segmentation algorithm for CNV events). Context and technical annotation was used to filter findings, resulting in a total of 8,870 deletions, 2,633 inversions and 238 duplications identified across the 982 samples. On average, 242 events per sample overlapping one of the 59 genes deemed as actionable by the ACMG were called.

**Discussion/Conclusion:** We found a frequency of 0.2% of known pathogenic deletions in our cohort. Two 11kb germline heterozygous deletion encompassing the BRCA1 gene were identified. One deletion belonged to a female with strong personal and family history of breast and colon cancer; while the other was found on a male with no personal or family history of cancer. Our experience demonstrates the utility, feasibility and challenges in technical and context annotation associated with interrogating a WGS dataset for SV. Replication of our SV calling and filtering strategy in larger sample sizes may inform the clinical advantage of our approach for comprehensive interrogation of WGS in “healthy” cohorts.

## PgmNr 2615: Clinical evaluation of rapid whole-genome sequencing in the intensive care unit.

### Authors:

B. Wu; P. Zhang; Y. Lu; H. Wang; W. Zhou

---

**Background and aim:** Rapid diagnosis of genetic disease in critically ill newborns is vital to the swift initiation of targeted treatment. The constellation of symptoms that constitute the clinical diagnosis of a genetic disorder may be non-specific and difficult to recognize in the newborn period. Whereas, rWGS (P) technology has the potential interrogate a variety of genetic etiologies in a single test with the shortest time. In this study we aim to establish an rWGS workflow and evaluate its role in the diagnosis of patients suspected with genetic diseases in ICU.

**Methods:** Critical ill infants in NICU/PICU were enrolled according to the inclusion criteria. Clinical manifestations, laboratory results were ascertained comprehensively by physicians. DNA was isolated from the blood samples of trio-family numbers. Trio WGS sequencing were performed on Illumina NovaSeq 6000 sequencing platform. Rapid alignment, variant calling and interpretation will be conducted by Center for Molecular Medicine of Children's hospital of Fudan University. Variants are categorized according to American College of Medical Genetics (ACMG) recommendations for reporting sequence.

**Results:** Forty nine critical ill infants, including 26 males were enrolled and received the Trio-rWGS test, 71% of whom were less than 1 month of age. TAT time from sample collection to oral report was ranging from 7-12days. Twenty of 49 cases received diagnosis by rWGS. Pathogenic or likely Pathogenic variants were detected in 16 genes (6 AD, 8 AR and 2 XLR). In addition, pathogenic microdeletion and/or duplication were detected in 4 cases by using copy number variant calling on the WGS data. Case 28, who had an unbalanced chromosome aberration with a duplication in the long arm of chromosome 21 and a distal deletion in the long arm of chromosome 18, derived from a maternal balanced translocation. The results of genetic testing in 6 cases have a regulatory effect on clinical treatment, and 4 cases have turned to palliative care guidance.

**Conclusions:** Rapid WGS provide a timely diagnosis of genetic diseases, and may improve the outcomes of the critical ill patients in NICU and PICU.

---

Next generation sequencing (NGS) has been rapidly adopted in clinical laboratories. Stringent quality control of sample identity for each patient-derived specimen is critical, however the large number of steps and complexity of the clinical sequencing workflow create the potential for sample identification errors at all phases, from sample collection to the sequencing and return of results. Here, we demonstrate the power of monitoring assigned sample sex assignment, to assure process quality. Methods were developed for the NIH Electronic Medical Records and Genomics (eMERGE) Network, that has collected >25,000 samples from 11 clinical sites and sequenced each using a 'gene panel', at two sequencing core sites, the Human Genome Sequencing Center Clinical Laboratory (HGSC-CL) at Baylor College of Medicine (BCM) and Partners Healthcare Laboratory for Molecular Medicine (LMM) in partnership with the Clinical Research Sequencing Platform (CRSP) at the Broad Institute. Following sample transfer to the sequencing sites, an aliquot of each was immediately tested with a Fluidigm SNP array panel, providing a unique genotype based upon 96 single base sites, which can be later compared with the gene panel sequence data, to ensure no sample swaps occurred while at the sequencing centers. As six of these SNP markers are assigned to sex chromosomes, they also were used to identify putative sample sex-assignment discrepancies that were subsequently confirmed by either (or both) the gene panel data, or hybridization to an Illumina exome array with 14k sex chromosome sites. The two sequencing sites have collectively confirmed 110/25,015 samples (0.44%) with inconsistencies between data at the genome centers versus test submission-provided sex assignment. Further investigation in collaboration with eMERGE clinical sites resolved most inconsistencies as the samples were from transgender participants, stem cell or bone marrow

transplant patients, or else mis-assignments by traceable clerical errors. As a result, process improvements were made at each collection site. The SNP array assay was demonstrated to be a cost-effective and robust tool that can be implemented in the clinical laboratory for validating process integrity. Although checking sex assignment detects just 50% of possible sample swaps and a similar proportion of transplant recipients, it will detect all transgender participants and identify requirements for process improvements in new pipelines.

## PgmNr 2617: Standardising single nucleotide variant classification through external quality assessment.

### Authors:

**Affiliation:** GenQA/UK NEQAS, Edinburgh, United Kingdom

---

The aim of this external quality assessment (EQA) was to provide an online competency assessment for individuals routinely performing interpretation and classification of variants. Participants were required to apply their usual processes to classify five single nucleotide variants (SNVs) and to submit evidence supporting the assigned classification. Participation was delivered using the Genomics Training, Assessment and Competency Tool (G-TACT). This EQA has been developed for genomic centres to demonstrate the competency of individuals, both clinical and laboratory based, performing variant classification and to identify any unmet training needs.

The variants ranged from class 3, uncertain significance to class 5, pathogenic and included variants in the following genes: *COL4A4*, *ETFDH*, *GK*, *SHOC2* and *SPG7*.

The submissions were scored, reported to each participant and a summary report was issued. The report detailed the expected variant classifications and provided an overview of all submitted results. A follow up webinar summarised the evidence assessed, the expected variant classifications and addressed participant queries.

This trial scenario was used by 142 individuals, with 82 participants completing the classification of all variants. As G-TACT is web-based then participation is global and 34 countries were represented worldwide. None of the participants provided the expected classification for all five variants, with only 10% of participants providing the expected classification for four variants. This clearly demonstrates the challenges associated with variant classification and the need for education, competency assessment and standardisation worldwide.

Cardiomyopathy (CM) in childhood is a rare disease with substantial morbidity and economic burden. Identifying the underlying genetic etiology in a child with CM has the potential to guide management, improve risk stratification, and decrease risk of sudden death, but the genetic basis of early onset CM is not well understood. To study this, we performed exome sequencing in 528 unrelated children with CM. ACMG guideline-based clinical interpretation of rare variants in 37 known CM genes gave an overall diagnostic yield of 32%, including 19% in patients with dilated CM, 51% in hypertrophic CM, 50% in restrictive CM, 31% in left ventricular noncompaction (LVNC)/mixed, and 33% in non-LVNC mixed. Each phenotype exhibited differences with respect to age at diagnosis, family history, and ancestry. Infants were less likely to have diagnostic results than older children ( $p = 0.0009$ ). To identify new causal genes, we created a discovery set of 2188 genes for bioinformatics evaluation of rare ( $MAF < 0.01$ ) deleterious variants using MetaSVM and CADD. A prioritized candidate gene list was identified by ranking observed intolerance to variation in 1000 Genomes. Interestingly, ClinVar CM genes represented  $< 5\%$  of the prioritized genes, with genes derived from ontologies for abnormal heart morphology in mouse models and human heart development showing strong contribution ( $p < 0.0001$ ). Analysis of variant burden by ancestry, CM phenotype, and variant type (loss of function, nonsynonymous) identifies important patterns. Overall, our CM cohort is enriched for rare deleterious variants as compared to 1000 Genomes controls ( $p < 0.0001$ ). However, the rates of deleterious burden in cases versus controls for African and Admixed American as compared to European ancestries indicate that possible ancestry-specific genetic etiologies remain to be identified, especially for hypertrophic CM. There was phenotype-specific enrichment of patients with multiple rare deleterious variants and the greatest burden was seen in ClinVar CM genes. Loss of function variation accounted for only  $\sim 12.3\%$  of deleterious variant burden. Overall, this bioinformatics

approach identifies 63% of the pediatric CM cases with deleterious variants, an increase of 31% over clinical interpretation. This study represents a large pediatric cardiomyopathy cohort with comprehensive genetic evaluation and supports both shared and unique phenotype-, ancestry-, and age of diagnosis-specific contributions to CM.

## PgmNr 2619: Identification of rare de novo variants in transposition of the great arteries families using whole exome sequencing.

**Authors:**

Y. Zeng; W. Chen; Y. Liu; Z. Zhou

[View Session](#) [Add to Schedule](#)

**Affiliation:** Fuwai Hospital, Beijing, China

---

**Introduction:**

Transposition of the great arteries (TGA), one of the most common and severe types of congenital heart disease (CHD), is the leading cause of cardiac death in neonates and infants if not treated. The etiology of TGA is largely unknown, but increasing evidence supports that genetic factors play an important role in the pathogenesis of transposition of the great arteries. We used whole exome sequencing to assess the prevalence of rare deleterious and de novo variants in the cohort of familial TGA.

**Methods and Results:**

For this study, 66 TGA trios (proband and their parients) were recruited and screened together with a control population of 182 obesity patients using whole exome sequencing. Variants calling and filtering were performed according to GATK best practice pipeline. The screening criteria for rare variants were MAF < 0.001 in public cohorts (ExAC EAS; esp6500; 1000 Genome EAS; gnomAD exome EAS) and for damaging variants were LOF (frameshift; stop gain; splicing) or missense variants with CADD phred score > 15(DNS).The screening criteria for de novo variation were as follows: hitting by at least one de novo LOF/DNS allele in TGA, hitting by at least two LOF/DNS allele in TGA, no more than 1 LOF/DNS allele in control. All variations were verified using Sanger. We identified 11 genes carrying rare de novo variants including 1 loss-of-function variants and 41 missense variants among nine probands. Top candidate genes (4 in 12) with de novo damaging variants were FOXH1, TMEM260, DYNC2LI1 and USP9X.

**Conclusions:**

Our study revealed that a great portion of variants were de novo, suggesting that de novo variants played important roles in CHD pathogenesis. This may help stratify patients for guiding the therapeutic management.

## PgmNr 2620: Characterization of thoracic aortic disease in vascular Ehlers-Danlos syndrome: Defining the phenotype.

---

The arterial pathology, namely spontaneous dissection and rupture, is the primary cause of fatality in individuals with vascular Ehlers-Danlos syndrome (vEDS). In addition to the abdominal aorta, medium sized visceral, cervical, and peripheral arteries are most often affected. Challenges characterizing the phenotype in vEDS, including misdiagnosis, underdiagnosis, and a paucity of longitudinal data, still exist, but have lessened as more individuals are diagnosed via genetic testing. With newly generated data describing surgical outcomes and the impact of medical therapies, such as  $\beta$  blockers, the need for management guidelines has become more pressing. Unlike other heritable arteriopathies, such as Marfan syndrome, which is known to be associated with aortic root aneurysms and thoracic aortic dissections (TAAD), the thoracic aortic phenotype in vEDS remains poorly defined. We describe the thoracic aortic pathology in 12 individuals (7 female, 5 male) with pathogenic *COL3A1* variants ranging from 19 to 65 years at time of TAAD presentation; of which, 9 did not have a prior vEDS diagnosis. Missense variants (Gly substitutions) accounted for 8 cases, followed by 2 haploinsufficiency, and 2 splice-site. Four individuals were diagnosed with aneurysms of the aortic root or ascending aorta and 3 underwent successful elective repairs (4.7-5.7 cm). Acute type A dissections occurred in 5 cases, and type B dissections in 3. All 7 females had history of prior pregnancies, but only one had a major pregnancy-related complication--type B dissection with descending thoracic aortic rupture--immediately postpartum. Two individuals died from acute type A dissections; neither underwent surgical intervention. Surgery (elective and emergency) was pursued for 9 individuals and included 8 open repairs for ascending or aortic root aneurysm (3), type A dissection (3), and thoracoabdominal aneurysm associated with type B dissection (2). Thoracic endovascular repairs were performed for 3 cases (type A and type B dissections, descending thoracic aortic rupture). No fatalities occurred during surgery or within the 6 month post-operative period. These data confirm an increased risk for TAAD with associated mortality in patients with vEDS, and establish that elective thoracic aortic repairs can successfully be performed in experienced surgical centers. Thoracic aortic pathology is important to recognize as we consider optimal screening and interventional approaches for this population.

## PgmNr 2621: A rare splice-site variant in *TNNT2*: Cardiomyopathy and sudden death associated variant or common Polynesian polymorphism?

---

A rare variant in cardiac troponin T (*TNNT2*; NM\_001001430.2: c.571-1G>A) was found via exome sequencing in an Aboriginal Australian who had a sudden unexplained cardiac death aged 23 years, and in a 2 year old of Maori ancestry with restrictive cardiomyopathy who died from rapidly progressive heart failure. Cardiac troponin T is an integral protein in the cardiac sarcomere. Missense variants in *TNNT2* are an established cause of hypertrophic cardiomyopathy (HCM).

Variant curation was performed. A previous functional assay of the variant demonstrated altered splicing of *TNNT2* exon 12, resulting in an in-frame deletion of one amino acid. Review of cases in ClinVar and the literature revealed >20 probands with a cardiac phenotype, including 12 with HCM, 3 with DCM including presentation <3 years in two children. Seven probands died suddenly with the variant identified on postmortem genetic testing. At least 5 probands report a family history of sudden cardiac death in a close relative. Two segregations were reported.

Given the related ancestry of the two cases, we queried groups/laboratories previously reporting the variant about ancestry of their cases. Amongst the 20 cases, >15 were reported as being of Polynesian ancestry, including New Zealand Maori, Samoan, Tongan and Hawaiian. Only 1 patient was reported to have European ancestry. Allele frequencies of a large publicly available Polynesian reference population do not exist, therefore determining whether the variant is a common Polynesian polymorphism is not possible. Polynesians share origins with Southeast Asia and Taiwan, with a widely accepted theory suggesting migration of Taiwanese Aborigines between 3000-1000 BC to Pacific Islands. The variant is absent in the Taiwanese Biobank (WGS), though this comprises primarily Han Chinese n=1517 participants. In the Genome Aggregation Database it is seen in 5/249,022 (0.002%) alleles, with the highest sub-population frequency in South Asian alleles (5/30,444; 0.016%). We classified this as a variant of uncertain significance. Whether it is over-represented in cases with cardiac disease and sudden cardiac death remains to be determined.

We demonstrate the challenges of variant curation in ethnic minorities, currently under-represented in reference datasets. Further, reporting of ancestry should be routinely included in variant assertions. In our experience this was not commonly reported and required additional specific contact with the laboratories.

## PgmNr 2622: *De novo* mutation in a MAP kinase leading to cardiac malformation and loss of vascular integrity.

Mitogen activated protein (MAP) kinases are critical signaling proteins involved in transmitting extracellular signals to regulate cellular proliferation, survival, apoptosis and gene expression. Not surprisingly, variants in the MAP kinases have been implicated in multiple types of cancer and these signaling cascades have been shown to be activated in a wide range of physiologic and disease states. We have identified a *de novo* variant in a MAP kinase component in a female neonate who presented with cardiovascular malformations including hypoplastic left heart and fatal vascular permeability. Based on the phenotypic similarities with some mouse model knockouts for MAP kinase cascade components and targets, we have investigated the potential pathogenicity of this variant in causing the congenital malformations observed in the proband.

Primary dermal fibroblasts from the proband demonstrate no loss of mRNA or protein but have significantly reduced phosphorylation of the protein in response to multiple MAP kinase-activating stimuli (interleukin, growth factor and cellular stress). Additionally, we observe altered transcriptional profiles in the patient cells and exaggerated cellular stress responses. These cell responses correlated with an increase susceptibility to activation of caspases and decreased cellular viability. Further analyses of the variant in an isogenic cell model were performed to identify transcriptional targets with aberrant expression in the context of the MAP kinase mutant protein. Collectively, these data indicate that the variant in the patient acts in a dominant negative fashion to deregulate the MAP kinase cascade, resulting in aberrant activity of the MAP kinase protein and its targets. These cellular changes alter key developmental pathways that likely contributed to the cardiac malformation and significantly impaired vascular integrity in the proband.

## PgmNr 2623: An Amish neonate with fatal cardiomyopathy due to homozygous *MYBPC3* mutation.

### Authors:

D. Karahalios; S. Baluta; J. Anderson; F. Smith; R. Lebel

[View Session](#) [Add to Schedule](#)

**Affiliation:** Pediatrics, SUNY Upstate Medical University, Syracuse, NY.

---

**Introduction:** The Amish community is composed of genetically and geographically isolated, large, multigenerational families with similar environmental influences. The genetic isolation of these families increases the risk of homozygosity for rare autosomal traits due to founder effect.

**Case Report:** A 12 day-old Amish male presented to the emergency department with a history of respiratory distress, poor feeding, and cardiogenic shock. Term delivery was at home after an uncomplicated pregnancy. He was admitted to the pediatric intensive care unit for inotropic support and mechanical ventilation. An echocardiogram showed biventricular enlargement, hypertrophy, and moderate global hypokinesis, consistent with hypertrophic and dilated cardiomyopathy. After initiation of digoxin and an ACE inhibitor, the patient clinically improved, was extubated, and was discharged home on anticongestive medications. Two weeks later, he was readmitted to the pediatric intensive care unit with worsening congestive heart failure exacerbated by a viral upper respiratory infection. An echocardiogram showed worsening hypokinesis and an ejection fraction of 29% (normal >55%). Due to his poor prognosis, his parents declined further interventions. He was discharged home with palliative care and died the next day. Before his second discharge, genetic testing was performed and revealed that he was homozygous for a pathogenic variant in *MYBPC3* (c.3330+2T>G), which produces a truncated protein through frame shift and translation of a premature stop codon. Heterozygosity and homozygosity of this variant has been associated with both dilated and hypertrophic cardiomyopathy in the Amish population.

**Discussion:** Cardiomyopathy presenting in the neonatal period carries a poor prognosis that is even worse when associated with a genetic component. This patient's pathogenic variants in *MYBPC3* were inherited in an autosomal dominant fashion, and homozygosity profoundly worsens the prognosis. The parents of this patient are not significantly symptomatic, but as heterozygotes, they are likely to develop cardiomyopathy in the future. Since early medical treatment may reduce the progression of disease, cardiac assessment is indicated.

## PgmNr 2624: Rare association of mucopolidosis III alpha/beta with dilated cardiomyopathy.

### Authors:

---

Mucopolidosis III alpha/beta (ML III alpha/beta) is an autosomal recessive lysosomal storage disorder caused by N-acetylglucosamine-1-phosphotransferase (GlcNAc-phosphotransferase) deficiency. It is characterized by coarse facial features, developmental delay, short stature, and skeletal deformities. Its cardiovascular symptoms include valvular thickening or hypertrophic cardiomyopathy. A 32-year-old female patient received heart transplantation due to end-stage heart failure caused by dilated cardiomyopathy (DCM). We performed whole exome sequencing to determine the etiology of DCM and/or skeletal deformities. The test revealed c.2715+1G>A and c.3173C>G mutations in the GNPTAB gene encoding the alpha and beta subunits of GlcNAc-phosphotransferase. Finally, she was diagnosed with ML III alpha/beta. This report describes a rare case of ML III alpha/beta associated with DCM. Our findings expand the clinical spectrum of ML III alpha/beta.

## PgmNr 2625: Novel *SMAD3* in-frame indel associated with thoracic aortic aneurysm and dissection: Potential loss of function mechanisms.

### Authors:

M.L. Murray <sup>1</sup>; C. Wilson <sup>2</sup>; W. Allen <sup>2</sup>; J. Tusi <sup>1</sup>; D. Macaya <sup>1</sup>

---

Pathogenic variants in *SMAD3* are associated with a risk to develop aortic and arterial aneurysms/dissections with variable systemic features, referred to as aneurysm-osteoarthritis syndrome or Loeys-Dietz syndrome 3. While loss of function due to nonsense, frameshift, or canonical splice site variants is an established mechanism of disease, missense variants represent over 60% of those reported to date, most located in the MH2 domain. In clinical testing, rare missense and in-frame insertion/deletion (indel) variants can be difficult to interpret, especially in protein domains that are less well-characterized or in which few similar variants have been observed. We report a novel in-frame indel variant that segregates with disease in a three generation family with thoracic aortic aneurysm and dissection. Clinical features present in genotype-positive family members include thoracic aortic aneurysm/dissection, precocious osteoarthritis, pectus deformity, pelvic organ prolapse, and joint hypermobility. The variant, c.275\_281delinsC, p.Trp92\_Trp94delinsSer, is located in the MH1 domain of the *SMAD3*-encoded protein. Missense substitution of these residues, Arg93Gln and Trp94Leu, have been published as variants of uncertain significance, supporting the difficulty of clinical interpretation of variants in this region of the protein. The involved residues, Trp92-Arg93-Trp94, are highly conserved across species and in homologous SMAD proteins, and participate in hydrogen bonding critical for local protein structure/function. One important function of the MH1 domain is to bind DNA as a transcriptional factor; however, these residues do not directly participate in DNA binding. Published functional analysis of variants in the residues equivalent to Arg93 in homologous proteins (*SMAD2* Arg133Cys, *SMAD4* Arg100Thr), suggest multiple possible loss-of-function mechanisms, including increased autoinhibition, decreased DNA binding, and/or increased protein degradation. Association of p.Trp92\_Trp94delinsSer with an aortopathy and connective tissue phenotype in this family establishes the clinical importance of these residues, which will aid in interpreting similar variants encountered in clinical testing. Furthermore, review of similar variants in homologous proteins suggest loss-of-function by various mechanisms not readily predicted based upon variant type and location. Variants in other SMAD proteins may offer insight to novel *SMAD3* variants detected in clinical testing.

## PgmNr 2626: Ventricular septum defect can be a key for the early diagnosis of Brugada syndrome in young patients with *SCN5A* mutations.

### Authors:

S. Ohno <sup>1</sup>; J. Ozawa <sup>2</sup>; K. Sonoda <sup>1</sup>; T. Makiyama <sup>3</sup>; M. Horie <sup>4</sup>

[View Session](#) [Add to Schedule](#)

1) Department of Bioscience and Genetics, National Cerebral and Cardiovascular Ctr, Suita, Japan; 2) Department of Pediatrics, Niigata University Graduate School of Medical and Dental Sciences, Niigata, Japan; 3) Department of Cardiovascular Medicine, Kyoto University of Graduate School of Medicine, Kyoto, Japan; 4) Center for epidemiologic research in Asia, Shiga University of medical Science, Otsu, Japan

Background: Brugada syndrome (BrS) is an inherited disease characterized by the coved type ST elevation in right precordial leads and sudden cardiac death caused by ventricular arrhythmias (VA). Although BrS is frequent in middle aged men, young patients sometimes suffer VA due to BrS. Therefore, early diagnosis of BrS is indispensable to prevent sudden cardiac death. *SCN5A* encodes cardiac sodium channel, NaV1.5, and nearly 20% of the adult BrS patients carry mutations in *SCN5A*. BrS patients with *SCN5A* mutations frequently shows cardiac conduction block (CCB). CCB is also accompanied with ventricular septum defect (VSD). Therefore, VSD might be a key for the diagnosis of BrS.

Purpose: This study aimed to clarify the clinical phenotype of young BrS patients with VSD.

Methods: The study cohort is 44 (9 females) BrS probands who were diagnosed at age <20. We performed clinical evaluation including cardiac echography and genetic analysis for *SCN5A*.

Results: The mean age of diagnosis for BrS is  $11.0 \pm 5.4$  years old. Three (6.8%) patients accompanied with VSD. We detected *SCN5A* mutations in 18 (41%) patients, and all the patients with VSD carried the mutations. The first patient was an asymptomatic 4-year-old boy who received surgical repair of VSD at 8-month-old. His ECG 5 months after the operation showed complete right bundle branch block (CRBBB) without ST elevation. At the age of 4, ST elevations in V1-2 leads were detected, and pilsicainide loading test provoked coved type ST elevation. He carried a missense mutation, c.4035G>T, p.W1345C. The second patient was an asymptomatic 7-year-old boy who were diagnosed membranous VSD at the age of 2, and it was closed spontaneously. His ECG at 2 y.o. revealed CRBBB and coved type ST elevation, and CRBBB pattern diminished after spontaneous closure. His mutation was c.2677C>T, p.R893C. The last patient was an asymptomatic 2-year-old boy who received surgical repair for membranous VSD. His ECG before operation showed CRBBB and coved type ST elevation in V1-V3. He carried c.1099C>A, p.R367S. In NaV1.5, the first mutation, p.W1345C, locates in the segment 5 of domain 3, and p.R893C and p.R367S locate in the pore regions of domain 2 and 1, respectively.

Conclusions: Young VSD patients sometimes accompanied with BrS and carried *SCN5A* mutations. Careful ECG recording for VSD patients would be helpful for the early diagnosis of BrS with *SCN5A* mutations, leading to the prevention of sudden cardiac death.

## PgmNr 2627: *De novo* rare variants clustered in a limited region of *RNF213* lead to early onset and aggressive Moyamoya disease.

Moyamoya disease (MMD) is a rare cerebrovascular disease, characterized by progressive stenosis and occlusion of the distal internal carotid arteries with the formation of a compensatory network of collateral vessels. MMD predisposes to ischemic and hemorrhagic strokes with two incidence peaks of onset, one in children around 10 years of age and another in adults in their 30-40 years. The high incidence of MMD in Japan is due to *RNF213* founder variant, p.Arg4810Lys, present in 90% of Japanese MMD cases but only 2.5% in healthy controls with the same ethnic background. We identified other *RNF213* rare variants in European descent MMD cases that segregated with disease in families and these variants clustered in and around the RING domain spanning amino acids 3997-4035.

Exome sequencing of 145 individuals from 80 families, including 28 trios were analyzed. We identified 3 *de novo* variants in *RNF213* in 3 independent European descent cases in a highly conserved region (4114-4120). The first case carried a one amino acid deletion, p.Lys4115del, had his first stroke at 10 months, and died at 1 year old following revascularization surgery. The second case carried a missense variant, p.Thr4114Arg, and is a 10-month-old girl diagnosed with severe bilateral MMD requiring neurosurgical procedure. The third case carried the variant p.Phe4120Leu, had his first stroke at 1 year old, and was diagnosed with bilateral MMD at 3 years old. After revascularization surgery, he had no further strokes but did develop bilateral renal stenosis and right nephrectomy. He is currently 37 years old. Further, there is a published case of a Hispanic girl with a *RNF213 de novo* variant, p.Ser4118Phe, diagnosed with MMD at 3 months as well, and also had narrowing of the inferior abdominal aorta.

These results strongly support the conclusion that *de novo* missense or small amino acid deletion within the 4114-4120 amino acid region lead to early onset and aggressive MMD. Interestingly, one case presented with early onset and aggressive MMD that did not progress with age, but rather developed bilateral renal artery stenosis. Future studies will be focused on defining the role of this region in the *RNF213* protein to elucidate why alterations in this region lead to such early and severe

MMD.

---

Genome sequencing has the potential to characterize the molecular architecture of congenital heart disease, thereby contributing to improved clinical outcomes through personalized management and treatment plans. The Cardiac Genome Clinic (CGC) was established as a prospective multi-site project to investigate the optimal use of novel genome-based technologies in pediatric and adult cardiology settings.

As part of a pilot study, we obtained genome sequencing data of 88 families, and systematically analyzed for rare disease-causing sequence and copy number variants. In 10 families (11%), we identified pathogenic or likely pathogenic variants associated with cardiac disease (in *ANKRD11*, *FLT4*, *KMT2D*, *NEXMIF*, *NIPBL*, *NR2F2*, *PTPN11* (2x), *PTEN*, *PTEN/PURA*). Promising variants with insufficient evidence for disease causality were identified in *FLNC*, *DNAH8*, *DNAH9*, as well as microdeletions at 3p11.2-3p12.3, 2p13.1-2p12, and 3p26.1-3pter. We also present potential novel gene-disease associations for tetralogy of Fallot, hypoplastic left heart syndrome, congenitally corrected transposition of the great arteries, and early-onset cardiomyopathy. The identified candidate genes have critical functions in heart development, such as angiogenesis, mechanotransduction, regulation of heart size, chromatin remodeling, and ciliogenesis.

Findings from this dataset demonstrate the value of unbiased genomic testing and comprehensive data analysis in patients with congenital heart disease. With regard to the genetic heterogeneity, the delineation of novel gene-disease associations will require large-scale genomic initiatives.

## PgmNr 2629: The role of glycogenin in cardiac function using a glycogen storage disease XV mouse model.

Glycogen storage diseases (GSD) are the result of mutations in genes encoding enzymes involved in glycogenesis or glycogenolysis. Glycogenin (GYG) encodes a muscle glycosyltransferase that catalyzes glycogen synthesis by nucleating the first glucose polymer before elongation and branching. Deficiencies in *GYG 1* results in GSD XV (OMIM: 613507) and Polyglucosan Body Myopathy 2 (OMIM: 616199). GSD XV is an autosomal recessive condition that has been characterized in 22 patients that have both skeletal and cardiomyopathies due to abnormal storage of glycogen in muscle tissue. To date, four males have been reported with pathogenic variants causing arrhythmias, heart dilatation and reduced ejection fraction. Two patients ultimately required heart transplants. While diagnosed cases of cardiomyopathy in *GYG 1* deficient patients are rare, further understanding of the role GYG plays in myocardial metabolism is insightful to understanding cardiac energy homeostasis and diseases pathology.

The mouse homolog for *GYG 1* is *Gyg*. *Gyg* deficient mouse knockouts have been reported to accumulate excess glycogen in striated muscle. However, unlike in skeletal muscle, the primary source of fuel in the heart is fatty acid. To explore the role of glycogen synthesis in cardiac function, we generated a *Gyg*<sup>Tm1b</sup> mouse allele in which *Gyg* was replaced with a LacZ reporter. *Gyg*<sup>Tm1b/Tm1b</sup> mice exhibit postnatal lethality by day 2. To visualize *Gyg* expression, we performed LacZ staining in the *Gyg*<sup>Tm1b/+</sup> mice and observed broad cardiac expression as early as embryonic day 8.5 through late fetal stages. In the adult animals, LacZ expression is restricted to the atria. Analysis of myocardial morphology in which mice will be analyzed histologically. In addition, the glycogen content of the hearts will be examined by Periodic Acid Schiff –Diastase staining and by quantifying glycogen content. To assess the functional effect of *Gyg* deficiency, electrocardiograms and echocardiograms will be used to measure the electrical activity of the heart. This study is essential in elucidating the mechanisms that link glycogen metabolism to proper cardiac function and morphology. Furthermore, it will provide novel insights into the pathophysiology of GSD XV patients who lack glycogenin-1 and show high glycogen accumulation.

## PgmNr 2630: De novo RYR2 mutations are associated with severe phenotype of CPVT more strongly than inherited ones.

### Authors:

K. Sonoda <sup>1</sup>; T. Hattori <sup>1</sup>; M. Horie <sup>2</sup>; S. Ohno <sup>1,2</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Department of Bioscience and Genetics, National Cerebral and Cardiovascular Center, Osaka, Japan; 2) Center for Epidemiologic Research in Asia, Shiga University of Medical Science, Otsu, Japan

### Background:

Catecholaminergic polymorphic ventricular tachycardia (CPVT) is one of the causes of sudden cardiac death in the young people. RYR2 is a major causative gene for CPVT, and the disease follows an autosomal dominant trait. However, de novo mutations are often identified during familial genetic analysis, and phenotype differences between patients with de novo and other mutations have not been elucidated yet.

### Purpose:

We aimed to characterize the patients carrying de novo RYR2 mutations and compared with those carrying inherited ones.

### Methods and Results:

In 50 CPVT probands with RYR2 mutations, we genotyped their parents and confirmed the origin of the each mutation. We identified 24 probands with de novo mutations and 26 with inherited mutations. The comparison of clinical characteristics was summarized in the table. Median age at first symptom was younger in the probands with de novo mutations than those with inherited one ( $P = 0.01$ ). The detection rate of bidirectional VT and polymorphic ventricular premature beats or VT was significantly higher in the probands with de novo mutations ( $P = 0.02$ ).

### Conclusion(s):

In our study, the phenotype of probands with de novo RYR2 mutations was severer than those with inherited ones. The patients with de novo RYR2 mutations frequently suffer fatal ventricular arrhythmia, and we should treat them more carefully.

	De novo N = 24	Inherited N = 26	P value
Male	12 (50%)	16 (61.5%)	0.41
Median age at first symptom, y	8.0 [6.0 – 10.0]	10.0 [8.5 – 13.0]	0.01
Median age at diagnosis, y	10.0 [8.0 – 15.0]	12.0 [10.0 – 14.0]	0.25
Syncope	19 (79.2%)	19 (73.1%)	0.79
Cardiopulmonary arrest and/or Ventricular fibrillation	14 (58.3%)	12 (46.2%)	0.37
Bidirectional VT	17 (70.8%)	9 (34.6%)	0.02

Polymorphic ventricular premature beats or VT	21 (87.5%)	14 (53.8%)	0.02
Atrial arrhythmia	2 (8.3%)	3 (11.5%)	1.00

**Background:** The 2015 ACMG/AMP Variant Interpretation Guidelines (ACMG<sub>2015</sub>) have become a cornerstone of genetic test interpretation. As these guidelines were written generally for all Mendelian disorders, the application of individual criteria may be subjective resulting in variant classification discrepancies. In an effort to provide more gene- and disease-specific guidance, the ClinGen Channelopathy Working Group modified ACMG<sub>2015</sub> for application to *KCNQ1* in the context of congenital Long QT syndrome (LQTS).

**Objective:** To compare the classification of *KCNQ1* variants using ACMG<sub>2015</sub> and *KCNQ1*-modified guidelines (*KCNQ1*-M).

**Methods:** Fifty *KCNQ1* variants were independently reviewed and classified by three curators, using both ACMG<sub>2015</sub> and *KCNQ1*-M. Final classifications were compared for concordance between curators and overall distribution of individual variant classifications.

**Results:** Completely concordant inter-curator classification was higher using *KCNQ1*-M than ACMG<sub>2015</sub> (34/50[68%] vs 19/50[38%];  $p < 0.01$ ), while clinically significant discordance occurred less frequently using *KCNQ1*-M than ACMG<sub>2015</sub> (12/50[24%] vs 20/50[40%], NS). Overall *KCNQ1*-M resulted in a lower number of combined likely pathogenic (LP)/pathogenic (P) classifications than ACMG<sub>2015</sub> ( $17 \pm 3.1$ ; 13-20 vs  $23 \pm 3.2$ ; 19-27) and a higher number of variants of uncertain significance (VUS) ( $28 \pm 2.6$ ; 26-32 vs  $23 \pm 4.7$ ; 20-30). The increase in VUS using *KCNQ1*-M resulted primarily from the requirement

of stringent scrutiny of the medical literature with respect to the diagnosis of LQTS in the context of specific variants. It was also affected by changes to the use of functional evidence, with the introduction of more specific requirements to activate functional studies as evidence for pathogenicity.

**Conclusions:** *KCNQ1*-modified guidelines resulted in a higher rate of concordance in final variant classifications than ACMG<sub>2015</sub> suggesting that gene-specific guidelines may be useful in decreasing discrepancies in variant interpretation. Although clinically relevant discordance approached 25%, this is expected to decrease with additional *KCNQ1*-M refinements. The increased number of VUS and decreased LP/P classifications requires further investigation as to whether the modified guidelines are too stringent resulting in overly conservative variant classifications or whether the lack of specificity of ACMG<sub>2015</sub> may contribute to inappropriate attribution of disease causality to an identified variant.

## PgmNr 2632: Variable clinical presentation of Congenital Thrombotic Thrombocytopenic Purpura in a large cohort of patients carrying a novel mutation in ADAMTS13 gene.

---

**Introduction:** Congenital Thrombotic Thrombocytopenic Purpura (cTTP) is a life-threatening disorder, known to be caused by nearly 150 different mutations in ADAMTS13 gene. Its clinical manifestations are microangiopathic hemolytic anemia, thrombocytopenia and disseminated thrombosis.

**Materials and Methods:** PCR amplification of the exons of ADAMTS13 (NM\_139026) was performed after DNA extraction, followed by direct sequencing of the PCR products. We analyzed 17 patients; all belong to three closely related families with high rate of consanguinity. Presenting symptoms and disease severity among cohort members are markedly heterogeneous.

**Results:** We identified a novel mutation in ADAMTS13, causing a frameshift near the C-terminus of the protein. The mutation will result in the loss of the highly conserved amino acids of the full-length protein at the C-terminus of the protein, that contain CUB2 domain. We validated that all 17 patients of our study were homozygous for the mutation, while healthy individuals had the normal or heterozygous alleles. This cohort is one of the largest cTTP cohorts described in the literature and it is unique in the fact that all members have the same ADAMTS13 gene mutation. The mutation was not present in 254 Bedouin controls.

**Conclusions:** The novel frameshift mutation in ADAMTS13 further expands the spectrum of mutations seen in cTTP. We show that although all patients share the same mutation they vary significantly in the severity of the disease. Early identification of the mutation provides early preventive care instructions to the families in handling these patients and contributes for further family planning.

## PgmNr 2633: *TGFB3*-related Loews-Dietz syndrome causes arterial tortuosity in two patients and concurrent Klinefelter syndrome in one prevents aortic dilation.

### Authors:

Loews Dietz syndrome (LDS) is a connective tissue disease that has been associated with vasculopathies, including aortic dissection and arterial tortuosity. Transforming growth factor - beta (TGF- $\beta$ ) signaling is an important contributor to the pathogenesis of LDS. Recently, TGF- $\beta$  ligand, *TGFB3*, has been shown to cause aortic aneurysms and dissections if mutated. Unlike other genes in the TGF pathway associated with LDS (*TGFB1*, *TGFB2*, *SMAD3*, *TGFB2*), previous studies of mutations in *TGFB3* have not found significant association with arterial tortuosity. We describe 2 patients with LDS5, a truncating *TGFB3* mutation (c.1020T>A, p.Y340X), and radiographic evidence of arterial tortuosity. Patient 1 presented at the age of 10 years with pectus excavatum, positive thumb and wrist signs, hind foot deformity, flat feet, scoliosis, high arched palate with bifid uvula, and a dilated aorta (z score 2.4). CT angiography illustrated tortuosity of the internal carotid artery (ICA), vertebral arteries and proximal portions of the anterior and middle cerebral arteries. Patient 2 presented at the age of 23 years with joint hypermobility, pectus excavatum, scoliosis, dysmorphic facial features, and mosaic Klinefelter Syndrome (KS). He did not have aortic dilatation, but was found to have tortuosity of the ICA and the vertebrobasilar confluence. This is the first patient in literature that presents with both LDS and KS, with the latter possibly being protective against aortic dilation based on a prior study showing small vessel sizes in patients with KS. In conclusion, we report two patients with a truncating *TGFB3* mutation and arterial tortuosity, despite prior studies suggesting absence of arterial tortuosity in patients with *TGFB3* mutations.

### Findings of current and previously reported *TGFB3* patients

Physical sign	Patient 1	Patient 2	<i>TGFB3</i> review - Scheper, 2018
Pectus carinatum/excavatum	excavatum	carinatum	13/20 (65%)
Flat feet	Y	Y	19/23 (83%)
Scoliosis or thoracolumbar kyphosis	Y	Y	20/29 (69%)
Retrognathia	micrognathia	Y	10/20 (50%)
Malar hypoplasia	Y	Y	3/10 (30%)
Skin Striae	N	Y	4/18 (22%)
Myopia	Y	N	6/15 (40%)

Mitral valve prolapse	regurgitation	N	6/15 (40%)
Marfan systemic score	8	7	
Arachnodactyly	Y	Y	18/45 (40%)
Aortic dilation/aneurysm	Y	N	8/24 (33%)
Aortic dissection/rupture	N	N	5/16 (31%)
Tall stature - Height (cm)	>3SD	6' 5'	
BMI	15.58	17.64	
Wide/bifid uvula	bifid	wide	19/24 (79%)
Cleft palate	N	N	7/13 (54%)
Hypermobility	Y	Y	21/26 (80%)
Arterial tortuosity	Y	Y	1/8 (13%)

## PgmNr 2634: Whole exome sequencing identifies a homozygous nine base pair (9bp) deletion in ARSB associated with familial dilated cardiomyopathy.

Inherited cardiomyopathy is the major cause of sudden cardiac death (SCD) and heart failure (HF). The genetics of familial DCM are complex and accounting for 50% known disease-causing genes, but many causative genes are unknown. Here we aimed to identify the causative gene for DCM in a consanguineous family. The DCM case, unaffected sibs and parents had tested negative on a 181 candidate DCM genes. Whole-exome sequencing (WES) was performed on the affected DCM case, unaffected sibs and parents. *In silico* structural and functional analyses including protein modeling, structure prediction, and dynamic simulations were performed. Bioinformatics analysis identified a homozygous 9 base pair deletion in exon 1 of the *ARSB* gene that results in an in-frame deletion of three amino acids (Glycine and Alanine) at codon 38 to 40 in the affected DCM case. The variant is heterozygous in the parental samples, in the unaffected brother and was not detected in the unaffected sister. The mutation was predicted to cause a significant and deleterious change in the *ARSB* protein structure. The present study demonstrated *ARSB* mutation associated with life-threatening/pathogenic and recessively inherited DCM. This study highlights a limitation of the targeted gene sequencing and shows the potential for whole exome sequencing to identify the mutation(s) and novel gene(s) responsible for familial DCM of unknown genetic cause.

## PgmNr 2635: Rare variation in *SYNE1* is implicated in the development of childhood-onset essential hypertension.

---

Childhood-Onset Essential Hypertension (COEH) affects 1-2% of children, most often underrepresented minorities, and leads to an increased later-life risk for cardiovascular and renal complications. Although difficult to diagnose, the heritability of COEH is estimated to be 60-80%. In contrast to adult-onset essential hypertension and syndromic forms of childhood secondary hypertension, genetic contributors to COEH remain unknown; however, the high heritability and low prevalence suggest a role for rare genetic variation.

We performed whole exome sequencing on an extensively phenotyped cohort of 68 COEH probands and available family members. After QC and annotation using ATLAS tools, we focused on rare (minor allele frequency < 1%), predicted protein-damaging variants, particularly those in any of 832 known hypertension genes compiled from the literature. We then prioritized variants whose family segregation was consistent with pedigree-implied modes of inheritance. This analysis identified 18 rare, putatively-damaging, biallelic missense variants *in trans* in *SYNE1* in 10 probands (14.7%). This proportion was significantly higher than among 860 trios from the Baylor-Hopkins Center for Mendelian Genomics, (Fisher-Exact P=0.037) and differed significantly from expectations derived from Hardy-Weinberg proportions of rare *SYNE1* variation in gnomAD (biallelic probability =0.004), indicating that biallelic *SYNE1* rare variation is generally uncommon. In five other non-cohort children with compound heterozygous *SYNE1* variation, available blood pressures were above the median despite normal Body Mass Indices. Lastly, using multi-dimensional scaling, COEH individuals with biallelic *SYNE1* variation clustered with individuals of African ancestry, consistent with rare *SYNE1* missense variants in gnomAD having higher frequencies among individuals of African ancestry.

*SYNE1* encodes Nesprin - a part of the cytoskeletal LINC-complex, in which genetic variation has been linked to other childhood-onset cardiovascular phenotypes. Missense variants identified in our cohort were all within the spectrin repeat domain of Nesprin, which is highly expressed in smooth muscle cells. In addition, *SYNE1* has been implicated in two large GWAS of hypertension, and rare *SYNE1* variants have been associated with cardiomyopathy. Our results implicate rare variation in *SYNE1* as a predisposing factor in COEH that might also contribute to the increased incidence of COEH among US minority groups.

## PgmNr 2636: Next-generation sequencing identifies a homozygous mutation in *ALMS1* associated with familial dilated cardiomyopathy.

**Objective:** Cardiomyopathies represent the second largest group of patients in sudden cardiac death (SCD) victims, next to coronary artery disease. The genetics of familial DCM are complex and accounting for 50% known disease-causing genes, but many causative genes are unknown. Here we aimed to identify the causative gene for DCM in a consanguineous Saudi Arabian family.

**Patients and Methods:** The affected two children and their unaffected parents had tested negative on a 181 candidate DCM genes. Whole-exome sequencing (WES) was performed on the affected two children and their unaffected parents. The identified variant was screened in 50 clinically annotated controls and 50 DCM cases to evaluate its frequency in the Saudi Arabian general population and individuals with DCM. *In silico* structural and functional analyses including protein modeling, structure prediction, and dynamic simulations were performed.

**Results:** Bioinformatics analysis detected a homozygous nonsense variation in exon 8 of the Alstrom syndrome 1 gene (*ALMS1*) that results in a stop codon and premature truncation of the protein. The variant was heterozygous in the unaffected parents. The mutation was absent in 50 clinically annotated controls and 50 pediatric DCM cases. The mutation was predicted to cause a significant and deleterious change in the *ALMS1* protein structure.

**Conclusions:** The present study demonstrated *ALMS1* mutation associated with life-threatening/pathogenic and recessively inherited DCM. This study highlights a limitation of the targeted gene sequencing and shows the potential for whole exome sequencing to identify the mutation(s) and novel gene(s) responsible for familial DCM of unknown genetic cause.

## PgmNr 2637: Mutation spectrum of dilated cardiomyopathy from Korean patients.

---

Dilated cardiomyopathy (DCM) is defined as a myocardial disorder with left ventricular dilatation and contractile dysfunction. Among idiopathic dilated cardiomyopathy, hereditary cardiomyopathy accounts for up to 50% of it. More than 40 genes are known to cause dilated myopathy and next-generation sequencing made it possible to exam these genes at once. The aim of the study was to identify the mutational spectrum of DCM causing genes from Korean patients. We enrolled 109 patients who were diagnosed as DCM and requested for DCM panel testing. A targeted panel of 48 genes was done with next-generation sequencing on genomic DNA extracted from venous puncture. Low coverage region was covered with Sanger sequencing.

Thirty-two patients (29%) have more than one pathogenic or likely pathogenic variants of DCM causing genes and no variant was detected from 17 patients. *MYH7* and *LMNA* were the most common causative genes. Among the pathogenic or likely pathogenic variants, there are 25 missense (78.1%), 4 frameshift (12.5%), 6 nonsense (18.8%), and 1 in-frame deletion (3.1%) variants. Our study showed that the proportion of hereditary cardiomyopathy was significant. Also, it provides insights into the pathophysiology of dilated cardiomyopathy.

## PgmNr 2638: Aggregation of homologous protein domains identifies constrained positions in *TTN* and prioritises missense variants for evaluation of a role in dilated cardiomyopathy.

**INTRODUCTION:** The giant protein titin (encoded by *TTN*) is a crucial component of all striated muscle. *TTN*-truncating variants have been recognized as the most prevalent genetic cause of dilated cardiomyopathy (DCM). However, the assessment and interpretation of *TTN* missense variants in DCM has presented a profound challenge in clinical genome interpretation since rare missense variants in *TTN* are prevalent in the population, and indistinguishable from those in patients with DCM. Previous studies assessing the relevance of *TTN* missense variants, using sequence conservation across species or structural features of proteins, have been inconclusive.

**HYPOTHESIS:** The deleteriousness of missense variants depends on its molecular location within *TTN*. Since ~70% of the titin protein sequence is composed of ~300 Fibronectin type-III (fn3) and Immunoglobulin I-set (I-set) domains, the effect of missense variants in these two domains could be inferred from the genetic intolerance of the amino acid positions in the domain families to variation.

**METHODS:** To increase the power in prioritization of domain positions with large effect, we aggregated equivalent amino acid positions for each domain in the *TTN* canonical transcript. Using the variant data of 141,456 individuals in gnomAD, we then calculated the degree of depletion of neutral variation within the human genome at each position, based on a sequence context model.

**RESULTS:** We aligned 83 and 89 positions with high-coverage of residues across the fn3 and I-set domains respectively. In the fn3 domain, 57% of aligned positions are depleted of missense variants, four of them significantly ( $P$ -value<0.05). In the I-set domain, 42% of aligned positions are under constraint. To validate this approach, we evaluated the distribution of well-characterised myopathy-associated ClinVar variants between constrained and unconstrained positions. The top 5% most-constrained domain positions had a 1.8-fold increased disease association compared with the remaining positions, using a cohort of 990 patients with DCM and a control set of 2,090 healthy volunteers.

**CONCLUSIONS:** The aggregation of constraint within the human population on homologous domains represents complementary information to assess the relevance of domain positions, and highlights an

effective approach to prioritize missense *TTN* variants with large deleterious impact.

## PgmNr 2639: Common genetic variants associated with immune and inflammatory traits and disease severity phenotypes in hereditary hemorrhagic telangiectasia.

### Authors:

**Background:** Hereditary hemorrhagic telangiectasia (HHT) is an autosomal dominant Mendelian disorder caused by mutations in several TGF $\beta$ /BMP9 signaling pathway genes. HHT patients have variable phenotypes including skin and mucosal telangiectases, which cause severe and/or chronic nose and gastrointestinal bleeding and anemia, and organ vascular malformations (VM) and arteriovenous malformations (AVM), which can lead to stroke. Genetic modifier effects and inflammatory processes may contribute to HHT phenotypic heterogeneity. We hypothesized that common genetic variants associated with immune or inflammatory traits are associated with HHT phenotypes.

**Methods:** We genotyped 760 Caucasian HHT patients from the Brain Vascular Malformation Consortium (BVMC) on the Affymetrix Axiom UK Biobank array. We selected 5,081 common (MAF>1%) variants (or their LD proxies,  $r^2>0.8$ ) associated with 354 immune and inflammatory traits from the NHGRI-EBI Genome-Wide Association Study (GWAS) Catalog (version e93, October 2018). We evaluated 6 HHT severity phenotypes: any VM, lung AVM, brain VM, liver VM, anemia from HHT-related bleeding, and stroke (ischemic stroke from lung AVM or intracerebral hemorrhage from brain VM). Association of variant genotype with phenotype was evaluated using additive models adjusted for age, sex and 20 principal components.

**Results:** Six variants were associated with any VM, 6 with lung AVM, 6 with brain VM, 3 with liver VM, 6 with anemia and 10 with stroke at  $p<0.001$ , however no associations achieved FDR-corrected statistical significance. The strongest associations were for: any VM with a *MAZ* variant, previously associated with multiple sclerosis (OR=2.36,  $p=0.000054$ ), brain VM with a *MSI2* variant, associated with coronary artery calcification (OR=1.88,  $p=0.000095$ ), and lung VM with an *IGF1R* variant previously associated with endometriosis (OR=1.57,  $p=0.00034$ ). *MAZ* is a transcription factor involved in TGF $\beta$  signaling, cell proliferation and carcinogenesis. *MSI2* is an RNA-binding protein that modulates cell proliferation and IL6 signaling. IGF signaling has been implicated in HHT VMs. We will replicate top associations in a second cohort of 800 HHT patients from the BVMC.

**Conclusions:** GWAS catalog variants associated with immune or inflammatory traits may also be associated with disease severity phenotypes in HHT.

---

Spontaneous Coronary Artery Dissection (SCAD) is a rare type of Acute Coronary Syndrome (ACS) that primarily affects younger individuals who do not exhibit “traditional” cardiovascular risk factors. Previous genetic and epidemiologic studies indicate that connective tissue disorders (CTDs) such as Marfan syndrome, Loeys-Dietz syndrome, and Ehlers-Danlos syndrome with known genetic causes are more prevalent among SCAD than other ACS patients, however, these conditions combined are thought to explain less than 0.5% of SCAD cases. The arteriopathy fibromuscular dysplasia (FMD) is also enriched in SCAD patients, and common variants at the *PHACTR1/EDN1* locus previously associated to FMD are also associated with SCAD. While many patients report extreme emotional episodes or physical exertion at SCAD onset, these environmental factors may serve as a trigger in patients with an underlying genetic cause of vascular weakness.

Previous genetic studies of SCAD have used CTD and familial thoracic aortic aneurysm and dissection (TAAD) gene panels to screen for causative mutations, however this approach achieved only an 8% rate of genetic diagnosis. In addition, due to the potential phenotypic heterogeneity of vascular weakness and low penetrance (only 1.2% of cases show familial inheritance) the use of trios, a common practice for Mendelian diseases, may not be useful. New approaches are needed to facilitate improved screening, diagnosis, treatment, and genetic counselling for SCAD patients.

We have Whole Genome Sequenced 45 SCAD patients in the GENESIS-PRAXY cohort, which consists of individuals who had an ACS event at or under age 55. SCAD individuals were significantly more likely to be female ( $p < .001$ ) and have an earlier age of onset ( $p = .006$ ) and less likely to smoke ( $p = 0.15$ ), be obese ( $p = .02$ ), or have hypertension ( $p = .15$ ), dyslipidemia ( $p = .06$ ), or diabetes ( $p = .35$ ). We constructed a pipeline to identify likely causal variants using previous reports of pathogenicity in ClinVar, computational predictions of variant deleteriousness, and allele frequencies in gnomAD. A pilot analysis of exomes revealed possible disease causing variants in the *FBN1* and *LEMD3* genes, which have known connective tissue functions.

## PgmNr 2641: Pathological variants in PLEKHO2 predispose individuals to heritable thoracic aortic disease.

Up to 25% of individuals with thoracic aortic aneurysms and dissections (TAD) have multiple family members affected, termed heritable TAD (HTAD). Pathogenic variants in 11 genes are confirmed to predispose to HTAD, including genes that encode proteins involved in canonical TGF $\beta$  signaling (e.g., *TGFBR1* and *TGFBR2* encoding the type I and II TGF $\beta$  receptors). To identify additional HTAD genes, exome sequencing on affected individuals in HTAD families was analyzed and a rare heterozygous variant, p.Gly392Glu, in *PLEKHO2* was identified that segregated with TAD in a large HTAD family with a LOD score of 4.2. This variant is absent in the gnomAD v2.1.1 exome controls and has a combined annotation dependent depletion (CADD) score of 25.2. Analysis of exome sequencing data from 577 individuals from 367 HTAD families and 374 unrelated individuals with early-onset ( $\leq$  56 years of age) sporadic thoracic aortic dissections identified 7 additional rare *PLEKHO2* missense variants with CADD score  $>20$  and minor allele frequency less than 0.005 in the gnomAD v2.1.1 exome controls. *PLEKHO2* encodes a protein with no known function and is homologous to CKIP-1, which increases ubiquitination of bone morphometric signaling proteins (Smad1 and 6). When *PLEKHO2* was expressed in HELA with ubiquitin and various components of the canonical TGF $\beta$  signaling pathway, *PLEKHO2* was found to dramatically increase ubiquitylation of activated TGFBR1. *PLEKHO2* shRNAs were used to knockdown expression in smooth muscle cells (SMCs), which resulted in increased the expression of SMC differentiation genes by immunoblot analyses. Analysis of signaling pathways altered in these cells found increased TGFBR1 levels, but also increased levels of phosphorylated p38 MAPK levels. P38 MAPK levels are also present in SMCs from a Marfan mouse model (mgN/mgN mice). In summary, heterozygous rare variants in *PLEKHO2* cause HTAD, and loss of *PLEKHO2* in SMC alters the same signaling pathways identified in the SMCs of MFS mice, specifically activation of p38 MAPK.

## PgmNr 2642: Sex-limited penetrance of lymphedema to females with CELSR1 haploinsufficiency: A second family.

---

Development of the lymphatic system is complex and involves products of numerous genes. We report here a multi-generation family with hereditary lymphedema secondary to a novel frame shift variant (NM\_014246.1, c.5121dupC, p.1708fs\*44) in the planar polarity gene, *CELSR1*, a non-classic cadherin known to influence vascular endothelial cell migration and proliferation. This variant has not been reported in the publicly available human genomics databases: gnomAD, 1000 Genomes, the Exome Aggregation Consortium, or dbSNP and is highly conserved across multiple species. The dominant inheritance of the variant was discovered using whole exome sequencing and confirmed by Sanger sequencing. 22 family members were interviewed, examined, and blood drawn. Five females, and no males, exhibited lymphedema as determined by history and physical examination, and staged by International Society of Lymphology (ISL) staging criteria (I mild, II moderate, III severe). No other phenotypes such as kidney diseases or hearing loss were identified. Whole exome sequencing was performed in an affected female, her obligate carrier father, and her affected paternal aunt. All three subjects were shown to be heterozygous for *CELSR1* (p.1708fs\*44) variant, which was further confirmed by Sanger sequencing. Totally, 17 family members were subjected to Sanger sequencing and the heterozygous variant was shown in all 5 affected females and 4 obligate carrier males, but not in the unaffected females or non-carrier males, confirming the segregation of *CELSR1* (p.1708fs\*44) variant with lymphedema in females and carrier status in males in this family. Lymphoscintigraphy in affected females showed previously undescribed lymphatic abnormalities consistent with lymphangiectasia, valve dysfunction, and thoracic duct reflux. Interestingly, the first family with lymphedema with a variant (p.W1957X) in *CELSR1* gene also exhibits sex-limited penetrance to females (Gonzalez-Garay et al., 2016). The sex-limited manifestation of lymphedema is unique for hereditary lymphedema. The underlying mechanism is unknown but one possible explanation is hormonal regulation of lymphatic development consistent with sex variation in some other primary lymphedemas. In summary, the discovery of two multi-generation families with hereditary lymphedema, each with a novel loss of function *CELSR1* gene variant co-segregating with the disease, strongly suggests a role for *CELSR1* in human lymphatic development and function.

## PgmNr 2643: Development of a novel mouse genetic model to study vascular malformations and its use in understanding hereditary hemorrhagic telangiectasia.

Studying the molecular etiology of rare genetic conditions is important to the understanding of select disease processes and can provide crucial insights into the molecular etiology of more common conditions. Hereditary Hemorrhagic Telangiectasia (HHT) is a rare Mendelian condition characterized by multiple arteriovenous malformations (AVMs). Small AVMs (telangiectases) are apparent on mucocutaneous surfaces while larger AVMs may form in the lung (PAVM), brain, or liver. Patients often present with spontaneous and recurrent epistaxis, though hemorrhage from visceral AVMs can be sudden and catastrophic. Most cases of HHT are caused by mutations in *ENG* or *ACVRL1*, which encode endothelial receptors for TGF- $\beta$ s and BMPs. However, the cellular and molecular mechanisms driving HHT pathobiology are still unclear, though aberrant angiogenesis is thought to play a role. Our lab previously showed that human polymorphic variants of *PTPN14* associate with PAVM formation in both HHT type I and II. Our current study investigates the molecular genetics of PAVM formation in HHT using mouse knockout models for *ENG* and *PTPN14*. Our overarching hypothesis is that *PTPN14* interacts with the TGF $\beta$ /BMP9/endoglin/ *ACVRL1*/Smad4 signaling pathway to stabilize blood vessels such that reduced expression or loss of *PTPN14* will potentiate the formation of AVMs under conditions of genetic loss of an *ENG* allele. To test this hypothesis, we will investigate formation of the retinal vascular network during the first seven days of post-natal life in mice that are germline *Eng*<sup>+/-</sup>. *Ptpn14*<sup>+/-</sup> versus *Eng*<sup>+/-</sup> versus wild type mice. Additionally, we are constructing a mouse model with doxycycline-inducible endothelial cell-specific KO of the *Ptpn14* gene, utilizing a mouse with a *Ptpn14*<sup>flox</sup> allele that will be bred to an EC-specific CRE-ER recombinase. We will utilize immunohistochemistry to assay for arterial, venous, and lymphatic malformations in skin, lung, liver, and gastrointestinal tract as well as molecular techniques, including RNA-Seq, western analysis and IHC of lung tissues, to assess qualitative and quantitative changes in Smad and Taz signaling and global gene expression that may be correlated to clinical findings in HHT. Ultimately, this study has the potential for significant short- and long-term impacts on our understanding of the pathogenesis of vascular malformations and hemorrhage control both in HHT and more broadly, and may provide novel insights into drug treatment for HHT.

## PgmNr 2644: Validation of a genome-wide polygenic risk score on South Asian individuals for prediction of Coronary Artery disease risk.

Recent studies have shown that the predictive power of polygenic risk scores (PRS) is substantial when the effects of common genetic variants are summed across the entire genome to create genome-wide PRS (GPS). The predictive power of GPS can be orthogonal to commonly used clinical tests such as LDL cholesterol, implying that GPS will be important tools in clinical practice and public health planning. GPS are dependent upon allele frequencies and effect sizes that vary between population groups, so calibration and validation will be needed before they can become broadly useful. South Asia (SA) has a very large burden of cardiovascular disease and an appropriate GPS will have enormous impact on human health in this part of the world. We carried out preliminary calibration and evaluation of an existing GPS algorithm (LDPred method and CARDIoGRAMplusC4D GWAS summaries) and demonstrated its utility in predicting individuals with high risk for coronary artery disease (CAD) in South Asians.

In this study, we genotyped 1,173 patients with coronary artery disease and 1,445 age and gender matched healthy controls using Illumina's Global Screening array (GSA) (1,173 patients and 942 controls) or whole genome sequencing (WGS) at 30X (503 controls). Development of a GPS requires a high-quality reference panel for imputation that is optimized for SA populations. We evaluated imputation of the quality passed common genotypes between GSA and WGS using a GenomeAsia Project (GAsP) reference panel containing 30X WGS from 1,739 individuals including 724 individuals from 72 distinct SA population groups. For comparison we used the HRC reference panel or the 1000 Genomes Phase3 (1000G) callset. Imputation with 1000G recovered only 59% of the European CARDIoGRAMplusC4D model variants and was not used to generate a GPS. Imputation with the GAsP reference panel recovered the high proportion (90%) of the variants in the CARDIoGRAMplusC4D GWAS summary. GPS were generated by LDPred and optimized with SA cases and controls from UKBiobank data (630 cases, 6,614 controls). Using the GAsP reference panel, we obtained an odds-ratio of 1.72 for those in the top decile compared with the median GPS. We further observed that the early onset individuals (age  $\leq 45$  years) had 3-fold higher median GPS ( $p < 0.05$ ) as compared to

those with later events. Our study shows that a properly calibrated and validated GPS can be an extremely useful clinical tool for predicting CAD risk in SA groups.

## PgmNr 2645: Transcriptomic changes of individual peripheral blood mononuclear cells in mild stroke patients.

**Purpose:** Minor and transient ischemic strokes are easily missed with current diagnostic tools. Its diagnosis may be improved by peripheral blood biomarkers. In this study, we examined peripheral blood mononuclear cells (PBMCs) transcriptome profile at the single cell level as the potential biomarker for the minor strokes.

**Methods:** Peripheral blood samples were collected from acute minor ischemic stroke patients (National Institutes of Health Stroke Scale <5) within 24hr after stroke onset and age/gender matched controls. Transcriptome libraries of individual PBMCs were prepared and sequenced.

**Results:** Based on single cell RNA-seq data from 12,418 cells in 11 minor stroke patients, 12 cell type clusters were identified, while 13 cell type clusters were identified from 12,285 cells in 8 controls. Distribution of cell clusters was significantly different between patient and control groups. Cell type clusters commonly identified from both groups were compared to obtain differentially regulated genes. From 9 common clusters, 137 differentially regulated genes were found, and S100A9 from B cells cluster was the most upregulated gene in stroke patients.

**Conclusion:** As the first pilot study of transcriptome changes after minor stroke in a single cell level, it might provide a guidance for the future biomarker study.

## PgmNr 2646: Insights into the genetic architecture of spontaneous coronary artery dissection through sequencing 392 cases and >13,000 UK Biobank controls.

Spontaneous coronary artery dissection (SCAD) occurs when one of the coronary arteries is occluded by a tear in the lining of the arterial wall and/or a haematoma in the vessel wall that is not caused by trauma, atherosclerosis or medical treatment. It can cause acute coronary syndrome, myocardial infarction, and sudden death. The prevalence of SCAD has been reported as 0.07% to 1.1%, and it is likely to be significantly underdiagnosed. Pathogenic variants in genes associated with connective tissue disorders have previously been implicated in the aetiology of SCAD, however, very little is known about the genetic architecture of this condition.

We have whole-genome sequenced a cohort of 392 individuals with SCAD with the aim of discovering novel variants and genes associated with SCAD and improving understanding of phenotypic heterogeneity. A multi-pronged approach is being taken to analysis. First, we have identified pathogenic variants in genes previously implicated in SCAD including protein-truncating variants in *COL3A1* (associated with vascular Ehlers-Danlos syndrome), *SMAD3* (associated with Loeys-Dietz syndrome type III), and *PKD1* (associated with autosomal dominant polycystic kidney disease, a known risk factor for SCAD). Second, gene-level collapsing analysis has been performed to identify genes enriched for rare variants in cases compared to >13,000 controls from the UK Biobank. These controls have had WES and have no reported cardiovascular disease or connective tissue disease. We found no gene to be study-wide significantly associated with SCAD. Several genes previously implicated in SCAD or connective tissue disorders rank highly in this experiment including *COL3A1* ( $p = 0.0013$ ), *PKD1* ( $p = 0.0016$ ) and *TGFB2* ( $p = 0.0024$ ). Further analyses of these data, including follow up of potential novel candidate genes, are ongoing and will be presented.

Additional ongoing analyses include variant and pathway level association studies, analysis of structural variants, genotype-phenotype correlation analyses, and candidate gene prioritisation using a machine learning approach. This is the largest SCAD cohort to have undergone whole-genome sequencing, and alongside sequenced and deeply phenotyped UK Biobank controls, provides rich opportunity for novel discoveries.

**Introduction:** Idiopathic ventricular fibrillation (IVF) is one of the major causes of sudden cardiac death in younger subjects who have no structural heart disease or identifiable inherited primary arrhythmic syndromes. The genetic background of IVF is still unclear.

**Methods:** Whole exome sequencing on 184 subjects (39±19 years, 71% male) who had been resuscitated from VF without any structural heart diseases was conducted. We aligned short read sequences to human reference genome (build38) by using two methods, namely BWA (0.7.15) and Bowtie2 (2.3.2), and performed variant calling by GATK (3.8.1) haplotype caller. To increase accuracy, we annotated (by ANNOVAR) and analyzed only single nucleotide variants (SNVs) commonly detected by both mapping methods and passed standard quality control.

**Results:** A total of 55,107 SNVs, which either affect splicing events or reside in exons of genes/non-coding RNAs, have reported minor allele frequencies (MAF) of  $\leq 0.01$  in publicly available East Asian and Japanese population databases (including the 1000 Genomes, ExAC, Gnomad, HGVD, and ToMMo). 1,581 among these rare SNVs were residing in the 295 genes potentially associated with heritable heart and vascular conditions (Invitae Cardiology Gene Panel). Based on ACMG-AMP Guidelines for clinical interpretation of variants (by InterVar software), we identified 27 pathogenic or likely pathogenic (PLP) SNVs in cardiovascular diseases-related genes in 15% of the IVF subjects (28/184). The proportion of PLP SNVs in cardiovascular diseases-related genes was significantly higher in the 184 IVF patients (27/1581) compared to the 1210 Japanese subjects in the HGVD database (34/3624) ( $P=0.0256$ ). Furthermore, many of the PLP SNVs in IVF patients could be observed in the arrhythmia-related genes (10/480 in IVF vs 7/1366 in HGVD;  $P=0.0048$ ) and cardiomyopathy and muscular diseases-related genes (23/1048 in IVF vs 24/2456 in HGVD;  $P=0.0068$ ).

**Conclusion:** In IVF patients, 15% had some PLP SNVs in genes associated with cardiovascular diseases, but many of these were not directly related to lethal ventricular arrhythmias but rather potential genes associated with cardiomyopathies and/or neuromuscular diseases.

## PgmNr 2648: Association of a genome-wide polygenic risk score for low-density lipoprotein cholesterol and coronary artery disease risk.

### Authors:

Coronary artery disease (CAD) is the leading cause of death and disability in the world. Low-density lipoprotein cholesterol (LDL-C) is a causal risk factor for CAD. Recently, a genetic study showed that polygenic risk scores (PRS) associated with CAD can be predictive of CAD. In the present study, we assessed whether PRS associated with LDL-C can be predictive of LDL-C and CAD in individuals from the UK Biobank. We calculated the PRS for LDL-C using summary statistics from Global Lipids Genetics Consortium and calculated the PRS from different sets of SNVs and parameters from the LDpred method in a training dataset of 50,000 self-identified white British. In this analysis, we observed that the optimal parameters, as measured by the variance explained by the LDL-C PRS on LDL-C, was LDpred with  $\rho=0.3$ . We calculated the LDL-C PRS using  $\rho=0.3$  on a test dataset of 324,551 separate individuals also from the UK biobank. We observed consistent strong associations of the LDL-C PRS on LDL-C in White British ( $\beta=0.255$  [0.25 - 0.26],  $P<2.11 \times 10^{-16}$ ) and Non-White British Europeans ( $\beta=0.248$  [0.24 - 0.26],  $P<2.11 \times 10^{-16}$ ) with weaker significant associations in Africans ( $\beta=0.167$  [0.14 - 0.19],  $P=5.53 \times 10^{-34}$ ), East Asians ( $\beta=0.185$  [0.13 - 0.24],  $P=2.11 \times 10^{-11}$ ), and South Asians ( $\beta=0.177$  [0.15 - 0.2],  $P=1.22 \times 10^{-50}$ ). Overall, in a meta-analysis of all ancestries, we observed association of the LDL-C PRS on LDL-C ( $\beta=0.211$  [0.18 - 0.24],  $P=1.09 \times 10^{-48}$ ). Similar trends were observed with the LDL-C PRS on CAD across the different ancestries. Furthermore, individuals in the top 1% of the LDL-C PRS had 1.12 SD units increased LDL-C and 1.6-fold increased risk for CAD compared to the bottom 10% of individuals. Plasma LDL-C was observed to be elevated in the top 1% of individuals with the LDL-C PRS (median= $150 \pm 38$  mg/dL) as compared to the bottom 10% (median= $120 \pm 30$  mg/dL). We expect to replicate these results in the multiethnic clinical care cohort, BioMe, and assess whether individuals with high LDL-C PRS are being adequately recognized for their inherent genetic risk and whether risk modification strategies are being employed.

## PgmNr 2649: Whole-exome sequencing in 249 transposition of the great arteries patients unveils central role of cilia related etiology.

### BACKGROUND

Congenital heart diseases (CHDs) are the most common types of birth defects, affecting approximately 1% of live births and remaining the leading cause of mortality. Transposition of the great arteries (TGA) is a kind of most severe life-threatening congenital heart disease. There was an increased recurrence risk among sporadic TGA cases suggest that genetic factors lead an important role underlying this disease. However, the exact etiology of TGA remains unclear.

### METHODS

We performed whole exome sequencing in 249 non-syndromic TGA samples to quantify the genetic burden and causal factors. 189 obesity cases with normal cardiac phenotype were recruited as a control cohort and another group of 130 TGA patients as a replication cohort. The pathogenicity of de novo variants, loss of function genes, compound heterozygous variants and X-linked variants in CHD related gene and pathway were considered using a semi-automatic automatic bioinformatics filtering process. Loss of function genes were then performed functional enriched analysis.

### RESULTS

Eleven de novo variants, 62 genes with rare loss of function (LOF) variants, 4 genes with compound heterozygous variant and 8 X-linked variants were identified using our analytical strategy. Cilia related genes were occupied a major position in our results: it showed up as strong pathogenic genes in de novo, X-linked and compound heterozygous condition. Notably, ciliopathies related gene *DYNC2LI1* encoding a component of the dynein-2 complex shown a significantly high risk of TGA disease (OR: 2.51; 95% [CI]:1 to 5.22; p value: 0.02). Overall, except one mutation: p.G241D, the rest 4 mutation: p.D80E, p.D80A, p.L130P, p.R232H were located in a critical functional domain. Using sanger sequencing technique, we found 2 more mutation a replication cohort of TGA (n=130) on *DYNC2LI1* gene at the same chromosome loci. Even more interesting, cilium assembly or organization pathway was significantly enriched in functional annotation and enrichment analysis (P-value<0.05).

### CONCLUSIONS

Among the patients in our study, TGA related causal genes arose from in de novo, LOF, compound heterozygous and X-linked condition. A mount numbers of variants affecting genes involved in cilium assembly or organization that exacerbate the widespread genetic susceptibility associated with TGA. The results reveal extensive genetic heterogeneity underlying TGA, and posit potential novel strategy of genetic investigation for rare disease.

## PgmNr 2650: Untargeted lipidomic profiles as endophenotypes for CVD risk.

---

Cardiovascular disease (CVD) is the leading cause of mortality worldwide. Risk is attributable to several factors including blood pressure, smoking, increasing age, sex, and genetics. Although CVD risk is heritable and there have been a number of successes localizing QTLs influencing disease risk, the genetic basis is still relatively unknown. Quantitative endophenotypes that are related to disease liability can offer more power for gene localization than dichotomous disease status and thus serve as valuable endophenotypes for disease gene identification. Lipids and their constituent components are important factors in CVD risk. The human lipidome is the total complement of these lipid species and represents a wealth of endophenotypes that may influence CVD risk. To identify CVD endophenotypes, we performed untargeted plasma lipidomic profiling in 500 individuals from 6 extended pedigrees of the San Antonio Family Study (SAFS). Untargeted lipidomic profiling was performed by liquid chromatography-ultrahigh resolution mass spectrometry and conditions optimized for separation of both polar and non-polar lipids. Quantitative measurements were obtained in positive and negative ion modes using MS analysis, and characterization was achieved by leveraging off our existing targeted lipidomic platform and a combination of DDA/DIA MS<sup>2</sup> and MS<sup>3</sup> acquisitions. Prior to processing, the untargeted method identified 135,414 features with less than 10% missing values across all individuals. To identify genetic factors influencing levels of each of these lipid features, we performed variance-component based heritability analyses, using age, sex and their interactions as covariates. Using a very conservative Bonferroni threshold, 72,184 (~50%) lipid features were significantly heritable, with heritabilities of 20-80%. We examined whether variation in these heritable features was associated with future CVD. The 10 most significantly associated features ( $p=7.95 \times 10^{-6}$  to  $p=4.04 \times 10^{-5}$ ) include lipid species in 5 classes with changes of ~0.7 SDUs observed in individuals who develop CVD. The heritability of each of these features was greater than 40% indicating a significant genetic component to variation. These preliminary results provide strong evidence that using an untargeted approach will identify many more lipid species associated with CVD than targeted only profiling methods thus providing a powerful approach for identification of endophenotypes influencing CVD risk.

## PgmNr 2651: Polygenic risk scores substantially improve risk stratification based on traditional non-genetic risk factors.

---

There has been considerable recent interest in the use of polygenic risk scores (PRS) to identify individuals at increased risk of common diseases. Early risk stratification offers the potential for targeted screening or interventions. Much attention to date has focussed on the use of PRS as standalone tools. But for many diseases clinicians already assess risk based on non-genetic risk factors. A key question is the extent to which PRS add to current risk assessments.

We address this question using coronary artery disease (CAD) because of its major impact on mortality and because there are widely-used risk assessment tools based on non-genetic risk factors, including age, gender, lipid levels, and blood pressure.

For definiteness we consider the American Heart Association (AHA) risk score. We use a CAD PRS developed internally whose performance is comparable to, and in some ways improves on, other published CAD PRS. A subset ( $n = 100K$ ) of UK Biobank is used as training to optimise the AHA/PRS combination. Remaining samples are used to compare the performance of the AHA score with the combined AHA/PRS score.

The CAD PRS is uncorrelated with the AHA non-genetic score ( $r = 0.01$ ), hence clearly provides additional information. The CAD PRS is also almost uncorrelated with family history ( $r = 0.09$ ). The combination of AHA and PRS provides a substantial improvement in classification for CAD (net reclassification improvement of 0.36). Next, we considered the binary classification problem which approximates current guidelines used to determine whether statin prescription is recommended (broadly equivalent to AHA non-genetic score  $> 20\%$ ). Firstly, because the combination of non-genetic and PRS scores improves risk stratification, substantially more individuals ( $\sim 2$ -fold) are above the relevant absolute risk level using the combined score. Secondly, the set of individuals above this level (who would thus be recommended statins) is different: 5.4% of the UK Biobank population not classified at high risk is reclassified as high risk using the combined score. Critically, these individuals meet guideline levels of risk for statin prescription but are not currently identified as such. In addition, 11% of the individuals classified as high risk using AHA score only have medium levels of risk when PRS is incorporated. These data show that CAD risk prediction provides a potential first application for the integration of PRS with traditional risk factors in clinical care.

---

We recently developed and validated a genome-wide polygenic score (GPS) for coronary artery disease (GPS<sub>CAD</sub>) in individuals of European ancestry. Whether this GPS can generalize to other ancestries is unknown.

We used imputed genotyping data or whole-genome sequencing data to calculate GPS<sub>CAD</sub> in 469,964 individuals (26,476 cases) of European ancestry and 37,977 individuals (3,916 cases) of African (1,371 cases), South Asian (873 cases), East Asian (435 cases), and Hispanic (1,237 cases) ancestries across 6 multi-ethnic cohorts from 4 countries. Those included the UK Biobank, hospital-based case-control studies (VIRGO, TaiChi Consortium, and BRAVE), and hospital-based biobanks (BioMe and Partners Biobank). Self-report ancestry was validated by principle component analysis to 1000 Genomes Project data. We measured the strength of GPS<sub>CAD</sub> in predicting CAD in each ancestry of each cohort, using a logistic regression model adjusted for the first four principle components of ancestry. We then performed a meta-analysis for similar ancestries across cohorts to compare the predictive power of GPS<sub>CAD</sub> across different ancestries.

The strength of association of GPS<sub>CAD</sub> in European ancestry was as reported previously, with an odds ratio per standard deviation (OR<sub>SD</sub>) of 1.60 (1.45-1.75) for CAD. The European GPS<sub>CAD</sub> predicted CAD reasonably well in East Asian (OR<sub>SD</sub> = 1.66 [1.45-1.88]), South Asian (OR<sub>SD</sub> = 1.47 [1.36-1.58]), and Hispanic (OR<sub>SD</sub> = 1.53 [1.44-1.65]) ancestries. The score remained predictive, but had a reduced strength, in individuals of African ancestry (OR<sub>SD</sub> = 1.25 [1.14-1.37]). Within each ancestry, variability in the Area Under the Curve (AUC) and OR<sub>SD</sub> was confounded with the study design and case definition.

A polygenic score of CAD developed in individuals of European ancestry is generalizable to non-European ancestry in diverse settings but shows weakest strength of association in African ancestry.

Polygenic risk scores (PRS) for coronary artery disease (CAD) may quantify an individual's risk for developing atherosclerosis. Carotid intima-media thickness (IMT) and carotid plaque measures are associated with coronary artery atherosclerotic lesions. We evaluated whether the PRS for CAD is associated with carotid IMT, plaque severity and plaque presence, assessed using high resolution B-mode ultrasonography in up-to 2405 European ancestry individuals from 499 families recruited for exceptional longevity (age:  $72.1 \pm 11.7$ , range: 42-110 years old). To generate the PRS, 177 independent SNPs ( $r^2 < 0.2$ ) identified from genome-wide association studies (GWAS,  $p < 5.0 \times 10^{-8}$ ) for CAD were aligned to their risk alleles. The PRS for each participant was computed using the allele count of 177-SNPs multiplied by CAD effect size ( $\beta$ -coefficients or odds ratio using natural-logarithm (log) transformation). The products of allele counts and  $\beta$ -coefficients were summed over all 177 CAD SNPs for the total PRS (mean  $\pm$  S.E. =  $11.08 \pm 0.48$ ). Carotid IMT and plaque severity (ranging from 0 (no) to 30 (highest) plaque index +1), were log transformed and adjusted for age, sex, field centers, cardiovascular risk factors (smoking, diabetes, systolic blood pressure, hypertension, low-density lipoprotein, high-density lipoprotein, and waist circumference) and accounting for population stratification (principal components). Then, linear mixed effects models accounting for kinship (lme4 function in R-package) were employed in residuals of carotid IMT and plaque severity with PRS as the independent variable. A generalized estimating equations approach (SAS® 9.4) was used for plaque presence (Yes/No) and included the PRS, cardiovascular risk factors and principal components in the model. The CAD PRS was significantly associated with carotid IMT ( $\beta \pm$  S.E. =  $0.140 \pm 0.046$ ,  $p = 2.23 \times 10^{-3}$ ), plaque severity ( $\beta \pm$  S.E. =  $0.191 \pm 0.044$ ,  $p = 1.48 \times 10^{-5}$ ) and plaque presence ( $\beta \pm$  S.E. =  $0.387 \pm 0.105$ ,  $p = 2.17 \times 10^{-4}$ ) considering Bonferroni correction (0.05/3 phenotypes,  $p = 0.0167$ ). Our findings show that CAD PRS is associated with early markers of atherosclerosis even among adults selected for exceptional survival independent of established cardiovascular disease risk factors. Patients identified by high polygenic risk scores may ultimately benefit from prevention strategies, including early lifestyle change and therapeutic interventions, to help modify the trajectory of CAD.

## PgmNr 2654: Phenome-wide association of functional coding variants and cardiometabolic phenotypes in American Indians.

---

There has been a great interest in phenotyping individuals with predicted protein-altering functional variants (rare loss of function and missense variants) to understand the health effects in populations. In our ongoing genetic investigation in American Indians, we recently genotyped 1,127 participants from the Strong Heart Family Study, in a case-control study of chronic kidney disease, for single nucleotide variants (SNV) and small indels identified by whole exome sequencing in a subset of individuals and that had predicted protein-altering function. Among 1,206 SNVs and indels that passed quality control (average minor allele count [MAC] = 20, range of 1 to 1,064), ~43% were not present in publicly available repositories, and may be specific to American Indians. Most of the novel coding variants were missense SNVs/indels (n=228), frameshift substitutions (n=73), stop-gain or stop-loss variants (n=8), and splice acceptor/donor (n=11). We performed association analyses of SNVs/indels with a MAC>10 for 32 cardiometabolic biomarkers, using variance component models to account for relatedness, while adjusting for age, sex, center and case-control status. Using a multiple-testing adjusted significance threshold of  $p < 5.5 \times 10^{-6}$  to account for 9,122 effective independent tests including 32 traits tested, we identified 11 trait-variant associations. For example, we detected a missense SNV at *ABCA10* (p.G1369W, MAC=17,  $p=8 \times 10^{-9}$ ) associated with increased fasting triglycerides and explaining 2.5% of trait variability. *ABCA10* protein is involved in macrophage lipid homeostasis suggesting that it is a cholesterol-responsive gene. A missense SNV located at *TRPM3* (p.V1249M, MAC=185,  $p=5 \times 10^{-8}$ ) was associated with lower fasting insulin concentration and accounted for 1.7% of serum insulin variance. *TRPM3* protein is a non-selective cation channel expressed in pancreatic  $\beta$ -cells, which has been shown to regulate insulin secretion. Additional findings include a novel missense SNV at *EXTL2* (MAC=23,  $p=9 \times 10^{-9}$ ) associated with serum creatinine, and a missense SNV at *PNPLA5* (MAC=13,  $p=3 \times 10^{-7}$ ) associated with increased HbA1c. In conclusion, our study focused on predicted damaging coding variants in American Indians identified new gene associations with cardiometabolic phenotypes, demonstrating the advantages of strategies that leverage whole exome sequencing findings to select predicted functional variants for association screenings in less genetic characterized populations.

## PgmNr 2655: Oligogenic inheritance of a human heart disease involving a genetic modifier.

---

Complex genetic mechanisms are thought to underlie many human diseases, yet experimental proof of this model has been elusive. Here, we show that a human cardiac anomaly can be caused by a combination of rare, inherited heterozygous mutations. Whole-exome sequencing of a nuclear family revealed that three offspring with childhood-onset cardiomyopathy had inherited three missense single-nucleotide variants in the *MKL2*, *MYH7*, and *NKX2-5* genes. The *MYH7* and *MKL2* variants were inherited from the affected, asymptomatic father and the rare *NKX2-5* variant (minor allele frequency, 0.0012) from the unaffected mother. We used CRISPR-Cas9 to generate mice encoding the orthologous variants and found that compound heterozygosity for all three variants recapitulated the human disease phenotype. Analysis of murine hearts and human induced pluripotent stem cell-derived cardiomyocytes provided histologic and molecular evidence for the *NKX2-5* variant's contribution as a genetic modifier.

## PgmNr 2656: RYR2 and KCNQ1 ion channel single nucleotide polymorphisms are contributing to myocardial infarction susceptibility in middle-aged Mexican men.

---

Cardiovascular disorders (CVD) are the leading cause of death in low and middle-income countries where more than three-quarter of CVD caused deceased occur. Of these, ischaemic heart disease contributes to 85% of deaths, exhibiting a higher trend in middle age men (18 – 50 years). Genome-wide association studies have identified common risk-variants related to CVD, which frequencies have exhibited multi-ethnic variations among populations. Next-generation sequencing is a powerful tool to study and discover rare gene variants contributing to complex disease development. Herein, sixteen young men (range: 26 - 46 years;  $41.05 \pm 4.71$ ) and their controls were studied by sequencing 174 genes, (TruSight Cardio Sequencing kit, Illumina®) with Illumina Miseq System, to identify their genetic contribution to acute myocardial infarction risk. Quality control analysis guaranteed reliable results, which were evaluated to identify those variants with potential to cause disease using ten *in silico* algorithms. Our results suggested the contribution of two SNP in ion channel genes: ryanodine receptor 2 (RYR2; rs561321743; H877P), and potassium voltage-gated channel subfamily Q member 1 (KCNQ1; rs199472800; R555H). R555H has been related to abnormal potassium channel functions. This variant was also found in affected individuals with long QT syndrome, reinforcing our findings. H877P has been considered as a gene variant likely benign, but it is feasible that this it ion channel single nucleotide polymorphism could be in linkage disequilibrium with causal variants given that RYR2 polymorphisms have been associated with ventricular arrhythmias risk. Hitherto, the allele frequencies of these two ion-channel single nucleotide polymorphisms are unknown in the Mexican population, making further studies necessary to reveal their clinic implication.

---

**Introduction:** Ventricular fibrillation (VF) in the absence of coronary disease or left ventricular (LV) dysfunction often remains unexplained. Given its heritability, identifying the genetic culprit is important for family screening. **Hypothesis:** Systematic whole-exome sequencing (WES) identifies a pathogenic or likely pathogenic (P/LP) variant in a significant proportion of unexplained cardiac arrest (UCA) survivors. **Methods:** We performed WES in consecutive unrelated survivors of UCA, defined as VF in the absence of overt structural or electrical disease. Joint variant calling was performed as per the GATK best practice guidelines. For the present study, we limited our analysis to rare (allele frequency, AF <1/10,000 in the Genome Aggregation Database, gnomAD) protein-coding variants in 60 genes unequivocally associated with cardiac arrhythmia, cardiomyopathy or systemic disease with a cardiac manifestation. Variant classification was performed according to the American College of Medical Genetics and Genomics (ACMG) guidelines. **Results:** WES was performed in 234 UCA probands (66% males; age at arrest 38±13). WES identified a total of 17.6M high quality genetic variants, of which 172 were rare variants in 60 cardiac disease genes (mean 0.7 variants/case). We observed a significant enrichment of rare missense RYR2 variants in UCA compared to gnomAD (combined AF 4.1% vs. 2.0%; P=0.004) as well as an enrichment of rare truncating variants in cardiomyopathy genes (2.8% vs. 1.1%; P=0.003). Of the 234 probands, 30 (12.8%) had ≥1 P/LP variants as per ACMG criteria. Phenotype-driven clinical genetic testing prior to research WES only identified the P/LP variant in 12 (40%) of the 30 cases, suggesting an added value of systematic genetic testing compared to the current standard of phenotype-driven testing. **Conclusions:** Systematic comprehensive genetic testing of cardiac genes identifies a disease-causing variant in 13% of unexplained cardiac arrest survivors. Truncating variants in cardiomyopathy genes are enriched in UCA supporting an association of structural genes with ventricular arrhythmias in the absence of overt cardiomyopathy. Further studies are needed to understand the implications of these

findings in cascade family screening.

---

Carotid intima-media thickness (CIMT) and presence of carotid plaque, evaluated non-invasively using ultrasound, are markers of atherosclerosis and useful in detecting subclinical cardiovascular disease. The largest published genome-wide association study (GWAS) found 11 CIMT and 5 plaque loci. Utilizing whole genome sequencing (WGS) generated by the National Heart, Lung, and Blood Institute's Trans-Omics for Precision Medicine (TOPMed) program, we sought to investigate potentially novel genetic associations with CIMT and carotid plaque that may have been missed by GWAS based on genotyping arrays. WGS data was available for 22,443 participants from 9 studies who had CIMT measured and 20,254 participants from 7 studies who had carotid plaque evaluated. Participants were of European, African-American, Hispanic, or East Asian ancestry. CIMT was transformed through inverse rank-based normalization. Linear and logistic mixed models accounting for relatedness, implemented in SAIGE, were used to perform single variant tests for CIMT and plaque, respectively. Analyses were adjusted for age, sex, study, ancestry group, and principal components and limited to variants with a minor allele frequency (MAF) >0.1%. Using a significance threshold of  $P < 5 \times 10^{-8}$ , we identified two loci (*APOE* and *CCBE1*) associated with CIMT and one locus (*HNF4G*) with plaque. While the *APOE* locus has been previously linked to CIMT, *CCBE1* and *HNF4G* represent potential novel associations. *CCBE1* plays a role in extracellular matrix remodeling and is important to the formation of lymphatic vessels. *HNF4G* is a part of a family of transcription factors known to play important roles in development, homeostasis, and metabolism. The index variant for *CCBE1* (rs747874008) was rare in all ancestry groups (MAF=0.12%). In contrast, the index variant for *HNF4G* (rs1817002) was intergenic and common across all ancestry groups (MAF=26.4%). Population specific analyses suggest associations with both variants are primarily driven by European participants. Through our analysis, we confirmed an association between *APOE* and CIMT, and identified two potentially novel loci for CIMT and plaque. The *CCBE1* variant may have been missed by previous GWAS due to its low

MAF. However, the common *HNF4G* variant was evaluated in prior array-based GWAS and was not associated despite being well imputed. Replication is required in order to confirm or refute the association of these novel loci with carotid atherosclerosis.

Compared with array-based, imputation-based, and exome-focused analyses, whole genome sequencing (WGS) data provides better coverage of the genome and better representation of non-European variants.

To better understand the genetics underlying several hemostasis traits, we leverage Freeze 6 deep whole genome sequences from NHLBI's Trans-Omics for Precision Medicine (TOPMed) program to investigate plasma levels of 4 hemostasis measures: fibrinogen (n= 32,572), fibrin D-dimer (n=19,049), tissue plasminogen activator (tPA; n=4,393), and plasminogen activator inhibitor 1 (PAI-1; n=7,857). Phenotypes were centrally harmonized across up to 12 studies that included participants of European, African, Asian, and Hispanic ancestry. Association analyses were conducted using inverse normalized and rescaled residuals adjusting for age, sex, study, TOPMed phase, study-specific parameters, self-reported ancestry, 11 ancestry informative principal components, and a

kinship matrix. All analyses were conducted on the Analysis Commons cloud computing platform using the SMMAT function implemented in GENESIS. Single-variant analyses included all variants with a minor allele count  $\geq 40$ . Gene-based aggregate analyses used 3 strategies for variant selection: 1) loss of function (LOF), 2) LOF and deleterious missense (LDM), and 3) coding, enhancer and promoter variants. The latter aggregation tests were restricted to variants with a minor allele frequency (MAF)  $< 0.05$ , whereas no restrictions were implemented for LOF aggregation tests.

Significantly associated regions were found in single variant tests for fibrinogen ( $n=7$ ) and D-dimer ( $n=3$ ). All were in loci previously associated with these phenotypes, and the majority were common variants in high linkage disequilibrium with previously reported variants. The most significant association for fibrinogen was a previously reported rare missense mutation (rs148685782,  $p=6.8 \times 10^{-48}$ , MAF=0.003, *FGG*) located within the region containing the fibrinogen structural genes: *FGA*, *FGB*, *FGG*. LOF and LDM aggregation tests demonstrated associations with these genes only. No significant associations for genes with  $>5$  alternate alleles were identified for D-dimer. No significant associations were detected for tPA or PAI-1.

Fine-mapping analyses are planned within several regions for fibrinogen to leverage the resolution provided by WGS. Meta-analysis using external cohorts imputed to the TOPMed reference panel is planned to improve power for discovery.

Coronary artery disease (CAD) is a leading cause of death worldwide. According to a European twin study, the ratio of genetic contribution to the development of CAD is estimated to be more than 50%. Although genome-wide association studies (GWAS) revealed numerous disease susceptibility loci, the explained heritability by GWAS did not reach the expected ratio partly because their target was limited to low frequency to common variants. Therefore, investigation of rare variants is mandatory to unveil the entire genetic architecture of CAD. But the contribution of rare variants has not been fully characterized thus far. Here, we conducted whole genome sequencing (WGS) on 4417 Japanese samples (1781 myocardial infarction cases, 2636 healthy controls) and analyzed rare variants. Functional annotations for the variants called in the WGS were performed using ANNOVAR and RefSeq. For the analysis, we grouped together frameshift insertion/deletion, stop gain/loss, splicing variants as loss of function (LOF) variants. We also grouped missense variants with combined annotation dependent deletion (CADD) score greater than 20 as LOF variants. Next, we excluded the variants reported in 1000 Genomes Phase 3 in East Asian cohorts to have just rare variants. We then compared the number of these rare LOF variants between case and control by Fisher's exact test. We observed a significant excess of LOF variants in *LDLR* (14 in case and 0 in control,  $P = 3e-6$ ). We also found significant differences in *PCNX4* (11 in case and 1 in control,  $P = 3.4e-4$ ), *BCLAF1* (0 in case and 16 in control,  $P = 3.9e-4$ ), *TMEM255B* (8 in case and 0 in control,  $P = 6.9e-4$ ), *TMC7* (10 in case and 1 in control,  $P = 7.8e-4$ ). To validate the result, we explored LOF variants in another Japanese cohort (200 myocardial infarction cases and 832 controls) and confirmed a significant burden of LOF variants in *LDLR* (8 in case and 0 in control). These results suggest that rare LOF variants can be a risk for CAD and contribute to the heritability. Because of relatively small sample size and classical statistical

method for evaluation, our results should be re-confirmed by large sample size cohort studies with a sophisticated statistical method tailored to rare-variant analysis.

Coronary artery disease (CAD) is a leading cause of death worldwide. CAD is known as a common, heritable disease. Numerous genome-wide association studies (GWAS) were conducted to elucidate the genetic architecture of CAD and have identified over 160 disease susceptibility loci. To contribute broader knowledge on the genetics of CAD, we conducted a large-scale genetic analysis of CAD in combination with whole-genome sequencing.

We sequenced genomes of 1782 CAD cases and 3148 controls recruited from the Japanese population. By the whole genome sequencing, we found several “pathogenic” variants for CAD. To leverage enriched disease-specific haplotype information, we constructed a novel reference panel for haplotype imputation. Newly developed reference panel significantly improved imputation quality in the Japanese population, especially for rare to very rare [minor allele frequency (MAF) < 0.001] variants. Using these densely imputed genotypes, we performed a large-scale GWAS for CAD (25,859 cases and 69,359 controls) in the Japanese population. We identified 9 previously unreported loci at the genome-wide significance level and additional associated independent signals. These independent signals included rare and high impact coding variants in CAD-relevant genes. Especially we found rare, coding variants in established causal genes [*LDLR*, MAF 0.05%, odds ratio (OR) 7.2, *PCSK9* MAF 1%, OR 1.5, *APOB* MAF 3%, OR 1.5] as independent signals. These variants are specific to the East Asian population and have a large effect size in CAD development. To characterize the carriers of these rare variants, we performed phenome-wide analyses using a biobank-based dataset. These variants are enriched in acute coronary syndromes, and the carriers showed worse clinical phenotypes exemplified by worsened cholesterol profile and early-onset myocardial infarction. As expected from these surrogate markers, individuals with these variants showed increased long-term cardiovascular mortality (Hazard ratio 1.21 [1.09-1.39],  $p=6 \times 10^{-3}$ ). In summary, population and disease-specific reference panel provided improved imputation performance and accurate estimation of the prevalence and penetrance of rare-pathogenic variants in the context of GWAS.

## PgmNr 2662: Pathways affecting polygenic risk for supralvalvar aortic stenosis in Williams-Beuren syndrome.

Williams Beuren syndrome (WBS) is caused by the deletion of 26-28 genes on chromosome 7 and produces a characteristic set of multi-organ phenotypes. Haploinsufficiency for elastin (*ELN*) causes the cardiovascular features of the condition, including supralvalvar aortic stenosis (SVAS), but severity varies widely. To identify factors that impact SVAS risk, we performed exome sequencing in 104 individuals with WBS and looked for differences in variant burden among the phenotypic groups. Single variable analysis revealed no statistically significant effect of sex, race, or WBS deletion size on SVAS outcomes. Likewise, neither second hits in *ELN* itself nor other genes in the WBS critical region had significant effect on the SVAS phenotype. Exome wide gene-based analyses (SKAT-O) performed on nonsynonymous variants in an extreme phenotype subset (n=62) revealed no single gene with exome wide significance. However, gene set enrichment showed a preponderance of variants affecting the adaptive immune system (False Discovery Rate (FDR) =  $1 \times 10^{-7}$ ). Studies in *Eln*<sup>+/-</sup>; *Rag1*<sup>+/-</sup> mice showed larger aortic caliber in the double mutant animal (p<0.01), confirming the role of the adaptive immune system in modifying aortic disease in elastin insufficiency.

Subsequent gene set enrichment analysis performed on a subset of variants with CADD\_phred >10 and more than 10% difference in allele frequency between those with no and severe SVAS identified modifiers in extracellular matrix (ECM), GPCR signaling, lipid metabolism and immune pathways. Focused burden evaluation of those pathways by SKAT-O yielded positive results for each with FDR = 0.001-0.03, while Qtest Wald testing resulted in even more significant findings with ECM variant burden FDR =  $2 \times 10^{-26}$ , while the other three pathways had FDR on the order of  $10^{-7}$ . Investigation of *Eln*<sup>+/-</sup> mice on diverse genetic backgrounds confirmed a role for variation in the ECM in modifying vascular features of elastin insufficiency.

Taken together, our studies have allowed us to detect important genomic variations in adaptive immunity and ECM pathways that contribute to SVAS risk in individuals with WBS. Replication is needed but our findings show that focus on pathway level, rather than gene level analysis may reveal more meaningful results in small cohorts. Orthogonal methods in animal models can help to confirm suggestive results from exploratory studies.

\*PCR Parrish is the study's first author and BA Kozel is the senior author.

**Background:** Type 2 diabetes (T2D) increases the risk of coronary heart disease (CHD), yet the specific mechanisms involved remain poorly described. Traditional clinical risk factors, including blood pressure, serum lipids, glycemic control, obesity and smoking fail to identify all individuals who will develop CHD, particularly among the diabetics, suggesting that some risk of CHD in diabetics is not captured by these clinical risk factors. Polygenic risk scores (PRS) provide an opportunity to explore the mechanisms involved in disease, because this data driven approach surveys the genome and makes no prior mechanistic assumptions. We tested whether a PRS for CHD influenced risk of CHD in patients with T2D and which known CHD mechanisms were associated.

**Methods:** We first tested the association of a previously published CHD PRS with CHD amongst patients with T2D in UK Biobank [N = 21,102 patients with T2D, of whom, 1,898 (9.0%) developed CHD]. To better understand which mechanisms were influenced by this PRS, we tested its association with CHD traditional risk factors amongst these patients. However, atherosclerotic burden is not assessed in UK Biobank. We therefore undertook coronary angiograms, clinical risk factor measurement and genome-wide genotyping in a cohort of 352 patients with T2D and tested whether the PRS for CHD was associated with multivessel stenotic disease, as detected by angiogram, and/or traditional CHD risk factors.

**Results:** In the UK Biobank we found that the CHD PRS was strongly associated with CHD amongst patients with T2D (OR per standard deviation = 1.50; 95% CI 1.43-1.57;  $p < 2 \times 10^{-16}$ ). Amongst patients with T2D, the CHD PRS was not associated with hypertension, hypertriglyceridemia, glycemic control, obesity or smoking, and was moderately associated with hyperlipidemia (OR = 1.22 per standard deviation increase; 95% CI 1.12-1.33;  $p = 3.5 \times 10^{-6}$ ). On the other hand, the CHD PRS was strongly associated with multivessel stenosis (OR = 1.65; 95% CI 1.25-2.20;  $p = 4.9 \times 10^{-4}$ ). Further, the CHD PRS was associated with increased number of major stenotic lesions (OR = 1.35; 95% CI 1.08-1.69;  $p = 9.4 \times 10^{-3}$ ).

**Conclusions:** Amongst individuals with T2D, the CHD PRS was strongly associated with atherosclerotic burden and this effect is largely independent of traditional clinical risk factors. The mechanisms leading to increased atherosclerotic burden should be investigated to understand CHD risk in T2D.

## PgmNr 2664: Returning polygenic risk information for coronary artery disease and other traits to biobank participants.

We have recruited 3449 participants from a biobanked population-based study cohort FinHealth to a separate study called P5 FinHealth. Here, we will return polygenic risk scores (PRS) for three common diseases via internet portal to these volunteering participants. To validate the PRS, have tested how for coronary artery disease (CAD), type 2 diabetes and venous thromboembolism affect the risk of disease within the following ten years in participants from a population-based study FINRISK .

Based on follow-up data from national health care registries we validated PRS in whole genome genotyped population based FINRISK cohorts with multiple registry follow-up for incident cases (N=21726) and used validated PRS to model P5.fi FinHealth participants from FinTerveys 2017 (N= 3449) using Cox regression models. We estimated the impact of genetic and traditional risk factors on a risk of disease within the next 10 years.

We compared the CAD classification of Cox regression model with traditional risk factors and polygenic additive model with 6,6M variants. From basic model risk class 10-20% PRS reclassified 205 (17%) participants to highest >20% risk class. In FINRISK participants risk for CAD was higher for men and smoking adds to risk of disease in all PRS classes. Risk for disease increases with BMI being highest in BMI class 30-35. Our initial analysis in Finnish population cohorts shows that individuals with very high genetic risk, the PRS class over 2, may get the disease significantly younger than 60-70 years which is conventionally considered the peak.

The validation showed that adding PRS to the traditional risk factors significantly changed the risk enabling reclassification of as many as 17% of the participants. Polygenic risk information is returned to volunteering participants through an internet portal. Changes in life style are followed up using questionnaires through the portal and the morbidity will be collected through health registers. P5 study is a pilot for P6 which will recruit 100 000 participants and include at least 6-10 diseases for similar feedback study, including randomized controlled trial for PRS stratified intervention.

Atrial fibrillation (AF) is one of the common arrhythmias in the world and can lead to stroke, heart failure and sudden death. Genome-wide association studies (GWAS) have revealed more than 150 AF-related loci and enhanced our understanding of the underlying mechanism of AF. While most of previously reported loci were discovered in Europeans, some loci were only identified in East Asian and other populations, which emphasizes the significance of GWAS in non-European populations. Moreover, AF is often related to structural heart diseases and other comorbid chronic conditions, but the shared genetic basis between AF and such disorders remains unclear. To tackle those problems, we carried out a Japanese GWAS, followed by a trans-ethnic meta-analysis for AF and exploring the association of AF with other diseases.

First, we conducted a GWAS in the Japanese population that encompassed 10,250 cases and 148,998 controls. We identified 32 loci associated with AF ( $P < 5.0 \times 10^{-8}$ ), of which 4 loci were novel. Next, we performed a trans-ethnic meta-analysis by MANTRA using the result from a European GWAS and discovered 21 additional new loci ( $\log_{10}$  Bayes' factor  $> 6$ ). In total, our study identified 25 novel loci associated with AF. These new loci were involved in cardiac development, contractility and electrophysiological function. Gene set enrichment analysis revealed the association of AF with FHL2 subnetwork ( $P = 1.12 \times 10^{-11}$ ) and SRF subnetwork ( $P = 1.26 \times 10^{-11}$ ), which were prevalent in cardiomyopathy. In tissue and cell type enrichment analysis, we found significant enrichment in cardiovascular system (Heart Ventricles,  $P = 3.79 \times 10^{-7}$ , Heart Atria,  $P = 2.47 \times 10^{-6}$ , Atrial Appendage,  $P = 2.95 \times 10^{-6}$ ) and musculoskeletal system (Muscle Striated,  $P = 5.17 \times 10^{-4}$ , Muscle Skeletal,  $P = 5.17 \times 10^{-4}$ ). We evaluated the genetic correlations between AF and other diseases using Japanese GWAS by means of bivariate LD score regression. AF showed significant positive genetic correlation with blood pressure and coronary artery disease. Finally, we explored associations between genome-wide significant loci for AF and clinical measurements. We then observed that several loci were

associated with cardiovascular traits, such as elevated blood pressure, decreased ejection fraction and left ventricular enlargement.

In conclusion, we identified 25 novel loci for AF and showed the shared genetic basis between AF and other associated diseases. Our results may help us understand the underlying mechanisms of AF.

## PgmNr 2666: Exome sequencing in multiplex families with left sided cardiac defects has high yield for disease gene discovery.

The genetic architecture of congenital heart disease (CHD) is complex. In addition, cardiac phenotyping can be challenging and parsing individuals with additional congenital anomalies or neurodevelopmental disorders that may indicate a multisystem syndrome is complicated. Recent large-scale exome sequencing projects have identified single gene causes in as many as 10% of trios. Most have been in individuals with multisystem disease, with the yield in isolated CHD of 1-3%. We sought to overcome these problems by a family based approach to CHD gene discovery, using multiplex families to better phenotype cases and use segregation as an additional criterion for variant pathogenicity. We performed exome sequencing on 19 families with 2 or more individuals with isolated left sided cardiac defects, specifically aortic valve stenosis, coarctation of the aorta and hypoplastic left heart syndrome. After quality control and filtering for minor allele frequency (<0.001), we ranked loss of function and missense variants with a minimum CADD score of 30. Five families had segregating predicted pathogenic variants in previously described genes known to cause CHD (*CTBP2*, *MATR3*, *MCTP2*, *MYH6*, *NOTCH1*). Segregating variants in three novel CHD gene candidates were identified; two showed functional changes (*BMP10*, *CASZ1*), and functional studies are ongoing for one (*ROCK1*). A variant in *BMP10* was shown to have normal mRNA and protein expression in transfected HEK293 cells but the variant protein was not secreted by cell based assay. A variant in the nuclear localizing signal domain of *CASZ1* was shown have normal mRNA and protein expression. Transfection of the mutant into HEK293 cells demonstrated the protein did not localize to the nucleus, and compared to wild type was unable to transactivate a tyrosine hydroxylase luciferase reporter construct. We identified two additional segregating predicted pathogenic variant candidates, but luciferase transactivation assays studies for a *HEY1* variant and potassium current studies in *Xenopus* oocytes for a *KCNJ2* variant failed to show any functional differences. Lowering the CADD cut point to 20 has identified candidates in six other families, leaving three families without a reasonable disease gene candidate. We demonstrate that family based approaches have a much higher yield for identifying left sided CHD causing genes compared to parent-case trio approaches, at over 40% (8/19) for known or functionally validated novel CHD genes.

## PgmNr 2667: Assessing the role of rare genetic variations in heart failure via whole exome sequencing.

---

Several sequencing studies have found causal genetic variants for distinct subtypes of heart failure (HF) such as hypertrophic or dilated cardiomyopathy. However, the role of genetic variants in unselected HF patients has not been assessed so far.

We performed whole exome sequencing of almost 6,000 cases with unselected HF from the CHARM (Candesartan in Heart Failure-Assessment of Reduction in Mortality and Morbidity) and CORONA (Controlled Rosuvastatin Multinational Trial in Heart Failure) studies and compared them to a set of 13,000 unrelated controls. Using a gene-based collapsing approach, we looked for genes with an excess of rare and presumably deleterious variants among cases compared to controls.

We detected a significant enrichment of rare protein-truncating variants (PTVs) in the *TTN* gene. Truncating variants in *TTN* are a known cause of dilated cardiomyopathy, but only if they are located in exons that are spliced into most of the *TTN* transcripts present in the heart. We used the presence of PTVs in such exons as additional criterion for defining qualifying variants, which increased the statistical significance of enrichment further. In order to investigate the burden of pathogenic variants in other known cardiomyopathy genes, we performed a diagnostic analysis of all cases and classified variants based on the American College of Medical Genetics and Genomics (ACMG) guidelines for clinical sequence interpretation criteria. We defined diagnostic variants as those that were classified as “pathogenic” or “likely pathogenic” according to ACMG and could be linked to heart failure. In addition to PTVs in *TTN*, we found diagnostic variants in other cardiomyopathy genes such as *MYBPC3*, *MYH7*, *SCN5A*, and *TNNT2*.

Using whole exome sequencing, we have demonstrated that even in a group of unselected HF patients a significant number of individuals harbor diagnostic variants in genes that have previously been associated with cardiomyopathy.

## PgmNr 2668: Increased burden of nsSNVs in cardiomyopathy genes predicts dilated but not hypertrophic cardiomyopathy.

**Rationale:** Dilated and hypertrophic cardiomyopathy are important causes of heart failure and both cardiomyopathy subtypes result from autosomal dominant inheritance with variable expressivity and penetrance.

**Hypothesis:** We hypothesized that additional genetic variation contributed to the manifestation of the pathogenesis of dilated cardiomyopathy (DCM), in which the left ventricle becomes enlarged and poorly contractile, versus hypertrophic cardiomyopathy (HCM), a condition accompanied by a thickened ventricle. We conducted whole genome sequencing to isolate genes responsible for cardiomyopathy expressivity.

**Methods and Results:** Genome sequencing was performed on subjects with dilated (n=71) or hypertrophic (n=56) cardiomyopathy. Variation was assessed in cardiomyopathy genes (n=102) derived from gene panels routinely tested during cardiomyopathy genetic testing. Genetic variation was correlated with measures of heart function and size. Principal component analysis of left ventricle measures using echocardiographic data separated the two cardiomyopathy subtypes (DCM and HCM). Regression of the first principal component using all nonsynonymous single nucleotide variants (nsSNVs) in cardiomyopathy panel genes showed that the number of nsSNVs predicted DCM but not HCM. The likelihood of DCM in the cohort significantly increased as the number of cardiomyopathy gene nsSNVs increased ( $p < 0.02$ ). The increase in cardiomyopathy gene nsSNVs also significantly associated with reduced left ventricular ejection fraction and increased left ventricular diameter, both measures indicative of DCM. Genomewide gene expression in the heart was characterized with data from the Genotype-Tissue Expression (GTEx) database intersecting left ventricle and left atrial RNAseq data. Resampling methods identified genes with deviant cumulative allele frequencies in DCM vs HCM, and potential cardiomyopathy modifying genes were identified in the cardiomyopathy gene panel and all cardiac genes as defined by GTEx.

**Conclusions:** Dilated cardiomyopathy subjects carried a greater burden of nsSNVs in cardiomyopathy genes. In contrast, nsSNV burden in cardiomyopathy genes did not correlate with the

probability or manifestation of left ventricular measures of hypertrophic cardiomyopathy. These data support a complex genetic architecture where increased cardiomyopathy gene variation establishes a genetic background that predisposes to dilated cardiomyopathy and decreased left ventricular function.

## PgmNr 2669: *Cis-ANXA11* and *DYDC2* and *trans-KCNMA1* variants are associated with heterogeneous phenotypes in arrhythmogenic dilated cardiomyopathy.

### Authors:

**Objectives:** Cardiomyopathies are genetic diseases of heart muscle caused by mutations in cytoskeletal genes. Disease severity and penetrance of mutations vary greatly among patients carrying the same mutations and single-gene variants often do not reliably predict cardiomyopathy phenotypes.

**Background:** The chromosome 10q21-q23 locus was previously associated to familial arrhythmogenic dilated cardiomyopathy (aDCM), heart failure, Wolff-Parkinson-White (WPW) syndrome, mitral valve prolapse (MVP) and/or mitral regurgitation (MR). However, the exact variants responsible for heterogeneous phenotypes remained unknown.

**Methods:** A large family of 62 members was studied using whole exome and direct sequencing. Phenotype-genotype correlation and systems genetics analysis were performed. Quantitative co-segregation studies combined with systems genetics analysis were performed using online functional enrichment analysis tools.

**Results:** We identified missense *KCNMA1*-M802T, *ANXA11*-I457V, and *DYDC2*-P123R variants at 10q21-q23. The proband and ten family members carried *ANXA11*-I457V and *DYDC2*-P123R identified *in cis* (digenic heterozygosity). Seven digenic variant-carriers were affected with DCM (n=3), heart failure (n=1), left ventricular dysfunction (n=3), arrhythmia (n=2), MVP (n=2) and MR (n=3). A single *KCNMA1*-M802T was identified in 11 individuals, including 4 affected with MVP (n=3), MR (n=4), ventricular arrhythmia (n=2), and WPW (n=1). All three variants as a multigenic heterozygosity were identified in three family members and all were affected. Computed genetic and phenotype QTL correlations predicted that rare variants in *CORIN*, *DSP*, *TTN*, *KCNMB3*, *TRM7* and *OTX1* may effect on function of *KCNMA1*, *ANXA11*, and *DYDC2* at the major 10q21-q23 locus.

**Conclusions:** Different variant combinations identified at 10q21-q23 underlie the clinical heterogeneity of aDCM phenotypes. The *in cis* digenic heterozygous *ANXA11*-I457V and *DYDC2*-P123R variants co-segregate with the DCM and HF phenotypes in this family, while *KCNMA1*-M802T is associated with MVP/MR and arrhythmias. Rare variants in cardiomyopathy-related genes located beyond the 10q21-q23 may function as the genetic modifiers in inter-, sub-, and intra-familial phenotypic variability.

## PgmNr 2670: Impact of healthy lifestyle and genetic variants on lipid metabolites and incident risk of coronary heart disease.

Adherence to healthy lifestyles is associated with a considerable reduction of coronary heart disease (CHD) risk. We quantified how much of the effects of healthy lifestyles on CHD risk are mediated through lipid metabolites, and compared the effect of healthy lifestyle and genetic scores for two LDL-C lowering targets on the lipidomic profile. A prospective case-control sample of 4,681 participants from the China Kadoorie Biobank aged 30 to 79 years without prior cardiovascular disease or statin use was selected for a metabolomics study. Smoking, alcohol consumption, dietary habit, physical activity, and BMI and waist circumference, assessed by questionnaire and physical measurements at baseline, were used to define five healthy lifestyles. A comprehensive lipid profile in baseline plasma samples was measured by nuclear magnetic resonance. Genetic instruments for lipid-lowering effects of statins and ATP citrate lyase (ACLY) inhibition were used to examine their impact on lipid metabolites. Adherence to healthy lifestyles was associated with 50 components of the lipid profile (FDR < 0.05), including substantially lower very low-density lipoprotein (VLDL) particles and their cholesterol concentration, smaller VLDL particle size, increased high-density lipoprotein (HDL) particles and their cholesterol concentration, and larger HDL particle size. The triglycerides within all lipoproteins, including most HDL particles, were lower among participants who adhered to a healthy lifestyle. A total of 35 lipid metabolites showed significant mediation effect from healthy lifestyle to CHD. The strongest mediator, ratio of apolipoprotein B to A1, accounted for 11% of the reduced CHD risk associated with healthy lifestyle. All lipid metabolites jointly explained 14% of the protective effect of healthy lifestyle on CHD. Genetic scores for the targets of statins and ACLY showed similar effect on reducing concentrations of intermediate- and low-density lipoprotein particles, and cholesterol within these particles, while healthy lifestyle more strongly improved VLDL- and HDL-related measures, and triglycerides in almost all lipoprotein subfractions. The effects of adherence to healthy lifestyles on lower CHD risk were partly mediated by an improved lipid profile. Lifestyle interventions and lipid-lowering drug may target different components of the lipid profile, suggesting that they are not redundant strategies but could be combined for improved benefits.

## PgmNr 2671: A genome-wide polygenic score for coronary artery disease to stratify risk among South Asians.

---

Genome-wide polygenic scores (GPS) integrate information from many sites of common DNA variation into a single measure of inherited risk. We recently developed a GPS for coronary artery disease that enabled stratification of a primarily European ancestry population into varying trajectories of coronary risk, with the upper tail of the distribution having risk equivalent to that of rare monogenic mutations such as those related to familial hypercholesterolemia. The use of a GPS to identify high-risk individuals may be particularly useful amongst South Asians (who develop coronary artery disease at higher rates and significantly earlier in life) but the predictive value in this population had remained uncertain. Here, we derive a GPS using the LDpred computational algorithm based on the largest GWAS summary statistics to date and validate it in 8,025 South Asian participants of the UK Biobank. We built a South Asian specific reference distribution for the GPS using whole genome sequencing data of 1,741 participants and systematically compared GPS in an independent cohort of 1,059 cases and 718 controls. We observed an odds ratio per standard deviation increase in the GPS of 1.46 (95%CI 1.35 -1.57), AUC = 0.60, results overall similar to those previously observed in studies of European ancestry. As compared to average risk (defined as the middle quintile of the score distribution) the GPS identified 14%, 2.5%, and 0.6% of the population with 2-fold, 3-fold, and 4-fold increased risk for CAD. These results confirm the predictive utility of a GPS among a South Asian population and provide a framework for ancestry-specific score validation and testing. Ongoing efforts are designed to integrate these scores with rare monogenic mutations and optimize a strategy to disclose GPS to interested individuals, with the ultimate goal of empowering high-risk individuals to take advantage of targeted screening or prevention measures prior to disease onset.

## PgmNr 2672: Whole exome sequencing reveals novel pathogenic variants in left ventricular noncompaction cardiomyopathy.

### Authors:

**Background:** Left ventricular noncompaction (LVNC), a subtype of cardiomyopathy, has been recognized as a genetically and phenotypically heterogeneous cardiac muscle disorder. Although much progress has been made, the genetic basis still remains incomplete. The aim of this study is to identify the genetic causes of LVNC using whole exome sequencing.

**Methods:** Study included 42 patients with LVNC and 17 unaffected family members from 33 families. Whole exome sequencing was followed by read mapping, variant calling, annotation, and bioinformatics filtering to prioritize pathogenic or likely pathogenic variants. The disease-causing variants were selected according to MAF < 0.01 in 1000G, ExAC, ESP6500, or gnomAD, variant class (stop gain/loss, frameshift, nonsynonymous, and splice site variant), functional impact (deleterious predicted by SIFT, Polyphen2, MutationTaster, PROVEAN, and CADD). The candidate variants were further verified by Sanger sequencing.

**Results:** 59 pathogenic or likely pathogenic variants were identified in 35 genes, in which 25 were novel variants. Pathogenic variants in *TTN* (10 variants in 7 families), *MYH7* (6 variants in 6 families), *MYBPC3* (4 variants in 3 families), and *DSP* (3 variants in 3 families) were the most common. Two pathogenic variants were found in *ACADVL*, *CPT2*, *DMD*, *DSC2*, *TNNT2*, and *PLEC*. One pathogenic variant was identified in 25 genes including four sarcomere associated genes, *ANKRD1*, *HAND1*, *LDB3*, and *OBSCN*. Digenic and polygenic variants were identified in 9 individuals/pedigrees. For example, a 22-year-old female patient carried pathogenic variants in genes such as *TTN*, *ACADVL*, *CPT2*, *DSP*, and *AARS2*. Trigenic variants in *MYH7*, *ANKRD1*, and *NRG1* were co-segregated in a family with two family members affected with dilated cardiomyopathy (DCM) and LVNC.

**Conclusions:** Our results unravel several known and novel LVNC associated mutations and expands the genetic spectrum of this disorder. The diverse di-, tri- and polygenic profile of inheritance may be associated with heterogeneous LVNC phenotypes.

## PgmNr 2673: Pathway-specific polygenic risk scores identify subgroups with distinct pathway contributions in people with high overall polygenic risk scores for coronary artery disease.

---

Polygenic risk scores (PRSs) have been shown to have robust risk prediction performance for coronary artery disease (CAD), with high CAD PRSs reflecting an increased risk from multiple underlying pathways. However, it has not been studied whether there is heterogeneity in genetic risks among individuals with similar high PRS, and what proportion of the PRS have pleiotropy with the known pathways for CAD. Here we propose to develop pathway-specific PRSs (PS-PRSs) to represent contributions of pathways and investigate whether clinically meaningful subgroups exist among people with high CAD PRS based on PS-PRSs. We considered the UK Biobank samples consisting of 407,060 European participants, divided into training and testing sets. State-of-the-art methods were used to generate the CAD PRSs, with the optimal PRS being the AnnoPred PRS using 233,538 variants validated in the testing set (15,668 cases and 309,980 controls) with area under the receiver-operator curve (AUC) = 0.639 (95% CI, 0.635-0.644) which was significantly higher than the AUC = 0.628 (95% CI, 0.623-0.633) given by LDpred. We partitioned the optimal CAD PRS into multiple PS-PRSs corresponding to the following CAD risk factors: low-density lipoprotein (LDL-C), triglycerides (TG), body mass index (BMI), systolic blood pressure (SBP), insulin resistance (IR) and smoking. Each PS-PRS had around 25,000 variants that were selected based on the GWAS summary statistics of the pathway-corresponding CAD risk factors. Variants belonging to none of the PS-PRSs were integrated as the unknown-pathway PRS. Of individuals having the top 5% overall CAD PRS, the contributions to the overall PRS from specific pathway were 0.151 (95% CI, 0.137-0.164) for LDL-C, 0.083 (95% CI, 0.069-0.097) for TG, 0.029 (95% CI, 0.016-0.043) for BMI, 0.069 (95% CI, 0.056-0.083) for SBP, 0.038 (95% CI, 0.024-0.052) for IR, 0.048 (95% CI, 0.035-0.062) for smoking and 0.488 (95% CI, 0.476-0.500) for unknown components according to the linear regression model where the outcome was the overall CAD PRS. The subgroups with high PS-PRSs had higher levels or prevalence of the corresponding risk factors. For example, the mean LDL-C level in the top and bottom decile of LDL-C PS-PRS was  $3.92 \pm 0.94$  mmol/L versus  $3.40 \pm 0.81$  mmol/L ( $P < 2.2e-16$ ). These results suggest that individuals with overall high CAD PRS are heterogeneous with respect to different pathways, and PS-PRSs might help identify subgroups developing CAD through specific pathways.

## PgmNr 2674: From GWAS to Mendelian randomization: *UGT1A1* variant identified as causally influencing bilirubin level and reduced risk of hypertension in Africans.

### Authors:

G. Chen; A. Adeyemo; J. Zhou; A. Doumatey; A. Beneley; D. Shriner; C. Rotimi

**Affiliation:** CRGGH/NHGRI/National Institutes of Health, Bethesda, Maryland.

---

**Objective:** Serum total bilirubin is associated with several clinical outcomes, including hypertension, cardiovascular disease, diabetes and drug metabolism. Here we describe our findings of the first large-scale GWAS of serum bilirubin in continental Africans and investigate the causal effect of bilirubin on hypertension in African ancestry individuals.

**Methods:** Participants included 1,094 West Africans enrolled as part of the African American Diabetes Mellites (AADM) study and 1,739 African Americans enrolled from Washington DC in the Howard University Family Study (HUFs). After genotyping on a high density GWAS array and imputation, a generalized linear mixed model was used to test association with serum bilirubin levels while adjusting for covariates (age, sex, BMI, type 2 diabetes and significant principal components) and relatedness as a random effect. Genome-wide conditional analysis and CAVIARBF were used to fine-mapping significant loci. Mendelian randomization was used to assess the causal effect of bilirubin on hypertension.

**Results:** *UGT1A1* rs887829 was significantly associated with serum bilirubin levels with p value of  $9.13 \times 10^{-54}$  [effect allele (T) frequency 0.40,  $\beta$  (SE) = 0.59 (0.04)] in West Africans, a finding that was replicated in HUFs study with p value of  $9.51 \times 10^{-69}$  [effect allele (T) frequency 0.45,  $\beta$  (SE) = 0.59 (0.03)]. The joint association testing of both study samples yielded a p value of  $3.93 \times 10^{-128}$  and a model  $r^2$  of 0.16. Genome-wide conditional analysis and regional fine mapping resolved rs887829 as a causal variant on bilirubin level with the highest posterior inclusion probability (PIP) of 0.99. Additive Bayesian Networks (ABN) modeling was used to show serum bilirubin level as mediator in the causal relationship between *UGT1A1* rs887829 variant and hypertension. Two-stages least squares Mendelian randomization showed a causal effect of bilirubin associated with lower risk of hypertension with OR of 0.64 [0.51, 0.81]. Cox proportional hazard model showed that bilirubin significantly decreased the risk of hypertension with observational multivariate hazard ratio of 0.55 [0.51,0.60].

**Conclusion:** This first GWAS of serum bilirubin in continental Africans confirms rs887829 (*UGT1A1*) as a major causal locus influencing bilirubin levels. We also show the causal effect of bilirubin associated with reduced the risk of hypertension.

## PgmNr 2675: Complete sequence of the 22q11.2 allele in 1,053 subjects with 22q11.2 deletion syndrome reveals modifiers of conotruncal heart defects near the *CRKL* gene.

---

The 22q11.2 deletion syndrome (22q11.2DS) results from non-allelic homologous recombination between low copy repeats termed LCR22. About 65% patients with the typical deletion of 3 million base pairs (Mb) from LCR22A-D have congenital heart disease, mostly of the conotruncal type (CTDs), while others have a healthy heart. In this study, we tried to determine if variants in the hemizygous LCR22A-D region can partially explain such variability in CTDs based upon whole genome sequence data of 1,053 22q11.2DS subjects, all with the same 3Mb LCR22A-D deletion. We found a significant association between CTDs and a cluster of 73 common single nucleotide variants in a single LD block of the 0.7 Mb LCR22C-D interval harboring the *CRKL* gene ( $P$  ranging from  $10^{-3}$  to  $2.59 \times 10^{-5}$ , 63 passed FDR correction, Alternate Allele Frequency  $>0.05$  from logistic regression analyses). Most of the variants confer increased risk to CTDs with a median OR of 2.96, ranging 1.64 from 4.75, while alternate alleles of five are protective with a median OR of 0.51, ranging 0.33 from 0.52. The association signal was not driven individually or collectively by rare variants in the same region. Associations of four variants, representing two independent association signals were consistently

found in three independent cohorts of the general population based on meta-analyses ( $P=6.0\times 10^{-3}$ , OR=0.86 [0.76-0.96] for rs178252;  $P=0.04$ , OR=1.10 [1.00-1.16] for rs178252, 165912 and rs6004160). The 73 variants map to a single topologically associated domain. The variant, rs178252, locates in an open chromatin region and resides in the double-elite enhancer, GH22J010947, predicted to regulate *CRKL* (CRK like proto-oncogene, cytoplasmic adaptor) expression. Approximately 23% of patients with nested LCR22C-D deletions have CTDs and inactivation of *Crkl* in mice causes CTDs, implicating this gene as a modifier. Both rs178252 and rs6004160 are eQTLs of *CRKL*. Further, set based tests identified an enhancer predicted to target the *CRKL* gene that is significantly associated with CTD risk (GH22J020946, SKAT test  $P=7.21\times 10^{-5}$ ) in the 22q11.2DS cohort. These findings suggest CTD penetrance variances among the 22q11.2DS population may be explained in part by disturbance of enhancer-target gene interactions, leading to dysregulation of genes within the LCR22C-D region, in particular for regulation of *CRKL* expression.

## PgmNr 2676: Using eQTL effect size correlation across tissues to cluster coronary artery disease variants.

A primary methodology in systems genetics is integrating heterogeneous datasets. Interpreting emergent or complex phenotypes relies on synthesizing multiple forms of phenotype data with genotype in order to infer the impact of genetic variants. In order to make inferences about human tissue expression qualitative trait locus (eQTL) data, we implement an effect-size based clustering strategy to associate eQTL data with disease risk variants identified in genome-wide association studies. Our approach relies on clustering eQTLs identified by the Genotype Tissue Expression Consortium using effect size observations across tissues as a proxy for cell-type localization of eQTL effects. Specifically, we use hierarchical density-based spatial clustering of applications with noise to detect clusters of eQTL/eGene associations using correlation as a distance metric. This approach allows for the unsupervised detection of eQTL/eGene association clusters in which cluster detection is dependent on eQTL covariance in effect size across human tissues.

After correcting for linkage disequilibrium, we performed clustering on a random subset (n=250,000) of Genotype Tissue Expression Consortium eQTLs. We found that coronary artery disease associated loci (nominal p-value < 0.05) are enriched in 30 out of 87 eQTL clusters; these 30 clusters contained unique 1728 eQTLs with associations to 114 unique transcripts as 2579 unique eQTL/eGene pairs. We find that one cluster enriched for coronary artery disease risk loci has eQTLs with high effect size in the left ventricle and atrial appendage of the heart and in skeletal muscle. This cluster contains 64 unique eQTLs with associations to 13 unique transcripts as 64 eQTL/eGene pairs.

For future work, we will attempt to determine whether cell-type localization can explain the effect size patterns of clustered eQTLs, and we will investigate whether any epistatic interactions may exist between clustered eQTLs.

## PgmNr 2677: The human leukocyte antigen locus and susceptibility to rheumatic heart disease in Oceanian, South Asian, and European populations.

---

**Background** Rheumatic heart disease (RHD) is an autoimmune disease of the heart valves that causes an estimated 319,400 deaths and 10.5 million disability-adjusted life-years each year globally. Several candidate gene studies have linked the disease to the human leukocyte antigen (HLA) locus but with little consistency. More recently, two genome-wide association studies (GWAS), one in the Aboriginal Australian population and our own unpublished study in South Asian and European populations, have associated HLA variants and alleles with susceptibility. However, the specific variants implicated in the two studies differ, finding signals in the class II and class III regions, respectively. Moreover, a negligible HLA signal was observed in our earlier GWAS set in the Pacific region. Therefore, in an effort to clarify the role of the HLA locus in susceptibility to RHD, we sought to identify common HLA variants with consistent effects across distinct ancestral groups. **Methods** We undertook a GWAS of RHD susceptibility in 1707 cases and 4060 controls of Oceanian, South Asian and European ancestry. In addition to our previous case-control study from the Pacific region, we included cases of RHD and healthy controls from Lucknow, Northern India, as well as cases of mitral stenosis (a surrogate for RHD) and matched controls from the UK Biobank study. Having performed linear mixed model analyses in each of the seven ancestral strata, we performed fixed and random effects meta-analyses at each of the 4.2 million variants present in all seven groups with frequency of 5% or more. **Results** The lead HLA signal mapped to a missense variant (rs2894232) in *TNXB* located within the class III region (odds ratio 0.80, 95% CI 0.72-0.89,  $P=5.74 \times 10^{-5}$ ). There was little heterogeneity in this signal across populations ( $I^2=0\%$ ,  $P=0.97$ ). This region is upstream of several immune genes, including components of the complement pathway, and has previously been implicated in age related macular degeneration. **Discussion** This analysis is the largest study of RHD susceptibility reported to date, and the first to identify an HLA variant impacting RHD susceptibility with consistent effects across ancestral groups. While offering important new insight into pathogenesis, more work is required to understand the causal relevance of this signal, which is likely to be complex, to RHD susceptibility.

## PgmNr 2678: African-specific variants reveal novel susceptibility genes for carotid intima-media thickness in Sub-Saharan African populations with sex-differences: An AWI-Gen study.

### Affiliations:

1) Clinical Research Unit of Nanoro (CRUN)/IRSS, Burkina Faso; 2) Sydney Brenner Institute for Molecular Bioscience, Faculty of Health Sciences, University of the Witwatersrand, Johannesburg, South Africa; 3) Division of Human Genetics, National Health Laboratory Service and School of Pathology, Faculty of Health Sciences, University of the Witwatersrand, South Africa; 4) School of Electrical and Information Engineering, Faculty of Engineering and the Built Environment, University of the Witwatersrand, South Africa; 5) Department of Medical and Molecular Genetics, Faculty of Life Sciences and Medicine, King's College London, London, United Kingdom

Atherosclerosis precedes the onset of many clinical manifestations of cardiovascular diseases such as stroke and myocardial infarction which are the leading causes of death worldwide. Consequently, genetic susceptibility to atherosclerosis has been widely investigated, but not yet in sub-Saharan Africans (SSA). Considering the evolutionary roots and the genetic diversity on the continent, GWASs in SSA represent an opportunity to shed new light on understanding the genetic architecture of complex traits such as atherosclerosis. We used carotid intima-media thickness (cIMT), to investigate genetic susceptibility to atherosclerosis in SSA.

Our sample included 7894 middle-aged adults (3963 women, 3931 men) aged 40 to 60 years, from the AWI-Gen study (with participants from East, South and West Africa). cIMT was measured by ultrasound and genotyping was performed on the H3Africa SNV Array (~2.3M SNVs). After imputation using the Sanger Imputation Server African reference panel, we tested for association using BOLT-LMM with adjustment for age, sex and 8 principal components (PCs). In the combined sample we identified two new African-specific genome-wide significant loci (*SIRPA* ( $p=4.7E-08$ ) and *FBXL17* ( $p=2.5E-08$ )). Sex-stratification analysis revealed two male-specific loci (*SNX29* ( $p=6.3E-9$ ) and *MAP3K7* ( $p=5.3E-8$ )), and two female-specific loci (*ARNT2* ( $p=2.4E-09$ ) and *PROK* ( $p=1.0E-08$ )). We replicated regional associations with known loci for atherosclerosis and CVDs, but with different lead SNVs. In a gene-based analysis there were significant associations with *CALD1* ( $p=5.9E-07$ ) for the entire dataset and *FLT4* ( $p=4.3E-07$ ) for female-specific analysis. We found significant enrichment for oestrogen response genes for female-specific signals. The genes identified in our study showed previous biological evidence of involvement with atherosclerosis/CVDs (*SIRPA*, *FBXL17*, *MAP3K*, *ARNT2*, *PROK1*) and sex-difference (*SNX29*, *ARNT2*).

Our study successfully replicated loci and identified novel African-specific variant and gene associations for cIMT. Sex-stratified analyses highlighted sex differences in atherosclerosis risk. Transferability of signals from non-African studies provide opportunities for fine-mapping using African data. Greater inclusion of African populations in medical genomics is important for accelerating

discoveries and identifying new genetic associations with traits for variants absent from other populations.

**Background:** Coagulation factor VII (FVII) and factor VIII (FVIII), and its carrier protein von Willebrand factor (vWF) are implicated in modulating the risk of arterial and venous thrombosis. The NHLBI's Trans-Omics for Precision Medicine (TOPMed) program brings together extensive whole genome sequence (WGS) resources and hemostasis phenotypes, and capitalizes on advances in computational analysis to better understand the genetic architecture of hemostatic factors. **Methods:** We leveraged Freeze 6 WGS from TOPMed. Plasma levels of FVII (n= 16,335), FVIII (n= 19,766), and vWF (n= 14,020) were harmonized across 9 studies that included participants of European, African, Asian, and Hispanic ancestry. Association analyses were conducted across all individuals using inverse normalized and rescaled residuals adjusting for age, sex, ancestry, principal components, and a kinship matrix. Analyses were conducted on the Analysis Commons cloud computing platform using the SMMAT function implemented in GENESIS. Single-variant analyses assessed all variants with a minor allele count  $\geq 40$ . Aggregate analyses grouped low-frequency and rare variants (minor allele frequency [MAF]  $< 0.05$ ) by gene, using 3 strategies for selection of variants within gene-based aggregation units: 1) loss of function (LOF) variants; 2) LOF and deleterious missense variants; and 3) coding, enhancer and promoter variants. **Results:** Single-variant analyses identified significant associations ( $P < 5E-8$ ) at 4 known loci for FVII, 8 for FVIII, and 8 for vWF. New FVIII associations

included rs538727675 located between *FNDC3B* and *GHSR* (MAF=0.0015; P=2.2E-8) and rs114894279 downstream of *TBL1XR1* (MAF=0.012; P=3.4E-8). A new vWF association was identified with rs147142418 in *DPF3* (MAF=0.017; P=1.1E-8). Conditional analyses revealed multiple independent signals at *F7*, *VWF*, *STAB2*, and *ABO*. Gene-based aggregate analyses identified associations at 1 known locus for FVII (*F7*), and 3 known loci each for vWF and FVIII (*VWF*, *STAB2*, and *ABO*). Additionally, LOF variants in *CD36* were associated with FVIII, representing a novel locus for FVIII. The driving variant, rs3211938, causes CD36 deficiency and is associated with a range of hematological phenotypes. **Conclusions:** WGS analysis of hemostatic factors yielded novel genetic associations with FVIII and vWF. Replication of these findings will be completed in up to 30,000 individuals from studies with imputed genotypes based on a TOPMed reference panel.

## PgmNr 2680: Trans-ethnic meta-analysis of genetic determinants of blood pressure trajectory.

---

Genome-wide association studies (GWAS) have identified thousands of genetic variants associated with cross-sectional blood pressure (BP) traits, however, there are limited GWAS of longitudinal BP data. We performed GWAS followed by meta-analysis of longitudinal BP traits using 21,900 multi-ethnic individuals from four studies: i) the Atherosclerosis Risk in Communities Study (ARIC); ii) the Bambui-Epigen Cohort Study of Aging (Bambui, Brazil); iii) the Health, Aging and Body Composition Study (Health ABC) and iv) the Multi-Ethnic Study of Atherosclerosis (MESA). We found 10 new loci genome-wide significantly associated with longitudinal BP outcomes, and most of these were ancestry specific with six found in African Americans, three in European Americans and one in Chinese and Hispanic American individuals. The strongest signal was the intronic rs140659580-C allele associated with higher systolic BP average (mean of measurements over time) ( $p = 1.45 \times 10^{-10}$ ) in Hispanic and Chinese American individuals from the MESA study. rs140659580 is in *GLG1* which is highly expressed in the aorta and coronary arteries and was previously associated with varicose veins. Furthermore, the T allele of rs73601659 was associated with increasing systolic BP trajectory (rate of change over time) ( $p = 4.10 \times 10^{-8}$ ) in African Americans. This variant is in *CHD9*, which has been previously associated with baseline plasma renin activity and plasma fibrinogen concentration, which are established predictors of hypertension. By comparing the meta-analysis results using longitudinal (BP trajectory and average) and baseline traits, we observed a highest correlation between the results using baseline and average outcomes ( $\rho=0.48$ ) and as expected, trajectory was more correlated with average ( $\rho=0.35$ ) than with baseline results ( $\rho=0.18$ ). In summary, in this study longitudinal data of cohorts of diverse ancestry facilitated discovery of novel BP signals, most of which were ancestry-specific. Notably, and despite some degree of overlap between the associations using longitudinal and cross-sectional outcomes, there is evidence for different genetic associations underlying these traits.

## **PgmNr 2681: Identification of disease susceptibility through 3,283 protein-polygenic-risk-score phenome-wide association studies in Penn Medicine BioBank electronic health records.**

### **Affiliations:**

1) Institute for Translational Medicine and Therapeutics, University of Pennsylvania School of Medicine, Philadelphia, PA; 2) Department of Surgery, University of Pennsylvania School of Medicine, Philadelphia, PA; 3) NIHR Blood and Transplant Research Unit in Donor Health and Genomics, Department of Public Health and Primary Care, University of Cambridge, Cambridge, UK

Polygenic risk scores (PRS) have recently shown promise for predicting disease susceptibility based on cumulative effects of genetic variants. Here we generated polygenic scores using the protein genome-wide association studies (GWAS) in the UK INTERVAL study. Although many of these proteins have not previously been associated with disease, we tested a protein polygenic score (PPS) against all phenotypes in the Penn Medicine BioBank (PMBB), by integrating the PPS with corresponding electronic health records (EHRs).

The protein GWAS in INTERVAL, also described as protein quantitative trait loci (pQTL), were analyzed on the SOMAscan platform to quantify plasma proteins. SOMAscan is an aptamer-based assay that profiles more than 3,000 proteins for each sample, enabling unbiased discovery of potential biomarkers for disease.

We generated PPS using LDpred method for the 3,283 proteins GWASs from INTERVAL, a cohort of 3,301 European subjects, using summary statistics. We first validated the PPS against a subset of PMBB samples for which we had measured plasma protein levels (protein n=565). We then tested the association between PPS and PMBB EHR.

Working with the Regeneron Genetics Center, we obtained genome-wide SNP genotype data of 17,560 individuals in PMBB (n=5,988 African Americans, n=11,580 European ancestry after quality control). EHRs were available for each from the University of Pennsylvania Health System. Adopting the phenome-wide association study (PheWAS) approach, we asked which phenotype in the EHR is associated with each PPS, across nearly 2,000 phenotypes aggregated from the International Classification of Disease 9th edition (ICD9) codes to representative phenotypes.

We identified a set of significant associations with many congenital disease phenotypes, including Forkhead box protein C2 (FOXC2), a known transcription factor mutated in congenital heart disease. In the PheWAS analysis, FOXC2 was shown to be associated with valvular heart disease and diseases that affect the heart chambers.

In summary, the novel method of PPS-PheWAS analysis connects cumulative genetic effects to disease through integration of large-scale EHR data with plasma proteome. This approach allows us to directly identify disease susceptibility of the genetically determined protein values.

## PgmNr 2682: Interrogating the proteome to identify putatively causal protein biomarkers of platelet count and mean platelet volume: The Framingham Heart Study.

1) Framingham Heart Study, National Heart, Lung, and Blood Institute, Framingham, MA; 2) Department of Pediatrics, Boston Children's Hospital, Boston, MA

---

Mean platelet volume (MPV) and platelet count (PLT) are commonly used platelet metrics associated in some studies with cardiovascular disease (CVD) and mortality. Identifying causal protein biomarkers for MPV and PLT may yield insights into CVD mechanisms and improve platelet regeneration therapies or platelet transfusion outcomes. To this end, we conducted integrative analyses of GWAS hits for PLT and MPV with protein quantitative trait loci (pQTLs) of plasma proteins, Mendelian randomization (MR) for protein to PLT/MPV inference, and protein-PLT/MPV trait association in the Framingham Heart Study (FHS). Seventy-one proteins were selected based on prior associations with CVD. A total of 4,348 participants (52% female, mean age 58 years) were included in the protein-trait association analyses for MPV and 4,272 participants (53% female, mean age 58 years) were included for PLT. Among 71 proteins, 11 were associated with MPV and 31 were associated with PLT after Bonferroni correction ( $P < 0.05/71$ ). We identified 15 pQTLs (4 *cis* and 11 *trans*) that overlapped with MPV GWAS SNPs and 17 pQTLs (5 *cis* and 12 *trans*) that overlapped with PLT GWAS SNPs at  $P < 1.25e-07$  for *cis* and  $P < 7.04e-10$  for *trans*. MR analyses identified 4 putatively causal proteins for MPV and 4 proteins for PLT at  $P < 0.05/37$ . Integrating all the results identified 3 putatively causal proteins for PLT. Glycoprotein V (GP5) and granulin (GRN) were positively correlated with PLT and melanoma cell adhesion molecule (MCAM) was negatively correlated with PLT in both protein-trait association and MR analyses. GP5 is a well-known receptor on platelets, but MCAM and GRN are not well-characterized as platelet proteins. Utilizing iPSC-derived megakaryocyte clones that produced variable numbers of functional platelets, we conducted megakaryocyte RNA-sequencing and analyzed transcriptome-wide differences between low- and high-platelet producing clones. Results were concordant with our population-based causal associations; GRN and GP5 were over-expressed and MCAM was down-regulated in high-platelet producing clones. In total, the results suggest that GP5, GRN and MCAM are causally linked to platelet generation and/or turnover and may play important roles in CVD via a platelet-based mechanism. These may also represent potential therapeutic biomarkers or targets for CVD prevention, and genes that could be manipulated to increase platelet production in bioreactors for transfusion medicine purposes.

## PgmNr 2683: A genome wide association study on postural orthostatic tachycardia syndrome.

### Authors:

H. Qu <sup>1</sup>; J. Glessner <sup>1</sup>; N. Williams <sup>1</sup>; J. Qu <sup>1</sup>; X. Chang <sup>1</sup>; A. Wenocur <sup>1</sup>; F. Mentch <sup>1</sup>; M. Lemma <sup>1</sup>; M. Behr <sup>1</sup>; L. Tian <sup>1</sup>; P. Sleiman <sup>1,2,3</sup>; J. Boris <sup>4</sup>; H. Hakonarson <sup>1,2,3</sup>

---

Postural orthostatic tachycardia syndrome (POTS) causes significant functional impairment and psychological distress to the patients, and is affecting about 0.2% to 1.0% US population. The pathophysiology of POTS has been described as being a failure of ability to maintain vascular tone with a compensatory tachycardia. There is associated chronic orthostatic intolerance and severe debilitating symptoms. However, the actual genetic mechanism of POTS is not understood. We performed a genome wide association study (GWAS) to determine the genetic underpinnings of POTS. We recruited 465 patients diagnosed with POTS and available family members. We obtained a biological sample (blood or saliva) for DNA isolation and GWAS analysis using the Illumina Infinium Global Screening Array. We performed transmission disequilibrium testing (TDT) in available family trios. With Bonferroni correction, significance was defined as  $7.14E-08$ . TDT analysis was performed in 99 family trios, and case control analysis in 207 unrelated patients versus 4,328 ethnicity-matched controls. An intronic variant in the gene encoding phosphorylase 1 regulatory subunit 12B (*PPP1R12B*) for myosin, located at chromosome 1q32.1, demonstrated significance at  $P=5.44E-16$ . This was replicated in both independent TDT and case-control analysis. Also, a non-coding variant of human zinc ribbon domain antisense RNA 1 (*ZNRD1-AS1*), in the major histocompatibility class (*MHC*) I region located on chromosome 6, demonstrated significance at  $P=1.82E-09$ . *PPP1R12B*, which dephosphorylates the regulatory light chain of myosin II, could be a clinically plausible gene for POTS, as myosin II functions in multiple locations in the body, including myocardium and vascular smooth muscle. *ZNRD1-AS1* is a long non-protein coding RNA. Many patients have onset of symptoms after an infection or concussion, suggesting an autoimmune etiology involving the *MHC* region. While *ZNRD1-AS1* is considered to be non-coding in human, its variants could interfere with RNA expression of other genes. Further exome and RNA sequencing is underway to delineate these loci to help determine further clinical validity.

## PgmNr 2684: Meta-analysis of 26,643 individuals identifies two genetic loci associated with left ventricular ejection fraction.

### Authors:

C. Schaefer<sup>1</sup>; K.K. Thai<sup>1</sup>; C. Jiang<sup>1</sup>; D.K. Ranatunga<sup>1</sup>; T.J. Hoffmann<sup>2,3</sup>; A.S. Go<sup>1</sup>; M.G. Ehm<sup>4</sup>; D.M. Waterworth<sup>4</sup>; A.C. Lindsay<sup>4</sup>; N. Risch<sup>1,2,3</sup>; H. Choquet<sup>1</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Kaiser Permanente Northern California (KPNC), Division of Research, Oakland, CA 94612, USA; 2) Institute for Human Genetics, UCSF, San Francisco, CA 94143, USA; 3) Department of Epidemiology and Biostatistics, UCSF, San Francisco, CA 94158, USA; 4) GlaxoSmithKline, King of Prussia, PA 19406, USA

**Purpose:** Left ventricular ejection fraction (EF) is an indicator of cardiac function, assessed in individuals with heart failure and other cardiac conditions. Although family studies indicate that EF has an important genetic component, with heritability estimates up to 0.61, to date only 3 EF-associated loci have been reported in a Japanese cohort. Here, we conducted a genome-wide association study (GWAS) of EF in the multiethnic Genetic Epidemiology Research on Adult Health and Aging (GERA) cohort.

**Methods:** Our discovery GWAS analysis included 22,160 GERA participants from 4 ethnic groups (African American, East Asian, Hispanic/Latino, and non-Hispanic white) having EF measured. For each participant, the 1<sup>st</sup> EF measurement was extracted from electronic health records. Genetic association analyses with EF were performed using linear regression adjusted for age, sex, and ancestry principal components. Confirmation of GERA findings was conducted in the UK Biobank (UKB) European sample (N=4,483 individuals) and a meta-analysis combining GERA and UKB results was performed. We replicated meta-analysis findings using summary statistics from a published GWAS of EF conducted in the Biobank Japan Project (BBJ) (N=19,516). Sensitivity analyses of the effects of EF-associated loci on EF adjusting for antecedent conditions (heart failure/cardiomyopathy, hypertension, myocardial infarction, or atrial fibrillation) were performed in GERA.

**Results:** Our discovery GWAS analysis across the 4 GERA ethnic groups identified a unique locus, *BAG3*, significantly associated with EF (lead SNP rs17617337;  $P=4.72 \times 10^{-11}$ ). The association between *BAG3* rs17617337 and EF replicated in UKB at Bonferroni significance ( $P=3.42 \times 10^{-7}$ ). A meta-analysis combining GERA and UKB identified an additional locus: *TMEM40* (rs11719526;  $P=3.10 \times 10^{-8}$ ). The association between *TMEM40* rs11719526 and EF replicated in BBJ ( $P=0.016$ ). In GERA, *BAG3* rs17617337 was associated with heart failure/cardiomyopathy and *TMEM40* rs11719526 was associated with atrial fibrillation. When we included these heart conditions as covariates in the models, the associations between *BAG3* rs17617337 or *TMEM40* rs11719526 and EF remained significant in GERA.

**Conclusions:** This largest study conducted to date on EF reports 2 novel loci, including *BAG3*, consistent with prior work involving this gene in cardiac conditions. However, sensitivity analyses demonstrated significant effects of the lead SNPs on EF independently of these conditions.

## PgmNr 2685: Genome-wide genotype imputation using SNP dense arrays and meta-analysis implicates *RTN4* variants association with blood pressure traits in Arab population.

### Authors:

**Aim:** Conglomeration of low levels of physical activity and high calorie food intake in Middle East resulted in a high prevalence of hypertension along with obesity. Global genetic studies have implicated many single nucleotide variations for hypertension however, Arab population lacks in convincingly determined genetic variants for hypertension. In this study, we imputed genome-wide genotypes using in-house genotype data from two genotyping arrays and then performed statistical tests for associations and followed by performing meta-analysis. The study implicates rs2920844\_T, rs2968781\_G of *RTN4* gene with elevated levels DBP and SBP.

**Method:** we used genome-wide genotype data of 1434 and 1298 unrelated individuals of Arab ethnicity genotyped on Illumina Cardio-Metabo BeadChip and Illumina HumanOmniExpress BeadChip respectively to perform genome-wide genotype imputation using 1KGP as reference panel. We harnessed quality genotypes (RSQ>0.5 with MAF≥5%) from imputed data and performed statistical association analysis (using RvTests software) on DBP and SBP traits. Further, we combined association results of both data sets with meta-analysis using Metal program. We considered variant-trait association signals with genome wide p-value threshold <5E-08. In addition, we performed fine mapping analysis using the FINEMAP tool and formed 95% credible causal SNPs around the top signals.

**Result:** Imputation of genotyped markers generated 6.08 million (with a mean RSQ value of 0.822) and 1.52 million variants (with a mean RSQ value of 0.759 and mean imputation quality score >0.50 and MAF≥ 5%) in Illumina OmniExpress and Cardio-Metabo data respectively. Statistical association analysis followed by meta-analysis of two data sets showed association of rs2920844\_T (DBP:beta=5.617, p-value=1.94E-08; SBP: beta=5.483, p-value=4.18E-08), rs2968781\_G (DBP:beta=5.618,p-value= 1.93E-08; SBP: beta= 5.688,p-value= 1.29E-08) of *RTN4* gene with elevated levels of blood pressure traits. Both the effect alleles were alternate alleles and showed a frequency of 15% in imputed data. Further, fine mapping analysis included them in 95% credible set of causal variants with posterior inclusion probability 0.45.

**Conclusion:** Literature evidences suggest that reticulon 4 (*RTN4*) is implicated in coronary heart disease. Isoforms of *RTN4* have been demonstrated to regulate blood pressure. Hence, the rs2920844\_T and rs2968781\_G of *RTN4* could be novel regulators of blood pressure in Arab population.

## PgmNr 2686: Non-genetic and genetic risk factors for aortic stenosis in patients with a bicuspid aortic valve.

### Introduction

Bicuspid aortic valve (BAV) is the most common congenital valvular heart disease and causes ~40% of aortic stenosis (AS) requiring aortic valve replacement (AVR) surgery. AS in the BAV population presents at a younger age, with AVR occurring ~15 years earlier than those with a tricuspid aortic valve (TAV) (1,2). In TAV disease, genetic risk factors for AS include variation in the number of Kringle IV repeats in the *LPA* gene that encodes the Apo(a) protein, determining both protein function and also levels of the lipoprotein(a) particle, a low-density lipoprotein. Its role in AS in BAV individuals has not yet been reported. We investigated non-genetic and genetic risk factors of AS in the BAV population.

### Methods

We examined 3,249 individuals with echocardiography-confirmed BAV to identify risk factors for AS. Patients were identified from a health system-wide registry and included individuals age >20 years with detailed aortic valve phenotyping of BAV and AS. Separately, we genotyped individuals with the Illumina GSA array to identify genetic risk factors for AS, including the *LPA* locus.

### Results

Of the 3,249 patients with BAV, 1,300 (40%) had no to mild AS, 398 (12%) had moderate AS, and 1,551 (48%) had severe AS. Multinomial logistic regression showed that AS severity increased with advancing age and COPD due to smoking (OR=1.38, CI 1.06-1.80), but not with gender (OR=0.88, CI 0.74-1.05). A unicuspid valve phenotype was associated with increased AS severity (OR=6.52, CI 3.43-12.4), while the aortic valve leaflet configuration (R-L vs R-Non) was not. Genotyping results will be provided at the meeting.

### Conclusions

In patients with BAV, more severe aortic stenosis is associated with older age, a unicuspid aortic valve phenotype, and history of COPD. Valve configuration was not associated with more severe aortic stenosis. In contrast to published associations of AS in tricuspid aortic valves, we did not observe associations with gender, diabetes and other cardiovascular risk factors.

## PgmNr 2687: Importance of the additional risk factors for the heart failure manifestation and progression in patients carrying mutations in the *TNNT2* “hot” codon.

### Authors:

**Introduction.** Non-ischemic dilated cardiomyopathy (DCM) is a group of progressive myocardial disorder with a poor prognosis. The probability of death or heart transplantation is 70% in 5 years after initial diagnosis. But clinical manifestation and progression rate may vary significantly within members of the family. Up to 80 different genetic forms of DCM are known with a predominantly autosomal dominant mode of inheritance. Even these genetic forms can be significantly influenced by an individual's risk factors and present mixed pathogenesis.

The aim of this study was to demonstrate the importance of gene-environmental interaction in patients with DCM carrying pathogenic variants affecting codon 173 in the *TNNT2* gene. Position Arg173 places in T1-fragment of the cTnT, highly conservative, and when mutated alter sarcomere organization, Ca<sup>2+</sup>-regulation and contractility.

**Methods.** The cohort included 92 DCM probands. Clinical evaluation included personal and family history taking, general examination, ECG, Echo-CG, cardiac MRI. Genetic testing was performed by NGS of the target panel flanking 81 DCM-associated genes with following Sanger sequencing of all clinically significant findings, and cascade familial screening.

**Results.** We revealed three heterozygous pathogenic variants in the *TNNT2* gene affecting codon 173: (p.Arg173Gln, p.Arg173Leu, and p.Arg173Trp) in 3 index cases diagnosed with familial DCM. Cascade familial screening revealed 3 more mutation carriers. Two patients have had well-known risk factors associated with DCM. Two male probands (p.Arg173Leu and p.Arg173Trp) were initially diagnosed with toxic cardiomyopathy soon after chronic alcohol consumption at 40 and 38 y.o., respectively) and one female (p.Arg173Leu, younger daughter) was diagnosed with peripartum cardiomyopathy at 20 y.o. Heart transplantation was recommended to all of them due to rapid heart failure progression. Carrier of p.Arg173Trp variant (39 y.o.), his daughter (11 y.o.), and female carrier of the p.Arg173Leu variant (29 y.o.) had no identifiable risk factors. Contractility and LV ejection fraction was slightly decreased but preserved for years.

**Conclusion.** The mutation rate in the *TNNT2* gene is 3.2% in the Russian DCM cohort. We suggest that “second hit” (genetic or environmental) might be crucial for rate of cardiac remodeling in patients with mutations affecting codon 173 of the *TNNT2* gene.

Diseases of the heart constitute a major health care burden encompassing a range of comorbid conditions including Myocardial Infarction (MI), Coronary Artery Disease (CAD), Heart Failure (HF), and Atrial Fibrillation (AF). Being *multifactorial* in nature, these conditions result from multiple additive gene contributions (*polygenic*) in combination with lifestyle and environmental factors. In the past decade, there has been major progress in identifying genetic loci contributing to heart disease risk. Genome-wide association studies (GWAS) have identified >160 loci for CAD and >30 for AF, whereas other heart conditions, like HF, is less studied. Still, the majority of GWAS SNPs reside in non-coding regions and the causal genes remain largely unknown.

In this study we set out to identify and characterize causal biology in human heart disease(s) leveraging public domain genomics data. To pinpoint casual genes at heart disease GWAS loci likely to act through the heart ("cardiac effector genes"), we cross-interrogated GWAS SNPs (GWAS Catalogue,  $p \leq 5.0 \times 10^{-8}$ ), along with their proxies, against expression quantitative trait loci (eQTL) from heart ventricle, atrium and coronary arteries (GTEx Consortium).

We identified a total of 87 cardiac effector genes distributed across 49 genomic loci, from 387 GWAS SNPs (9446 with proxies) originating from 54 heart disease studies. The number of identified genes per disease category was as follows; 58 (67%) CAD, MI and/or Coronary Artery Calcification, 10 (11%) AF, 8 (9%) Sudden Cardiac Arrest, 5 (6%) HF, 5 (6%) Cardiac Hypertrophy and/or Left Ventricular Function and Mass and 1 (1%) Dilated Cardiomyopathy. Twenty-three (26%) genes are non-protein coding (long non-coding-, antisense RNAs or transcribed pseudogenes), 63 (72%) are novel in the context of Cardio-Vascular Disease biology, and 4 (5%) are targets for approved drugs.

To identify causal biological mechanisms, cardiac effector genes were further analyzed in a pathway and network biology context. Biological themes emerging from these analyses could provide novel mechanistic entry points into treatment of heart disease.

In summary, retrospective review of drugs in development demonstrates that those targeting proteins with a genetic underpinning are more likely to progress to marketed drugs. Hence, the present findings not only provide novel insights into hitherto unexplored heart disease biology but also expands the repertoire of novel drug target candidate genes.

## PgmNr 2689: The causal link between rheumatoid arthritis, usual walking pace, and coronary heart disease: A network Mendelian randomization study.

### Authors:

[View Session](#) [Add to Schedule](#)

**Affiliation:** School of Life Science and Technology, Xi'an Jiaotong University, Xi'an, Shaanxi, China

---

It is believed that patients with rheumatoid arthritis (RA) have a 1.5-2.0 fold increased risk of developing heart diseases. Due to joint pain/stiffness or other joint problems, physical fitness (e.g. walking speed) is often reduced in RA patients. However, the causal link between RA, usual walking pace, and CAD remains unclear. Here we aim to examine whether usual walking pace mediate the causal pathway from RA to CAD using a network Mendelian randomization design. Summary statistics from genome-wide association studies (GWASs) were used for 2-sample Mendelian randomization analyses. The European GWAS of 14,361 RA cases and 43,923 controls were used to identify instruments and genetic association estimates for RA. GWAS summary data for usual walking pace (N = 452,264) of the UK Biobank cohort were obtained from the GenAtlas database. Summary data for CAD from the meta-analysis of UK Biobank cohort (34,541 CAD cases and 261,984 controls) and CARDIoGRAMplusC4D (88,192 cases and 162,544 controls) were downloaded from CardiOmics.net. Inverse variance weighted (IVW) analysis was used as the main method for MR estimates. As complementary methods, MR-Egger, weighted median, and weighted mode analyses were also performed. Potential horizontal pleiotropy was assessed by MR-Egger and MR-PRESSO. MR analyses showed that RA was positively associated with the risk of CAD (OR = 1.0227, CI: 1.0122 to 1.0333,  $P = 2.06 \times 10^{-5}$ ) and negatively associated with usual walking pace (OR = 0.9959, CI: 0.9939 to 0.9979,  $P = 8.49 \times 10^{-5}$ ). Significant negative causal effect of usual walking pace on CAD was also observed (OR = 0.3859, CI: 0.3072 to 0.4849,  $P = 2.89 \times 10^{-16}$ ). Mediation analysis showed that usual walking pace might account for about 15% of the association between RA and incident CAD. In conclusion, our results indicate that RA may be causally associated with slower walking pace, which mediates a significant proportion of the relationship between RA and CAD.

# PgmNr 2690: Detection of mutations associated with thrombophilia in the *MTHFR*, *F2* and *F5* genes in Colombian patients: Incidence in diagnosis, treatment and cost for the Colombian health system.

## Authors:

---

**Introduction.** Factor V Leiden (FVL) mutation is the most common cause of hereditary thrombophilia (TP) among the white population. The FVL carrier frequency ranges from 2% in Southern Europe to 15% in southern Sweden. Heterozygous carriers frequency is estimated to be 2.2% in Hispanics. The ethnic distribution of the prothrombin G20210A is similar to that of FVL. It is estimated that >25% of Hispanics and between 10 and 15% of North American Caucasians are homozygous for the “thermolabile” variant of *MTHFR* (C677T).

**Methods.** Results of *MTHFR*, prothrombin and FVL mutational tests from 150 patients with TP diagnosis were included. Tests were performed in a private genetics laboratory of Bogota, Colombia. This is a descriptive study in which mutations C677T and A1298C were investigated in *MTHFR*, G20210A mutation of *F2* and R506Q of *F5*, using real-time PCR. Demographic and clinical data from patients were correlated with tests results, according to ACMG guidelines recommendations.

**Results:** 40 blood samples were tested for *MTHFR* C667T mutation, 12 samples for *MTHFR* A1298C mutation, 64 samples for *F2* G202110A mutation and 34 samples for *F5* R506Q mutation. 75% of the *MTHFR* tests were positive for the C667T mutation and 42% for A1298C mutation. On the contrary, only 6,25% and 3% were positive for *F2* G202110A mutation and *F5* R506Q mutation respectively.

**Discussion.** The global incidence of TP is high so laboratory testing for hereditary TP and selected acquired TP is common. A wide variety of both non-genetic and genetic factors have been recognised as predisposing risk factors for thrombosis. Given the costs of testing and multiple pre-analytic and analytic variables affecting it, careful patient selection and timing of testing and diligent application to patient management are critical to providing high-value clinical care. Collaboration between the ordering providers and performing laboratories has the potential to achieve these goals. Data from several studies strongly suggest that the pathogenesis of thrombosis is multifactorial and requires interactions between both inherited and acquired risk factors. We found that, despite the recommendations of the ACMG, physicians continue to order mutational studies for the *MTHFR* gene in thrombosis patients. Likewise, they order mutational studies for the *F2* and *F5* genes without adhering to the proper selection criteria of patients, causing additional and unnecessary costs to the Colombian health system.

## PgmNr 2691: Integration of polygenic risk score in CAD risk models for clinical use.

Different groups have developed Polygenic Risk Scores (PRS) for Coronary Artery Disease (CAD) based on inference from millions of Single Nucleotide Polymorphisms (SNP). In one study, a PRS-based model was able to identify the 8% of the individuals of the European population with a CAD risk, comparable to that conferred by monogenic mutations. In a second study, men in the top 20% of PRS distribution reached a threshold of 10% cumulative CAD risk by 61 years of age, ten years earlier than men in the bottom 20% distribution.

However, although PRS-based risk models demonstrate higher predictive performances than any currently used risk factor they are not yet used in clinical practice. We therefore addressed the following questions to build the use case for the use of PRS into current clinical risk models. Following analyses are based on the UK Biobank population of European descent.

First, we assessed the impact of adding published PRSs to clinical risk models (e.g., Framingham score). At present, a 10% 10-year risk threshold is used in risk models to decide whether life-style or medical interventions should be implemented. We found that the addition of PRS to the Framingham score determined consistent reclassification of individuals based on the 10% risk threshold.

Second, we tested if PRSs were able to stratify individuals already considered at risk on the basis of conventional risk factors. For men with family history of CAD for example, we detected a strong PRS-based stratification with CAD prevalence ranging from 2.5% to 23% for the first and last percentile of PRS distribution. This indicates that even in individuals with family history, risk trajectories can be substantially modulated by the addition of PRSs. Additionally, we find no correlation between PRS and LDL-cholesterol blood levels indicating that these are orthogonal risk factors.

Finally since the majority (99.9%) of SNPs composing such PRSs have a low median effect size ( $10^{-6}$ ), researchers have argued about the relevance of such SNPs in contributing to the overall PRS predictive performances. By generating PRS with different subsets of SNPs, we found that full set PRS (6.6 millions SNPs) displays higher Positive Predictive Values compared with either effective-SNPs PRS (top 0.1% SNPs) or genome-wide significant PRS (74 SNPs). This shows that even low weight SNPs play a role in classifying a large proportions of individuals into the higher-risk CAD category.

## **PgmNr 2692: A polygenic risk score for atrial fibrillation is associated with the development of post-operative atrial fibrillation following cardiac surgery, independent of a patient's history of atrial fibrillation.**

### **Authors:**

M. Shuey; E. Farber-Eger; J.D. Mosley; F.T. Billings; N.J. Cox

[View Session](#) [Add to Schedule](#)

**Affiliation:** Vanderbilt University Medical Center, Nashville, TN.

---

**Background:** Post-operative atrial fibrillation (PoAF) is the most common complication of cardiac surgery, occurring in 20 to 40% of patients. The clinical risk factors of PoAF are well described, however, recent work has attempted to incorporate genetic variants into prediction models. Our objective was two-fold: 1) develop an algorithm to identify adult cardiac surgery patients and determine PoAF status using the Vanderbilt University Medical Center biobank (BioVU) and 2) develop a polygenic risk score (PRS) of AF and test its ability to predict PoAF.

**Methods:** Using current procedural codes and natural language processing we developed an algorithm capable of identifying adult patients that developed PoAF following cardiac surgery and prior to hospital discharge. Algorithm performance was validated by blinded chart review. Next using linkage disequilibrium-driven clumping and thresholding over a range of p-value cut-offs, we developed multiple PRSs for AF using GWAS summary statistics from the AFGEN Consortium. The optimal PRS was determined by the maximal AUC in a logistic regression model with AF as the outcome in all BioVU subjects. We then calculated the PRSs for all non-Hispanic White subjects in the BioVU cardiac surgery cohort and tested the association between the GPS and PoAF using a logistic regression model. To determine the potential for PRS to enhance perioperative risk prediction models of PoAF we incorporated GPS to models including genetic ancestry and predefined clinical risk factors.

**Results:** The frequency of PoAF was 40.5% (n=2,177) in the BioVU adult cardiac surgery cohort (n=5,364). Development of PoAF was significantly associated with known clinical risk factors, including history of AF (p<0.001, for all). We estimated the GPSs for 721 subjects that developed PoAF and 908 subjects that did not. The GPS was significantly associated with development of PoAF (p<0.001) and remained an independent predictor after adjustment for known risk factors and genetic ancestry (p<0.001).

**Conclusions:** We successfully developed an electronic algorithm for the identification of PoAF following cardiac surgery in a DNA databank for genetic studies. Further, AF PRS is an independent predictor of PoAF and the addition of GPSs to prediction models may improve clinical prediction of PoAF particularly in patients who are at an increased genetic risk of developing AF but who have not yet developed AF by surgery date.

### Introduction

Major improvements in human health and longevity could be seen if individuals at high-risk of preventable diseases were identified and treated pre-emptively. One approach is via accurate estimation of a genetic risk score (GRS) which captures polygenic disease risk with individuals in the top percentile of GRS having an odds of disease equal to or exceeding monogenic disease risk for some complex diseases (Khera et al). We hypothesize for most common diseases and in most populations, family history will improve identification of at-risk individuals in population screening compared to using GRS alone.

### Methods and Results

By combining genotype and imputation, dense phenotyping and comprehensive electronic health records, and self-reported family history in the Nord-Trøndelag Health Study (N=69,635), we demonstrate the additive relationship between family history and GRS and estimate a new metric, the Family History informed Genetic Risk Score (FHiGRS). FHiGRS provides a better predictor of disease prevalence than GRS or family history alone, for both Myocardial Infarction (MI) using a Coronary Artery Disease (CAD) GRS, and for Type 2 Diabetes (T2D) using a T2D GRS. For example, in classification of MI cases the area under the curve of the receiver operator characteristic (AUROC) for FHiGRS was 0.65 versus 0.58 for GRS alone, and for classifying T2D cases the AUROC for FHiGRS was 0.71 versus 0.61 for GRS alone.

For CAD, the odds ratio (OR) for MI in individuals in the top 5% of CAD GRS with positive family history compared to the remaining population is 2.85 (95%CI=2.48-3.27) while the OR for all individuals in the top 5% CAD GRS compared to the overall prevalence in the population is 1.98 (95%CI=1.80-2.18). Similarly, the OR for T2D in the top 5% of T2D GRS with family history (OR=4.51, 95%CI=3.70-5.50) is almost double that compared to the GRS that does not take family history into account (OR=2.42, 95%CI=2.13-2.75).

### Conclusion

Self-reported family history is easily ascertainable early in life (e.g. does not require lab measurements) and is an indicator of shared environmental factors and genetic predisposition to disease. This work suggests family history is an informative addition to GRS, and FHiGRS can be used to accurately identify individuals at greatest risk of CAD or T2D. We are evaluating broad applicability by estimating FHiGRS in UK Biobank and for additional complex disease traits.

---

Genome-wide polygenic risk scores (PRS) are strongly associated with first cardiometabolic and cancer events, but evidence about their impact on predicting subsequent disease events and disease complications is limited.

Using Finnish nationwide biobank data (FinnGen,  $n = 135,300$ ) with genome-wide genotyping and up to 46 years of prospective follow-up within nationwide registries, we studied whether disease-specific PRSs are associated with recurrent disease events and complications for coronary heart disease (CHD; 19,767 cases), atrial fibrillation (AF; 12,809), type 2 diabetes (T2D; 17,519), breast cancer (3,904), and prostate cancer (3,263).

Compared to individuals without CHD, those with only one CHD event had on average 0.29 standard deviations (SD) higher CHD PRS, and those with two or more CHD events, 0.51SD higher PRS ( $p = 2.25 \times 10^{-40}$  for one vs two or more events). The CHD PRS was associated with the risk of CHD in both T2D patients (HR 1.26, 95% CI 1.23–1.29,  $p = 1.34 \times 10^{-67}$ ) and in T1D patients (1.25, 1.16–1.33,  $p = 2.30 \times 10^{-10}$ ). Compared to individuals without T2D, T2D patients without complications had 0.36SD higher T2D PRS, and those with one or more complications 0.53SD higher T2D PRS ( $p = 4.17 \times 10^{-21}$ ). Compared to individuals without AF, those without heart failure had 0.48SD higher AF PRS, and those with heart failure following or at diagnosis of AF had 0.56SD higher AF PRS ( $p = 0.001$ ).

The CHD PRS was also associated with CHD deaths (HR 1.15 per SD increment, 95% CI 1.12–1.18,  $p = 2.20 \times 10^{-24}$ ), and a PRS combining both the CHD PRS and T2D PRS was strongly associated with CHD death (HR 1.23, 1.19–1.26,  $p = 9.79 \times 10^{-45}$ ). In a smaller subset of 10,258 men with cancer death information available, the prostate cancer PRS was associated with death due to cancer (HR 1.12, 1.03–1.22,  $p = 0.007$ ).

Our results show that the polygenic risk scores derived for first events of diseases are also associated with the risk for recurrent disease events and death in CHD, for diabetes complications in T2D, and for cancer-related deaths. These results suggest that the potential utility of polygenic risk scores extends beyond primary prevention and may be beneficial also for disease prognosis, secondary prevention, and disease management in common complex diseases.

**Introduction:** Takotsubo cardiomyopathy (TC) is a severe but usually transient cardiovascular syndrome characterized by left ventricular (LV) dysfunction and apical LV ballooning. It predominantly occurs in older women after a physical or emotional stress trigger, but its biological etiology remains unclear. Proposed mechanisms include catecholamine-mediated toxicity, vascular dysfunction due to increased susceptibility to endothelin, and dysregulated myocardial calcium regulation. We hypothesized that identifying rare variants in genes related to these pathways may help clarify the biological underpinnings of susceptibility to TC.

**Methods:** The study population consisted of individuals from the CATHGEN biorepository with a diagnosis of TC based on the following parallel approaches: ICD-9 search; echocardiogram reports of hypocontractile, akinetic, aneurysmal, or dyskinetic LV apex in patients without coronary artery disease; and health record keyword search (Takotsubo, broken heart, stress cardiomyopathy, apical ballooning). All cases were adjudicated by deep chart review using clinical diagnostic criteria for TC. Whole exome sequencing was performed on all cases and 98 candidate genes involved in endothelin signaling, calcium regulation, and familial cardiomyopathy were selected.

**Results:** Of 340 potential TC patients, eight had a diagnosis substantiated after chart review (TC set), leaving 8583 non-Takotsubo CATHGEN subjects for comparison. We identified 36,258 candidate gene variants, 17 of which were present only in the TC set. Two rare variants (gnomAD maf<0.001%) were identified in genes not previously associated with cardiomyopathy: rs771740107 in *EDNRA* (endothelin receptor) and rs746335414 in *CACNG1* (calcium channel subunit). The remaining TC set-specific variants were in known familial cardiomyopathy genes: six novel variants in *PRDM16*, *MYH6*, *TTN*, *EYA4*, and *HFE*, and known rare variants in *PRDM16*, *TTN*, *EYA4*, *CTNNA3*, *LDB3*, *ABCC9*, *MYH6*, and *ACTC1*.

**Conclusion:** Using exome sequencing, we have identified both novel and known variants present only in TC patients in CATHGEN. Identification of variants in known cardiomyopathy genes suggests that TC may share pathophysiological elements with more common cardiomyopathies, while the TC-specific variants in endothelin and calcium regulation genes indicate these pathways may be relevant for future study into TC susceptibility.

## PgmNr 2696: Rare loss-of-function variant analysis in lone atrial fibrillation.

---

Atrial fibrillation (AF) is a complex heritable disorder that substantially increases the risk for stroke, sudden death and all-cause mortality. Lone AF is a subset defined by early diagnosis (less than 60 years) and with no evidence of cardiopulmonary disease. Genome-wide association studies have associated loci near genes for structural integrity and function of muscles with AF susceptibility. In addition, some studies have identified rare loss-of-function (LoF) variants in dilated cardiomyopathy (DCM) genes in lone AF. The increased burden of these variants in lone AF patients may indicate a shared predisposition between AF and DCM.

We performed a retrospective study on 252 adult patients and a control group of 503 healthy European subjects. Exome sequencing and microarray assays were performed at the McGill Genome Center while control's exome data was retrieved from 1KG Consortium. Principal component analysis was performed to define a group with common ancestry using SVS software. Variants within candidate DCM genes were filtered by minor allele frequency of  $\leq 0.1\%$ , a Combined Annotation Dependent Depletion (CADD) Phred score of  $>20$  and a LoF variant type (frameshift, splice acceptor, splice donor and stop gain). All variants were confirmed with Sanger sequencing. Cascade screening was attempted on all cases positive for variants.

The AF cohort, an ethnically homogenous composite of 181 lone AF cases, had 6 heterozygous LoF variants, including 4 novel variants, in 6 individuals, while the controls had 4 in 503 individuals. Half of variants in the cases were in the *TTN* gene (3/6). The prevalence of rare LoF variants in the lone AF cohort was 3.3% while in the control cohort 0.79%, the odds ratio of rare LoF variants found in lone AF patients compared to controls is 4.28 (95%CI: 1.19-15.33, P-value: 2.5E-02). Cascade screening in one family demonstrated co-segregation of one of the rare *TTN* variants and AF.

Patients with lone AF carry a significant burden of heterozygous LoF variants in DCM genes. Our results are in agreement with a previous study identifying *TTN* variants in lone AF patients. Further, we identified novel variants in different DCM genes and confirmed the co-segregation of a *TTN* variant and AF in one family. Our findings may indicate a common genetic predisposition between lone AF and DCM, which may help elucidate novel pathophysiologic mechanisms, and improve diagnosis and treatment.

## PgmNr 2697: Targeted sequencing of linkage region in Dominican families implicates *PRIMA1* and the *SPATA7-PTPN21-ZC3H14-EML5-TTC8* locus in carotid-intima media thickness and atherosclerotic events.

Carotid intima-media thickness (cIMT) is a subclinical marker for atherosclerosis. Previously, we identified a quantitative trait locus (QTL) for total cIMT on chromosome 14q. Using a common variants (CVs)-based approach via high throughput genotyping, we have found evidence for association in *PRiMA1*, *FOXN3* and *CCDC88C*. Herein, we further evaluated the genetic contribution of the QTL to cIMT by surveying both CVs and rare variants (RVs) via resequencing the linkage region. We sequenced all exons within the QTL and genomic regions of *PRiMA1*, *FOXN3* and *CCDC88C* using next generation sequencing coupled with targeted sequence enrichment. Dominican families (N=7) with evidence for linkage to the QTL (family specific LOD>0.1) were sequenced. Unrelated Dominicans from the Northern Manhattan Study (NOMAS, N=561) were used for validation using HumanCoreExome with custom content. Single-variant-based analysis was performed for CVs and gene-based analysis were performed for RVs, adjusting for significant covariates identified using a polygenic screen. Top cIMT-associated CVs were further tested for association with clinical atherosclerotic events, including myocardial infarction, ischemic stroke or vascular death, in NOMAS. Total cIMT was calculated as a composite measure of the near and the far wall IMT of all carotid sites from both sides. The family size ranged from 11 to 25, with 116 individuals in total from the 7 families. The strongest evidence for association with CVs was found in *PRiMA1* ( $p=8.2 \times 10^{-5}$  in families,  $p=0.01$  in NOMAS at rs12587586), and in the five-gene cluster *SPATA7-PTPN21-ZC3H14-EML5-TTC8* locus ( $p=1.3 \times 10^{-4}$  in families,  $p=0.01$  in NOMAS at rs2274736). A top marker in *PRiMA1* (rs7152362) was associated with fewer atherosclerotic events (OR=0.67;  $p=0.02$  in NOMAS) and smaller cIMT ( $\beta=-0.58$ ,  $p=2.8 \times 10^{-4}$  in Family,  $\beta=-0.01$ ,  $p=0.047$  in NOMAS). No evidence for association with RVs was found in *PRiMA1*. Within the five-gene cluster, evidence for association was found for exonic RVs ( $p=0.02$  in families,  $p=0.28$  in NOMAS), which was enriched among RVs with higher functional potentials ( $p=0.05$  in NOMAS for RVs in the top functional tertile). In summary, targeted resequencing provided validation and novel insights into the genetic architecture of cIMT in Dominicans. We found that RVs with higher functional potentials have stronger effects for cIMT. Furthermore, our data support the clinical relevance of subclinical atherosclerosis-associated CVs.

## PgmNr 2698: Excess of population-specific rare functional variants in *ANGPTL3* increase hypertriglyceridemia and coronary artery disease risk in Punjabi Sikhs.

Elevated circulating triglyceride levels are well-established risk factor for cardiovascular disease and a principal cause of mortality in individuals with type 2 diabetes. Despite high heritability (50-80%) of triglycerides, previous genome-wide association studies (GWAS) have only been able to account for a fraction of the heritability (<10%) in genes involved in triglyceride (TG) and lipid metabolism. In contrast to the existing common association signals with blood lipid phenotypes, there is extreme paucity of data on the spectrum of rare and private variants in diverse ethnic groups especially in populations of Asian Indians. Most rare variants are of recent origin, they may vary between ethnic groups.

We sequenced 940 individuals [572 cases with high serum TG (>150mg/dl) and 368 controls with low TG (<100mg/dl)] and performed replication in additional 2,239 samples from the same Punjabi population. All 3,179 participants were part of the Asian Indians Diabetic Heart Study. A known common polymorphism in *ANGPTL3* (M259T) present in 10% of African Americans and associated with lower plasma levels of TG in Africans and Europeans, was not observed in this population. We observed three rare missense variants, earlier found in Caucasians (Asn296Ser, Ala364Val, and Phe295Leu), earlier found in Caucasians, were associated with high TG levels (ranging between 290 mg/dl to 313 mg/dl) in our sample. Additionally, our data revealed several new variants at 5'UTR, 3'UTR, missense and loss-of-function variants, which were not found in any public database. Large proportion of these variants were present in people with >75%TG and some rare variants were only present with subjects with lower TG levels (<25%).

In summary, our study found notable differences in the profiles of rare/private variants and their association with lipid traits between Panjabi population from North India and Europeans. Results of our currently ongoing validation study of the most significant rare variants for their association with TG, other lipid traits, and cardiovascular disease risk in additional samples of South Asians, Europeans and Mexicans populations will be presented.

This study was supported by NIH grants -R01DK082766 (NIDDK) and NOT-HG-11-009 (NHGRI), R218 RS&G Service, U.S. Federal Government contract # HHSN268201100037C (NHLBI).

## PgmNr 2699: Comprehensive structural variation map for 19,652 humans and impact on translation for disease phenotypes utilizing long reads.

---

Although structural variations (SV) have been shown to impact expression and play a key role in certain diseases we still lack a large-scale study to include SVs and investigate their impact on the protein level. Here we have analyzed 19,652 whole genomes (30x+) human samples across multiple ethnicities to capture the so far hidden variability within and among populations across multiple ethnicities. To achieve this we have implemented Parliament2 our novel population level SV calling pipeline. We have discovered and genotyped 304,533 SVs ranging from small deletions to large rearrangements and amplifications across GRCh38. We further analyzed the ancestral alleles for these SVs with respect to chimps and gorillas.

We optimized the use of long reads for population studies to validate and extend the SV catalog. We developed a novel sampling framework (SVCollector) that operates based on the variations called in the short read data to maximize the validation efficiency. Using this framework we sequence 18 PacBio genomes with matching RNA-Seq data to validate and obtain further insights on these samples. Using the 18 PacBio genomes we were able to validate a large proportion of the SVs from the short read cohort. This analysis resulted in haplotype resolved SNP and SVs per sample across the genome. We are currently in the process to genotype insertions and initially missed SVs into the association cohort study using Paragraph. Paragraph is a novel graph-based genome method to genotype SVs in short reads even though these SVs were initially missed.

Overall our study highlights multiple ethnicity-specific SVs, which alter genes and impact their protein levels and structure. In total, we identified 2,336 protein-coding genes impacted by common SVs (MAF >0.05) and 234 genes that are affected by multiple SVs specific to only one ethnic group (MAF >0.05). Given the new set of SVs, we have analyzed 4,156 proteins in a subset of 4,021 multi-ethnic samples. We also identified 58 significant SV-protein associations that comprise 33 cis- and 25 trans-acting relationships, explaining a median of 7-9% protein variations in African- and European-Americans. Our findings elucidate a more complete mapping from a comprehensive genomic architecture to regulatory and translational pathways to endophenotypes and ultimately to disease endpoints. Furthermore, this study is a role model on how to efficiently integrate long read

technologies for haplotype resolved variant detection.

# PgmNr 2700: Novel loci linked to impaired ejection fraction and risk of cardiomyopathy among childhood cancer survivors of African-descent: A report from the St. Jude Lifetime Cohort.

## Authors:

Y. Sapkota<sup>1</sup>; D.A. Mulrooney<sup>1,2</sup>; G.T. Armstrong<sup>1</sup>; C.L. Wilson<sup>1</sup>; Z. Wang<sup>1,3</sup>; J. Zhang<sup>3</sup>; M.M. Hudson<sup>1</sup>; L.L. Robison<sup>1</sup>; Y. Yasui<sup>1</sup>

## Affiliations:

1) Epidemiology and Cancer Control, St Jude Children's Research Hospital, Memphis, Tennessee.; 2) Oncology, St Jude Children's Research Hospital, Memphis, Tennessee.; 3) Computational biology, St Jude Children's Research Hospital, Memphis, Tennessee.

**Background:** Survivors of childhood cancer are at increased risk of treatment-related cardiomyopathy. To our knowledge, no study has assessed genetic risk of cardiomyopathy in childhood cancer survivors of African-descent.

**Methods:** We utilized whole-genome sequencing data (36.8-fold) of 301 childhood cancer survivors of African-descent from the St. Jude Lifetime Cohort (SJLIFE) study and examined associations between genetic variants and ejection fraction (EF) as a continuous outcome. Common (MAF>0.05) and rare/low-frequency (MAF≤0.05) variants were assessed separately using single-variant and burden/SKAT tests, respectively, adjusting for demographic characteristics and childhood cancer treatment exposures.

**Results:** We identified two novel loci for reduced EF at 1p13.2 (rs6689879: MAF=0.16; per-allele reduction=4.2%;  $P=1.7 \times 10^{-9}$ ) and 15q25.3 (rs9788776: MAF=0.08; per-allele reduction=5.6%;  $P=3.3 \times 10^{-8}$ ). None of the burden/SKAT results was statistically significant. Among 246 survivors of African-descent exposed to either anthracyclines or heart radiation, both loci retained genome-wide significance: rs6689879 (per-allele reduction=4.3%;  $P=3.0 \times 10^{-8}$ ) and rs9788776 (per-allele reduction=6.0%;  $P=3.4 \times 10^{-8}$ ). The association between the 1p13.2 locus and EF was replicated among 1645 survivors of European-descent from the SJLIFE study who were also exposed to anthracyclines or heart radiation, with an attenuated effect size (rs6689879: MAF=0.30; per-allele reduction=0.5%;  $P=0.045$ ); the 15q25.3 locus is monomorphic in Europeans. Both loci were significantly associated with an increased risk of clinically-diagnosed cardiomyopathy: Common Terminology Criteria for Adverse Events (CTCAE) grade 2+ [rs6689879: OR=1.83;  $P=6.2 \times 10^{-4}$  and rs9788776: OR=4.44;  $P=4.5 \times 10^{-3}$ ] and CTCAE grade 3+ [rs6689879: OR=3.76;  $P=1.8 \times 10^{-14}$  and rs9788776: OR=3.24;  $P=0.039$ ]. rs6689879 maps to *MAGI3* which encodes a scaffolding protein that acts at cell-cell junctions, regulating cellular and signaling processes. rs9788776 is located ~61.7 kb away from *AGBL1* which encodes a glutamate decarboxylase that catalyzes the deglutamylation of polyglutamylated proteins. The *AGBL1* locus has been shown to be associated with reduced activated partial thromboplastin time.

**Conclusions:** This study among childhood cancer survivors of African-descent identified two novel loci for reduced EF and increased risk of cardiomyopathy. Further research is needed to elucidate the pathophysiology underlying these associations.

## PgmNr 2701: Assessing the transferability of genetic associations with aortic stenosis to non-European ethnicities.

---

Aortic stenosis (AS) is a debilitating heart valve disease with no known medical treatments. While genetic association studies in Europeans have highlighted novel therapeutic targets for AS, it is unknown whether these findings are transferable to non-European ethnicities. We have derived a genetic risk score (GRS) for AS from risk variants previously discovered in European populations. We determined the extent to which the unweighted GRS predicted AS in 55,192 Europeans, 1,917 African-Americans and 3,482 Latin-Americans from the Genetic Epidemiology Research on Adult Health and Aging (GERA) cohort. In addition, we assessed each variant independently for associations with AS. To investigate the influence of ancestry on these associations, we estimated global ancestry proportions in each admixed individual. In total, 6 variants from 5 different loci were included in the GRS. As expected, the GRS was a strong predictor of AS in Europeans (OR per risk allele [95% CI], 1.10 [1.08, 1.13];  $P=4.4e-17$ ). While the GRS demonstrated a consistent effect in African-Americans (OR = 1.14 [0.97, 2.34]), it was not significantly associated with AS in either admixed population. These results remained virtually unchanged after adjustment for non-European ancestry. Of the variants included in the GRS, only rs10455872 in *LPA* and rs2069832 in *IL6* were associated with AS in African-Americans, with rs10455872 demonstrating the largest effect seen to date (OR per risk allele, 4.52 [1.50, 13.6];  $P=0.0074$ ). Consistent with European populations, each risk allele of rs10455872 was associated with increased levels of lipoprotein(a) in individuals with mixed European-African ancestry from the UK Biobank ( $P=3.1e-20$ ). In both GERA African-Americans and Latin-Americans, carriers of this variant had significantly more European ancestry ( $P=1.6e-07$  and  $P=2.2e-07$ , respectively). Notably, none of the risk variants investigated were significantly associated with AS in Latin-Americans. Our results suggest that genetic associations with AS in European populations may differ in admixed populations, hindering the predictive power of a GRS. Additional work is needed to determine if non-European ethnicities possess unique risk loci for this disease.

## PgmNr 2702: Miransertib (ARQ 092) prevents the formation of *PIK3CA*<sup>H1047R</sup>-driven vascular malformations in mice.

### Authors:

P. Kobińska<sup>1</sup>; S.D. Castillo<sup>1</sup>; H. Sabata<sup>1</sup>; Y. Yu<sup>2</sup>; B. Schwartz<sup>2</sup>; M. Graupera<sup>1</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Vascular Signalling Laboratory, Institut d'Investigacio Biomedica de Bellvitge, Hospitalet de Llobregat, Barcelona, Spain; 2) ArQule, Inc, Burlington, MA 01803, USA

Venous malformations are congenital lesions that consist of abnormal dilated venous channels with scarce mural cell coverage, they can be of different sizes and be present in any tissue, such as subcutaneous tissue or internal organs. Venous malformations are painful and disfiguring, many leading to bleeding, obstruction of organs and intravascular coagulopathy with an overall incidence of 1:5000. Most venous malformations are caused by either somatic mutations in the *TEK* or the *PIK3CA* genes in endothelial cells, both types of mutations leading to an increased PI3K signalling. PI3K activation in endothelial cells triggers the activation of the AKT serine/threonine kinase promoting a plethora of cellular effects, including increased cell proliferation and loss of mural cell coverage, which contribute to the pathogenesis of venous malformations. In a previous study, we have created a genetically modified mouse model that displays mutant *PIK3CA*<sup>H1047R</sup>-driven congenital vascular malformations with features pathognomonic for human VMs.

Miransertib (ARQ 092) is a potent and selective allosteric pan-AKT inhibitor that potently inhibits AKT1, 2, and 3 isoforms. Biochemical and cellular studies showed that miransertib suppresses AKT activity by inhibiting membrane-bound active form of AKT and preventing activation of inactive form of AKT. Miransertib is currently in clinical studies in patients with PIK3CA-Related Overgrowth Spectrum and Proteus syndrome. To assess the efficacy of miransertib in *PIK3CA*-driven vascular malformations, we treated postnatal mice at the same time of *PIK3CA*<sup>H1047R</sup> induction in the endothelium and analysed the retinal vasculature. By measuring the area of isolectin-B4 staining (IB4 labels the plasma membrane of endothelial cells) and the number of Erg-positive cells (marker for endothelial cells), we showed that miransertib treatment reduced the vascular density and the number of endothelial cells driven by *PIK3CA* mutation. Mechanistically, miransertib suppressed the hyperproliferation of endothelial cells driven by *PIK3CA*<sup>H1047R</sup> mutation.

In conclusion, treatment of miransertib prevents *PIK3CA*<sup>H1047R</sup>-driven vascular malformations in postnatal mouse retinas. The results provide a rationale for treating vascular malformation driven by activating mutation of *PIK3CA* in patients.

## PgmNr 2703: Variation of alpha-1 antitrypsin levels with pulmonary and cardiometabolic traits in the multi-ethnic study of atherosclerosis.

### Introduction / Objectives

Alpha-1 Antitrypsin Deficiency (AATD), most commonly caused by the missense variant rs28929474 in the *SERPINA1* encoding AAT, is the most well-documented genetic cause of emphysema and chronic obstructive pulmonary disease (COPD). Research in diverse populations on the relationship of AAT levels with pulmonary and cardiometabolic traits is limited. Therefore, we sought to fill this gap using the Multi-Ethnic Study of Atherosclerosis (MESA).

### Methods

MESA recruited participants ages 45-84 years old who were free of clinical cardiovascular disease. The Proteinase inhibitor (PI) type and AAT levels were measured in plasma by isoelectric for 2,255 African, 1,865 Hispanic, and 500 non-Hispanic White. AAT levels were compared across race/ethnicity and stratified by PI type, with 93% PiMM (no altered AAT), 5% PiMS (one altered *SERPINA1* allele, minimal risk for AATD), and 1% PiMZ (heterozygote carrier for AATD). We examined the relationship of AAT levels with cardiometabolic and pulmonary traits measured by cardiac CT scans and spirometry. Analyses were performed by linear (or logistic) mixed models, adjusted for age, sex, study site, race/ethnicity, principal components of ancestry, Pi type, and other confounders (e.g., smoking history). Analyses were (1) pooled across all participants and (2) stratified by race/ethnicity and smoking history (current/former/never).

### Results

African Americans had lower AAT levels than both Hispanics ( $\Delta = 3.6$  mg/dL,  $P = 0.003$ ) and whites ( $\Delta = 5.4$  mg/dL,  $P < 0.001$ ). Further analysis showed that the proportion of African ancestry was related to AAT levels among Hispanics ( $\beta = -9.622$ ,  $P = 0.006$ ). Systolic blood pressure, BMI, hypertension, presence of calcium, and Agatston calcium score were positively associated with AAT levels ( $P < 0.01$ ), and fasting glucose showed an inverse relationship with AAT levels ( $P = 0.005$ ), in pooled analysis. Lower AAT levels were associated with higher percent emphysema ( $P = 0.027$ ) and percent emphysema in the lower lobes ( $P = 0.006$ ) among current smokers only.

### Conclusions

AAT levels vary across race/ethnicity and were significantly associated with some cardiovascular risk factors, while a relationship with percent emphysema was observed in current smokers only. These results reinforce the need to evaluate protein biomarkers across race/ethnic groups and may help inform future efforts to develop proteins encoded by rare or Mendelian disease variants as potential disease biomarkers.

---

Cardiovascular disease (CVD) is the leading cause of mortality in the United States, leading to 1 in every 4 deaths. The role of inherited susceptibility to CVD is well established, from rare monogenic disorders to pharmacogenetics and more recently studied polygenic traits. Thus, precision medicine efforts focusing on CVD genetics have the potential to advance adult clinical genetics in a similar fashion that exome sequencing did for pediatrics.

Within the Baylor College of Medicine Human Genome Sequencing Centers-Clinical Laboratory (HGSC-CL), we developed a 158-gene NGS panel, ('HeartCare'), designed to assay genetic risk associated with CVD in four distinct categories: 1) High-penetrance, monogenic conditions including cardiomyopathies, aortopathies, arrhythmias, and dyslipidemias, 2) coronary artery disease polygenic risk score (PRS), 3) *LPA* common variants associated with increased CVD risk, and 4) pharmacogenetic variants contributing to simvastatin-induced myopathy and warfarin metabolism.

For a pilot of 5,000 participants, individuals are enrolled at multiple clinical sites, samples analyzed in a CAP/CLIA-certified laboratory and results returned to the ordering physician and uploaded to the electronic medical record. To date, 126 individuals have been enrolled, primarily from a cardiology dyslipidemia clinic. Of those with results, approximately 7% had a pathogenic/likely pathogenic variant in the high-penetrance, monogenic category, all in the *LDLR* gene consistent with a diagnosis of familial hypercholesterolemia. Nearly 9% of patients were in the highest CVD risk group (top 5%) according to the PRS while 30% carried common *LPA* variants associated with increased Lp(a) lipoprotein and CVD risk in certain populations. Lastly, approximately half harbored variants that increase their risk of simvastatin-induced myopathy and/or affect warfarin metabolism. Management changes and additional lab follow-up have already resulted from these findings with genetic counseling instituted to facilitate familial cascade testing and explore behavior changes. Our results to date support the use of genetic information in routine cardiovascular health management.

## PgmNr 2705: MEK inhibitor treatment in a preterm newborn with Noonan syndrome and severe obstructive hypertrophic cardiomyopathy.

A female infant was born at 33+6 weeks of gestation complicated by polyhydramnios and fetal hypertrophic cardiomyopathy (HCM). At birth, excessive nuchal skinfolds and facial features allowed a clinical diagnosis of Noonan syndrome (NS). She required resuscitation and mechanical ventilation for 10 days. At the 2<sup>nd</sup> day of life, she developed a grade II cerebral ventricular haemorrhage. Echocardiography confirmed severe obstructive HCM and dysplastic pulmonary valve. She was found to carry a heterozygous *de novo* p.Ser257Leu pathogenic variant in *RAF1*, typically associated with severe NS phenotype, progressive HCM and pulmonary hypertension. In the subsequent 40 days she developed severe congestive heart failure (CHF) that, in spite of furosemide administration, required mechanical ventilation and amine administration. With no treatment options for the near-terminal CHF, Trametinib – a selective reversible inhibitor of MEK1/2 activity approved for selective treatment of cancers with RAS/MAPK pathway activation – was introduced (0.022 mg/kg/day, day 0). A prompt improvement in clinical condition was observed, allowing to withdraw inotropes at day 5 and mechanical ventilation at day 12; nt-pro-BNP decreased from 30,805 pg/ml (pre-treatment) to 2,355 (day 14), consistent with HCM stabilization. During the next month, treatment was continued at the same dosage with drug level monitoring without side effects. Clinical conditions allowed a progressive reduction of non-invasive respiratory support. Cardiac ultrasound monitoring showed a tendency to HCM improvement but revealed the sudden appearance (day 23) of pulmonary artery dilation (18 mm). At 3 months of age, she underwent ventriculoperitoneal shunt device placement for obstructive posthaemorrhagic hydrocephalus and showed, after surgery, a rapidly worsening of CHF needing mechanical ventilation and maximal CHF supportive therapy, with an increase in nt-pro-BNP (47,000 pg/ml). The infant died at 3 months and a half of age (day 58) from untreatable CHF. Autopsy showed an obstructive HCM with obstructed ventricles, severe dilation of pulmonary artery trunk and branches with complete disarray of both gross and fine pulmonary vascular anatomy. Global RNA sequencing of white blood cells before and during treatment was performed to define transcriptional

effects of MEK inhibition. The latter might represent a promising treatment option for HCM in the RASopathies.

## PgmNr 2706: Comparing polygenic risk scores between the healthy elderly and the UK Biobank.

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Department of Epidemiology and Preventive Medicine, School of Public Health and Preventive Medicine, Monash University, Melbourne, VIC, Australia; 2) Garvan Institute of Medical Research, Sydney, Australia; 3) Genetic Medicine and Family Cancer Clinic, Royal Melbourne Hospital, Melbourne, Australia; Department of Medicine, University of Melbourne, Melbourne, Australia; 4) Department of Family Medicine and Rush Alzheimer's Disease Center, 2468 Rush University Medical Center, Chicago, IL, USA; 5) Berman Center for Outcomes and Clinical Research, Hennepin Healthcare Research Institute Minneapolis, MN, USA.

**Background:** ASPirin in Reducing Events in the Elderly (ASPREE) is a primary prevention trial of daily low-dose aspirin in 19,114 healthy elderly individuals. At enrolment (median age 74 years), participants did not have a history of cardiovascular disease (CVD), life-threatening illness or evidence of dementia. Primary trial outcomes were published in three NEJM papers in 2018 (McNeil et al), and include CVD events, cancers, dementia and death over median 4.7 years follow-up. ASPREE is now extended to an observational study of healthy ageing, with longitudinal clinical outcome and deep phenotype data, comparable to the UK Biobank. ASPREE has genotyped 15,000 participants (Axiom PMDA) and we hypothesize depletion of common and rare damaging alleles in the healthy elderly, and enrichment of protective alleles, compared with the UK Biobank.

**Aim:** To assess whether the distribution of polygenic risk scores (PRS) varies between the healthy elderly and the UK Biobank, across a range of disease and clinical phenotypes, and whether the depletion of damaging common alleles contributes to healthy ageing.

**Methods:** GWAS-based QC using Plink v2 on both datasets, ASPREE has 15000 samples and UKBB ~500,000 samples (UKBB Project: 47061), SNPs and samples passing 98% genotyping rates, imputed variant R<sup>2</sup> >0.3, Hardy-Weinberg equilibrium, LD threshold of r<sup>2</sup> <0.2 across 500 kb, minor allele frequency (MAF) <0.05, unrelated individuals and European ancestry. Plink v2 to undertake the PRS analysis on imputed genotype data from UK-Biobank and ASPREE using summary GWAS data for each clinical outcome as reference data PRS distribution between the two populations compared using Plink. Disease outcomes include CVD, cancers (breast, colorectal, prostate), Alzheimer's disease (AD), T2D, and depression.

**Results:** We observe a significant depletion of PRS in the healthy elderly compared to the UK Biobank, suggesting a unique genetic architecture of healthy ageing. The most significant depletion was in PRS for cardiovascular disease, including early-onset coronary artery disease and atrial fibrillation. Depletion was also found for cancer (breast and prostate), Alzheimer's disease and 'short lifespan' PRS.

**Conclusion:** The healthy elderly have, on average, depletion of common damaging variants, and enrichment of common protective alleles, across a range of disease phenotypes compared to the UK Biobank population. This, in part, may contribute to the complex phenotype of healthy ageing.

## PgmNr 2707: Anti-inflammatory statins: An insight into the relationship between *UGT1A* and statin metabolism.

### Authors:

S. Yee; C. Drum

[View Session](#) [Add to Schedule](#)

**Affiliation:** Medicine, Yong Loo Lin School of Medicine, National University of Singapore, Singapore

---

**Background** – HMG-CoA reductase inhibitors, or statins, are one of the most prescribed drugs for the prevention of cardiovascular disease and act by reducing plasma LDL cholesterol. In Singapore, 47% of adult patients use either atorvastatin or simvastatin. Statin medications are known for their various lipid independent effects and these effects can contribute to clinical decision making regarding the prescription of statins.

**Methods** – 1,500 subjects on atorvastatin and simvastatin were recruited at two outpatient heart clinics, with each clinic contributing half of the study population. Two blood draws, three hours apart, are done per patient per visit via venipuncture. Blood drawn is used for genomic analysis then spun down to plasma for clinical biomarker measurements via COBAS c111 and drug and metabolite measurements via LC-MS/MS.

**Preliminary Results** – To discover personalized predictors of inflammation reduction, we studied 1,500 Singaporeans recruited from restructured hospitals over 3 years. Mass spectrometry was performed on all samples to quantify individual profiles of parent drug and active metabolites. Genome-wide genotyping was performed on all samples (~647,000 SNPs) to determine common variants associated with statin metabolism and clinical outcomes. Clinical case annotation was provided from case report forms and electronic medical records. Plasma atorvastatin and metabolite levels were quantified and analysed. Our data demonstrates that despite individualized variance in statin metabolism, there is a strong correlation between the ratios of drug metabolite to parent drug and hsCRP ( $p < 0.001$ ), whereas quantified levels of the parent drug have no correlation. Genetic determinants of altered statin metabolism also identify patients with decreased levels of CRP. Coding variants known to reduce function of the statin metabolizing enzyme, UDP glucuronosyltransferase 1A (*UGT1A1*), result in a unique statin phenotype ( $p < 10^{-14}$ ) and result in low CRP values when compared with controls ( $p < 0.05$ ).

**Conclusion** – We have used community derived statin measurements to discover new variants that could be involved in statin metabolism. Using this method, we could expand our methods to look at the other pleiotropic effects of statins and also to discover new variants involved in the metabolism of other drugs

## PgmNr 2708: Cardiovascular pathophysiology in the KATP channelopathy Cantú syndrome: Mechanisms and pharmacotherapy.

Cantú syndrome (CS) is an autosomal-dominant, multi-organ disorder, characterized by hypertrichosis and craniofacial dysmorphology, which arises from gain-of-function mutations in the genes encoding the cardiovascular KATP channel subunits Kir6.1 and SUR2 (*KCNJ8* and *ABCC9*, respectively). Multiple cardiovascular abnormalities are reported in CS including dramatic cardiomegaly, alongside vascular dilation and low systemic blood pressure. How KATP dysfunction results in these complex abnormalities is not fully understood and there are no known therapies for the disorder. Using “Cantú mouse” models, in which disease-causing Kir6.1[V65M] and SUR2[A478V] substitutions were introduced, we have identified the pathophysiological mechanisms underlying CV remodeling and tested the efficacy of the KATP inhibitor glibenclamide in reversing abnormalities.

Cantú mice exhibit markedly decreased systemic vascular resistance (SVR) and high-output cardiac hypertrophy alongside decreased exercise tolerance – suggestive of decreased cardiac reserve and mirroring clinical observations. Expression of transgenic, dominant-negative Kir6.1 subunits specifically in smooth muscle reverses cardiac hypertrophy in Cantú mice, suggesting that cardiac remodeling occurs secondary to vascular dilation and chronically lowered SVR. We demonstrate that renin-angiotensin signaling (RAS) is upregulated in Cantú mice and drives cardiac hypertrophy. Finally, we show that chronic administration of the KATP channel inhibitor glibenclamide results in normalization of vascular and cardiac abnormalities in Cantú mice.

These results demonstrate that KATP over-activity results in decreased electrical excitability in vascular smooth muscle (VSM), upregulation of RAS, and maladaptive cardiac remodeling. We propose that the complex CV phenotypes observed in CS may represent a defining example of the systemic consequences of VSM hypo-excitability, emphasizing how the study of rare, genetically defined diseases can reveal novel insights into broad physiology. Demonstration of the *in vivo* efficacy of glibenclamide in targeting cardiovascular KATP channels suggests that the drug can be clinically repurposed for the treatment of CS specifically - and potentially for diverse cardiovascular conditions arising from decreased smooth muscle excitability in general.

## PgmNr 2709: Large scale proteome-wide imputation and association analysis identifies disease biomarkers and candidate drug targets.

Imputing molecular data into large cohorts without such measurements is a powerful and affordable way to identify and prioritize molecular markers associated with disease risk.

Previous studies have focused on imputation of RNA expression data by calculating risk scores using machine learning approaches, followed by Transcriptome Wide Association Studies (TWAS). However, variation in expression levels does not always translate to variation in protein levels, the latter appearing to be far more conserved. This phenotypic buffering is the result of (post-) translational regulation of gene expression, and may result in sub-optimal prioritization of risk-associated biomarkers. Furthermore, proteins are the most common targets of drugs, therefore identification of protein disease biomarkers may be more informative.

Here we perform the largest imputed proteome-wide association study (PWAS) to date to identify proteins and novel genomic regions for 20 complex diseases and traits for up to 1 million samples. We constructed protein expression models by performing elastic net regression on 2,869 autosomally coded plasma proteins (SomaLogic) in 3,301 individuals from the INTERVAL study. Ten-fold nested cross-validations were performed to compute the coefficient of determination  $R^2$  to assess model performance.

For 626 probes (584 unique proteins) we were able to build models with a minimal prediction performance ( $R^2_{cv}$ ) of at least 0.01, with the largest  $R^2_{cv}$  for CLEC12A (0.77). Next, we used our prediction models to identify previously unknown protein-disease associations with a set of 20 traits and common complex diseases for which GWAS summary statistics were publicly available. We identified 51 previously unknown associations with biological relevance. For osteoarthritis as an example, we identified 7 novel protein associations, including VIT and CRELD1, both, (extra-) cellular matrix proteins, as well as ITIH1 and HP, both of which are implicated in multiple inflammatory diseases.

In summary, we have created a powerful new paradigm for allowing imputation of expensive plasma protein measurements into large-scale biobanks and subsequent association analyses, and highlighted its potential to identify new biomarkers and drug targets for complex diseases.

## PgmNr 2710: Epigenetic mapping of African American hepatocyte methylation quantitative trait loci (meQTLs) in Clopidogrel response: An ACCOuNT Study.

### Authors:

Genetic variation may give rise to different patterns of gene expression and DNA methylation. However, the combination of genetic variability and epigenetic modifications that control gene expression and gene-drug interactions is understudied in minority populations. In particular, DNA methylation in the liver may affect gene expression of important hemostatic factors which may in turn affect response to cardiovascular medication. Moreover, the greater degree of genetic variation and differences in gene expression seen in African Americans (AAs) may uncover novel hepatocyte meQTLs. Here we investigate the role of hepatocyte meQTLs in explaining variability in the anti-platelet medication, clopidogrel.

In this study, we used genotype and methylation array data from 44 AA primary hepatocyte cultures to first map meQTLs in AA hepatocytes and then to investigate these potential regulatory variants for association with clopidogrel response. We identified 404 cis-meQTLs mapped to 142 unique CpG sites using a window size of  $\pm 500$  kb of the CpG (FDR < 0.05). These 404 hepatocyte meQTLs were analyzed for their association with P2Y<sub>12</sub> reaction units (PRU) in clopidogrel-treated AA patients. PRU is a clinical measure of response and has previously been shown to vary widely in AAs. After adjusting for age and first PC, we found a meQTL (rs115789536,  $\beta = 0.0257$ , FDR = 0.0298), which increased the methylation at a nearby CpG site (cg07110418), was associated with decreased on-treatment PRU ( $\beta = -1.387$ ,  $p = 0.01$ ).

rs115789536 is predominantly observed in populations with African ancestry (minor allele frequency = 7%) and is a non-coding variant in Prostaglandin I<sub>2</sub> Synthase (*PTGIS*), a PharmGKB very important pharmacogene (VIP). Previous studies have shown that SNPs within *PTGIS* were associated with myocardial infarction risk, systolic hypertension and cerebral infarction. We previously found *PTGIS* gene expression to be negatively associated with increased percentage of inferred African ancestry.

Our data suggests that altered gene expression of *PTGIS* in the liver due to the meQTL rs115789536 may lead to increased response to clopidogrel. This analysis provides evidence for a novel role of *PTGIS* in platelet aggregation and potentially in response to clopidogrel as a result of altered methylation. Functional validation is needed to validate the effect of rs115789536 in both altered methylation and gene expression of *PTGIS*.

## PgmNr 2711: Development of a gene-diet interaction-based dietary fat response score for cardiometabolic risk factors.

**Authors:**

K. Westerman; L. Parnell; J.M. Ordovás

[View Session](#) [Add to Schedule](#)

**Affiliation:** Nutrition and Genomics Laboratory, JM-USDA Human Nutrition Research Center on Aging, Boston, MA

---

Many gene-diet interactions (GDI) have been uncovered for cardiometabolic risk factors (CRFs), but personalized nutrition recommendations will require the incorporation of an ensemble of variants across the genome in predicting diet response. Dietary trials typically lack the sample sizes required to identify genome-wide signals of diet response. Using the Women's Health Initiative (WHI) dataset, we set out to replicate previously-identified GDIs and develop genome-wide dietary scores for CRF response to dietary fat response. First, known GDIs for dietary fat were collected from the CardioGxE database for each of six CRFs: body mass index, systolic blood pressure, LDL-cholesterol, HDL-cholesterol, triglycerides, and fasting glucose. These GDIs were tested for nominal replication ( $p < 0.05$ ) with respect to food frequency-based binary dietary fat percentage in women from WHI not participating in the dietary modification (DM) trial. We found that only a small percentage of these GDIs could be replicated in this almost 10,000-person dataset, suggesting that these literature-reported interactions are population-specific or reflect confounding factors. Next, GDIs were calculated in this same cohort for suggestive SNPs for each risk factor (main-effect GWAS  $p < 1e-5$ ) and aggregated using the pruning and thresholding method into a series of "fat response scores". These scores were tested for prediction of changes in the associated CRF after 3 years in WHI women participating in the fat reduction-focused DM trial. Only the HDL responder score was meaningfully predictive, predicting a 3.1 mg/dL lower change in HDL-C per score standard deviation in DM trial participants ( $p = 0.01$ ). Finally, this HDL response score was assessed with respect to incident coronary heart disease events in DM trial participants, but failed to discriminate between incident cases and non-cases.

## PgmNr 2712: Transcriptome sequencing of patients with hypertrophic cardiomyopathy reveals deep intronic variants amenable to antisense oligonucleotide therapy.

Hypertrophic cardiomyopathy (HCM) is an inherited heart disease with a prevalence of 1 in 500 in the general population. DNA-based genetic testing fails to identify a genetic cause of disease in up to 50% of families with HCM. RNA sequencing of diseased tissue is a new genetic testing approach that could increase the diagnostic yield, especially for recently described deep intronic variants, which are often overlooked. However, there is limited access to heart tissue for most patients. We have developed a novel genetic testing approach involving sequencing RNA extracted from induced pluripotent stem cell cardiomyocytes (iPSC-CMs) derived from the patient's fresh blood. We have also used the iPSC-CMs to explore antisense oligonucleotide (AO) inhibition of RNA splicing errors that are caused by deep intronic variants in *MYBPC3*, the most common HCM gene.

We derived iPSC-CMs from (a) fresh blood of two patients with HCM caused by deep intronic variants in *MYBPC3*, (b) a patient with familial HCM where no genetic cause was identified after genome sequencing, and (c) two people without HCM. Transcriptome sequencing was performed on iPSC-CMs and analysed for RNA splicing errors. Splicing errors were confirmed with RT-PCR analysis of RNA extracted from iPSC-CMs, and the primary heart tissue of one patient. We designed a series of AOs to inhibit RNA splicing errors in iPSC-CMs of patients with deep intronic variants.

Transcriptome sequencing of iPSC-CMs identified known exon-gain RNA splicing errors in two people with deep intronic variants in *MYBPC3* (c.1090+453C>T and c.1224-52G>A). In a patient with a previously unresolved genetic cause of HCM, transcriptome sequencing of iPSC-CMs revealed gain of two novel exons due to an underlying *MYBPC3* c.1928-569G>T intronic variant. The same RNA splicing error was confirmed in primary heart tissue of the patient. We used a gradient of AOs (0.5-20  $\mu$ M) to determine the optimal concentration for inhibition of RNA splicing errors. Treatment of iPSC-CMs derived from all 3 patients with deep intronic variants using a series of AOs inhibited splicing errors, whereas a control AO did not inhibit splicing.

Our novel genetic testing approach involving sequencing of iPSC-CM RNA can provide additional genetic diagnoses over current DNA based testing, including genome sequencing. Patient derived iPSC-CMs provide a unique opportunity to explore and optimise the design of AOs for patient-specific inhibition of RNA splicing errors.

## PgmNr 2713: Actionable cardiac genetic variants and variants of uncertain significance in diverse biobank participants.

---

**Rationale:** Genetic profiling of medical biobanks offers the opportunity for risk identification and risk reduction. However, many biobanks lack sufficient population diversity to adequately represent the US population. We now analyzed whole genome sequence of 900 diverse medical biobank participants from a single US medical center.

**Methods:** We evaluated variation among participants of different ancestry. Nonsynonymous genetic variants, as reported in ClinVar were compared across racial/ethnic groups. Echocardiographic measures, obtained from the electronic health record, were correlated with genetic variation in the medically actionable genes for cardiac conditions in order to ascertain whether variation correlates with clinical phenotypes.

**Results and conclusions:** Biobank subjects were equally split representing European, African, Hispanic, and mixed race/ethnicities. Compared to those of European descent, genetic diversity was greater among those of African, Hispanic, and mixed race/ethnicity. When evaluating all nonsynonymous protein coding variants, African ancestry participants were more likely to have variants of uncertain significance (VUS) compared to other groups ( $p < 0.05$ ) and were also more likely to have variants not previously reported in ClinVar ( $p < 0.05$ ). We evaluated the American College of Medical Genetics and Genomics (ACMG) medically actionable list of 59 genes across races/ethnicities focusing genes for cardiovascular conditions (30 of 59 genes). We identified 19 individuals with pathogenic/likely pathogenic variants in the 30 cardiac medically actionable genes. African ancestry participants had more uncertain variants in the cardiac medically actionable genes. Longitudinal measures of left ventricle size, corrected for body surface area, from approximately 400 biobank participants (1,723 patient years) correlated with genetic findings. The presence of one or more uncertain variants in the actionable cardiac genes correlated with increased left ventricular internal diameter in diastole ( $p < 0.05$ ) and in systole ( $p < 0.01$ ), and these analyses identified excess variation in *MYBPC3*. We hypothesize subsets of the uncertain variants confer risk. Furthermore, we note that uncertain variants are not normally returned to participants or providers. These data suggest that in some settings, sharing this information with participants and providers offers opportunity for risk reduction.

## PgmNr 2714: Whole exome sequencing and monogenic hypertension in a multiethnic cohort of 28,000 individuals.

### Authors:

I. Paranjpe; K. Johnson; S. Coca; L. Chan; J.C. He; B. Murphy; J. Narula; R. Do; G. Nadkarni

[View Session](#) [Add to Schedule](#)

**Affiliation:** Icahn School of Medicine, New York, NEW YORK.

Hypertension (HTN) is a major cause of morbidity and mortality and a subset may be caused by monogenic mutations which influence treatment decisions and prognosis. We identified the prevalence of these secondary HTN mutations in a multiethnic cohort and determined their association with blood pressure, receiving a diagnosis of secondary HTN, and adverse cardiovascular outcomes.

In 27,972 individuals from the Mount Sinai BioMe Biobank (8304 European, 6993 African, 9985 Hispanic, and 2690 Other ancestry), we selected ClinVar mutations pathogenic for secondary hypertension using whole exome sequencing.

3,125 individuals (11.2%) had pathogenic mutations with a majority in genes associated with catecholamine excess (*SDHD*, *SDHB*, *TMEM127*, *RET*; n=2210) and sodium handling/hyperaldosteronism (*SCNN1G*/*CYP11B1*; n=524). (Table 1) In a linear model adjusted for sex, age, BMI, and 10 genetic principal components (PCs), individuals with mutations had elevated mean arterial pressure (b=0.7±0.6 mmHg; p=0.03) and increased odds of coronary artery disease (CAD) (adjusted OR=1.12, 95% CI 1.0 to 1.3, p=0.04). Individuals with mutations in sodium handling/hyperaldosteronism genes had increased odds of congestive heart failure (CHF) (adjusted OR = 1.44, 95% CI 1.04 to 1.97; p=0.02) adjusted for age, sex, 10 genetic PCs, and systolic blood pressure. The majority of individuals with mutations were diagnosed with essential HTN (54.2%) and only 7.8% had appropriate diagnoses of secondary HTN or received appropriate biochemical evaluation. (Table 2)

Individuals with pathogenic mutations had higher blood pressures, elevated risk for CAD/CHF and the majority were not appropriately evaluated or diagnosed. These results suggest whole exome sequencing may have utility in hypertension diagnosis and management.

**Table 1**

Gene	Condition	Number of Individuals with Variant
<i>SDHD</i>	Pheochromocytoma	1219 (3.9%)
<i>SDHB</i>	Pheochromocytoma	611 (2%)

Naturally occurring genetic variants are being used as tools for drug target discovery and to guide clinical trial design. Ivabradine is a heart rate lowering drug that reduces cardiovascular outcomes in patients with heart failure (SHIFT trial), but it does not reduce cardiovascular outcomes in patients with stable coronary artery disease (SIGNIFY trial), presenting a challenging model for a proof of concept demonstration of the value of genetics to support drug trial development. Ivabradine also increases the risk of atrial fibrillation (AF), which can lead to cardioembolic stroke.

Using the UK Biobank data and summary statistics from large GWAS, we evaluated the effect of a heart-rate lowering polymorphism at the *HCN4* locus encoding the drug target of ivabradine. Genetic association recapitulated the increase in AF risk (OR=1.09, 95%CI: 1.06-1.13,  $p=9.3 \times 10^{-9}$ ) in the UK Biobank and cardioembolic stroke (OR=1.08, 95%CI: 1.03-1.13,  $p=0.0015$ ) in MEGASTROKE. Using a competing risk model accounting for AF with the UK Biobank prospective data, we show that the heart rate reducing *HCN4* variant reduced incident heart failure (HR=0.90, 95%CI: 0.83-0.98,  $p=0.013$ ), recapitulating results of the SHIFT trial. We used bi-directional Mendelian randomization to show that AF and heart failure are mutually causal of each other, supporting the competing risks approach. The effect of the *HCN4* variant on AF exceeds the effect estimated by Mendelian randomization with genome-wide variants, which suggests a pleiotropic effect of *HCN4* on heart failure. The *HCN4* variant did not associate with coronary artery disease in CARDIOGRAMplusC4D, recapitulating results from the SIGNIFY trial.

Our approach supports the usefulness of human genetics data to guide drug development and trial design even in more complex clinical settings.

## PgmNr 2716: Inter-individual genetic variation leads to differences in exosomal miRNA profiles in response to kinase inhibitors and the development of cardiotoxicity.

The use of targeted oncologic treatments, such as kinase inhibitors (KIs), have greatly improved therapeutic outcome and significantly reduced mortality. However, for many patients, drug-related adverse effects (AEs) including cardiotoxicity occur. Human induced pluripotent stem cell-derived cardiomyocytes (hiPSC-CMs) allow for the study of inter-individual response to KIs, the identification of biomarkers for AEs and the potential for a personalized approach to drug selection and dosing. Recent studies have found circulating exosomal miRNAs (miRNA<sup>EXO</sup>) to be promising biomarkers for drug response. The aim of this study was to comprehensively analyze inter-individual exosomal miRNA expression in hiPSC-CMs in response to KIs to identify exosomal miRNA profiles associated with cardiotoxicity. For toxicity modeling, we utilized six individual hiPSC-CM lines. Each line was treated in triplicate with three KIs, sunitinib (SUN), vandetanib (VAN) and gefitinib (GEF). Physiological measurements of beat rate, cell index and ATP viability were used to test for CM toxicity (20% change +/- from the control value). Exosomes were isolated from cell conditioned media and miRNA libraries were prepared. Next-Gen sequencing and differential expression analysis (DESeq2) identified miRNAs associated with KI response and cardiotoxicity. For VAN and GEF, we identified significantly differentially expressed miRNA<sup>EXO</sup> (n=35 and n=3, adj. p-value ≤ 0.05) in response to each KI common in all cell lines, establishing a miRNA<sup>EXO</sup> profile exclusive to each drug. Interestingly, with SUN and VAN, we observed miRNA<sup>EXO</sup> profiles unique only to cell lines that developed a cardiotoxic drug response. Differential expression analysis of the miRNA<sup>EXO</sup> comparing the cell lines that developed cardiotoxicity to those that were resistant identified 13 miRNAs with significant differential expression for SUN and 11 miRNAs for VAN (adj. p-value ≤ 0.05). In summary, our methodology of combining functional CM analysis in response to KIs with exosomal miRNA expression allows for the identification of potential biomarkers of cardiotoxicity. Our results highlight the inter-individual response to KIs and the need for toxicity screening in multiple, genetically diverse cell lines. Further studies will identify the functional effects of these differentially expressed miRNAs and further determine their utility as a predictive pharmacogenomic biomarker for individualized drug dosing and response.

## **PgmNr 2717: An intergenic variant near *C12orf42*, *LINC02401* and *STAB2* is associated with acute coronary syndrome among Filipinos.**

Acute coronary syndrome (ACS) pertains to a group of conditions consistent with the clinical manifestations of acute myocardial ischemia or infarction secondary to the decrease in blood flow to the coronary arteries. Because ACS is a life-threatening disease, prevention is of utmost concern especially among patients who have a genetic predisposition. Early detection of these markers may improve the risk prediction of ACS by considering both traditional risk factors and the presence of these variants. While various genes have been studied, Filipinos are underrepresented in most studies looking at the genetic determinants of acute coronary syndrome (ACS). This study sought to determine the association of previously identified genetic variants linked with the development of ACS among Filipinos. A total of 123 adults unrelated Filipinos with ACS were compared with 228 controls in an age- and sex- matched case-control study that looked at 81 genetic variants associated with ACS and similar phenotypes. Genotyping using DNA from blood samples was done using customized Illumina Goldengate microarray chips. Candidate variants and clinical data were correlated with the incidence of ACS using chi-square and logistic regression analysis. An intergenic variant located upstream of *C12orf42* (~22kb), downstream of *LINC02401* (~28kb), and of *STAB2* (~68kb) exhibited robust association with development of ACS among Filipinos (TT vs CC: adjusted OR 2.33,  $p = 0.022$ ), as adjusted for presence of hypertension, borderline to high LDL and history of smoking. The variant is also found 110 bp downstream from a DNase I hypersensitivity site, which is a general feature of cis-regulatory functions, involving enhancers, promoters, insulators, boundary elements, and locus control regions. Previous genome-wide association studies among European and American populations showed, however, that the C allele was associated with restenosis after percutaneous coronary intervention, coronary events and all-cause increased mortality. Validation studies will be done prior to concluding definite association between this marker and coronary artery disease among Filipinos.

## PgmNr 2718: Transcriptome-wide association study of novel copy number variant: associated with venous thromboembolism in African Americans.

### Authors:

H. Zhang; L. Nahwahli; W. Hernandez; M. Perera

[View Session](#) [Add to Schedule](#)

**Affiliation:** Northwestern University, Chicago, Illinois.

Venous thromboembolism (VTE) is a disorder consisting of deep vein thrombosis and pulmonary embolism and the third leading cause of cardiovascular-related mortality in the United States. VTE is multifactorial disease including environmental and genetic risk factors. African Americans (AAs) have a 30 to 60% higher incidence compared to other ethnicities. Although several risk and genetic factors have been investigated, the concrete mechanism underlying the ethnic disparities remains unclear. Through the first genome-wide analysis of copy number variation (CNV), we identified a deletion of approximately 18 kb on Chromosome 10. This CNV region (CNVR) was validate using a custom 8x15K oligonucleotide array (Agilent) and was significantly associated with decreased risk of VTE in AAs. Previous GWAS identified a SNP near this CNVR (rs2420915) which was associated to fibrinogen level, lending support for the importance of this region in coagulation.

To identify other potential gene expression traits linked to this CNVR, we performed transcriptome-wide association study (TWAS), which imputes gene expression in relevant tissues and tests the association of the CNVR to imputed gene expression. Our gene expression imputation was the method employed in PredXcan, however, we used previously published genotype weights trained in AAs from Multi-Ethnic Study of Atherosclerosis (MESA) in monocytes. We identified a subset of well-predicted genes and integrated gene ontology (GO) and Kyoto Encyclopedia of Genes and Genomes (KEGG) pathway annotations as features to characterize these genes. We obtained 10 optimal GO terms ( $p < 0.05$ ) and 1 KEGG sphingolipid metabolic pathway ( $p = 0.0018$ ) that characterized these genes well. Interestingly, Phospholipase D1 (PLD1,  $p = 0.0147$ ), Sphingomyelin Phosphodiesterase 2 (SMPD2,  $p = 0.0147$ ), and Sphingosine Kinase (SPHK1,  $p = 0.0373$ ) regulate the lipid metabolism and significantly associated with the deletion of CNVR.

Previous studies have shown that plasma sphingolipids regulate blood coagulation system and related to VTE and stroke. Through this functional annotation analysis, our data suggested that the sphingolipid metabolic pathway might related to the VTE underlying the mechanism of deletion of the CNVR to decrease the risk of VTE in AAs.

## PgmNr 2719: Genome-wide association study of on-aspirin platelet aggregation identifies *ACYP2* and other loci as novel pharmacogenetic candidates.

Aspirin is often used in primary and secondary prevention of cardiovascular disease (CVD). The efficacy of aspirin and other anti-platelet treatments is linked to their ability to suppress platelet activation, a key component in thrombosis. The concept of aspirin resistance is controversial, with unknown prevalence and many studies finding on re-testing that suspected aspirin resistance was due to non-compliance or self-report error. Thus, the extent of differences in aspirin efficacy in the population due to genetic or environmental effects remains to be determined. To study the genetic factors influencing on-aspirin platelet aggregation in the European ancestry Offspring cohort of the Framingham Heart Study, we used a gold standard platelet activation assay (light transmission aggregometry) after addition of arachidonic acid as a sensitive determinant of aspirin takers. Then we conducted WGS-imputed GWAS analysis in a subset of individuals who were taking aspirin at the time of platelet activation measurement. We focused on QTL analysis of platelet activation via 3 agonist pathways (ADP, epinephrine and collagen) that partially escape aspirin inactivation. From these analyses we found 2 genome-wide significant loci ( $P < 5E-8$ ), and 2 borderline loci ( $P < 1E-7$ ) for platelet activation. All four loci (*ABAT*, *MMD2*, *CSH1*, *ACYP2*) had a minor allele associated with decreased epinephrine-induced platelet activation, indicating those individuals had greater platelet suppression on aspirin treatment. We attempted replication in a smaller, diverse sample – the Framingham Omni cohort – and a Welsh population sample – the Caerphilly Prospective Study in Men – and found evidence for association in the same direction in aspirin takers in the region of *ACYP2*. In interaction models including non-aspirin takers there was a significant interaction with the *ACYP2* peak SNP ( $P < 0.03$  interaction). This sentinel SNP is ~6kb upstream of the consensus start site and overlaps an area of epigenetic activity in megakaryocytes, the precursor cell for platelets. Acylphosphatase-2 (*ACYP2*) hydrolyzes calcium channel intermediates, and calcium signaling plays a critical role in platelet activation, particularly for epinephrine-based stimulation. Efforts are currently underway to evaluate whether the identified SNPs contribute to future risk of CVD or bleeding in the Women's Genome Health Study, a randomized trial of aspirin, vitamin E and placebo with >20 years follow-up.

## PgmNr 2720: A genomics-based approach identifies gender-specific modifiable risk markers of left ventricular mass variability within a population.

**Background:** Left ventricular (LV) mass is a prognostic biomarker of incident heart disease and all-cause mortality. Over time, LV mass may increase due to exposure to risk factors such as high blood pressure. Treating these risk factors using medications or other interventions attenuates or reverses these LV mass increases. We hypothesized that probing the genetic architecture of an integrative phenotype like LV mass, which captures the duration and severity of exposure to risk factors over time, would identify insufficiently treated cardiac risk mechanisms in a target population.

**Methods:** We developed a polygenic single nucleotide polymorphism predictor of LV mass variation in 7,601 individuals with transthoracic echocardiography measurements collected as part of routine clinical care at Vanderbilt University Medical Center. We then tested for associations between this predictor and 894 clinical diagnoses measured in 58,838 genotyped individuals in the Electronic Medical Records and Genomics (eMERGE) network. We used polygenic risk (PRS) scores for the candidate diagnoses in conjunction with inverse-weighted meta-analyses to further define the etiological relationships between the diagnoses and LV mass.

**Results:** There were 29 clinical phenotypes associated with the LV mass genetic predictor at FDR  $q < 0.05$ . Higher LV mass was associated with modifiable cardiac risk factors including obesity, hypertension and type 2 diabetes as well as conditions associated with pathological LV mass changes including heart failure and atrial fibrillation. Analyses using polygenic predictors confirmed significant associations between higher LV mass and body mass index (BMI) (each unit increase in BMI was associated with a 0.11 [0.09 - 0.13] unit increase in log[LV mass],  $p = 6.4 \times 10^{-25}$ ) and systolic blood pressure ( $\beta = 0.003$  [0.001 - 0.004],  $p = 0.002$ ). The magnitude of the body mass-related genetic effects was larger in women ( $p = 0.002$ ). In men, there was an association with atherosclerotic disease including myocardial infarction ( $\beta = 0.003$  [0.001 - 0.004],  $p = 0.002$ ).

**Conclusions:** We show that a polygenic predictor of a integrative phenotype which stably captures an individual's cumulative exposure to risk can be used to identify disease mechanisms contributing to morbidity within a target population. These results can guide precision treatment and prevention strategies directed toward the target population.

## PgmNr 2721: Association of polygenic risk scores for body mass index and systolic blood pressure in a pediatric cohort requiring surgery for congenital heart defects.

---

Congenital malformations are the leading cause of infant mortality in the United States. Congenital heart disease (CHD) represents the most prominent congenital malformation, affecting 40,000 US births per year. Approximately half of these children require surgical intervention(s), many of which experience postoperative complications. To date, no studies have evaluated associations of polygenic risk scores (PRS) for anthropometric traits with postoperative outcomes in a pediatric CHD cohort. Further, the utility of PRS to predict outcomes such as obesity in pediatric subjects is largely unknown. We used high-quality imputed genotypes from pediatric participants requiring surgery for CHD (mean age at surgery  $\pm$  SD =  $3.38 \pm 5.39$  years,  $n = 1978$  subjects). Base data for a body mass index (BMI) PRS used the Genetic Investigation of ANthropometric Traits (GIANT) consortium GWAS transehtnic 2015 BMI data ( $n_{\text{max}} = 322,154$  subjects). Base data for a systolic blood pressure (SBP) PRS used recently published GWAS SBP data ( $n_{\text{max}} = 760,226$  subjects). Target data were pruned for linkage disequilibrium at an  $r^2$  threshold of 0.1 at a maximum distance of 250 kilobases and scores were calculated in PLINK. Associations of PRS for BMI and SBP with BMI and length of hospital stay following surgery (LOS) were modeled using linear regression in R and adjusted for age, sex, and 10 PCs. The SBP model was also adjusted for BMI. BMI PRS was associated with BMI (PRS  $P$  value threshold = 0.001,  $n$  SNPs = 1,603,  $\beta \pm \text{SE} = 0.58 \pm 0.15 \text{ kg/m}^2$ ,  $P = 8.5 \times 10^{-5}$ ) and LOS (PRS  $P$  value threshold = 0.05,  $n$  SNPs = 16,244,  $\beta \pm \text{SE} = 1.67 \pm 0.83$  days,  $P = 0.045$ ). The SBP PRS was associated with LOS (PRS  $P$  value threshold = 0.0001,  $n$  SNPs = 2,985,  $\beta \pm \text{SE} = -0.45 \pm 0.15$  days,  $P = 3.02 \times 10^{-3}$ ). These results demonstrate the ability of PRS developed in adults to predict pediatric traits and outcomes. Specifically, the association of the BMI PRS with BMI provides proof of principle for the use of adult-derived PRSs in younger populations. PRS associations in pediatric participants may identify individuals at higher risk of negative cardiometabolic outcomes.

## PgmNr 2722: An externally validated artificial intelligence driven integrated genetic-epigenetic DNA test for 3-year risk for incident coronary heart disease.

### Authors:

M. Dogan<sup>1,2,5</sup>; S. Knight<sup>3</sup>; A. Lendasse<sup>4</sup>; K. Knowlton<sup>3</sup>; R. Philibert<sup>1,2,5</sup>

---

Coronary heart disease (CHD) is the most common type of heart disease, accounting for over 350,000 deaths and 750,000 heart attacks annually. CHD associated morbidity and mortality are largely preventable. Current primary prevention measures include the use of risk estimators that aggregate multiple conventional risk factors. Here, we describe a novel, simpler and more sensitive DNA-based method that we have developed and externally validated. It is an integrated genetic-epigenetic risk estimator for predicting the 3-year risk for incident CHD. The implementation of this Precision Medicine tool only requires DNA from a small amount of blood and its predictive power is driven by Artificial Intelligence (AI). For its development, we utilized genome-wide DNA methylation (DNAm) and SNP data from the Framingham Heart Study (FHS) Offspring cohort. This data was split into training (34/1172 incident CHD cases) and test (8/512 incident CHD cases) sets. The external validation was performed in partnership with Intermountain Healthcare (IM), which was split into validation (23/80 incident CHD cases) and test (21/79 incident CHD cases) sets. Data mining, feature selection and model development were performed on the FHS training set and validated on the IM validation set. The final incident CHD prediction model (ensemble of SVM, Random Forest and Logistic Regression) consisted of 6 loci (3 DNAm and 3 SNPs). It performed with a sensitivity, specificity and AUC of 0.75, 0.72 and 0.74, respectively, in the FHS test set and 0.71, 0.69 and 0.70, respectively, in the IM test set. The performance of our approach was compared to that of the Framingham Risk Score (FRS) and the Pooled Cohort Equation (PCE). The sensitivity, and specificity in the FHS cohort was 0.15 and 0.94, respectively, for FRS, and 0.41 and 0.80, respectively, for PCE. Similarly, the sensitivity and specificity in the IM cohort was 0.31 and 0.89, respectively, for FRS, and 0.56 and 0.63, respectively, for PCE. The superior sensitivity of our tool suggests that its use in a clinical setting could better identify patients at risk for incident CHD that may benefit from primary prevention interventions. Also, because DNAm signatures are dynamic and map to actionable risk factors, they may be used to personalize interventions and continuously monitor risk for incident CHD. This tool is being translated into a Laboratory Developed Test and being extended to include more ethnically diverse cohorts.

## PgmNr 2723: **SOX7** ablation in endocardium results in downregulation of **WNT4** and **BMP2** and abnormal endocardial cushion development.

### Authors:

---

### Background

*SOX7* is located on chromosome 8p23.1 in a critical region that is commonly deleted in individuals with complex cardiovascular malformations. *SOX7* is highly expressed in vascular endothelium and endocardium but its role in these cells remains unclear.

### Hypothesis

*SOX7*-deficiency may play a critical role in endothelial-to-mesenchymal transition (EMT) during the endocardial cushions (EC) formation, modulating the expression of *Wnt4* and *Bmp2*.

### Material and Methods

To explore the role of *SOX7* in cardiovascular development, we created standard and conditional *Sox7* knockout mice. Embryos were harvested from E8.5, to E15.5 for phenotypic, histology, immunohistochemistry, collagen gel, RNA-In Situ Hybridization (RNA-ISH), bioinformatics and RNA-seq analysis.

### Results

- *Sox7*<sup>-/-</sup> embryos die around E11.5 with signs of heart failure, pericardial edema and failure of vasculature remodeling.
- The same phenotype was observed when *Sox7* was ablated in endothelial cells using a Tie2-Cre. This suggests that *SOX7* plays a critical role in vasculogenesis.
- One out of two *Sox7*<sup>flox/flox</sup>;Tie2-Cre embryos that escaped early lethality had a ventricular septal defect.
- *Sox7*<sup>-/-</sup> embryos at E9.5 had hypocellular EC with severely reduced numbers of mesenchymal cells.
- In atrioventricular (AV) canal explant studies, *SOX7* deficiency leads to a severe reduction in EMT.
- *Wnt4*, *Pik3r3* and *Bmp2* transcript levels were downregulated in RNA-seq studies on E9.5 hearts harvested from *Sox7*<sup>-/-</sup> embryos. These genes have been shown to positively regulate EMT.
- RNA-ISH showed undetectable levels of *Wnt4* transcripts in the endocardium of *Sox7*<sup>-/-</sup> embryos and markedly reduced *Bmp2* expression in myocardium of null embryos.
- *SOX7* plays a dual role in the endocardium of the AV canal, separated from its role in endothelial progenitors.

- In Silico analysis suggests multiple SOX family binding sites exist in predicted promoters of *Wnt4* and *PiK3r3*.

### **Conclusions**

Since SOX7 is a transcription factor, we conclude that SOX7 promotes endocardial cushion development regulating the expression of *Wnt4*, which is then expressed in endocardium, and promotes EMT by acting in a paracrine manner to increase the expression of BMP2 in the contiguous myocardium. BMP2 subsequently, promote EMT to ensure the AV cushion formation. Conversely, decreased expression of SOX7 results in *Wnt4* and *Bmp2* downregulation and hypocellular EC, and may contribute to the congenital heart defects seen in individuals with recurrent 8p23.1 microdeletions.

## PgmNr 2724: *Ascc2* as a novel regulator of cardiac progenitor specification.

The cardiovascular system is the first functional organ system to form in vertebrate embryos and is essential for subsequent development. In humans, congenital heart defects are among the most common birth defects, often resulting in lethality. Congenital muscular dystrophies (CMDs) are one group of early onset congenital disorders that can present with cardiac and respiratory failure. Recently, human loss of function alleles of Activating signal co-integrator (ASC) complex members, TRIP4 and ASCC1 were shown to lead to CMD with heart and respiratory failure; indicating a novel role for the ASC complex in cardiovascular development and disease. The ASC complex consists of Trip4, *Activating signal cointegrator 1 complex subunit 1* (Ascc1), Ascc2, and Ascc3. This complex has been shown to interact with Serum response factor (SRF) and LIM domain protein, CSRP1, which regulates cardiac mesoderm migration. Here, we begin to dissect Ascc2 function during mouse embryogenesis. We found that *Ascc2* is expressed broadly in early post implantation embryos and like *in vitro*, interacts with other Asc complex members. Interestingly, *Ascc2* expression is only restricted anteriorly with highest expression in the developing heart at embryonic day (E) 8.5. Utilizing *Ascc2*<sup>Tm1d(KOMP)Wtsi</sup>, we have determined that a homozygous mutation in *Ascc2* results in lethality by E9.5. At E8.5, mutant embryos have under-developed hearts, and in some cases, complete absence of heart tube formation. Despite the disruption of cardiac development in *Ascc2* mutants, early cardiac mesoderm markers showed a significant increase in genes required for cardiac progenitor specification and migration, but no change in endothelial cell markers. *Nkx2.5* conditional knock out of *Ascc2* mice are subviable as adults with morphological and function cardiac defects. These data suggest that *Ascc2* is an essential regulator of early cardiac specification and is required for normal heart development.

## PgmNr 2725: Deletions in the *ANGIOTENSINOGEN* gene among preeclamptic/eclamptic women in Calabar, Nigeria.

---

Preeclampsia is a disorder of human pregnancy characterized by the onset of high blood pressure and often a significant amount of protein in the urine. Eclampsia is characterized by the syndrome of severe preeclampsia with addition of convulsion, seizures, hemorrhage, and coma leading to fatal maternal and neonatal outcomes. The prevalence of pre-eclampsia/eclampsia varies greatly in different ethnic and geographical regions. Mutations of the *ANGIOTENSINOGEN* (*AGT*) gene have been implicated in the development of preeclampsia/eclampsia in some ethnic groups but no such studies have been reported in Calabar, Nigeria. This was a pilot study to investigate the mutations in *EXON 2* of the *AGT* gene among preeclamptic/eclamptic women in Calabar, Nigeria. A total of fifty-eight pregnant women comprising 19 pre-eclamptic, 19 eclamptic and 20 apparently healthy volunteer pregnant women as controls were recruited into the study from the University of Calabar Teaching Hospital, Calabar. Ethical approval and informed consent was obtained from the UCTH Ethics committee and the women respectively. Demographic information was obtained and analyzed using student t-test, 2- 3mls of blood was also collected from all the women. DNA was extracted and PCRs performed and the amplicons were sequenced for the *AGT* mutations. The chromatogram was decoded into nucleotide sequences using chromaPro. Multiple sequence alignment was performed for all the sequenced products. This mutation study identified a deletion of guanine at position 26 in 19(100%) pre-eclamptic women and 16(84.2%) eclamptic women, 3 other deletions 12 del A, 2-5 del CCTT, 2-6 del CCTTT were observed among the 19 eclamptic women. But these mutations were not observed among the control pregnant women in the study population.

**Keywords:** *ANGIOTENSINOGEN*, Preeclamptic/Eclamptic women, Deletions, Calabar.

## PgmNr 2726: Identification of novel variants and transcriptomic alterations in pediatric restrictive cardiomyopathy via exome and RNA sequencing.

---

Restrictive cardiomyopathy (RCM) is a rare myocardial disorder characterized by normal chamber size and thickness with impaired ventricular filling due to diastolic dysfunction. Pediatric RCM has limited therapeutic approaches leaving cardiac transplant as the primary treatment. Although pathogenic variants in sarcomeric genes can cause RCM, the underlying etiology is frequently unknown. To investigate causation and pathogenesis of RCM we performed exome, mRNA- and small RNA-sequencing (RNA-seq) analysis using explanted left ventricular heart tissue from pediatric RCM transplant subjects (n=14) and compared them to pediatric controls (n=4). From exome data, *BAG3* (p.Pro209Leu) and *FLNC* (p.Tyr2563Cys) pathogenic variants were identified in three RCM patients and a fourth patient had a 21bp in-frame insertion in *FLNC* in a domain important for targeting to the Z-line. Multiple novel or rare variants of uncertain significance (MAF <0.0001 and CADD scores ≥20) in cardiomyopathy genes were identified in remaining samples highlighting the genetic heterogeneity and opportunity for novel gene discovery. Using RNA-seq data, we identified 1922 differentially expressed genes (upregulated; n=820 and downregulated; n=1102) which predicted enrichment of ERK/MAPK signaling, p38 MAPK signaling, actin cytoskeleton and adherens junction signaling (IPA™) pathways in RCM. Because aberrant splicing occurs in cardiomyopathy, we analyzed alternative splicing and differential exon usage by rMATS and DEXseq computational tools. We observed sarcomere and cytoskeleton genes, cardiac stress signaling and spliceosomal components alternatively spliced or differentially expressed in RCM. Genes involved in mRNA splicing were also identified as differentially spliced. We therefore performed rMAPS analysis for 115 RNA binding proteins (RBPs) to identify RBP motifs enriched in observed splicing events in RCM and identified *SRSF2*, *SRSF7*, *DAZAP1*, *QKI*, *RBM5* and *RBM24* as likely mediators of observed dysregulated splicing in RCM. These findings suggest that RBP-mediated disruption of splicing is a common pathogenetic mechanism irrespective of underlying genetic cause in RCM. These findings indicate that despite genetic heterogeneity, similar patterns of transcriptome dysregulation and splicing abnormalities may characterize disease pathogenesis in RCM, suggesting an opportunity for development of therapy.

## PgmNr 2727: Absence of aortic disease in *Acta2*<sup>R149C/+</sup> mice is associated with defective release of mutant smooth muscle $\alpha$ -actin from the CCT complex.

### Authors:

**Rationale:** ACTA2 encodes the smooth muscle cell (SMC) specific isoform of actin, SM  $\alpha$ -actin. Mutations in ACTA2 predispose to various vascular diseases, including thoracic aortic aneurysms and dissections (TAAD), early onset coronary artery disease (CAD), and premature stroke. The most common mutation is ACTA2, p.Arg149Cys, which accounts for 25% of all ACTA2 mutations. ACTA2 p.Arg149Cys mutation carriers present with either TAAD or CAD but rarely have both diseases. The factors dictating whether a mutation carrier has TAAD or CAD are not known.

**Objective:** The purpose of this study is to identify the molecular mechanisms dictating whether an individual with ACTA2 p.Arg149Cys has TAAD or CAD.

**Methods and Results:** We used CRISPR/Cas9 technology to generate an *Acta2* R149C mutant mouse, *Acta2*<sup>R149C/+</sup>, in a C57BL6 background. Aortas from *Acta2*<sup>R149C/+</sup> mice have decreased contraction in response to agonist stimulation compared to wildtype (WT) mice. The mutant mice do not have premature deaths when followed for 48 months and do not have thoracic aortic aneurysms as assessed by echocardiography, even when fed a high salt diet and L-NG-nitroarginine methyl ester to increase blood pressure. When crossed into an *Apoe*<sup>-/-</sup> background and fed a high fat diet, the *Apoe*<sup>-/-</sup> *Acta2*<sup>R149C/+</sup> mouse has increased atherosclerotic plaque burden in the aorta ( $p < 0.01$ ). *In vitro* studies expressing WT and ACTA2 mutants in *Acta2*<sup>-/-</sup> smooth muscle cells (SMCs) found that no SM  $\alpha$ -actin was present when mutations associated with early onset CAD are expressed despite qPCR analyses showing the mutant transcript is present at the same level as the WT transcript. Two dimensional gel electrophoresis studies confirmed reduced levels of the mutant compared to WT SM  $\alpha$ -actin in the cytoplasm in *Acta2*<sup>R149C/+</sup> SMCs. Actins are folded in the chaperonin containing t-complex polypeptide (CCT) complex, raising the possibility that the mutant actin may be retained in this complex. Immunoprecipitation of the CCT complex using CCT1 antibody followed by immunoblot analyses for SM  $\alpha$ -actin demonstrated increased SM  $\alpha$ -actin associated with the CCT complex in the *Acta2*<sup>R149C/+</sup> SMCs.

**Conclusions:** These data indicate that the *Acta2*<sup>R149C/+</sup> mice do not develop aortic disease but rather have increased atherosclerotic burden when bred into a hyperlipidemic background. Our data suggests that decreased levels of mutant versus WT SM  $\alpha$ -actin in the cytoplasm may be responsible for the lack of aortic disease in this mouse model.

## PgmNr 2728: Mutations in the prostaglandin I2 receptor gene as potential causes of fibromuscular dysplasia.

Kravis Center for Cardiovascular Health, Icahn School of Medicine at Mount Sinai, New York, NY, USA; 5) Department of Hypertension, Institute of Cardiology, Warsaw, Poland

**Background:** Fibromuscular Dysplasia (FMD) is a vascular disease characterized by non-atherosclerotic stenosis of small and medium-size arteries. FMD predominantly affects early middle-aged women and is independent of typical cardiovascular risk factors, such as age and dyslipidemia. Observation of FMD familial cases and clinical similarity with connective tissue disorders suggest inherited or spontaneous protein-coding mutations could cause FMD. However, previous re-sequencing of candidate genes was inconclusive.

**Methods and results:** We performed exome sequencing in 30 individuals including familial cases (N=21 sibs), 2 trios (N=6) and sporadic cases (N=3). Filtering for shared loss-of-function rare mutations (LoFs) among at least 2 families was negative, as was the trios filtering. We curated the results for predicted LoFs shared among sibs from the same family in genes with documented roles in vascular and smooth muscle cell biology. We identified in two sisters a shared rare LoF (rs199560500, p.Gln163Ter) in the sequence of prostaglandin I2 receptor gene (*PTGIR*), a key player in pulmonary arterial hypertension and vascular remodeling. Targeted amplicon-NGS sequencing of *PTGIR* and 19 functionally connected genes in 384 unrelated FMD patients revealed 1 additional LoF in *PTGIR* (rs199560500). Sanger sequencing of *PTGIR* in a total of 1,011 FMD patients identified *PTGIR* nonsense variants in 3 additional patients (1 with rs199560500, p.Gln163Ter, 2 with rs754755149, p.Pro17ArgfsTer6). We estimate the frequency of *PTGIR* LoF alleles to 0.25% in our FMD cohort, compared to a 0.048% estimate from Non-Finnish European populations (gnomAD database). We also identified six uncharacterized missense variants, each in one patient.

Using transient overexpression in HEK293 (human epithelial kidney) cells, we tested the ability of mutant proteins to increase cAMP concentration in response to iloprost, a prostacyclin analog. We confirmed that rs199560500 and rs754755149 nonsense variants result in fully non-functional *PTGIR* protein. All missense variants were sensitive to iloprost and mostly indistinguishable from wild-type *PTGIR*. Western Blot showed a reduced protein expression of two of the variants (rs1397542892, p.Leu67Pro and rs199969416, p.Arg137Cys), suggesting a moderate hypomorphic phenotype.

**Conclusions:** Our study shows that rare *PTGIR* mutations are a putative cause of FMD and should be taken into consideration for further clinical and biological studies.

## PgmNr 2729: High-throughput patch clamping identifies dozens of novel Brugada syndrome-associated *SCN5A* variants.

The accurate classification of variants in Mendelian disease genes is a major challenge for the successful implementation of personalized medicine. Variants in *SCN5A* are a major cause of inherited arrhythmia syndromes, including partial or complete loss of function *SCN5A* variants, which can cause Brugada Syndrome. The pathogenicity of *SCN5A* variants is often unknown or disputed; indeed, most observed *SCN5A* variants are classified as a variant of uncertain significance (VUS). The widely adopted American College of Medical Genetics and Genomics (ACMG) classification scheme includes *in vitro* functional data as a strong criterion for variant classification. Our aim was to determine the *in vitro* function of dozens of variants in *SCN5A* to improve variant classification. After a literature review of 1,712 reported *SCN5A* variants, we selected 58 variants that had not been functionally characterized (10 suspected benign and 48 suspected Brugada-associated). As a control, we also selected 12 well-characterized variants that had a range of functional defects. We generated each variant with Quikchange mutagenesis and stably expressed each variant in HEK293 cells. For each cell line, we used high-throughput automated patch clamping to measure 5 important functional parameters: peak current, late current, activation and inactivation kinetics, and recovery from inactivation. All 12 previously studied variants had functional properties similar to previously published manual patch clamp results. 9 of the 10 suspected benign variants had wildtype-like channel function. 34 of the 48 suspected Brugada-associated variants (71%) had partial or total loss of channel function. Suspected Brugada Syndrome variants that had been observed in more patients were more likely to result in loss of channel function ( $p < 0.01$ ). Applying ACMG classification criteria, 48 of 58 previously unstudied variants were reclassified with the patch clamp data, including the reclassification of 27 variants from VUS to likely pathogenic and 9 variants from VUS to benign. These results demonstrate that high-throughput *in vitro* functional characterization can identify dozens of novel *SCN5A* variants with loss of function features consistent with Brugada Syndrome. This method can reclassify *SCN5A* variants at scale and help “de-VUS” this important gene.

## PgmNr 2730: PACSIN3 is a modifier gene for hypertrophic cardiomyopathy.

Hypertrophic cardiomyopathy (HCM) is characterized by increased chamber size and reduced ejection fraction. Inherited HCM is commonly associated with mutations in sarcomeric genes, including the gene for  $\beta$ -cardiac myosin (MYH7). High variability in disease presentation and penetrance in patients with MYH7 mutations has caused some to question the single variant nature of this disease. We previously identified 96 genes with potential for modifying the HCM phenotype through a combination of MYH7 patient genome, public transcriptome, and HCM model system RNAseq analysis.

One novel potential modifier we identified is PACSIN3, which has not been previously associated with cardiac disease. PACSINs are intracellular adapter proteins that are involved in endocytosis and actin reorganization, and PACSIN3 is the muscle-enriched isoform.

To investigate the role of PACSIN3 in HCM, we analyzed PACSIN3 expression in septal myectomy tissue of a separate cohort of 39 HCM patients. PACSIN3 expression was significantly higher in HCM patients compared to 10 healthy control septae ( $p < 0.01$ ). NPPB, a marker for cellular hypertrophy, was also higher in HCM ( $p < 0.02$ ), as expected. RNA sequencing analysis of PACSIN3 knockdown (KD) in neonatal rat ventricular myocytes (NRVMs) showed downregulation of the oxidative phosphorylation pathway ( $N=4$ ,  $FDR < 1e-4$ ). PACSIN3 KD led to higher NPPB expression, indicating hypertrophy, an effect that was exacerbated by phenylephrine treatment (PE). Immunofluorescent imaging also showed that PACSIN3 KD in combination with PE increased NRVM cell size compared to PE alone. In epithelial cells, PACSIN3 was shown to be required for ectodomain shedding of HB-EGF, which stimulates cellular hypertrophy through activation of the EGF receptor. Treating NRVMs with HB-EGF in combination with PACSIN3 KD increased NPPB expression to a similar extent as control, likely bypassing the effect of PACSIN3 KD.

In conclusion, we identified PACSIN3 as a novel modifier of cardiac hypertrophy. PACSIN3 is elevated in cardiac tissue of HCM patients, while reduced levels in cardiac myocytes leads to higher NPPB expression, indicative of acute induction of hypertrophy, an effect that is further exacerbated by a hypertrophic stimulus. Induction of PACSIN3 in HCM may present a compensatory protective mechanism.

## PgmNr 2731: A deep mutational scan of *KCNE1* via a high-throughput cell-surface trafficking assay can identify functionally deleterious variants.

---

With the increase in clinical genetic testing, precision medicine faces a new challenge: rapid discovery of VUSs requires accurately classifying Mendelian disease gene variants at scale. One such gene is *KCNE1*, which encodes an accessory subunit for  $I_{Ks}$ , a potassium channel important for cardiac repolarization. Loss of function (LoF) variants in *KCNE1* can lead to type 5 long QT syndrome, a disorder associated with susceptibility to potentially fatal arrhythmias. Previous data suggest that LoF mutations in *KCNE1* either disrupt interactions with other  $I_{Ks}$  subunits, encoded by *KCNQ1*, or reduce trafficking of  $I_{Ks}$  channels to the cell surface. In this study, we conducted a deep mutational scan of *KCNE1* by generating all possible amino acid variants in the 127-amino acid long protein and assessed their trafficking in a high-throughput, multiplexed fashion. We generated a comprehensive library of coding variants in *KCNE1*, expressed them in HEK-293 cells engineered to incorporate a single variant per cell, and then tested this library with a flow-cytometry based assay to identify variants that disrupt *KCNE1* cell surface trafficking. The library tested contained 59.4% of the 2540 possible variants, and showed a bimodal distribution of cell surface *KCNE1* staining, with peaks of the distribution corresponding to wild-type and a known trafficking-deficient variant, respectively. This work successfully deployed a high-throughput trafficking assay to comprehensively interrogate large numbers of protein variants for a clinically important ion channel subunit. Our results will provide the functional information needed to supplement the American College of Medical Genetics and Genomics functional assay criterion by identifying pathogenic *KCNE1* variants, and facilitate clinical interpretation of novel variants and VUSs.

# PgmNr 2732: Cardiac $\beta$ -myosin heavy chain ( $\beta$ -MYH7) head motor domain mutations and understanding their mechanisms leading to cardiomyopathies: a structural point of view.

## Abstract

### Cardiac $\beta$ -myosin heavy chain ( $\beta$ -MYH7) head motor domain mutations and understanding their mechanisms leading to cardiomyopathies: a structural point of view

**Deepa Selvi Rani and K Thangaraj**

Mutations in cardiac  $\beta$ -myosin heavy chain gene ( $\beta$ -MYH7) are the major cause of inherited cardiomyopathies and sudden cardiac deaths (SCD), yet the molecular mechanisms for the disease have not been fully understood. Cardiac head motor domain of  $\beta$ -MYH7 is a fundamental force-generating element for muscle contraction. However, not many studies on  $\beta$ -MYH7 are carried out in Indian hypertrophic (HCM) and dilated (DCM) cardiomyopathies. Therefore, we sequenced the  $\beta$ -MYH7 in 101 HCM and 147 DCM against 207 controls and found 45 variations (including 29 novel), of which 8 missense mutations were detected in myosin head motor domain, besides 3 splice-site variations, 3 frame-shift mutations and 5 allelic-heterogeneities. When compared this data with our previous data set, we identified a rare digenic mutations in  $\beta$ -MYH7 and *TNNT2* genes, and a compound mutation in  $\beta$ -MYH7, *TMP1* and *ACTC* genes. In addition, we performed PCA for population stratification using a panel of 47 ancestry-informative markers along with Hap Map data sets to show that the cases and controls are from same ethnic background. Further, homology models were built for 8 missense mutations observed in the head motor domain of  $\beta$ -MYH7, and compared each with native structure by using several structural parameters. We found that each homology model perturbs the structure differently, and followed a unique mechanistic pathway. Interestingly, of the 8 homology models analyzed, three mutants (p.Leu510, p.His723 and p.Met431) showed comparatively high RMS deviations of  $\sim 3.4$ ,  $\sim 3.8$ , and  $\sim 3.9$  respectively. Non-bonding interactions showed that these deviations might be due to an additional aberrant hydrophobic interaction within the hydrophobic core (Leu510 with Trp508; His723 with Pro727; Met431 with Leu352) and that led to drastic deviations in their structures. Therefore, structural deviations may partake in cardiac remodeling and may alter the morphology of heart into HCM/DCM. Certainly, identifying the causative mutations and their structural mechanisms would help for pharmacogenomic studies with special emphasis laid on personalized medicine.

In the genomics era, the diagnosis and treatment of disease is becoming increasingly individualized based on a person's unique genetic signature. However, understanding the effects of rare variation, a significant contributor to human disease, remains a largely unresolved issue. Over 100,000 exomes have been gathered in GnomAD and over 4 million coding variants have been discovered to date, ~99% of which are rare. Yet, of these, just 2% have a clinical interpretation in ClinVar, the bulk of which are interpreted as variants of unknown significance. As such, we aim to develop and apply high-throughput sub-functional assays that couple a genotype to a selectable phenotype, thereby enabling the analysis of all possible coding sequence variations on a protein's function. To this end, our group employs a framework termed Deep Mutational Scanning (Matreyek *et al.*, 2017) to interrogate the function of all possible coding variation in a disease gene, thereby allowing us to understand the effects of rare, often novel, genetic variation. I am applying this method to study genes related to Coronary Artery Disease (CAD), the prevailing cause of mortality worldwide.

To do so, an input library of random codon-mutagenized coding sequences is subjected to a sub-functional assay to test the effects of each variant on protein function. The resulting post-selection library is deep sequenced using TileSeq and unmeasured variant effects are imputed using machine learning. My current focus is the study of the CHD-related genes LDLR, LDLRAP1, LRP6 and PCSK9, which function in the regulation of circulating low density lipoprotein (LDL) levels, an important marker of CAD risk. To generate variant effect maps for these genes, LDL uptake assays are adapted to high-throughput fluorescence activated cell sorting via a fluorescently labelled LDL molecule. Following CRISPR mediated knockout of the relevant gene, we observed a measurable decrease in LDL uptake, which is to be rescued by the integration of the wild-type sequence into an engineered landing pad constitutively expressed in the cell's genome. Variations of this method will be expanded to screen thousands of variants *en masse* for a number of CAD-related genes, the final maps of which can then be used to interpret the effects of previously unknown variation, potentially improving diagnosis and treatment of CAD.

## PgmNr 2734: Contribution of CPS1 gene to atherosclerosis in mice and humans.

We recently identified a variant (rs715) in the gene encoding carbamoyl phosphatase 1 (CPS1), the first committed and rate-limiting step of the urea cycle, as demonstrating sexually dimorphic associations with multiple metabolites in the pathway leading from choline to urea, particularly increased circulating glycine levels in women. Most notably, rs715 showed a striking female-specific association with decreased risk of coronary artery disease (CAD). To replicate and further investigate these findings, we examined the association of rs715 with CAD in UK Biobank and subclinical atherosclerosis in women participating in five clinical trials (ELITE, EPAT, VEAPS, WELLHART, and WISH), as well as through genetic and dietary perturbations in mouse models. We corroborated the female-specific association of rs715 with CAD in UK Biobank (OR=0.960, SE=0.016, p=0.014). In a meta-analysis of women from the five clinical trials, rs715 was associated with significantly reduced carotid artery intima-media thickness (CIMT) in a linear regression using log-transformed CIMT (beta=-0.046, SE=0.011, p=1.6x10<sup>-5</sup>, n=1430). In a mouse model of CPS1 deficiency, heterozygous knockout (CPS1<sup>+/-</sup>) mice on an AAV-PCSK9-induced hyperlipidemic background exhibited sex-specific attenuation of atherosclerosis. CPS1<sup>+/-</sup> mice had 25% reduced lesion formation (p=0.0061, n=15-18) in the aortic root and *en face* stained aorta (p=0.0118, n=4-6), and 40% reduced necrotic core area (p=0.0007, n=15-20), but these effects were primarily observed in male. As a complementary approach, we placed ApoE<sup>-/-</sup> mice on a 2.5% glycine-supplemented diet or a control diet (0.3% glycine) for 16 weeks. Glycine supplementation had no effect on aortic lesions, suggesting the cardioprotective association of decreased CPS1 activity is not due to glycine. However, our results provide further evidence for the species-sex-specific importance of CPS1 in atherosclerosis but the causal cardioprotective metabolite or biological mechanism(s) remains to be determined.

---

Cardiomyopathy is a disease of the heart muscle that leads to arrhythmias and heart failure. As the number of people diagnosed with heart failure increases, it is imperative to gain a better understanding of the genetic and environmental factors leading to cardiomyopathy. We have established a cell culture model to explore gene-environment interactions (GxE) in cardiomyocytes (CMs). We have reprogrammed lymphoblastoid cell lines (LCLs) from 6 individuals into induced pluripotent stem cells (iPSCs), which have been further differentiated into CMs. A key feature of this system is the ability to expose these cell types to the same panel of treatments to investigate cell type specific response and treatment-by-cell type interactions. To this end, we have exposed all cell lines from the 3 cell types to a panel of 28 treatments, including hormones, vitamins, environmental contaminants, and common drugs. Twelve treatments induced a significant response for hundreds of genes in at least one cell type. We identified 4,835 genes expressed in all cell types and that show evidence of treatment-cell type interactions as measured by likelihood ratio test in DESeq2 (FDR < 10%). In particular, 96% of differentially expressed genes in CMs in response to treatment with insulin are not differentially expressed in LCLs or iPSCs. These unique insulin-CM genes are enriched for cholesterol and ADP metabolic processes. To dissect the sources of gene expression variation across individuals, we used a random effects model accounting for interactions with cell-type and treatment, while taking advantage of experimental replication and accounting for other technical variables. We estimate that 64% of interindividual variation is explained by interactions with cell-type, while 34% of variation is due to interactions with treatments (potential GxE). To identify SNPs which could be responsible for these interactions in the CMs, we performed allele-specific expression (ASE) analysis. We identified 3,933 unique SNPs across all cell types displaying ASE, corresponding to 1,993 genes. When contrasting each treatment to the appropriate control, we identified 62 instances of conditional ASE (cASE) at 43 unique SNPs in 38 genes (FDR < 20%). One of these genes is *TSPAN17*, which plays a role in cardiovascular development. This and other examples show that genetic interactions with environmental exposures (treatments) have a strong contribution to inter-individual variation in health and disease.

## PgmNr 2736: MPRA-based *cis*-regulatory variant screen of QT interval GWAS variants in cardiac open chromatin elements.

Sequence variation in multiple *cis*-regulatory elements (CREs) modulating a target gene's expression is the leading hypothesis for GWAS signals in the noncoding genome. However, we require convincing experimental data to identify these causal *cis*-regulatory variants. Here, we perform a massively-parallel reporter assay (MPRA)-based screen to identify association-based CRE sequence variants at all QT interval GWAS loci. All genome-wide significant variants from the QTIGC study and common variants from the 1000 Genomes Project (EUR MAF>1%) in high LD ( $r^2>0.9$ ) with QT GWAS sentinel variants were selected ( $n=4,647$ ). These were further filtered by overlap with potential cardiac CREs for assay design ( $n=927$ ). As a control, we added all variants at the *SCN5A* GWAS locus regardless of CRE overlap ( $n=138$ ). 200-base long oligos with a 20-base 5' flank, variant-centered 129-base target sequence, 18-base spacer with EcoRI and SbfI site, 13-base unique barcode and a 20-base 3' flank were designed. Barcode sequences were designed to contain all four nucleotides and GC-content of 0.4-0.6, and further avoid microRNA seed binding sites,  $\geq 3$ -base homopolymers, the two restriction sites, and to have a minimum edit distance of two between any pair of barcodes. All sequences with additional EcoRI and SbfI sites were discarded. The final design included 1,018 variants with both alleles, each with 50 different barcodes for a total of 101,800 oligos across two equally-sized pools. Each oligo pool was cloned into lentiMPRA vector, pLS-mP, lacking the minP-eGFP reporter cassette, to generate a pre-reporter library from over 5 million clones to preserve library complexity. Paired-end sequencing was performed to check the quality of synthesized oligos and representation of individual barcodes. The minP-eGFP cassette was then cloned into the EcoRI-SbfI site of the two pre-reporter libraries to generate the final reporter plasmid libraries from over 5 million clones each. The two libraries are transfected into the mouse cardiomyocyte cell line HL1 in 10 parallel replicates, each with 5 million cells and cells harvested two days post-transfection to generate input plasmid- and reporter cDNA-based Illumina libraries to sequence the barcodes and assess allele-specific reporter activity. We expect our MPRA screen to not only identify causal variants underlying QT interval GWAS signals but also to serve as an experimental validation of putative CRE and predicted variant effect on CRE function.

## PgmNr 2737: Investigating clinical, socio-demographic, and genetic associations of 26 targeted kidney dysfunction-related variants among sickle cell patients from Cameroon.

---

**Background:** Renal failure is one of the leading causes of morbidity and mortality among sickle cell disease (SCD) patients. Several genetic factors are associated to renal failure, however there are limited studies in this field particularly for SCD patients in Africa.

**Objective:** To investigate the prevalence of 26 genetic variants, clinical and socio-demographic variables associated with kidney dysfunction for a group of SCD patients in Cameroon.

**Methods:** SCD patients were recruited in Yaoundé and Douala main hospitals. Socio-demographic and clinical features, anthropometric variables, blood pressure, hematological indices, creatinine, and crude albuminuria were measured. Estimated glomerular filtration rates (eGFR) were calculated using the CKD-EPI-creatinine and Schwartz formula. Kidney dysfunction was defined as an eGFR < 90 ml/min per 1.73 m<sup>2</sup>. Participants were genotyped for 26 kidney dysfunction-related gene-variants. Linear regression frameworks were designed in R to elucidate associations between gene variants and eGFR / microalbuminuria.

**Results:** A total of 413 SCD steady-state patients were studied. The median age was 15.5 years range (2 – 58) with 51% male. Sixty-one percent of these patients had micro-albuminuria, 2.4% proteinuria, 36% with glomerular hyperfiltration and 28% renal dysfunctions. Twenty-seven percent had both micro-albuminuria and kidney dysfunctions. In a simple regression model, considering only genetic factors, 22 and 23 variants out of 26 were significantly associated with micro-albuminuria and eGFR respectively. However, in a multi-variable model when combining clinical and socio-demographic factors with genetic variants, only the *Signal Induced Proliferation Associated 1 Like 3* (*SIPA1L3-rs11666497*) and *Uromodulin* gene variant (*UMOD-rs4293393*) were found to be significantly associated with eGFR with P-values of 0.04359 and 0.04091, respectively.

**Conclusion:** These results confirmed a high proportion of micro-albuminuria, among Cameroonian children and adolescents living with SCD. The study identified *rs4293393* in *Uromodulin* and

*rs11666497* in *SIPA1L3*, as key risk factors for chronic kidney diseases in SCD patients. These results demonstrate the need for further research to evaluate the feasibility of using multifactorial models (genetic, clinical and sociodemographic) for kidney dysfunction risk assessment in African populations.

## PgmNr 2738: Novel *de novo* *CUL3* mutation results in altered function of Cullin-RING E3 ubiquitin ligase and associated with a rare form of hypertension.

---

Hypertension is a principal risk factor for cardiovascular diseases such as heart failure and stroke. Pseudohypoaldosteronism type II (OMIM 614496, PHA2E) is a rare Mendelian form of hypertension caused by the imbalance between renal salt reabsorption and K<sup>+</sup> and H<sup>+</sup> excretion resulting in hyperkalemia and metabolic acidosis. Rare mutations in *CUL3* have been associated with PHA2E. *CUL3* (Cullin-3), a critical subunit of the multi-subunit CUL3-Ring-Ligase (CRL3) ubiquitin ligase complex, acts as a scaffold protein. It recruits ubiquitin-loaded E2 (Ub-E2) conjugating enzyme and adaptors in order to facilitate ubiquitination of substrates including With-no-lysine (K) kinases (WNKs), which control potassium homeostasis and blood pressure by regulating the activity of Na<sup>+</sup>Cl<sup>-</sup> cotransporter (NCC) along the distal convoluted tubule of the kidney. The activation of CRL3 to ubiquitinate substrates requires flexibility in the structure, which is introduced by the covalent attachment of Nedd8 (neddylation). CRL3 activation is readily reversed by the action of the COP9 signalosome (CSN) complex. Here we report a child with a novel *de novo* heterozygous mutation (NM\_001257198.1: c.1435\_1446del; p.F480\_M483del) in *CUL3* who presented with elevated serum potassium without renal tubular acidosis, short stature, global developmental delay, and frequent pulmonary and gastrointestinal infections. Extensive clinical and biochemical phenotyping also revealed glycosylation abnormalities. Functional analysis utilizing patient-derived dermal fibroblasts demonstrated increased neddylation and reduced levels of *CUL3* protein. Transient over-expression analysis in human embryonic kidney (HEK) cells suggested altered recycling of mutant *CUL3*, mediated by the catalytically active subunit of CSN. Consequently, the ubiquitination of WNK1 is increased, resulting to reduced steady-state levels. We thus hypothesize that pF480\_M483del mutation affects the function of CRL complex leading to altered ubiquitination of substrates. These findings support the role of the pF480\_M483del mutation in *CUL3* in hyperkalemia and hypertension.

## PgmNr 2739: 100,000 Genomes Project identification and validation of a novel pathogenic variant in *GDF2* (BMP9) responsible for hereditary hemorrhagic telangiectasia and pulmonary arteriovenous malformations.

---

Hereditary hemorrhagic telangiectasia (HHT) is a multisystemic vascular dysplasia inherited as an autosomal dominant trait, and characterized by arteriovenous malformations (AVMs), mucocutaneous telangiectasia and nosebleeds. HHT is caused by a single pathogenic null allele in *ACVRL1*, *ENG*, or *SMAD4*. These genes encode proteins mediating bone morphogenetic protein (BMP)9 signaling. Although three variants identified in the *GDF2* gene encoding BMP9 were reported to cause a vascular anomaly syndrome similar to HHT, none meet ACMG-AMP Guideline criteria for pathogenicity, and no *GDF2* variants have been identified to date in *ENG/ACVRL1/SMAD4*-negative HHT families across the VASCERN HHT European Reference Network. Genomics England protocols were followed for the nomination of HHT, generation of a data model based on human phenotype ontology terms, development of a PanelApp HHT gene panel, and recruitment of HHT families from NHS Genomic Medicine Centres across the UK. Whole genome sequencing and tiering protocols identified a novel, heterozygous *GDF2* sequence variant in all three affected members of an HHT family. All had nosebleeds and typical HHT telangiectasia, and one (with severe pulmonary AVMs) had previously screened negative for *ENG*, *ACVRL1* and *SMAD4*. No other *GDF2* variants were identified in more than 100 *ENG/ACVRL1/SMAD4* negative probands with HHT or pulmonary AVMs. As part of the Respiratory GeCIP (Clinical Interpretation Partnership) subdomain established specifically to analyse HHT WGS data, the variant was introduced into a human BMP9 expression construct by site-directed mutagenesis and transfected into 293T cells. Conditioned media was collected for ELISA and western blotting. BMP9 is synthesized as a pro-protein that then dimerizes and is cleaved to produce the mature secreted protein. Western blotting showed the mutant construct expressed the pro-protein but lacked mature BMP9 dimer, suggesting the mutation disrupts correct cleavage of the protein. ELISA confirmed that mature BMP9 was undetectable in the conditioned media from the mutant construct compared to WT. Furthermore, conditioned media from the mutant construct failed to upregulate BMP-induced target genes in cultured endothelial cells. Analysis of circulating BMP9 levels in plasma from affected and unaffected family members is currently underway. In conclusion, we propose that heterozygous inheritance of this *GDF2* variant is a rare cause of HHT associated with pulmonary AVMs.

## PgmNr 2740: Mitonuclear discordance in 22q11 deletion syndrome admixed patients.

**Authors:**

---

Chromosome 22q11.2 deletion syndrome (22q11DS) has an incidence of 1 in 4,000 and it accounts for ~2% of congenital heart disease (CHD) cases. Most patients share the same deletion, but show wide variation in phenotypic manifestations. For example, CHD is present in 50-60% of 22q11DS cases. There are six nuclear-encoded mitochondrial genes within the deleted region. Mitochondria have their own genome (mtDNA) containing only 37 genes. The remaining mitochondrial genes are nuclear-encoded, prompting the cell to coordinate both genomes to guarantee proper function. Differences in the genetic background for the mtDNA and nuclear genes (mitonuclear discordance, MND), obtained from crossing model organisms, have been shown to impact mitochondrial function. However, whether these incompatibilities naturally exist and contribute to phenotypic variation in humans is currently unknown. Admixed latinos present a great opportunity to study MND, since the mtDNA is predominantly of Native American (NAT) origin, and their nuclear genome reflects a gradient of Native American, European (EUR) and African (AFR) components.

We are interested in the genetic determinants of CHD in 22q11DS patients, so we evaluated the contribution of MND to the cardiac phenotype. We compared 145 22q11DS patients genotyped with the Affymetrix SNP 6.0 platform: 81 cases of CHD and 64 controls. We calculated the mtDNA haplogroup and the global Native American, European, and African ancestry of each patient. We defined global MND as the proportion of the nuclear ancestry not represented by the mtDNA ancestry. We found no statistical evidence to relate Native American haplogroups or global mitonuclear discordance to CHD in our cohort. We concluded that CHD might not be related to global mitochondrial genomic variation in 22q11DS admixed Chileans.

## Background

Current cigarette smoking (CS) has profound transcriptomic effects and is a risk factor for many diseases. Cells use post-transcriptional RNA processing mechanisms to respond rapidly to environmental stresses, such as oxidative stress caused by CS. However, post-transcriptional changes induced by CS exposure have not been studied on a genome-wide level.

## Methods

To assess changes in isoform usage induced by CS, we analyzed blood RNA-seq data from 1,221 current and former smokers in the COPDGene Study. We estimated isoform abundance using the pseudoalignment method implemented in the Salmon program, and we also performed analysis to detect differential exon usage using limma. For 125 genes with significant evidence of differential expression or usage, confirmation of these results was performed via PacBio long read RNA sequencing (Iso-Seq) from three COPDGene current and former smokers.

## Results

We identified 1,062 isoforms in 891 genes with evidence of differential usage and 10% FDR in current versus former smokers (i.e. usage = significantly different fold change relative to all other expressed isoforms of a gene). 426 isoforms showed evidence of increased usage as opposed to 636 with decreased usage. We observed a systematic tendency for up-used isoforms to be the longest isoform for a given gene, and this length difference was largely accounted for by the 3' untranslated regions (UTRs) which were significantly longer in up-used isoforms (median length = 1125 nucleotides) than both down-used and non DIU isoforms (median lengths = 617 and 666, respectively,  $p < 0.05$  for both). Exon-level confirmed these results and demonstrated that for genes where CS induced 3' UTR lengthening, the effect was to decrease overall expression levels. We also observed that up-used 3' UTRs were enriched for both polyadenylation and micro-RNA binding sites. To validate a subset of these findings, we used targeted long-read sequencing (ORF Capture-Seq). With a single Sequel 1M SMRT cell, we obtained 488 on-target transcripts representing 73 of 125 targeted genes. We observed 138 annotated and 215 novel isoforms, with 83% concordance between the dominant isoform in long read and short read data from the same samples.

## Conclusions

CS exposure causes widespread lengthening of the 3' UTR via usage of alternative polyadenylation sites, resulting in acquisition of novel micro-RNA binding sites with a tendency towards lower overall

expression of these genes.

## PgmNr 2742: Integrated Hi-C, ATAC-Seq, and RNA-seq studies in bronchial epithelial cells (BECs) identifies both known and novel asthma candidate genes.

---

Asthma is a complex disease with an estimated 50% heritability. Although GWASs have identified over 60 asthma-associated loci, most SNPs at these loci are in non-coding regions and the relevant gene(s) remain unclear. Because BECs are a central cell type in asthma pathogenesis, we focused our studies in these cells to: 1) Identify differentially expressed genes (DEGs) and differentially accessible chromatin (DACs) between cells from asthmatic and non-asthmatic individuals, 2) Map functional interactions between DEGs and DACs using promoter capture Hi-C, and 3) Assess transcriptional and epigenetic patterns at known asthma loci and identify novel biological pathways. BECs were obtained from donor lungs from the Gift of Hope Regional Organ Bank of Illinois that were not used for transplant. Cultured cells from 18 donors (9 with asthma, 9 without asthma) were used for ATAC-seq and RNA-seq, and freshly isolated BECs pooled from 8 donors were used for promoter capture Hi-C. We first identified 1,907 DEGs and 2,655 DACs at an FDR  $\leq 0.05$ . Next, we mapped all predicted Hi-C chromatin interactions (loops) between gene promoters and DACs. Overall, there were 9,473 physical interactions between gene promoters and DACs, of which chromatin accessibility and transcript levels were significantly correlated for 1,015 DAC-promoter pairs, corresponding to 443 unique genes (Spearman FDR  $\leq 0.05$ ). Of these unique genes, 124 were also differentially expressed between asthmatics and non-asthmatics and formed 261 significantly correlated DAC-DEG pairs (Spearman FDR  $\leq 0.05$ ). These included genes at known asthma loci (e.g. *CCL20* on chromosome 2q36.21 and *TSLP* on chromosome 5q22.1), as well as genes not previously implicated in asthma (e.g., *FAM131C* on chromosome 1p36.13 and *IL4I1* on chromosome 19q13.33). Gene ontology (GO) analysis was performed using ToppGene's ToppFun-functional analysis tool to determine the functional categories enriched in these 124 genes. The top GO terms included fluid shear stress, cell migration and motility and response to vitamin E. In summary, combining multi-omic data from RNA-Seq, ATAC-Seq and Hi-C from a relevant asthma cell type yielded a set of asthma candidate genes and genomic regions implicated in their regulation, and provides a strategy for assigning genes with function in BECs to GWAS loci.

## PgmNr 2743: A meta-analysis of gene expression profiles in hypertensive African American women and mice.

---

Hypertension is a major risk factor for cardiovascular and cerebrovascular diseases, including heart failure, atherosclerosis, and stroke. Over 85 million people in the United States live with hypertension and African Americans (AAs) have the highest prevalence. Nearly 50% of AA women will be diagnosed with hypertension at some point in their life, however, few studies examine how hypertension develops and affects this population. Our goal is to understand how differential gene expression (DGE) contributes to hypertension health disparities in AA women. DGE is considered an important contributing factor to the predisposition or pathology of diseases. Previously, our lab found that mRNAs are differentially-expressed in AA women with hypertension and differentially-expressed microRNAs (miRNAs) play a regulatory role governing these gene expression patterns. For this follow-up analysis, we hypothesized that comparing our previous datasets of gene expression in AA women with hypertension with gene expression datasets in different animal models of hypertension, might identify an overlap of mRNA or miRNA genes, suggesting their importance for hypertension. For this meta-analysis, we compared a microarray examining DGE in peripheral blood mononuclear cells isolated from AA and white women with hypertension (n=6/group) and compared this with a microarray of DGE in endothelial cells, isolated from the left coronary artery of mice with induced shear stress (n=6/group). We found that DGE of 13 mRNAs overlapped between human and mouse, including *PPP1R16B*, *GADD45A*, *ADAM15*, *ICAM15*, *SNN*, *BIRC3*, *FBXO34*, *ICK*, *STX6*, *HMGB2*, *CALML4*, *SIVA1*, and *EHBP1L1*. We also identified an overlap of 4 miRNAs, miR-19b-1-5p, miR-103a-2-5p, miR-20a-5p, and miR-30c-5p, between our human and mouse datasets. We used cut-off values of  $P < 0.05$ , an absolute value in fold-change  $\geq 1.5$ -fold, and an FDR or 0.3 to identify significant genes. We predicted miRNA binding within the 3' untranslated region (UTR) of each mRNA identified using the TargetScan database (v7.2). These four miRNAs are predicted to target *FBXO34*, *ICK*, *STX6*, and *CALML4* in human and mice and may contribute to their differential expression. We intend to validate the expression of these mRNA-miRNA pairs in hypertension physiology. In conclusion, we identified 13 mRNAs and 4 miRNAs that overlap between human and mouse which could play an important role in hypertension in AA women.

## PgmNr 2744: Unraveling regulation of *FOXF1* expression and lung transcriptome perturbations in patients with ACDMPV.

---

Alveolar capillary dysplasia with misalignment of pulmonary veins (ACDMPV) is a rare neonatal lethal lung developmental disorder featuring severe respiratory failure and refractory pulmonary hypertension (PAH). The vast majority of ACDMPV cases are sporadic and causative heterozygous SNVs or CNV deletions involving *FOXF1* or its distal lung-specific enhancer on 16q24.1 have been identified in 80-90% of ACDMPV patients. *FOXF1* is a forkhead family transcription factor, expressed in mesoderm-derived cells in response to SHH signaling mediated by *GLI2*. Interestingly, knockout mice for lncRNA *Fendrr*, which maps 1.5 kb upstream to *Foxf1* in the opposite orientation and likely utilizes the same bi-directional promoter, die due to cardiopulmonary anomalies. We studied transcriptomes in fetal lung-derived cell line IMR-90 depleted of *FOXF1*, *FENDRR*, or genes encoding transcription factors predicted by ChIP-seq to bind the *FOXF1* enhancer, using CRISPR/Cas9 or RNAi. We found that *TFAP2C* positively regulates expression of *FOXF1* and that *FENDRR* weakly suppresses expression of *FOXF1*, whereas *FOXF1* strongly promotes *FENDRR* expression. To further expand our previous ACDMPV and *Foxf1*<sup>+/-</sup> mouse transcriptome microarray studies (PMID: 24722050), and to identify additional genes downstream of *FOXF1*, we also performed comparative RNA-seq analyses of lung transcriptomes in ACDMPV neonates with pathogenic *FOXF1* loss-of-function variants and neonatal lung controls. In addition, we compared lung transcriptome perturbations in newborns with ACDMPV vs. acinar dysplasia and congenital alveolar dysplasia due to pathogenic variants in *TBX4* or *FGF10* (PMID: 30639323). We identified 39 genes with a statistically significant deregulation of their expression, including *GREM1* known to play a role in the pathogenesis of PAH and linked to pulmonary fibrosis (PF) and lung adenocarcinoma, *AVPR1A* expressed in vascular smooth muscles, *PDE2A* and *TTN* misregulated in pulmonary edema, *PLA2G4F* and *DIO2* associated with PF, and *CSH2*, *HOXD9*, and 21 other genes linked to lung cancer (abnormal cell proliferation, apoptosis, and epithelial-mesenchyme transition). Overall, our analyses provide insight into complex *FOXF1* regulation, confirm our previous microarray-based findings, and contribute to a better understanding of the differences between SHH-*FOXF1* and *TBX4*-*FGF10* signaling pathways in lung development.

## PgmNr 2745: The influence of poverty on gene expression in African Americans in HANDLS.

---

Socioeconomic status (SES) and other social determinants of health, including access to health care and nutritious food, correlates with health inequalities and contribute to health disparities. For example, African American (AA) men living below poverty in Baltimore City have a higher incidence of cardiovascular-related mortality when compared to either white males or AA females living below poverty. Previous studies in our laboratory and elsewhere suggest that environmental conditions are associated with differentially-expressed genes in white blood cells and this may contribute to the onset of diseases in the immune or cardiovascular systems. Differential gene expression (DGE) patterns observed in our laboratory have been associated with hypertension and cardiovascular disease and correlate with race and gender. However, no studies have investigated how poverty status affects DGE between male and female AAs and whites living in Baltimore City. We examined DGE in 54 AA and white participants of the Healthy Aging in Neighborhoods of Diversity across the Life Span (HANDLS) cohort, who are living above or below 125% of the 2004 federal poverty line. We performed a microarray to assess DGE patterns in peripheral blood mononuclear cells (PBMCs) from these participants. We identified genes related to tumor necrosis factor signaling (TNF), antigen processing and presentation, NF-kB signaling, toll-like receptor signaling, and other inflammation-related pathways that were differentially-expressed in our cohort, particular in AA males living below poverty. There were 1,616 genes differentially-expressed between AA men and women living in poverty. African American males living in poverty had 229 differentially expressed genes compared with AA men living above poverty, of which 46 were up-regulated and 183 down-regulated. We performed gene expression validation using RT-qPCR of target genes *CD36*, *KCTD12*, *DUSP2*, and *GIMAP1* to confirm our microarray results and validate the presence of DGE in AA men living in poverty. This study will serve as a link to clarify the social determinants responsible for health disparities and determine if poverty status influences gene expression in the immune system. The identification of the biological mechanisms linking poverty to health disparities can potentially improve health outcomes for populations at a higher risk for mortality or other cardiovascular-related diseases in disparate communities.

---

**Background.** Genome-wide association studies (GWAS) have identified 100s of loci associated with coronary artery disease (CAD) and blood pressure (BP)/hypertension. Many of these loci are not associated with traditional risk factors, nor include obvious candidate genes, complicating their functional characterization. We hypothesized that many GWAS loci associated with vascular diseases modulate endothelial functions. Endothelial cells play critical roles in regulating vascular homeostasis (e.g. selective barrier, inflammation, hemostasis, vascular tone) and endothelial dysfunction is a hallmark of atherosclerosis and hypertension.

**Results.** We generated an integrated map of gene expression (RNA-sequencing), open chromatin regions (ATAC-sequencing), and 3D interactions (Hi-C) in resting and TNF $\alpha$ -treated human endothelial cells. We showed that genetic variants associated with CAD and BP are enriched in open chromatin regions identified in endothelial cells. We used physical loops identified by Hi-C to link open chromatin peaks that include CAD or BP SNPs with the promoters of genes expressed in endothelial cells. This analysis highlighted 991 combinations of open chromatin regions-gene promoters that map to 38 CAD and 92 BP GWAS loci. At a CAD locus, we validated one of these pairs by engineering a deletion of the TNF $\alpha$ -sensitive regulatory element using CRISPR/Cas9 and measuring the effect on the expression of the novel CAD candidate gene *AIDA*.

**Conclusions.** Our data support an important role played by genetic variants acting in the vascular endothelium to modulate inter-individual risk in CAD and hypertension.

## PgmNr 2747: DNA methylation changes in newborn leucocyte: The mechanisms and the prediction of hypoplastic left heart syndrome.

### Authors:

---

**Purpose:** Hypoplastic Left Heart Syndrome (HLHS) is a severe Congenital Heart Defect (CHD characterized by aberrant development of the left ventricle and its outflow tract). It accounts for 1.4 to 3.8% of all CHDs. While volume of blood flow through the left heart and outflow tract is important, the molecular pathogenesis of HLHS remains largely unknown. Epigenetic changes reflect the impact of the environment on the genome and is an important mechanism for the control of transcription. We investigated the epigenetic changes (DNA methylation) associated with non-syndromic HLHS by the analysis of newborn leucocyte DNA. In addition, we evaluated the diagnostic accuracy of methylation of cytosine (CpG) biomarkers for HLHS detection.

**Methods:** Genome wide methylation profiling was conducted using Illumina Methylation assay in 24 HLHS subjects and matched controls using newborn heel-stick blood. Differential methylation analysis of individual CpG loci in cases versus controls was performed using “GenomeStudio” followed by Principal Component Analysis (PCA), heatmap, regression analysis, Area Under the Receiver Operating Characteristic Curve (AUC) using various “R” packages (v3.4). Pathway analysis was performed using Ingenuity Pathway Analysis (IPA) tool.

**Results:** 512 differentially methylated CpGs (1.5-fold or higher change in methylation in cases versus controls and Benjamini-Hochberg FDR  $p < 0.05$ ) in 557 genes were identified. In terms of individual predictive accuracy, 141 CpGs (153 genes) had excellent predictive accuracy ( $AUC \geq 0.90$ ) for HLHS detection. We identified statistically significant CpG methylation differences with HLHS in multiple genes previously known to play a role in heart developmental: *JARID2*, *MEF2A*, *MEF2C*, *RICTOR*, *IRX3* and *EP300*. Significant methylation changes were also identified in novel genes not previously linked to CHD. Known pathways such as TGF- $\beta$ , VEGF and Hypoxia signaling were identified to be dysregulated due to methylation of candidate genes. These pathways were previously established to be critical to cardiovascular morphogenesis.

**Conclusion:** We present the first genome-wide DNA methylation analysis in newborn HLHS subjects. In addition analysis was performed non-invasively using newborn blood. Epigenetic dysregulation was found to play a significant role in HLHS with DNA methylation changes in cardiac developmental genes. Finally, blood epigenetic markers appeared to accurately predict the presence of HLHS in the newborn.

## PgmNr 2748: Epigenome wide association study (EWAS) identifies *KDM4B* as a potential mediator of the link between psychosocial stress and cardiovascular disease.

### Authors:

R. Jiang<sup>1</sup>; L.C. Kwee<sup>2</sup>; J.W. Abdulrahim<sup>2</sup>; A. Singh<sup>1</sup>; B.H. Brummett<sup>1</sup>; M.A. Babyak<sup>1</sup>; I.C. Siegler<sup>1</sup>; R.B. Williams<sup>1</sup>; W.E. Kraus<sup>2,4</sup>; E.R. Hauser<sup>2,3</sup>; S.H. Shah<sup>2,4</sup>

### Affiliations:

1) Department of Psychiatry and Behavioral Sciences, Duke Univ Med Ctr, Durham, NC; 2) Duke Molecular Physiology Institute, Duke Univ Med Ctr, Durham, NC; 3) Department of Biostatistics and Bioinformatics, Duke Univ Med Ctr, Durham, NC; 4) Department of Medicine, Duke Univ Med Ctr, Durham, NC

**Introduction.** Psychosocial stress has been associated with cardiovascular disease (CVD) risk factors and outcomes. Epigenetic changes such as DNA methylation may be a potential mechanism to account for this association, namely that stress induces epigenetic changes which ultimately lead to increased CVD risk. Thus, we performed an epigenome-wide study (EWAS) for stress measures and then determined if differentially methylated CpG sites resulted in increased CVD risk.

**Methods.** The discovery cohort consisted of individuals enrolled in the CATHGEN cardiovascular study (N=845) and a validation cohort consisting of individuals enrolled in the Duke Caregiver study (N=285). Methylation profiling was performed with one of two Illumina methylation arrays: the 450K or EPIC arrays. Stress measure was previously constructed and validated, consisting of a sum of scores (0-5) of chronic psychosocial stress based on the availability of five components in both cohorts. METAL package was used for meta-analysis of the two different arrays within each study, only including CpG sites represented in both arrays. Individual CpG were tested for association with the composite stress measure using linear regression model, adjusted for age, gender, race and batch effects. CpG sites significantly associated with this stress measure in both cohorts were then tested as methylQTL using whole blood gene expression array data in CATHGEN, and further tested for association with incident myocardial infarction (MI) or death using Cox proportional hazards models in CATHGEN.

**Results.** Fifty-two CpG sites were differentially methylated for the composite stress measure ( $p < 0.0001$ ) in CATHGEN; one of these validated in the Caregiver study ( $p < 0.05$  and same direction of effect): cg23839891 (*KDM4B*). This site didn't have a significant methylQTL. Greater methylation at cg23839891 was associated with higher risk of death or MI ( $P = 0.04$ ). *In silico*, this site was shown to be in a DNase I hypersensitivity site in 24 cell types.

**Conclusions.** Using an EWAS approach for a composite measure of chronic psychosocial stress, we have identified a differentially methylated, potentially functionally relevant CpG site in the *KDM4B* gene that also predicts increased risk for incident CVD events. *KDM4B* encodes lysine demethylase 4B which is involved in chromatic regulation and thus is a good biological candidate for linking psychosocial stress and CVD disease.

## PgmNr 2749: WASF2 differential gene expression and its link to hypertension health disparities.

### Authors:

M. Arkorful <sup>1</sup>; A. Hewwit <sup>2</sup>; N. Arnold <sup>1</sup>; N. Noren Hooten <sup>2</sup>; Y. Zhang <sup>3</sup>; M.K. Evans <sup>2</sup>; D. Dluzen <sup>1</sup>

---

The prevalence of hypertension in African Americans (AA) in the US is among the highest in the world, where almost half of all AA women in the US have high blood pressure. Previous data from our laboratory suggest that differential gene expression (DGE) of *WASF2* may have a role in hypertension-related disparities in AA. *WASF2* forms a multiprotein complex that plays a role in the signaling of the actin cytoskeleton, influencing changes in cell shape, motility, or function, and has never been associated with hypertension pathology. The actin cytoskeleton, composed of actin filaments, is responsible for cell migration, and controlling the shape of the cell. The actin cytoskeleton in the endothelium provides a barrier which allows the cells beneath the endothelium to respond to environmental cues and make structural changes. Variation in the gene expression levels of *WASF2* may influence cardiovascular diseases, such as hypertension or atherosclerosis, and may be exacerbated by social determinants of health including factors like socioeconomic status and stress in the environment. We found that DGE of mRNAs and microRNAs (miRNAs) in peripheral blood mononuclear cells (PBMCs) isolated from AA and white women with or without hypertension were involved in hypertension-related pathways that were differentially-expressed by race and may contribute to predisposition to hypertension. Because of its effect on cell shape and function, we hypothesized that DGE of *WASF2* is involved in endothelial dysfunction in hypertension. *In silico* miRNA target prediction suggested that miRNA miR-1253 is involved in the expression of *WASF2* mRNA and protein. miR-1253 mimics were transfected into HUVECs and HAECs and *WASF2* mRNA and protein levels were significantly repressed ( $P < 0.05$ ), confirming miR-1253 regulates *WASF2* expression. Currently, we are performing experiments to confirm the downstream impact of this regulatory pathway on endothelial cell cytoskeleton function, and validate the miR-1253 binding site in the *WASF2* 3' UTR. Discovery of additional miRNAs which are involved in disparate diseases will provide more options for treatment and help to combat hypertension disparities, particularly in communities most at risk.

## PgmNr 2750: Multi-omics analysis identify microRNAs associated with cardiometabolic traits.

**Introduction:** MicroRNAs (miRNAs) are non-coding RNA molecules that regulate gene expression. Extensive research has explored the role of miRNAs in the risk for type 2 diabetes (T2D) and coronary heart disease (CHD) using single omics data, but much less using multi-omics data.

**Methods:** We aimed to link miRNAs with cardiometabolic traits by integrating multiple omics layers, including genomics, epi-genomics and miRomics. First, using publicly available summary statistics from large genome-wide association studies we sought genetic variants in miRNA-related sequences associated with cardiometabolic risk factors and diseases, including lipid and obesity-related traits, glycemic indices, blood pressure, and disease prevalence of T2D and CHD. Second, we used DNA methylation (N=1450) and miRNA expression data (N=2000) measured in blood from the population-based Rotterdam Study to further investigate the link between associated miRNAs and cardiometabolic traits.

**Results:** After correcting for multiple testing, 202 genetic variants annotated to 71 independent miRNAs were associated with the studied cardiometabolic traits. Alterations in DNA methylation levels of CpG sites annotated to 39 of these miRNAs were associated with the same trait. Moreover, we found that plasma expression levels of 6 of the 71 identified miRNAs were also associated with the same trait. Integrating the results of different omics data showed miR-148a, miR-125b and miR-100 to be strongly linked to lipid traits.

**Conclusion:** Our multi-omics analysis demonstrates multiple miRNAs associated with cardiometabolic risk factors that might be important regulators of biological processes involved in T2D and CHD. The identified miRNAs could be considered as candidate biomarkers for early diagnosis and progression of these cardiometabolic diseases.

## PgmNr 2751: Integration of DNA sequencing and transcriptome data for association analyses of rare variants and lipid traits.

Leveraging comprehensive regulatory knowledge, transcriptome-wide association studies utilize GWAS data to showcase their improved statistical power of identifying gene-trait associations and importantly, offer further biological insights. Comparing to common variants, the findings for rare variants are limited and their underlying role in regulating gene expression is not totally clear. To fill in the gaps, we integrate whole genome sequencing data with transcriptome data for rare variants. Using data from Framingham Heart Study, we demonstrate that rare variants play an important and universal role in predicting gene expression, which is not completely due to linkage disequilibrium with the nearby common variants: the variation of gene expression of more than 6,000 genes can be explained by rare variants and around 1,500 of which cannot be explained well by common variants. Moreover, by including rare variants, in addition to common variants, the predictivity for 79% of the examined genes has a trend to increase. Incorporating this functional genomics information, we perform association testing for five lipid traits in two UK10K cohorts by hypothesizing that cis-eQTLs, including RVs, are more likely to be susceptible. We discover two genes, *LDLR* and *TTC22*, that are genome-wide significantly associated with low-density lipoprotein cholesterol among 3,910 subjects and are ignored by analysis of common variants. We further demonstrate that a joint analysis of both common and rare variants identifies association signals that would be missed by testing on either common variants or rare variants alone.

## PgmNr 2752: Investigation of gene-gene interactions in cardiac diseases and fatty acids in LURIC.

Epistasis analysis elucidates the genetic effects of interactions between multiple loci for understanding complex traits. However, the large computational demands and the high multiple testing burdens impede their discovery. Here, we illustrate the utilization of two methods, main effect filtering based on individual GWAS results, and biological knowledge-based modeling through Biofilter, to reduce the number of testing interactions among Single nucleotide polymorphisms (SNPs) for 15 cardiac-related diseases and 14 fatty acids. We performed interaction analyses using the two filtering methods, adjusting for age, sex, BMI, Waist-Hip ratio, and principal components, among 2,824 samples from Ludwigshafen Risk and Cardiovascular Health Study (LURIC). Using Biofilter, one interaction was nearly Bonferroni significant: an interaction between *XRCC4* (rs7735781) and *XRCC5* (rs10804247) was identified for venous thrombosis with a Bonferroni-adjusted likelihood ratio test (LRT)  $p$ : 0.0627. The protein complex from *XRCC4* and *XRCC5* functions as the DNA ligase in the repair of double-strand DNA breaks and the completion of V(D)J recombination in the development of the lymphocytes. Lack of *XRCC4* expression would lead to the dysfunction in the development and homeostasis of hormones. A total of 429 interactions were identified from the main effect filtering for different diseases (10) and fatty acids (419) at Bonferroni-adjusted LRT  $p < 0.05$ . For diseases, the top interactions between *SNTG1* (rs1383819, rs12547263, and rs2467203) and gene close to rs1493939 or rs1389542 are associated with the history of arterial hypertension. *SNTG1*, a member of the syntrophin family, relates to idiopathic scoliosis which promotes the development of cardiac disease and pulmonary hypertension. For fatty acids, the top interactions between *KCND3* (rs4839193 and rs11102365) and an unknown gene close to *LOC107984022* (rs10829717) with Bonferroni-adjusted LRT  $p$  close to 0.00002 are both associated with linolelaidic acid (C18 2n6tt), an omega-6 trans fatty acid. *KCND3* is a part of the voltage-gated potassium channel which is widely expressed for regulating neurotransmitter functions, heart rate, and muscle contraction. Here, we successfully applied filtering approaches to identify numerous genetic interactions related to cardiac-related diseases and traits. These filtering methods offer the potential to detect epistasis in other common diseases and traits by overcoming the multiple testing burden.

## PgmNr 2753: Mendelian randomization of plasma transcriptome and proteome identify genes associated with blood pressure.

Despite Genome Wide Association Studies (GWASs) of blood pressure (BP) traits detecting numerous associations, it remains a challenge to identify the causal biological mechanisms that explain these. Therefore, we carried out Mendelian Randomisation (MR) study to identify molecular (gene expression and protein expression levels) causes of BP variation that could then be used to identify genes involved in the regulation of BP.

We used two-sample MR with summary data from GWAS of plasma expression quantitative trait loci (eQTLs) on blood pressure sourced from the eQTL-Gen Consortium (n = 31,684 samples) and of plasma protein quantitative trait loci (pQTLs) from five recent pQTL GWAS (Zheng et al, n ~3,000 samples) as the genetic instruments. Summary results from a GWAS of SBP and DBP undertaken in the UK Biobank were used as genetic instrument-outcome data (sample 2). MR estimates were calculated either using Wald Ratios (WR) or Inverse Variance Weighted (IVW) method if multiple QTL instruments were available. Top MR findings were determined using a multiple testing threshold of  $P < 3.64 \times 10^{-6}$  (13,725 independent tests). Sharing of the same causal variant between the gene expression and blood pressure traits in the genomic region was verified by colocalization analysis. MR analysis was performed using the TwoSample MR R package and colocalization using the coloc R package.

Of the 65,424 MR tests across 15,353 genes, 339 gene and 131 protein expression associations with DBP or SBP passed the multiple threshold correction. We found two gene-blood pressure associations, *MST1* and *TIE1*, were supported by evidence from both eQTL and pQTL analyses. *MST1* was associated with DBP only (eQTL WR  $\beta = -0.085$ , SE=0.017,  $P = 4.50 \times 10^{-7}$ ; pQTL WR  $\beta = 0.012$ , SE=0.0021,  $P = 3.33 \times 10^{-9}$ ). *TIE1* was associated with both SBP (eQTL WR  $\beta = 0.205$ , SE=0.035,  $P = 4.87 \times 10^{-9}$ ; pQTL WR  $\beta = -0.050$ , SE=0.010,  $P = 5.06 \times 10^{-7}$ ) and DBP (eQTL WR  $\beta = 0.180$ , SE=0.035,  $P = 2.69 \times 10^{-7}$ ; pQTL WR  $\beta = -0.048$ , SE=0.010,  $P = 1.95 \times 10^{-6}$ ). Of these associations, *TIE1* gene expression showed moderate evidence of colocalization with SBP (coloc prob=67%). Current literature on these genes supports a role in cardiovascular disease pathogenesis as *MST1* is known to promote cardiac myocyte apoptosis and *TIE1* to mediate angiogenesis.

Our study suggests that both the gene expression and protein levels of *TIE1* are casually related to BP, although latent horizontal pleiotropy could still confound this association.

---

**Background:** Coronary artery disease (CAD) is the leading cause of death worldwide. Circulating lipid levels play an important role in CAD and genetic investigations into the human lipidome may provide greater insight into disease risk. We have utilised a large community-based study, the Busselton Family Heart Study (n=4492), with the aim of identifying causal genetic risk variants for CAD, through the integration of lipidomic endophenotypes, genomic variants, and whole-genome sequence (WGS) data.

**Methods:** Targeted lipidomic profiling was performed using electrospray ionization-tandem mass spectrometry to identify 530 lipid species from 33 lipid classes/subclasses. To exploit both known and unknown relatedness, we estimated empirical kinship probabilities using LDAK. The general linear mixed model incorporated in SOLAR was used to estimate narrow-sense heritabilities of lipid species. Using BOLT-LMM, we performed genome-wide association studies (GWAS) of all 530 lipid species on ~14M imputed variants ( $R^2 > 0.3$  & minor allele copies  $\geq 5$ ). All analyses were adjusted by age, sex, and their interactions. GWAS were run both with and without adjustment for plasma lipid concentrations (i.e. HDL-C, total cholesterol and triglycerides).

**Results:** Over 99% of lipid species were significantly heritable ( $h^2$ : 0.07 to 0.51; FDR adjusted p-value:  $1.1 \times 10^{-2}$  to  $1.1 \times 10^{-54}$ ), with a median heritability of 0.30 (IQR=0.09). Of the 530 lipid species, 451 lipid species had at least one variant associated at the genome-wide level of significance ( $p < 5 \times 10^{-8}$ ). We identified over 60,000 significant associations between lipid species and genetic variants from approximately 150 gene regions. Approximately 70% of the observed associations were significant with and without adjustment for plasma lipid concentrations, while 30% were significant in only one analysis. Across all lipid species, 0.5% to 16.5% of the variation in species was attributed to the significantly-associated genotyped variants.

**Conclusion:** This is the largest GWAS of the human lipidome (largest sample size and number of lipid

species) in which we have shown that the plasma lipidome is heritable and have identified new genetic variant-lipid species associations. Future work includes interrogation of the WGS data within these gene regions in an attempt to identify putative causal risk variants for lipidome endophenotypes and CAD.

## PgmNr 2755: Multi-omic analyses implicate sphingolipids as biomarkers of recurrent stroke in African Americans.

### Affiliations:

1) Department of Biology, East Carolina University, Greenville, North Carolina.; 2) Center for Public Health Genomics, University of Virginia, Charlottesville, VA; 3) Department of Public Health Sciences, University of Virginia, Charlottesville, VA; 4) Department of Biostatistics and Data Science, Division of Public Health Sciences, Wake Forest School of Medicine, Winston-Salem, NC; 5) Department of Neurology, University of Virginia, Charlottesville, VA, USA; 6) Center for Health Disparities, Brody School of Medicine, East Carolina University, Greenville, NC

African Americans endure a nearly two-fold greater risk of suffering a stroke and are 2-3 times more likely to die from stroke compared to Caucasians. Among individuals who survive an initial stroke, African Americans have a greater risk of recurrent stroke and vascular events, which are deadlier and more disabling than initial events. Metabolomics provide insight of physiological states of systems and represent potential biomarkers that could influence or predict disease and/or recurrence. Combining metabolomics data with traditional genetic and epigenetic methods could help better understand disease etiology and progression for complex diseases with both heritable and environmental risk factors.

We conducted an integrative, multi-omic study on 922 plasma metabolites, 473,864 DNA methylation loci, and 556 SNPs from 50 African American participants in the Vitamin Intervention for Stroke Prevention (VISP) clinical trial. Welch's *t*-tests, survival and matched-pairs analyses were performed on metabolite profiles. Network analyses using Weighted Gene Co-expression Network Analysis (WGCNA) tested correlations between metabolites, methylation loci, and clinical traits. Epigenetic associations were identified using regression and WGCNA, while SNP-based tests were used to detect metabolite differences by genotype.

Sixteen metabolites, including cotinine ( $p=9.25e-13$ ), N-delta-acetylornithine ( $p=1.97e-05$ ), and sphingomyelin (d18:2/23:0, d18:1/23:1, d17:1/24:1) ( $p=3.00e-04$ ) were identified in *t*-tests of recurrent stroke outcome or baseline smoking status. Tricosanoyl sphingomyelin (d18:1/23:0) exceeded statistical significance in Cox Proportional Hazards survival analyses with time to recurrent stroke ( $p=1.56e-05$ ). Network analyses identified moderate correlations between sphingolipids and clinical traits including days to recurrent stroke ( $p=0.007$ ). Integrative analyses between genetic variants in sphingolipid pathway genes identified 11 SNPs nominally associated with metabolite levels in a one-way ANOVA, while epigenomic analyses identified xenobiotics, predominately smoking metabolites and pharmaceutical drugs, to be associated with methylation profiles.

Taken together, our results suggest that metabolites, specifically those associated with sphingolipid metabolism, are potential plasma biomarkers for stroke recurrence in African Americans. Furthermore, genetic variation and DNA methylation may play a role in the regulation of these

metabolites.

### Abstract

**Background:** High blood pressure (BP) is a leading global health risk factor and genome-wide association studies (GWAS), conducted predominantly in populations of European descent, have identified >1000 loci associated with blood pressure traits. Major ancestry groups exhibit differences in patterns of linkage disequilibrium and allele frequencies, and may harbor population-specific association signals. Thus, GWAS in non-European populations have the potential to identify additional loci.

**Methods:** We performed GWAS studies for systolic, diastolic, pulse and mean arterial blood pressure (SBP, DBP, PP, and MAP) in up to 100,473 Chinese participants aged 30-79 years from the China Kadoorie Biobank (CKB). We used linear mixed models testing an additive genetic model (BOLT-LMM v2.3.2) for each of the four blood pressure traits for ~10 million genotyped and imputed genetic variants (MAF>0.005, info>0.3) with adjustment for age, age-squared, sex, recruitment region, anti-hypertensive medication, genotyping array version, mean outdoor temperature, and body mass index. SNP based heritability was estimated using linkage disequilibrium (LD) score regression.

**Results:** The estimated SNP-wide heritability ( $h^2$ ) of the blood pressure traits in CKB was 0.213, 0.217, 0.171 and 0.225 for SBP, DBP, PP, and MAP, respectively. Low genomic control factors ( $\lambda_{GC} = 1.121-1.168$ ) and LD score regression intercepts (0.935-0.949) indicated little inflation and were consistent with the polygenic nature of BP traits. We identified a total of 135 independent loci associated with one or more the blood pressure traits at  $p < 5 \times 10^{-8}$ . Among them, 78 (5 novel) were associated with SBP, 89 (3 novel) with DBP, 44 (1 novel) with PP, and 98 (4 novel) with MAP. Thus, this CKB study confirms the transferability between ancestry groups of many associations, while also extending the list of East Asian-specific blood pressure-associated variants.

**Conclusions:** This study demonstrates that further GWAS analyses of blood pressure in diverse populations, including the Chinese population, can provide important additional information about the genetic determinants of blood pressure and other complex traits.

## PgmNr 2757: *TBX2* gene polymorphisms as factors for predisposing coronary artery diseases in South Indian population.

---

**Background:** Coronary artery disease (CAD) has been the leading cause of mortality and morbidity worldwide. It is projected that the annual number of deaths due to CVD will increase from 17 million in 2008 to 25 million in 2030 (World Health Organisation, 2012). Although it is a multifactorial disease, several studies have demonstrated that genetic factors play a major role in CAD.

*TBX2* transcriptional program plays central role for coronary smooth muscle formation and function, and mutations in *TBX2* are known to play an important role in congenital heart disease, they may also result in malformed coronary vasculature leading to increased susceptibility to CAD.

**Objectives:** Previous studies from our lab on various Indian populations suggest that the Indians are not only unique in their origin but are unique in the genetic etiology of various diseases. Considering the crucial role of *TBX2* in the myocardium formation, we evaluated the genetic variants of the *TBX2* gene to identify association if any with risk of CAD in patients from South India.

**Methods and Results:** We have sequenced all the exons of *TBX2* gene along with intronic boundaries in 700 South Indian CAD subjects along with 400 age and ethnically matched controls. We found two novel missense variants in one of the patients (R350G and R 350L) in exon 5. Another polymorphism (rs761618292) has an A allele frequency of 63% in contrast to world population where it is 0.008%. We also observed different allelic frequencies with respect to other polymorphisms in the *TBX2* gene like rs56298202 C>G, rs35619711 C>G, rs1057987 C>T which are very different from the other populations reported. However the *TBX2* gene polymorphisms did not show any significant association between the patient group and the control group in our study.

**Conclusions:** This is a study carried out for the first time in a cohort of patients from South India on *TBX2* gene. Our results suggest that although there are novel variations in *TBX2* gene they do not contribute to CAD susceptibility among South Indian Population. The frequency of variations observed in *TBX2* gene in our study are so different with respect to other population once again reiterates the fact that Indians as a group are unique in their genetic etiology and manifestation of disease pattern in general.

## **PgmNr 2758: Probands' variants of uncertain significance in established dilated cardiomyopathy genes may influence left ventricular size in family members: Preliminary data from the DCM Precision Medicine Study.**

### **Authors:**

The ongoing DCM Precision Medicine Study is obtaining exome sequence data on probands with idiopathic dilated cardiomyopathy (DCM) and adjudicating variants in 35 established DCM genes using modified ClinGen criteria. In preliminary data from this study, 43% of probands had variants of uncertain significance (VUSs) as their only clinical results. In order to determine whether these variants might be biologically relevant for DCM, we leveraged the study's family-based design to determine their contribution to variation in echocardiographic endophenotypes in family members aged  $\geq 20$  years. From the first three batches of exome sequenced individuals, we identified all families of self-reported white, non-Hispanic probands in which all of the proband's variants had been adjudicated. VUSs, as well as likely pathogenic (LP) and pathogenic (P) variants, identified in probands were Sanger sequenced in all enrolled family members with available DNA and echocardiographic data. The burden of the proband's variants of a particular class (VUS or LP/P) carried by an individual was defined as the number of variant alleles or zero if no variants of that class were identified in the proband. Associations between the burdens of variants of each class and the individual's sex- and height-specific left ventricular end-diastolic dimension z-score (LVEDDz) or left ventricular ejection fraction (LVEF) were estimated from data on 299 or 314 individuals in 97 or 101 families using a linear mixed model with an additive polygenic effect and pedigree-based kinship estimates. The model likelihood was conditioned on the proband's phenotype to account for single ascertainment through the proband. Because the age-dependent penetrance of DCM suggests that burdens of VUS and LP/P alleles may have age-dependent effects, these were allowed to differ between individuals aged  $\leq 40$  years or  $>40$  years. In an individual over 40, carrying an additional allele of the proband's LP/P variants was associated with an increase in LVEDDz of 1.35 (95% CI: 0.39-2.30;  $p=0.006$ ) and a decline in LVEF of 10.6% (95% CI: 4.9%-16.3%;  $p<0.001$ ). Conditional on this individual's LP/P burden, carrying an additional allele of the proband's VUSs was also associated with an increase in LVEDDz of 0.62 (95% CI: -0.01-1.25;  $p=0.05$ ) and a decline in LVEF of 2.9% (95% CI: -1.0%-6.7%;  $p=0.15$ ). Our preliminary results suggest that probands' VUSs in established DCM genes may be biologically relevant for DCM.

# PgmNr 2759: Sarcopenia-related traits and coronary artery disease: A bi-directional two-sample Mendelian randomization study.

## Background

Sarcopenia was defined as age-related loss of muscle mass and strength, which might lead to coronary artery disease (CAD) in traditional epidemiology study. However, this observational result might be confounded by many environmental factors. Therefore, we used bi-directional Mendelian randomization (MR) to assess the effect of sarcopenia-related traits (whole body lean mass and handgrip strength) on CAD.

## Methods

Inverse variance weighting estimates were obtained by applying genetic variants that predict whole body lean mass and handgrip strength, obtained from the UK Biobank GWAS, to the largest available European case-control study of CAD from Coronary ARtery Disease Genome wide Replication And Meta-analysis (CARDIoGRAM) consortium. Conversely, we also applied genetic variants that predict CAD to UK Biobank summary statistics for genetic association with whole body lean mass and handgrip strength. To further demonstrate the validity of the selected SNPs, we included myopia as negative control in our analysis. MR-Egger regression was performed to assess the horizontal pleiotropic pathway between genetic variants and outcome independent of exposure. As sensitivity analyses we used weighted median, Robust Adjusted Profile Score (RAPS), Mendelian Randomization Pleiotropy RESidual Sum and Outlier (MR-PRESSO), removed proxy SNPs and removed pleiotropic SNPs.

## Results

In this study, inverse variance weighted (IVW) analysis (left handgrip strength,  $b(95\% \text{ CI})$ : -0.54(-0.92, -0.17),  $P=0.005$ ; right handgrip strength,  $b(95\% \text{ CI})$ : -0.56(-0.90, -0.22),  $P=0.001$ ) shown that genetically predicted handgrip strength was significantly related to CAD without bias of horizontal pleiotropy (left handgrip strength, MR-Egger intercept= -0.0008363,  $P=0.807$ ; right handgrip strength MR-Egger intercept= 0.0084743,  $P=0.391$ ). The result was robustly validated in all the sensitivity analyses. However, we did not detect the relationship between genetically instrumented whole body lean mass and CAD in our bi-directional MR analysis.

## Conclusion

Genetically predicted handgrip strength is related to lower CAD risk. Handgrip strength could warrant further investigation as a possible target of intervention for CAD prevention.

Coronary artery disease (CAD) is the major cause of death in developed countries. Progressive atherosclerosis and CAD will result in angina pectoris, unstable angina and acute myocardial infarction. With the advancement of recent coronary intervention, CAD still comprises the major causes of mortality. Etiologies of CAD are complex and multifactorial, including family history, obesity, hypertension, smoking, diabetes and dyslipidemia. Family history and genetic factors are most important independent factors among those risk factors. Recent genome wide association studies have identified several genetic loci which are associated with CAD development. How these loci affect CAD and atherosclerosis development are still unclear. After these decades of intensive research on atherosclerosis and CAD, clinical management for the CAD patients has evolved dramatically. For further understand specific susceptibility genes of the CAD patients in our population. We performed a genome-wide association study (GWAS) which was conducted on 877 CAD patients and 1722 controls from a Han Chinese population of Taiwan. In this discovery stage, we Identified 4 single nucleotide polymorphisms (SNPs), *rs10738607*, *s10757278*, *rs1333049* and *rs4977574*, clustered with *CDKN2B* gene at *9p21.3* (all  $p < 10^{-9}$ ). One SNP, *rs671*, located at *12q24.12* in *ALDH2* gene ( $p < 10^{-6}$ ). The gene variants of *CDKN2B* and *ALDH2* have been found to be associated with CAD in a meta-analysis study included 48 studies with a total of 60,801 CAD cases and 123,504 controls[1]. Interestingly, we also identified three SNPs clustered with plaque formation gene ( $p < 10^{-5}$ ) which have not been reported in other GWAS studies of CAD before. This gene belongs cadherin superfamily. Recent studies indicated that a number of cadherins play an important role in cardiovascular disease progression including atherosclerosis and restenosis[2]. We speculated that this plaque formation gene might be a susceptibility gene for CAD specifically in Han Chinese population. We are now enrolling another cohort with 800 CAD patients for the replication. We believe our finding will shed light on the pathogenesis of CAD.

Coronary heart disease (CHD) is the most common type of heart disease, which is the leading cause of mortality among adults in the US. Numerous evidence has been accumulated to show that DNA methylation plays important roles in the development of CHD. This effect is believed to vary by age. However, due to the economic burden, in most studies, DNA methylation is measured only once, at a different age for each subject, which prohibits estimating age-dependent effects of methylation on CHD risk by conventional statistical methods. Here we provide two novel approaches to tackle this analytical challenge, namely separate models and super models. By separate models, we divide all subjects into different groups by their age of methylation measurement, and then estimate the methylation effects in these groups separately using landmark analysis. These estimates along the follow-up ages dynamically approximate the effect profile of methylation on CHD onset risk. On the other hand, the super models combine the above separate landmark analyses together and borrow information between adjacent age intervals to construct a smoother and more stable profile of the methylation effects on CHD risk. Simulation studies confirm these advantages of the super models. We apply both approaches to the Framingham Heart Study of 1540 subjects with CHD event data and methylation profiling at a single clinical visit, for illustration and demonstration of the comparisons between them. Our novel analysis reveals that methylation levels at several CpG sites show declining age-dependent effects on the CHD risk.

## **PgmNr 2762: Causality of blood lipoprotein cholesterol on coronary artery disease from multivariate Mendelian randomization analysis.**

Instrumental variables are critical for valid and efficient Mendelian randomization (MR) analysis. We developed a genetic variant selection method from the empirical selection approach of Do et al. (2013). Using this method, we selected 338 single-nucleotide-polymorphisms (SNPs) from a meta-analysis data set of genome-wide association study (GWAS) of lipid and coronary heart disease (CAD) and 363 SNPs from another joint GWAS meta-analysis data. From the multivariate MR analysis, we found that low density lipoprotein cholesterol (LDL-c) was strongly associated with increasing risk for CAD, high density lipoprotein cholesterol (HDL-c) was strongly associated with decreasing risk for CAD, and triglycerides (TG) were not associated with risk for CAD. We performed a simulation study accounting for the linkage disequilibrium among the selected SNPs and the pleiotropy among lipid components. The results from simulation study confirmed the result from the multivariate MR analysis for the causal relationship of lipoprotein cholesterol and CAD.

Hypertension is a common epidemic that is a strong risk factor for many health issues. Epidemiology studies show that aging is one of the strongest risk factors for hypertension, i.e. the prevalence increases from 7.5% (18-39 yrs) to 63.1% (60+ yrs). Genome-wide association studies have identified numerous blood pressure genetic signals, yet little has been done to explore the genetic architecture of aging-related hypertension. In this study, we performed a genome-wide interaction analysis to search for blood pressure genetic signals with age-dependent effects. Four blood pressure phenotypes were included, i.e. systolic blood pressure (SBP), diastolic blood pressure (DBP), mean arterial pressure (MAP), and pulse pressure (PP). Ten million imputed markers ( $MAF \geq 0.5\%$ ) were analyzed in 539K European individuals from UK biobank ( $N=459,333$ ) and DiscovEHR ( $N=79,761$ ). To search for coding variants with potentially larger genetic effects, 1.6 million exome sequencing markers from 224,249 individuals (141,527 from UKB and 82,722 from DiscovEHR) were also analyzed. Age was modeled as an interaction variable and interaction was tested using PLINK, adjusting for sex, BMI, ten principle components, and cohort specific covariates. After removing the HLA region, 1DF interaction model identified 15 independent signals with genome-wide significance ( $P < 5E-08$ ). A common SNP ( $AAF=45\%$ ), located in the first intron of gene *ELN* (elastin), was strongly associated with PP with an age-dependent effect ( $P_{1DF}=9.76E-10$ ). This SNP has a modest eQTL signal with a non-coding RNA (RP11-731K22.1,  $P=3.60E-05$ ), which is located upstream of *ELN*. The A allele was associated with a 0.09 mmHg lower ( $P=0.14$ ) and 0.50 mmHg higher ( $P=1.08E-07$ ) PP in young ( $<45$  years) and old ( $>65$  years) groups, respectively. Previous studies reported a genome-wide significant association between PP and a *ELN* downstream SNP (7:74076882:A:G). Further analyses suggest that this SNP had no significant interaction with age ( $P_{1DF}=0.70$ ) and both SNPs are in poor LD ( $R^2=0.0034$ ). Taken together, the newly identified *ELN* SNP is associated with PP with an age-dependent effect and is independent from the previously reported signal. In summary, genome-wide interaction analysis in 539K European individuals identified genetic signals with age-dependent effects. This study provides biological insights underlying age-related hypertension and suggests potential mechanisms and therapeutic targets for age-related hypertension.

## PgmNr 2764: Additive and multiplicative gene-lifestyle interactions in coronary artery disease in the UK Biobank.

---

Coronary artery disease (CAD) is the pre-eminent cause of death. Both genetic and lifestyle factors such as cigarette smoking and physical activity (PA) contribute to development of CAD. Over 160 loci have been linked with risk of CAD in genome-wide association studies. However, whether genetic risk of CAD can be modified by lifestyle factors remains unclear. We assessed interactions between CAD polygenic risk score (PRS) and lifestyle factors (i.e., smoking and PA) on both additive and multiplicative scales in a European ancestry sample of 307,147 adults from the UK Biobank. Primary incident CAD events were identified using in-patient hospitalization data and national death registry data. Four CAD-PRSs were constructed including: 1) an overall PRS based on 161 published CAD SNPs; 2) a blood pressure (BP) sub-PRS based on 26 SNPs; 3) a lipids sub-PRS based on 17 SNPs; and 4) a body mass index (BMI) sub-PRS based on 16 SNPs. Cox proportional hazards models were used to assess the association of CAD-PRSs with incident CAD as well as the interaction effects. Multiplicative interaction was assessed by the product term in each model, and additive interaction was assessed by calculating relative excess risk due to interaction (RERI). Comparing to the low CAD genetic risk group (quintile 1), those with intermediate genetic risk (quintile 2-4) and high genetic risk (quintile 5) had a 1.43-fold (95% CI: 1.35-1.52) and 2.16-fold (95% CI: 2.02-2.31) increased risk of CAD, respectively. Lipids sub-PRS had the strongest association with incident CAD, compared with BP sub-PRS and BMI sub-PRS. Overall, no significant multiplicative interaction was observed between any pair of CAD PRS and lifestyle factors. For the comprehensive CAD-PRS, synergistic additive interaction was observed with current smoking in both intermediate (RERI: 0.394, 95% bootstrap interval: 0.097, 0.729) and high (RERI: 1.051, 95% bootstrap interval: 0.615, 1.497) genetic risk groups, meaning the CAD risk due to smoking was increased in groups at higher genetic risk. An additive interaction with smoking was also identified for the BP sub-PRS but not lipids or BMI sub-PRSs. No additive interaction was observed between any pair of CAD PRS and PA. In this PRS-based interaction study, we identified synergistic excess risk among people with high lifestyle and genetic risk for CAD, which can provide novel mechanistic insights on CAD risk and may lead to innovative intervention strategy.

---

Improving our understanding of the genetic architecture and the role of gene-by-environment (GxE) interactions in complex multifactorial traits has become a major goal for the genetics community. Recently, the Gene-Lifestyle Interactions Working Group conducted a range of multi-ancestry genome-wide interaction studies (GWIS) focusing on interaction between genetic variants and two exposures namely alcohol consumption and smoking habits on lipids (triglycerides (TG), high and low-density lipoproteins) and blood pressure (diastolic and systolic blood pressure, mean arterial pressure, and pulse pressure) in up to 610,475 individuals from multiple ancestry groups.

In this study, we conducted series of cross-study analyses using the GWIS summary statistics. We observed important similarity and specificity of GxE effects across phenotypes and ancestries. For example, some interactions were found only in the African-ancestry population and involved genetic variants specific to this population. Meanwhile, several Gene-by-Alcohol interactions were identified only in the Asian-ancestry population for variants common in all populations, suggesting a potential contribution of the genetic or environmental background. Comparisons between the different GWIS also stressed the potential importance of specific phenotype-exposure pairs for the detection of new signal, such as lipid-drinking and blood pressure-smoking. We also highlighted small but persistent negative interaction effects between TG associated variants and current smoking.

To explore further the impact of these exposures on genetic mechanisms, we estimated the genetic

heritability for all traits in unexposed and exposed individuals. In each group, we also partitioned heritability by cell-type and looked for heritability enrichment by cell-types. We found substantial differences in both the overall heritability and the enrichment by cell type. These analyses suggest important differences in the genetic responses on phenotypes to the environmental stress. For example, we noted a reduced heritability of most phenotypes among smokers. In lipids traits, this reduction appears to be driven by a smaller contribution of liver-related variants among those individuals.

Our in-depth analyses of the GWIS results emphasize the importance of performing ancestry-specific analyses and suggest the existence of exposure-specific pathways, opening new paths for future in-silico and functional gene-environment interaction studies.

---

Both genetic and non-genetic factors can predispose individuals to cardiovascular health risk. Finding ways to alter their predispositions is important for cardiovascular disease (CVD) prevention. Here, using a novel whole-genome framework, we estimated genetic and non-genetic effects on—hence their predispositions to—cardiovascular health risk and determined whether they vary with respect to lifestyle factors. We performed analyses on the Atherosclerosis Risk in Communities Study (ARIC) and validated findings using the UK Biobank (UKBB), where cardiovascular health risk was measured using 23 traits in the ARIC and 8 in the UKBB, including body mass index, resting heart rate, white blood cell count and diastolic blood pressure; and lifestyle choice was captured in aspects such as physical activity, smoking and alcohol intake. In both datasets, we found that physical activity alters genetic effects on white blood cell count and HDL cholesterol level but non-genetic effects on heart rate, BMI and waist-to-hip ratio. Alcohol intake alters both genetic and non-genetic effects on BMI, while smoking alters non-genetic effects on heart rate and white blood cell count. In addition, saturated fat intake modifies genetic effects on BMI. These results highlight the relevance of lifestyle changes for CVD prevention. Using the whole-genome framework, we also stratified individuals into groups, according to their genetic predispositions, and showed that lifestyle effects on cardiovascular health risk could take on drastically different directions across groups, implying the need for individualizing lifestyle changes for CVD prevention, hence the importance of precision medicine. Finally, we showed that neglecting lifestyle modulation of genetic and non-genetic effects, on average, reduced SNP heritability estimates of cardiovascular traits by a small yet significant amount, primarily owing to overestimation of residual variance. Thus, current SNP heritability estimates for cardiovascular traits, which commonly do not consider modulating effects of lifestyles, are likely underestimated.

---

**Background:** Hypertrophic cardiomyopathy (HCM) is the most common inherited heart disease (approx. 1 in 500 individuals), characterized by left ventricular hypertrophy ( $\geq 15$  mm) that is not solely explained by abnormal loading conditions. To date, about 1500 mutations in genes encoding sarcomere proteins have been identified in HCM patients, but their mutation spectrum may be variable across different populations. **Objective and method:** The present study aimed to understand the genetic causes of HCM on the Azorean island of São Miguel (Portugal). To that end, we investigated a cohort of 18 unrelated adult patients (12 males, 6 females) who fulfilled criteria for HCM. In brief, we screened 29 cardiomyopathy-associated genes using targeted next-generation sequencing. Variants were filtered and classified according to standards and guidelines of the American College of Medical Genetics and Genomics and to recommendations of the ClinGen Inherited Cardiomyopathy Expert Panel. Pathogenic or likely pathogenic variants were confirmed by Sanger sequencing, *in silico* effect prediction analysis and published data from functional studies.

**Results:** We found that 11 (61.1%) patients harbored causative mutations in 3 genes encoding sarcomere proteins. Among them, 7 patients (pts) had pathogenic variants in *MYH7* (NM\_000257.2: c.1750G>C, p.Gly584Arg in 6 pts; c.1750G>A, p.Gly584Ser in 1 pt); 2 patients had likely pathogenic variants in *MYH7* (c.2389G>A, p.Ala797Thr), 1 in *MYBPC3* (NM\_000256.3: c.1484G>A, p.Arg495Gln) and 1 in *TNNT2* (NM\_001276345.1: c.842A>T, p.Asn281Ile). We also detected two variants of uncertain significance in *JPH2* (NM\_020433.4) gene: 1 patient carried the c.590G>T, p.Arg179Leu, the other one the c.692G>A, p.Arg231Gln. The remaining 5 patients had no mutation in the genes sequenced. All patients were heterozygous, except one (male) who was apparent homozygous for the *TNNT2*: c.842A>T, p.Asn281Ile. To clarify if this variant is homozygous or hemizygous, we are now performing MLPA analysis. Moreover, we will apply an extended NGS gene panel to investigate the genetic causes of HCM in the 7 (38.9%) patients without causative mutations identified.

**Conclusions:** On the São Miguel Island germline mutations in the *MYH7* gene account, at least, for 50% of unrelated patients with HCM. The identification of the causative mutations in HCM is essential since it confirms the diagnosis, enables genetic counseling to families and could allow individual therapy planning.

## PgmNr 2768: Targeted genome sequencing identifies multiple rare variants in Caveolin-1 (CAV1) associated with obstructive sleep apnea trait.

---

Obstructive sleep apnea (OSA) is a common disorder associated with increased risk for cardiovascular disease, diabetes, and premature mortality. There is strong clinical and epidemiologic evidence supporting the importance of genetic factors influencing OSA, but limited data implicating specific genes. Disease severity is most commonly measured by the apnea-hypopnea index (AHI), which quantifies the number of complete and partial episodes of upper airway obstruction per hour of sleep. We report genetic associations of AHI using high depth genomic sequencing data from the NHLBI Trans-Omics for Precision Medicine (TOPMed) project and focus on the Cleveland Family Study (CFS), a cohort with enrichment for OSA. We identified an associated 19 Mb linkage region on chromosome 7 in European Americans and examined rare variants that contributed to the observed linkage evidence in gene-based analysis. We identified 18 candidate genes ( $P < 0.05$ ) associated with AHI under the linkage peak in CFS. Follow-up analysis of these variants in the 18 candidate genes in 4 independent TOPMed studies identified 21 non-coding rare variants in Caveolin-1 (CAV1) significantly associated with AHI ( $P = 5.4 \times 10^{-7}$ ) in 3,259 European Americans. These non-coding variants significantly contribute to the CAV1 expression level in skeletal muscle ( $P = 3.8 \times 10^{-4}$ ) in GTEx data. Caveolin-1 is a membrane scaffolding protein that is essential in the formation of plasma membrane lipid rafts and mediates cholesterol trafficking and regulates several signaling molecules including TGF-beta, TLR4 and endothelial nitric oxide synthase (eNOS). It is implicated in disorders associated with OSA, including metabolic and endothelial dysfunction, immune regulation and inflammation and lung remodeling. Common CAV1 variants were associated with severe OSA in a small case-control study. Our results suggest that caveolin-1 may play a significant role in OSA pathogenesis.

## PgmNr 2769: Genetic architecture of cardiac repolarization dynamics.

**BACKGROUND:** Cardiac repolarization is a key cellular process and disruptions are linked with increased cardiovascular risk. The genetic basis of cardiac repolarization has been studied extensively by measuring the QT interval from the electrocardiogram (ECG) under resting conditions. However, repolarization varies with heart rate and abnormalities of these dynamics have shown to be important in modulating cardiovascular risk as well. This work investigates the genetic basis and the underlying biological mechanisms of repolarization dynamics during exercise and recovery alongside resting QT interval.

**OBJECTIVES:** To identify single nucleotide variants (SNVs) associated with ECG markers of repolarization dynamics during exercise and recovery and to study the overlap with resting QT.

**METHODS:** Exercise ECG data from 51,574 subjects of the UK Biobank study were analysed for two established markers of repolarization dynamics: QT dynamics, defined as the slope of the QT/RR profile and the T-wave morphology restitution (TMR), which quantifies the spatio-temporal heterogeneity of ventricular repolarization. Both markers were measured during exercise and recovery. We conducted genome-wide association studies (GWASs) for each trait and resting QT interval. Bioinformatics analyses were performed to annotate SNVs and identify candidate genes.

**RESULTS:** GWASs identified 20 loci for QT dynamics and indicated a heritability up to 10%. There was substantial overlap of shared loci between QT dynamics and resting QT. TMR was less heritable (~5%), with discovery of 12 genetic loci, of which 9 were also associated with resting QT interval and 7 with QT dynamics. Genetic variants were found at long-QT syndrome loci: KCNH2, KCNJ2, SCN5A and KCNQ1. These channel proteins underlie the major repolarising ventricular potassium currents and depolarising sodium current. Variations in these currents might lead to changes in the T-wave morphology and this is consistent with known physiology. Other candidate genes at TMR loci include: NOS1AP, known to modulate QT interval duration and risk of arrhythmias in the long QT syndrome and CAMK2D which regulates calcium dynamics.

**CONCLUSION:** This systematic investigation indicates that repolarization dynamics has a genetic predisposition. The important substantial genetic overlap with resting QT loci, suggests that biological mechanisms governing repolarization during steady state conditions are also important in modulating repolarization dynamics.

## PgmNr 2770: Combined-phenotype study of seven RBC traits in the PAGE study highlights the benefits of ancestrally diverse study populations.

Quantitative red blood cell (RBC) traits are highly polygenic clinically relevant traits, with nearly 500 reported GWAS loci. The majority of RBC trait GWAS have been performed in European- or East Asian-ancestry populations, despite evidence that rare or ancestry-specific variants contribute substantially to RBC trait heritability. Recently developed combined-phenotype methods which leverage trait correlation to improve statistical power have not yet been applied to these traits. Here we performed a combined-phenotype analysis of seven correlated quantitative RBC traits in a multi-ethnic study population.

Based on correct type I error rate and ability to evaluate opposite directions of effect by trait, we selected a simulation-based adaptive sum of powered scores (aSPU) method to test overall associations between ~22 million SNPs and univariate summary statistics from GWAS of seven RBC traits. A maximum of 68,633 study participants were included (42% MEGA-genotyped, 24% African American, 30% Hispanic/Latino, 43% European American, 76% female). Step-wise conditional analysis was performed to identify all independent, genome-wide-significant ( $P < 5 \times 10^{-9}$ ) lead SNPs.

Thirty-nine loci contained at least one significant association signal, with lead SNPs at five loci significantly associated with three or more RBC traits. A majority of the lead SNPs were common ( $MAF > 5\%$ ) across all ancestral populations. 19 additional independent association signals were identified at seven loci (*HFE*, *KIT*, *HBS1L/MYB*, *CITED2/FILNC1*, *ABO*, *HBA1/2*, and *PLIN4/5*). For example, the *HBA1/2* locus contained 14 conditionally independent association signals, 11 of which were specific to African and Amerindian ancestries. One variant at this region was common in all ancestries, but demonstrated a narrower locus in African Americans than European Americans or Hispanics/Latinos. GTEx eQTL analysis of all independent lead SNPs (excluding ancestry-specific SNPs not available in the GTEx database) yielded 31 significant associations in relevant tissues, over half of which were not at the gene immediately proximal to the lead SNP.

Conditional analysis revealed a complex LD structure at the *HBA1/2* locus, which also contains known

causal variants for monogenic blood disorders originating in malaria-endemic regions. Our work demonstrates the continued importance of including ancestrally diverse study populations when attempting to identify and characterization complex trait loci.

---

Despite considerable interest including several drug development programs, the role of high-density lipoprotein cholesterol (HDL-C) in coronary heart disease (CHD) is still unclear.

In observational studies, circulating low-density lipoprotein cholesterol (LDL-C) exhibits a positive association with CHD risk. Treatment trials of LDL-lowering drugs (statins, ezetimibe and PCSK9 inhibitors), each targeting different mechanisms (HMGCR, NPC1L1 and PCSK9 respectively), show consistent reductions in CHD risk. Naturally occurring genetic variation in the genes encoding these targets, and at other loci identified by the Global Lipid Genetic Consortium, accurately instrument causal effects of LDL-C on CHD using data from the CardiogramPlusC4D Consortium in Mendelian randomisation analysis.

By contrast, circulating HDL-C exhibits a negative association with CHD risk in observational studies, but treatment trials of several HDL-C raising agents e.g. targeting CETP and GPR109A have been negative, causing uncertainty about whether this association is causal and if the development of drugs that raise HDL-C is a useful therapeutic strategy for CHD prevention. Mendelian randomisation analyses of HDL-C in CHD have also been equivocal.

Here, we use Mendelian randomisation for drug target validation (*cis*-MR) leveraging genetic variants associated with HDL-C, LDL-C and triglycerides (TG) in-and-around loci encoding drugged and potentially druggable targets. We identify a number drug targets that exhibit similar effects to existing lipid-lowering targets. We also demonstrate that prior failure of certain CETP inhibitor drugs are molecule rather than target failures, and that modification of certain drugged/druggable proteins that affect HDL-C and TG metabolism is likely to offer new effective therapeutic mechanisms for CHD prevention.

### BACKGROUND

Reduced kidney function has been associated with hypertension and vice versa. It remains unclear if the association is causal. We used summary statistics from large-scale genome-wide association studies (GWAS) to conduct two-sample bidirectional Mendelian randomization (MR) analyses to examine the potential causal relations between kidney function and blood pressure.

### METHODS

Kidney function was represented by: i) estimated glomerular filtration rate (eGFR) using the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) serum creatinine equation and ii) blood urea nitrogen (BUN). We used index SNPs from the CKDGen Consortium European-ancestry GWAS results (eGFR, n=567,460; BUN, n=243,031) and the UKB-ICBP Consortium GWAS results of systolic and diastolic blood pressure (SBP and DBP, n=~1 million). Both eGFR and BUN have marker-specific determinants unrelated to kidney function. To reduce bias, we selected SNPs that are likely related to kidney function rather than to the biomarker metabolism by requiring that the index SNPs of eGFR had opposite direction of association with BUN at Bonferroni corrected significance threshold, and vice versa for BUN index SNPs. To address the observed widespread pleiotropy between kidney function and blood pressure, we used pleiotropy-robust MR methods for primary analyses: weighted mode and MRMix.

### RESULTS

Of the reported index SNPs (eGFR: 256, BUN: 75), 40 eGFR and 26 BUN independent SNPs were finally selected as instruments for kidney function. For blood pressure, 265 SBP and 259 DBP independent SNPs were used as instruments without filtering. We observed significant causal effects of reduced kidney function on higher blood pressure (weighted mode estimate per 1 SD lower in ln(eGFR): 0.18 SD higher in SBP,  $p=1.10 \times 10^{-6}$  and 0.16 SD higher in DBP,  $p=3.03 \times 10^{-5}$ ). Similar results were observed for BUN to SBP and DBP while results including all reported index SNPs were not significant. The

causal estimates of blood pressure on kidney function were not significant albeit in the direction observed in epidemiological studies.

## **CONCLUSIONS**

MR analyses, with SNP filtering for kidney effects excluding marker effects, support causal effects of lower kidney function to higher blood pressure while inconclusive on the causal effects of higher blood pressure to lower kidney function. These findings help the interpretation of observational epidemiologic associations.

# PgmNr 2773: Comprehensive investigation of serum biomarkers and their causal role in cardiometabolic disease.

## Background

Serum biomarkers representing glucose homeostasis, lipid metabolism, kidney and liver function, have been associated with cardiometabolic traits in observational studies, but the nature of these associations is incompletely understood.

## Methods

We performed multivariable-adjusted regression models to assess associations of 27 serum biomarkers with 7 cardiovascular traits in up to 469,628 participants of the UK Biobank. Further, we assessed the causal relationships of these biomarkers with the same outcomes using a two-sample Mendelian randomization (MR) approach combining data from UK Biobank with summary statistics from external GWAS meta-analyses. We applied a Bonferroni-corrected alpha threshold of  $2.7 \times 10^{-4}$  (adjusting for 27 biomarkers and 7 outcomes).

## Results

In our observational analyses, we replicated and extended associations implicated in previous, smaller studies. After multiple testing correction, we found a total of 21, 15, 9, 24, 26, 24 and 26 biomarkers strongly associated with atrial fibrillation, coronary artery disease (CAD), ischemic stroke, T2D, systolic blood pressure, body mass index (BMI) and waist-to-hip ratio (WHR); respectively. The MR analyses confirmed strong evidence of previously suggested causal associations for a number of glucose- and lipid-related biomarkers with T2D and CAD. In addition, we detected a causal role of alanine aminotransferase in the development of T2D and hypertension ( $\beta$ , 0.46 and 0.06, per SD change in exposure and outcome;  $P=4.8 \times 10^{-11}$  and  $P=2.7 \times 10^{-5}$ ). We highlighted a causal association of triglyceride levels with WHR ( $\beta$ , 0.18, per SD change in exposure and outcome;  $P=5.0 \times 10^{-15}$ ); and albumin with BMI ( $\beta$ , -0.02, per SD change in exposure and outcome;  $P=1.7 \times 10^{-5}$ ). With 99% statistical power, we excluded a causal effect of at least 0.1 SD change in vitamin D with CAD. Sensitivity analyses including MR-PRESSO provided consistent results and indicated no significant directional horizontal pleiotropy for any of the reported causal associations.

## Conclusion

Our study confirm a causal role of several serum biomarkers related with glucose and lipid metabolism with CAD and T2D. In addition, we highlight previously unknown possible causal links between liver function and T2D and hypertension. This knowledge will provide important insights regarding the etiological understanding of these diseases, likely accelerating new prevention strategies.

## PgmNr 2774: Genetic determinants in relation to metabolism of the Mediterranean diet and association with coronary heart disease risk.

Chan School of Public Health, Boston, MA

---

The Mediterranean diet is beneficial for coronary heart disease (CHD) prevention, possibly through its effect on human metabolism. In our previous study, leveraging metabolomic profiling in multiple cohorts, we identified a plasma metabolic signature (consist of 67 metabolites) that is robustly associated with adherence to the Mediterranean diet and predicts CHD risk. However, a large proportion of the variation in the metabolic signature cannot be explained by dietary intakes. We hereby performed a genome-wide association study (GWAS) for the metabolic signature in 1,925 participants with both metabolomic and genotype data, to identify genetic determinants related to the Mediterranean diet metabolism. Heritability estimation suggested that 13.1% of the total variance in the metabolic signature was explained by genetics ( $P=0.27$ ). We identified two loci associated with the metabolic signature at the genome-wide significance and one at suggestive significance; these included the fatty acid desaturase gene cluster *FADS1-3* (led by rs174541 on Chr11,  $P=3.7\times10^{-13}$ ), a locus near D-amino acid oxidase activator *DAOA* (led by indel chr13:105803942,  $P=7.3\times10^{-11}$ ), and *LINC01187* (led by rs9313494 on Chr5,  $P=1.8\times10^{-7}$ ). We further identified two loci influencing the metabolic signature through their interactive effects with adherence to the Mediterranean diet (*ABCC1-6*, led by rs115523483 on Chr16,  $P=1.9\times10^{-8}$ ; *LOC101928516*, led by rs525923 on Chr6,  $P=3.6\times10^{-8}$ ). Top variants on *FADS1-3* showed significant associations with expressions of *FADS1*, 2, and 3, and *TMEM258* in multiple tissues including brain, liver, muscle, heart, and arteries ( $P<2\times10^{-5}$ ). The lead variant on *LINC01187* was associated with expressions of lincRNA 1187 in lung, adipose tissue, and whole blood ( $P<2\times10^{-3}$ ). Taking advantage of recently published GWAS summary statistics for CHD (122,733 cases, 424,528 controls), a Mendelian randomization analysis showed that the genetic component of the metabolic signature was associated with an 11% reduction in CHD risk (based on 58 variants;  $P<0.001$ ). In conclusion, the metabolic signature of the Mediterranean diet reflects the combined effects of both dietary adherence and metabolic response determined by genetics; and may potentially point to causal metabolic pathways related to CHD development. The efficacy of the Mediterranean diet on CHD prevention may vary depending on individuals' metabolic capacity, especially metabolism of fatty acids and amino acids.

---

**Background:** P-wave duration (**PWD**) is an electrocardiographic (**ECG**) measurement that represents cardiac conduction in the atrium. Both shortened and prolonged PWD have been associated with atrial fibrillation (**AF**). Although PWD is heritable, genetic studies of PWD are limited. To identify novel variants for PWD, our study examined the effects of common and rare coding variants for maximum PWD, using exome chip data.

**Methods:** We included 15 studies comprising 64,452 individuals of four ancestries (56,955 European, 5,681 African, 1,186 Hispanic, and 630 Asian). Nearly 245,000 variants genotyped on the exome chip were tested for associations with maximum PWD on the 12-lead ECG. We performed single variant score tests in each individual study, adjusting for age, sex, RR interval, and study-specific covariates, and accounting for relatedness. Association results were summarized via meta-analysis. We used gene-based burden and SKAT tests to examine associations between low-frequency and rare variants with PWD. We then examined the directionality of PWD associations with AF risk by examining results from a previous genetic analysis of AF. We used Bonferroni corrections for multiple testing.

**Results:** We identified 20 common genetic loci (13 novel) associated with maximum PWD, including several well-known AF loci (*TTN*, *CAND2*, *SCN10A*, *PITX2*, *PLN*, *CAV1*, *SYNPO2L*, *SOX5*, *TBX5*, and *MYH6*). Notably, PWD variants governed diverse biological mechanisms, including cardiac development, cardiac electrophysiology, and muscle function. The top variants at known sarcomeric genes (e.g., *TTN*, *MYH6*) were associated with both increased PWD and increased AF risk. In contrast, top variants at loci involved in transcriptional regulation (*PITX2*) or ion channel function (*SCN10A*) were associated with increased PWD but reduced AF risk. Gene-based SKAT results using variants with  $MAF \leq 5\%$  identified 4 genes related to PWD (*TTN*, *DLEC1*, *TTC21A*, and *RPL3L*).

**Conclusion:** Our findings highlight the shared genetic components of atrial conduction and AF. The different directions of associations between loci with both PWD and AF suggest that AF may result from multiple genetic mechanisms, and PWD may be an endophenotype for these mechanisms. Future studies focused on ECG traits are warranted to determine if different pathophysiologic subtypes of AF can be identified.

## PgmNr 2776: Mendelian randomization reveals a causal role for obesity in stroke that varies across subtypes.

**Background and Purpose:** Obesity has a known association with cerebrovascular disease. We aimed to clarify the (i) causality of this association; (ii) differential effects across stroke subtypes; and (iii) the role of hypertension and hyperglycemia in mediating the effect of obesity.

**Methods:** We used summary statistics from genome-wide association studies (GWAS) for body mass index (BMI), waist-to-hip ratio (WHR) and multiple cerebrovascular disease phenotypes. We explored causal associations by employing two-sample Mendelian Randomization (MR) accounting for reciprocal influence between BMI and WHR with multivariable MR. We also assessed what proportion of the association between obesity and cerebrovascular disease was mediated by systolic blood pressure (SBP) and average blood sugar levels (using glycated hemoglobin, HbA1c, as a proxy).

**Results:** Genetic predisposition to higher BMI did not increase risk for cerebrovascular disease. In contrast, WHR was associated with all-cause ischemic stroke, and specifically large artery stroke (Odds Ratio (OR) for 1 log-increment in WHR = 1.75; 95% Confidence Intervals (CI)= 1.44-2.13); and across manifestations of small vessel disease, including small vessel stroke (OR=1.57; CI=1.29-1.91), non-lobar intracerebral hemorrhage (OR= 2.97; CI=1.59-5.57) and white matter hyperintensity (OR=1.1; CI=1.01-1.23). These WHR associations were confirmed when adjusted for BMI. Proportion of the observed effect of WHR mediated by SBP was significant for all-cause ischemic stroke (11.8%), LAS (13.4%) and SVS (11.0%), but no mediation was observed for HbA1c.

**Discussion:** Causal pathological processes, totally or partially independent from hypertension and glucose levels, may link abdominal adiposity with cerebrovascular disease. Potential targets of this cascade elucidated by further research could represent novel therapeutic targets for cerebrovascular disease.

## PgmNr 2777: Calibrated rare variant genetic risk scores for complex disease prediction using large exome sequence repositories.

Although rare variants cause Mendelian disorders, known disease-causing variants explain a negligible portion of population risk for complex diseases. We hypothesized that rare variants (minor allele frequency < 0.001) individually confer modest effects, but are collectively numerous and may account for a considerable proportion of complex disease risk. Identifying true rare variant associations is challenging due to the need for large sample sizes, presence of technical artefacts, and heterogeneity in population structure. We propose a novel method that leverages summary-level data from a large public exome sequencing database (gnomAD) as controls and calibrates rare variant burden at the individual and gene levels to circumvent biases in population substructure and mutation burden, respectively. First, we demonstrate the need for rare variant calibration by showing that gnomAD harbours systematic biases compared to gold-standard consensus sequences. Second, we show through simulations that our method leads to substantial improvements in power while controlling for false-positive associations. Third, applying our method to a comparison of healthy control exomes (N = 6,099) to gnomAD (N = 55,880) empirically demonstrates that it adequately controls for unadjusted genomic deflation ( $\lambda_{\text{unadjusted}} = 0.61$ ;  $\lambda_{\text{adjusted}} = 0.96$ ). The method was then applied to a European coronary artery disease (CAD) cohort (N = 5,921) where the *bonafide* CAD gene, *LDLR*, reached exome-wide significance (OR = 2.21;  $P = 2.09 \times 10^{-12}$ ). A rare variant genetic risk score was generated for the top 970 discovery genes (RVGRS970) and found to associate with CAD in two independent case-control samples: 1) UK Biobank Europeans (N = 45,850) (OR = 1.08 per SD; 95% CI, 1.05-1.12;  $P = 2.50 \times 10^{-6}$ ) and 2) Pakistan Risk of Myocardial Infarction South Asians (N = 6,654) (OR = 1.07; 95% CI, 1.02-1.12;  $P = 0.009$ ). Furthermore, RVGRS970 was independent of both common variant genetic risk score and clinical risk factors (OR = 1.08; 95% CI, 1.04-1.12;  $P = 7.90 \times 10^{-6}$ ), and significantly improved classification of CAD events (Net Reclassification Index = 0.0674;  $P = 7.02 \times 10^{-5}$ ) even when excluding *LDLR*. Current polygenic risk scores have only been derived from common genetic variants. Our method improved CAD risk prediction by accounting for the aggregate effect of rare variants through a polygenic model of inheritance, which was shown to

be robust to gene, individual, and population level biases.

## PgmNr 2778: Rare variant position: Predictor of pathogenicity in cardiomyopathy.

In many Mendelian disease genes, variants cluster in specific regions of the gene. For many observed clusters in the disease cohort, there is a corresponding depletion of variants at the same region in controls. A plausible mechanisms for this phenomenon are multiple loss or gain-of-function mutations in an important motif of the protein.

One Mendelian disease that displays this clustering is hypertrophic cardiomyopathy (HCM). In HCM, causal mutations are rare, dominant, observed in a small set of autosomal genes. Only around half of cases have a mutations in a known gene after genetic screening. Two explanations for this shortfall are; the causal gene is not on the gene panel or the causal variant was not detected. The most common way of determining a causal gene or mutation is an increase in the frequency of mutations in an affected group (cases) versus an unaffected group (controls). However, more power can be gained by integrating more features into the analysis such as allele frequency and pathogenicity scores from variant prediction algorithms. Here, we argue that protein position is a powerful and essential feature to consider.

Here we develop a rare variant association test (POSBURDEN) to screen for novel genes and a statistical model (hcmGAM) to interpret observed variants in core HCM genes. In both, position signal is used to improve power over existing methods. Using simulated data we demonstrate that POSBURDEN is powerful, fast and keeps type 1 error at alpha. When applied to our gene panel data, we see the landscape of burden and position signals across known HCM genes. For most known genes signal strength is increased when considering positional information. For the core genes with strong position signal our predictive model hcmGAM performs very well in distinguishing pathogenic and non-pathogenic variants. The model also outputs predicted odds-ratios with 95% confidence intervals that are useful for novel variant interpretation.

## **PgmNr 2779: DataSTAGE: Leveraging cloud technology to accelerate scientific discovery for heart, lung, blood, and sleep research.**

### **Authors:**

**Affiliation:** Renaissance Computing Institute, University of North Carolina at Chapel Hill, Chapel Hill, NORTH CAROLINA.

---

Biomedical and genomics research represent an exponentially growing source of data that far outstrips individual researchers' ability to store and analyze. Recognizing this challenge and the need to democratize data and tool access for the scientific community, NHLBI initiated DataSTAGE (Storage, Toolspace, Access and analytics for biG data Empowerment) in 2018. DataSTAGE's goal is to enable heart, lung, blood, and sleep research investigators to find, access, share, store, and compute on large data sets. DataSTAGE is a cloud-based platform providing tools, applications, and workflows to enable these capabilities in secure workspaces. DataSTAGE initially focused on opening access to TOPMed datasets, representing a high value, high return for NHLBI investigators.

DataSTAGE is agile and iterative, defining and supporting initial scientific use cases to accelerate infrastructure development. DataSTAGE focused on two initial use cases: 1) enabling large scale genomic analyses and 2) enabling investigators to conduct Deep Learning analyses on image data. Both require addressing extensive challenges, such as handling big data, computing on a large scale, and enabling easy data access. DataSTAGE addresses these by developing solutions on a cloud-based platform utilizing technology and expertise from multiple teams.

Currently, alpha users log in to the DataSTAGE platform with their eRA Commons ID and import datasets of interest into a secure workspace based on their dbGaP credentials. Users can access several tools to explore datasets and to gain a better understanding of cohort characteristics. Additionally, users can conduct high powered analyses such as Genome-Wide Association Studies (GWAS) or Deep Learning on large scale datasets utilizing cloud resources. Users can publish and share their results on the DataSTAGE platform. Users also have access to extensive IT support for questions or suggestions for improvements.

In summary, DataSTAGE has developed many solutions to address NHLBI's challenges. DataSTAGE utilizes cloud technology to empower big data and its computation. DataSTAGE utilizes federated, centralized storage to facilitate secure data access. DataSTAGE worked with TOPMed investigators to provide state-of-the-art, sophisticated tools for genomics and other analyses. DataSTAGE facilitates team science, collaboration, and the ability for investigators to bring-your-own data to the platform. Thus, DataSTAGE significantly accelerates research discovery.

## PgmNr 2780: Malacoda: A Bayesian framework for NGS high-throughput screens that enables knowledge integration.

NGS studies have uncovered an ever-growing catalog of human variation while leaving an enormous gap between observed variation and experimental characterization of variant function. High-throughput screens powered by NGS have greatly increased the speed of variant functionalization, but appropriate and generalized statistical methods to analyze screen data have lagged. In the massively parallel reporter assay (MPRA), short barcodes are counted by sequencing input DNA and output RNA in order to measure the shifts in transcription induced by thousands of genetic variants simultaneously. These counts present many statistical challenges, including over-dispersion, depth dependence, and uncertain DNA concentrations. So far, the statistical methods used have been rudimentary, employing transformations on count level data, disregarding experimental and technical structure, and failing to quantify uncertainty in the statistical model. Analysis is also typically performed in an *ad hoc* manner that has low power, poor specificity, and can be difficult to communicate and reproduce.

We have developed an extensive framework for the analysis of NGS functionalization screens available as an R package called malacoda. Our software implements a generative, fully Bayesian model of screen data. The model uses the negative binomial distribution with gamma priors to model sequencing counts while accounting for effects from input library preparation and sequencing depth. The priors are estimated empirically and can optionally use external annotations such as ENCODE data to obtain informative priors – a transformative capability for data integration. The package also includes quality control and utility functions, including automated barcode counting and visualization methods.

To demonstrate the power of our method, we analyzed published data, created simulations, and performed two MPRA studies to analyze variant-induced regulation of platelet genes. The first MPRA tested 81 variants in *CD36* and identified 10 affecting transcription, including one identified only by malacoda. The second MPRA assessed 2666 variants associated with 184 platelet-related genes, identifying 164 functional variants of which 79 were newly identified by malacoda. Validation experiments have confirmed the function of these variants, demonstrating the method's higher sensitivity and specificity. We have also demonstrated the advantages of our framework on simulated and public MPRA and CRISPR data.

## **PgmNr 2781: The pegasis pipeline for cardiovascular genetic discovery: Open-access pedigree-based shared genomic segment analysis on the American Heart Association Precision Medicine Platform.**

---

The genetics of cardiovascular disease (CVD) is not fully understood and a significant barrier to discovery is heterogeneity. Extended, high-risk pedigree designs can, in part, address this issue by providing a sizable and more homogeneous set of diseased individuals, as well as providing evidence for segregation of susceptibility alleles. However, genetic analyses in large pedigrees can add computational burden and complexity. To provide a more straightforward approach to large pedigree analyses for CVD phenotypes, we have developed a data resource and analysis workflow to facilitate collaborative gene-discovery studies. The Pegasis Pipeline (Pedigree-based Genetic Analyses) is hosted on the American Heart Association Precision Medicine Platform which uses Amazon Web Services. The pipeline consists of two main components: (1) pedigree identification and selection; and (2) shared genomic segment (SGS) analysis. The first component allows the user to define CVD phenotypes and assess the existence of pedigrees. The cardiovascular-based clinical dataset is searched using a Jupyter notebook to identify individuals with a defined phenotype ("cases"), then genealogy and DNA/genetic data from Intermountain Healthcare are used to identify pedigrees with at least four cases with DNA samples. There are a total of 8500 pedigrees defined by the genealogical data and genotype data is already available for a subset with coronary artery disease and atrial fibrillation. Pedigrees can also be drawn as part of the pipeline. The second component allows the user to analyze the genotypes within these pedigrees using SGS. As a pedigree segregation-based method, SGS identifies areas of the genome that cases in the pedigree are sharing and assigns statistical significances to that sharing. The genetic analysis component to the pipeline has a user interface with middleware and postgres database backend and uses the cloud computing environment to dramatically decrease analysis time. The pipeline completes a genomewide SGS pedigree analysis in less than one week. Importantly, the site has received HIPAA compliance certification and provides a secure platform which can be accessed by different institutions. Beta testing of the pipeline using 17 pedigrees with high rates of atrial fibrillation is currently underway. Future collaborative efforts are being developed and we anticipate the pipeline will be ready for external users by 2020.

## PgmNr 2782: Mutational Evidence Visualization (*MutEviz*): Integrated information rich interactive web-based clinico-genomic application of personalized medicine.

### Authors:

S. Krishna Murthy <sup>1</sup>; D. Carey <sup>1</sup>; H. Williams <sup>1,2</sup>; R. Metpally <sup>1</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

**Background:** Processing large information with minimal data handling expertise and time constraints require automated succinct visualization in the field of Precision Medicine. Existing tools that follow the standards and guidance by the ACMG for the variant interpretation have discrete functionality and require that end-users rely on multiple software with complex dependencies for analysis and interpretation. We propose to develop a publicly available tool that assists to easily interpret the clinical significance of variants through graphical representation of variants with adequate functional annotation.

**Methods:** A web-based application developed using R Shiny that helps to visualize variants represented upon the 2-dimensional protein structure from Pfam database with defined Uniprot domains markings and functional sites marked on them. Evolutionary conserved regions are plotted using the amino acid conservation scores from Consurf database provided by the user. Mutational densities of commonly altered local regions of benign variations in control population and hotspot regions are plotted using gnomAD variants with allele frequencies (AF) below the cut off defined by CardioDB's maximum credible population AF and Clinvar pathogenic variants respectively. Read depth and allele frequencies of gnomAD variants are plotted to represent presence or absence of the variants and coverage of the region.

**Results:** With concise visualization and comprehensive feature annotations to variants and genes including GWAS summary statistics, MutEviz is a rich one-stop resource and valuable tool that allow clinicians to meet the research needs head-on. For example, the tool provides supportive evidence to show variant T449I in MYH7 gene to be predictive pathogenic for hypertrophic cardiomyopathy (prevalence 1 in 500; maximum allowed AF 2e-04) as several tools predict this variant adversely affect protein function, it falls in the local Clinvar hotspot region, as well as Constrained Coding Regions of the myosin head domain and it is not detected in GnomAD, 1KG, and ESP databases.

**Conclusion:** MutEviz is easy-to-use visualization tool that delivers information-dense, publication-quality mutation plots. Through the presentation of clear and crisp visualization of variants overlaid on perceptible protein diagrams with ample functional annotation, the tool provides a valuable addition to enable the next round of applications in precision medicine with quick turnaround times.

## PgmNr 2783: Identification of causal transcriptional components for genome-wide association studies by integrating epigenomic data and sequence-based variant prediction.

### Authors:

D. Lee; A. Chakravarti

[View Session](#) [Add to Schedule](#)

---

Most genetic variants associated with diseases and traits from genome-wide association studies (GWAS) are thought to be transcriptional regulatory. Thus, identification of major transcriptional components (transcription factors, regulatory elements, causal variants, and target genes) for GWAS signals is a critical step to understand their underlying molecular mechanisms. To this end, we developed an integrative computational framework, combining genomic and epigenomic data with sequence-based predictive models for regulatory elements and variants. We first perform genome-wide identification of regulatory elements and their variants for each tissue of interest. This regulatory element/variant map is the basis of identifying potential causal variants at GWAS loci in a cell-type specific way. We next connect these trait-associated regulatory variants to their putative target genes using eQTL analyses and additionally predict their potential transcription factors (TFs) through TF binding site motif analysis. Our strategy is likely to identify causal and functional variants and their target genes since we restrict our attention to regulatory variants with plausible functions. As a result, we can establish a genetic link from a variant to a gene to a phenotype for each locus in a tissue-specific way. To validate our approach, we first performed partitioned heritability analysis for several phenotypes across multiple tissues to show that heritability is specifically enriched in phenotypically relevant tissues only. We found 16.5x heritability enrichment of QT-interval in cardiac regulatory variants, 15.2x heritability enrichment for hypothyroidism in thyroid regulatory variants, and 16.8x heritability enrichment for diastolic blood pressure in artery regulatory variants. Given the successful identification of the cardiac tissue from the heritability enrichment analysis for QT-interval, we further predicted target genes in the individual loci using GTEx eQTL data: 73 cardiac regulatory variants that are significantly associated with QT-interval are also heart left ventricle eQTL for 31 distinct genes in 18 loci. Notable genes include *NOS1AP*, *FADS2*, *NDRG4*, *SCN5A*, *KCNH2*, and *ANKRD9*. The identified regulatory variants and their target genes provide a testable hypothesis for further experimental validation. Our approach is generic and can be extended to any GWAS and any tissue of interest.

## PgmNr 2784: Decision support for cardiovascular genetic risk assessment.

---

Cardiovascular disease (CVD) is the leading cause of death for both men and women in the United States with estimates of genetic contributions to risk ranging from 5 to 30%. The Human Genome Sequencing Center Clinical Lab (HGSC-CL), along with sister departments at the Baylor College of Medicine and within the Common Spirit hospital network, have launched a CVD risk gene panel genetic screen (HeartCare™) to assess the merits of genetic testing and DNA screening, create a robust data set for genomic research and to provide a platform for development of data management tools.

Critical needs for the program included serving the clinical components of sample accessioning, consent management, DNA sequencing and EHR integration. Further, an interpretation and decision support pipeline were built, in order to speed the linking of DNA variation to clearly mandated physician action. This includes bioinformatics components for inferring clinical variant interpretation, pharmacogenomics and polygenic risk scores for clinical reporting. Components of this pipeline prompt clinical care directly by triggering best practice alerts in the EHR. For example, Lipoprotein(a) testing is automatically recommended via prompts for patients who are determined to carry LPA genetic risk variants. In aggregate these automated decision support tools greatly reduce the burden on non-genetic physician specialists.

The translational bioinformatics pipeline and infrastructure built for this CVD pilot program, is future proofed and engineered to support other clinical applications at the HGSC-CL. The use of a hybrid cloud and local infrastructure ensures effective capacity, security and compliance management. EHR integration implementations created for this program establish a baseline for future growth and standardization for integration and for building clinical decision support applications.

## PgmNr 2785: Annotation and functional characterization of lncRNAs using integrative GWAS, eQTL and network analysis in lncRNAKB.

### Authors:

M. Pirooznia; F. Seifuddin; A. Suresh; K. Singh; Y. Chen; V. Chaitankar; I. Tunc

**Affiliation:** NHLBI, NIH, Bethesda, MD

---

Advent of high-throughput sequencing technologies and development of efficient tools to analyze big data has led to the surprising discovery that only ~2% of the human genome is protein coding and that a majority of the genome though transcribed, falls into the non-protein coding transcript category. Several groups of researchers have used manual and automated techniques to identify and annotate lncRNAs in the human genome. However, questions remain about the purpose and function of these lncRNAs and whether they play a critical role in normal cell function and/or in disease. Here we present a pipeline that uses publicly available RNA-seq (across 31 solid organ human tissues) and genome-wide association (GWAS) data to functionally characterize ~100,000 lncRNAs available in the lncRNAKB built by step-wise integration of six commonly used lncRNA human annotation databases. First, our analysis addresses the conservation, tissue-specificity, and coding potential of all the lncRNAs curated in the lncRNAKB. Since the expression patterns of lncRNAs are considered to be tissue-specific, tissue-specific metrics were calculated using the RNA-seq data. A tau statistic, which determines the overall tissue specificity of genes, and preferential expression measure (PEM), which scores genes by individual tissue, were computed. In order to determine coding potential of lncRNAs, the FEELnc package which implements a random forest machine learning algorithm (considering various sequence features) was used to determine the coding potential as well as annotate these with respect to protein-coding mRNAs. Next, we constructed tissue-specific protein coding-lncRNA co-expression networks to functionally characterize the cellular processes that the lncRNAs may be involved in using Weighted Gene Co-expression Network Analysis (WGCNA). Finally, we perform tissue-specific expression quantitative trait locus (eQTL) analysis and overlay these to GWAS summary data to identify subsets of single nucleotide polymorphisms (SNPs) in lncRNA that may have an association between gene expression and disease phenotype using Summary-data Mendelian Randomization (SMR) analysis. Put-together, these analyses will provide deep insight into the underlying biology of lncRNAs in cell function and disease across several human tissues. Creating a co-expression network sheds light on the function of lncRNAs in heart failure and how they might contribute to gene expression and pathology.

## **PgmNr 2786: Quality of whole genome sequencing from blood versus saliva derived DNA in cardiac patients.**

Whole-genome sequencing (WGS) is becoming an increasingly important tool for detecting genomic variation. Blood derived DNA is the current standard for WGS for research or clinical purposes. We compared the level of microbial contamination, sequencing coverage, as well as yield and concordance of single-nucleotide polymorphism (SNP) and copy number variant (CNV) calls in WGS from paired blood and saliva samples from 5 pediatric heart disease patients. We found that although saliva samples contained a higher proportion of sequence reads that map to the human oral microbiome, these reads were readily excluded by mapping the reads to the human reference genome. Sequencing coverage was low only in 1 of 5 saliva samples. Over 95% SNPs (including rare SNPs) but <80% CNVs called in blood genomes were detected in paired saliva genomes. These findings suggest that most good quality saliva samples can serve as an alternative to blood samples for detection of sequence variants from WGS in cardiovascular disease patients.

## PgmNr 2787: Examining the lipidomic footprint of hypertension in African Americans.

**Authors:**

D. Nguyen; A. Gaye; G. Goodney; G. Gibbons

[View Session](#) [Add to Schedule](#)

**Affiliation:** National Human Genome Research Institute, National Institutes of Health

---

**Background**

Hypertension (HTN) is prevalent in African Americans (AA), affecting approximately 40 percent of the AA population. As a multifactorial condition, HTN involves many physiological processes and metabolic changes. Recent advances in metabolomic profiling has given rise to the opportunity to examine metabolites involved with HTN. The link between lipids and HTN in African Americans has not been well characterized. This study aims to identify lipid metabolites related to HTN in a sample of AA.

**Methods**

The data consists of plasma lipidomic profiles of 165 AA (99 hypertensives and 66 normotensives) from the Minority Health Genomics and Translational Research Bio-Repository Database (MH-GRID) study.. LC/QTOF MS was used for lipidomics analyses with a total of 407 lipids identified. These lipids were then used as predictor variables in a Random Forests (RF) classification to identify sets of lipid metabolites that predict HTN.

**Findings**

RF analysis identified 7 metabolites that classify hypertensive versus control with an area under the curve (AUC) of 0.80. Five of the seven lipids identified were phosphocholines. The other two lipids were cholesterol and a triglyceride.

**Conclusion**

It has been shown that the levels phospholipids like phosphocholines play an important role in the development of various components of metabolic syndrome. Although the lipid metabolites identified in this analysis are not well characterized, the unbiased and data-driven approach of this analysis suggests that they are likely to play an important role in the in the pathophysiology of HTN. Further work is underway to understand the link between these metabolites and HTN and if it's specific to the genetic ancestry of AA.

## PgmNr 2788: Calling and imputation of the common $\alpha$ -globin copy number variant with whole genome sequencing data in TOPMed and association with hematologic and other clinical phenotypes.

### Authors:

M. Jiang <sup>1</sup>; Y. Su <sup>2</sup>; T.W. Blackwell <sup>3</sup>; A. Correa <sup>4</sup>; G. Abeçasis <sup>3</sup>; A.P. Reiner <sup>5</sup>; Y. Li <sup>2,6,7</sup>; L.M. Raffield <sup>2</sup>

[View Session](#) [Add to Schedule](#)

---

Recent work has shown that inheriting a single copy of the sickle cell causing  $\beta$ -globin variant rs334 (i.e. sickle cell trait) can be associated not only with alterations of blood cell indices and hemoglobin A1c levels, but also with increased risk of certain medical conditions, such as chronic kidney disease. In individuals with sickle cell disease, co-inheritance of another globin gene variant, the 3.7 kb  $\alpha$  globin gene deletion (a common cause of  $\alpha$ -thalassemia in African populations), can modify the risk of stroke and other sickle cell disease complications. In this work, we first aim to better catalog this CNV in population-based cohorts via whole genome sequencing data from the NHLBI Trans-Omics for Precision Medicine (TOPMed) Consortium, assessing the performance of different structural variant calling methods. We next evaluate the ability to impute this CNV using SNP genotypes from commercial arrays. Lastly, we conduct association analysis for main effects of the  $\alpha$  globin CNV and its interactions with other globin gene variants on a battery of hematological traits and other clinical phenotypes including stroke, chronic kidney disease, and hemoglobin A1c levels. Preliminary results from 2,916 African Americans in the Jackson Heart Study demonstrated highly reliable calling using either GenomeSTRiP or LUMPY (correlation >0.99). In addition, we can achieve reasonable imputation quality for structural variant calls ( $r^2 = 0.629$  using minimac3) for imputation from Affymetrix 6.0 SNP genotypes in JHS. Finally, association analysis confirmed the CNV's significant main effects as well as interaction effects with other  $\beta$  globin variants on multiple traits. For example, the CNV is associated with higher hemoglobin A1c ( $p = 0.0001$ ) and also attenuates the increased risk of anemia in carriers of sickle cell trait ( $p_{interaction} = 0.031$ ). We anticipate that accurate calling and imputation of this CNV in additional African American and Hispanic/Latino cohorts will allow powerful interrogation of its main and interaction effects on a wide range of blood cell and other clinical phenotypes.

## PgmNr 2789: Transcriptome signature of declined kidney function in hypertensives from the Minority Health-GRID study.

### Authors:

M. Pavia; A. Gaye; G. Goodney; G. Gibbons

[View Session](#) [Add to Schedule](#)

**Affiliation:** NHGRI, NIH, Bethesda, MD.

---

### Background

The disproportionate burden of hypertension and chronic kidney disease (CKD) amongst African Americans is a well-documented public health concern in the United States. However, the relationship between these two conditions and the genes that predict them, particularly in this understudied population, requires further investigation. The purpose of this study was to explore whole-blood genome-wide transcriptome to identify clusters of genes related to declined kidney function in hypertensive subjects.

### Methods

The analysis used whole-blood transcriptome of 180 individuals from the Medicine Minority Health Genomics and Translational Research Bio-Repository Database (MH-GRID) Study. Cases are hypertensive with signs of declined kidney function based on eGFR and albumin-creatinine ratio (ACR). Weighted Gene Co-expression Network Analysis (WGCNA) was used to identify clusters of genes associated with the phenotype of interest.

### Results

A total of 3 network modules of respectively 133, 704 and 110 were found positively associated with reduced kidney function in hypertensive subjects. One of the modules is also associated with systolic and diastolic blood pressure (SBP and DBP) whilst the other 2 are associated with inflammasome proteins including MMP-3, MMP-7 and MMP-9. The top pathways enriched in the modules of co-expressed genes are respectively *Receptor-Mediated Endocytosis(RME)*, *STAT3* and *B cell Development*.

### Conclusion

The network analysis approach revealed a cluster of co-expressed genes enriched in RME pathway. The endocytic pathway is central in the uptake of low molecular weight protein in the proximal tubule of the kidney; if impaired this process leads to proteinuria. Matrix metalloproteinase (MMP) genes are involved in the degradation of the extracellular matrix (ECM) which is crucial in the development of CKD.

---

Short read sequencing with alignment to reference genome is the conventional approach to whole genome analysis but has difficulty resolving low-complexity repeats and structural variants (SVs), and performs poorly in variant phasing for haplotype construction. Exemplary challenges are genetic modifier loci of Cystic Fibrosis (CF) identified by GWAS, where several align to regions of the genome that are repetitive, GC-rich, or contain SVs (eg. *MUC5b*, *PRSS1*, *SLC9A3*). To understand the mechanisms by which these modifier loci contribute to CF disease severity we aimed to improve genome resolution with *de novo* assembly of individual genomes.

The 10x Genomics Chromium platform uses barcodes that link short reads from common DNA molecules. This linking information enables phasing and increased detection of SVs, but is still limited in low-complexity and repetitive regions. Pacific Biosciences (PacBio) technology allows sequencing of longer reads from single molecules but is highly error-prone and costly at high read-depth. We introduce a novel pipeline for building hybrid *de novo* assemblies using data from both platforms.

Our hybrid method uses separate 10x and PacBio assemblies as input. Scaffolds from 10x are split into 1kb chunks and aligned to the PacBio assembly. Contiguous chunks define blocks of homologous sequence between the assemblies and are used to fill gaps, correct misassemblies, scaffold contigs, and maximize nucleotide accuracy. A single hybrid assembly is produced and phased using both 10x and PacBio reads.

Our hybrid assembly pipeline will be applied to genomic DNA from participants of the Canadian CF Gene Modifier study (n=100 planned; 30x and 50x coverage for 10x and PacBio, respectively). Results for the first 8 hybrid assemblies displayed a mean of 2.81Gb in 837 scaffolds compared to 10x (2.87Gb, 19231) and PacBio (2.97Gb, 4055) assemblies. The average hybrid N50 (46Mb) was improved from the 10x (25Mb) and PacBio (15Mb) alone. An average of 44000 (98%) gaps within the 10x assemblies were resolved by our hybrid. Phasing produced large haplotype blocks, some on the scale of entire chromosomal arms.

The hybrid assemblies have resolved locus complexity at several CF modifier loci and informed specific regions of interest that are currently being investigated. Here we present our progress to

date, benchmark our method using data from the Genome in a Bottle Consortium, and demonstrate a high-quality hybrid even at reduced PacBio read depths.

## PgmNr 2791: Identification of novel genes associated with hypoxia response using Boolean implication relationships.

---

Hypoxia plays a major role in the etiology and pathogenesis of most of the leading causes of morbidity and mortality, whether cardiovascular diseases, cancer, respiratory diseases or stroke. Despite active research on hypoxia-signaling pathways, the understanding of regulatory mechanisms, especially in specific tissues, still remain elusive. With the accessibility of thousands of potentially diverse genomic datasets, computational methods are utilized to generate new hypotheses and expedite existing endeavors. Here we utilized Boolean relationships, a powerful method to probe correlated genes, of a well-known hypoxia-responsive gene, *VEGFA*, with very large human expression datasets ( $n = 25,955$ ) to identify novel hypoxia-responsive candidate gene/s. Subsequently, we utilized *in-vitro* analysis using human endothelial cells exposed to 1% O<sub>2</sub> environment for 2, 8, 24 and 48 hours to validate few of the top candidate genes. There were 160 genes with correlation coefficient value of  $>0.5$  with *VEGFA*. Our preliminary analysis of the top 15 genes which were also in a Boolean relationship with *VEGFA* reveals *FAM114A1* as a novel candidate gene significantly upregulated and *EPS8* downregulated in the endothelial cells at 24 and 48 hours of 1% O<sub>2</sub> environment. Furthermore, an additional 11 genes were previously reported as hypoxia responsive genes, validating our result. At this rate of  $>85\%$  (13 out of 15) positive hits our results confirm that the additional *in-vitro* validation of Boolean correlated genes will reveal novel hypoxia responsive candidate genes. Furthermore, since Boolean logic is an empirically observed invariant of gene expression levels of two genes, this method can simultaneously identify both HIF-dependent and HIF-independent hypoxia-responsive genes.

## PgmNr 2792: Establishing quality control practices for phenome-wide association studies (PheWAS).

Phenome-wide association studies (PheWAS) allow agnostic investigation of common genetic variants in relation to a variety of phenotypes. Preserving the power of PheWAS requires careful phenotypic quality-control (QC) procedures. While the QC of genetic data is well-defined, there are no established practices for QC of multi-phenotypic data. Manually imposing sample size restrictions, identifying variable types/distributions, and locating problems such as missing data or outliers is arduous in large, multivariate datasets. To this end, we utilized the novel R package CLARITE (CLEaning to Analysis: Reproducibility-based Interface for Traits and Exposures), which allows efficient QC. Data from the Ludwigshafen Risk and Cardiovascular Health Study (LURIC) was used for a coronary-related PheWAS in 2,824 samples. Initially, genome-wide single nucleotide polymorphisms (SNPs) were tested for association with 15 disease phenotypes using logistic regression. No results reached genome-wide significance. One result, mortality after follow-up, was close to significance ( $p:9.57e-07$ ) and involved in a missense mutation in *PDZRN4* (rs285584). A second PheWAS assessed association between genome-wide SNPs and 14 polyunsaturated fatty acids (PUFAs), as omega-3 fatty acids are implicated in heart disease. Seven SNPs were genome-wide significant in association with dihomo- $\gamma$ -linolenic acid. Five of those SNPs were within fatty acid desaturases *FADS1* and *FADS2*, which are key catalyzers of PUFA synthesis and well referenced in GWAS literature. The remaining SNPs were in *FEN1* and *MYRF*. Mutations in *MYRF* have been identified in congenital cardiac abnormalities. PheWAS is a useful tool to elucidate the genetic architecture of complex disease phenotypes within a single experimental framework. Here, we utilized CLARITE across a diverse set of variables, demonstrating its utility in QC of various variable types, which would be arduous to perform by hand. Finally, we provide a generic QC pipeline for phenotype data, widely applicable to genome-wide datasets.

## PgmNr 2793: Temporal variation of regulatory organization based on longitudinal RNA-seq data in twins.

---

A new study by our lab (Delaneau et al. Science 364 (6439), eaat8266, 2019) used population-based chromatin data to identify cis-regulatory domains (CRDs), which show cell type-specific coordinated chromatin activity and follow the local chromatin organization into topologically associated domains.

However, for most human genetic studies, chromatin data is not available and the identification of CRDs becomes difficult and expensive. Therefore, we extended our previous work to characterize regulatory organization of the genome using only gene expression data from RNA-seq studies and genotypes. Here, we define co-expression domains (CODs) as groups of significantly correlated proximal genes (Ribeiro et al. ASHG 2019). We use a gene-central approach, in which we identify for each gene individually all correlated genes located within a cis-window of 1Mb. From the resulting list of co-expressed pairs of genes we summarize connected pairs into CODs which therefore can span several Mbps and may overlap with each other.

In our current work we aim to understand how the regulatory organization changes over time using a longitudinal gene expression dataset. The MutliMuTHER study includes 335 individuals with whole-blood RNA-seq data collected at three time-points over seven years, as well as imputed genotypes from the TwinsUK cohort (El-Sayed Moustafa et al. ASHG 2019). We identify CODs in each of the three time-points as well as integrating across the three time points, and explore their association to genetic variation by performing QTL analysis, which identifies genetic variants associated to the level of expression coordination of the genes involved in each of the CODs. Furthermore, we investigate the stability of CODs over time, as well as age-associated changes in coordinated regulation. Using the unique properties of twins studies, we have performed a variance decomposition analysis to estimate heritability, i.e., the proportion of variance attributed to the genetic component in CODs as well as to the environmental contribution. Finally, we associate the CODs to clinically relevant phenotypes in an attempt to identify CODs involved in the regulation of cardiometabolic traits such as cardiovascular

diseases and diabetes.

## PgmNr 2794: Trans-ethnic GWAS with individual-level data identified potential risk for cleft lip.

### Authors:

Y. Jiang; C. Tian; S. Shringarpure; D. Hinds

[View Session](#) [Add to Schedule](#)

**Affiliation:** 23andme, Mountain View, California.

Cleft lip is one of the most common birth defects in the world. The prevalence for cleft lip varies across continents: it affects one in every 940 births in the US and 1 in every 500 births in East Asia. Although several studies have been conducted to identify the genetic etiology of the disease, the risk factors are not yet clear. The majority of these studies were conducted on case-parent trios of European- or East Asian-ancestry with follow up meta-analysis on the summary statistics. This poses two questions: 1) How well do these findings generalize to other under-represented populations? 2) Are meta-analyses of summary statistics under-powered compared to analysis utilizing individual-level data?

To tackle these issues, we conducted a trans-ethnic GWAS using de-identified and consented individual-level data in 23andMe's database. Our study included 1,410 cases and 146,0457 controls of European ancestry; 572 cases and 4,4611 controls of Non-European ancestry. Specifically, our non-European cohort including individuals from Latino, East Asian, African, South Asian, and Middle Eastern. We performed statistical tests using the generalized linear mixed model and estimated the distribution of the score-statistics using saddle-point approximation (implemented in SAIGE). We used 63,654 SNPs across autosomes to construct the genetic relationship matrix and did not observe genome-wide inflation caused by population structure. Our trans-ethnics mixed-model GWAS identified 8 loci (8q24, 10q25, 17p13, 20q12, 1p36, 1p22, 8q21, 2p21) reached genome-wide significance level ( $p\text{-value} < 5e-8$ ). These loci have been reported separately by various studies. We also found 10 more loci reached the suggestive significance level ( $p\text{-value} < 1e-6$ ). In parallel, we also ran GWAS on each population and conducted meta-analysis on the summary statistics. With nearly identical sample size, mixed model and meta-analysis have similar results, whereas mixed-model show stronger associations for certain loci. We will follow-up the hits with functional analysis.

In conclusion, with individual-level data across 6 populations, trans-ethnic GWAS on cleft-lip provides valid results without genome-wide inflation. With more related individuals in the database, e.g. UKbiobank, mixed-model will be a robust and powerful tool for carrying out trans-ethnic GWAS and help under-represented populations to benefit from genetic research.

## PgmNr 2795: Update from the NIH Oculocutaneous Albinism Natural History Protocol: Molecular characterization of the study cohort.

### Authors:

L. Lundh; D. Adams

[View Session](#) [Add to Schedule](#)

**Affiliation:** National Human Genome Research Institute, National Institutes of Health, Bethesda, MARYLAND.

---

Oculocutaneous albinism (OCA) comprises of rare, inherited disorders of melanin production. Clinical manifestations include skin, hair and eye hypopigmentation along with disrupted visual development. Pigment reduction in OCA occurs along a spectrum from complete absence of melanin to near-expected levels for a given ancestry. All defined types of OCA are inherited in an autosomal recessive manner. The reported rate of successful molecular diagnosis varies depending on residual pigment production—greater than 90% if no pigment is made and as low as 50% with near-normal pigment levels. There is no known treatment for OCA. The NIH OCA Study, established in 2008, works with volunteer study participants with OCA. As part of the process of collating study data for publication, we are re-visiting the molecular diagnoses of our 132 study participants. Presented here is an update about our observations about molecular diagnosis rates. Study participants are evaluated at the NIH Clinical Center as part of an IRB approved protocol. Blood DNA is routinely extracted for analyses including the sequencing of known albinism genes. Sequencing methodology has changed over the course of the study and includes direct Sanger sequencing and short-read based capture panels. In early stages of the study, sequencing of less common OCA genes occurred only if more common gene sequencing was unrevealing. Approximately 95.5%, 65.2% and 28.8% of study participants have been sequenced for the two most common, the four most common, and all known-genes respectively. Successful molecular diagnosis includes 42.7% OCA type 1 (*TYR* gene), 14.5% OCA type 2 (*OCA2* gene), 0.8% OCA type 3 (*TYRP1* gene), and 4.0% OCA type 4 (*SLC45A2* gene). Overall, 37.9% of our cohort has an incomplete molecular diagnosis. Using visual phenotypic categories, the success of molecular diagnosis was 94% in individuals with no residual pigmentation, 72% with trace pigment production and 46% with greater-than-trace pigment production. Missing heterogeneity in OCA is frequently debated and suggested etiologies include missing genes, gene-gene interactions, background pigment variation threshold effects and non-coding variation. Our data set supports previous observations that the successful molecular diagnosis rate is reduced in the setting of residual pigment production. We present further detail about our cohort and describe ongoing initiatives designed to explore and resolve basic questions about OCA inheritance.

## PgmNr 2796: Type-2 diabetes and cognitive function: Unravelling a potential causal relationship using bidirectional Mendelian randomisation in the UK Biobank.

Type 2 diabetes has previously been associated with poor cognition in the epidemiological literature, but the direction of effect and whether it is causal, remains unclear. We aimed to investigate, using a bidirectional Mendelian randomisation design, whether having diabetes is causally associated with poorer cognition, and/or whether poorer cognition might lead to diabetes. We used data from both men and women in the UK Biobank, a population-based study of 500,000 individuals, aged between 40-60 years. Diabetes was defined using a validated algorithm. Cognitive function tests at baseline included a reaction time test. Mendelian randomisation analyses used an inverse-variance weighted approach, and MR-Egger as a sensitivity analysis to detect unbalanced horizontal pleiotropy. Our type-2 diabetes genetic instrument consisted of 163 single nucleotide polymorphisms (SNPs) from the latest genome-wide association study, whilst our genetic instrument for reaction time comprised 43 SNPs. There were complete data for 349,326 white European participants who passed genetic quality control and had cognition data, with ~14,000 type-2 diabetes cases. Inverse-variance weighted Mendelian randomisation showed no evidence of a causal effect of diabetes on reaction time ( $\text{Exp}(\beta) = 1.00$ , 95% CI = 0.99; 1.00). In addition, there was no causal effect of reaction time on diabetes risk (OR = 0.96, 95% CI = 0.63; 1.46). MR-Egger indicated that there was unlikely to be unbalanced horizontal pleiotropy in either of the above,  $P_{\text{Egger intercept}} = 0.342$  for reaction time and  $P_{\text{Egger intercept}} = 0.457$  for diabetes. In UK Biobank, we found no evidence of a causal relationship between diabetes and reaction, or reaction time and diabetes, using bidirectional Mendelian randomisation. We conclude that in white Europeans, this relationship appears not to be causal, but this may not be the case in other ethnic groups, who are disproportionately burdened by diabetes.

## PgmNr 2797: Robust methods to combine *p*-values from independent experiments.

---

Meta-analysis increases statistical power by combining statistic from multiple studies. Meta-analysis methods have mostly been evaluated under the assumption that all the data in each study are associated with the given phenotype. However, data in some studies can yield nearly random statistic due to different experimental conditions or genetic heterogeneity. Here, we propose two robust methods to combine *p*-values obtained from independent studies, a novel weighted Fisher's method and *p*-value of minimum marginal *p*-value in joint order distribution. *T*-test and GWAS simulation analysis demonstrated that proposed methods outperformed existing *p*-value combining methods and also compared favorably with state-of-the-art methods for GWAS, when only a small number of experiments (or cohorts) were associated with the phenotype. Finally, our methods were applied to exome sequencing data composed of eight cohorts and detected a novel locus (rs37411300; BUD13) associated with triglyceride level.

## PgmNr 2798: Resilience to polygenic risk of severe obesity: The Hispanic Community Health Study/ Study of Latinos (HCHS/SOL).

**Introduction:** Severe obesity (SevO) is a global public health threat, especially for African and Native American ancestries, and is highly heritable with multiple polygenes, environmental, and behavioral determinants. Polygenic risk scores (PRS) are a novel approach to quantify inherited susceptibility that affords new opportunities for clinical prevention and mechanistic assessment. Yet even when PRS perform well, those at highest risk may be resilient to obesity. Thus, we applied PRS to Hispanic/Latino (H/L) participants of HCHS/SOL to find factors associated with leanness in the context of an obesogenic environment and high polygenic risk.

**Methods:** HCHS/SOL is a community-based prospective cohort of 16,415 H/L adults aged 18-74 years at screening from randomly selected households at 4 US field centers. We constructed PRS with PRSice using a BMI MEGA analysis of GIANT and UK Biobank and applied to 10,122 HCHS/SOL participants with BMI ( $29.8 \pm 6.0$ ) and genotype data (Illumina SOL Omni2.5M array imputed to 1000 Genomes Phase 1). We categorized resilience as normal weight (NW) persons in the top PRS decile ( $N=113$ , BMI= $22.9 \pm 1.8$ , age  $41.6 \pm 14.8$ , 42% male) and compared their lifestyle and cardiometabolic traits to those of SevO persons in the same PRS decile ( $N=121$ , BMI= $45.3 \pm 4.7$ , age  $46.6 \pm 12.6$ , 19.4% male) and to NW in the lowest decile ( $N=330$ , BMI= $22.5 \pm 1.9$ , age  $45.9 \pm 15.0$ , 43% male), adjusting for age, sex, and population substructure.

**Results:** The NW resilient group was significantly healthier than the SevO top PRS group with respect to hypertension (12.4 vs 40.5%), T2D (15.0 vs 41.3%), HDL-C (53.8 vs 45.0mg/dL), and triglycerides (102.1 vs 143.7mg/dL), potentially related to higher physical activity (2.8 vs 1.5hrs/day), shorter time living in the US (19.5 vs 28.3yrs), higher rates of foreign birth (13.1 vs 21.0%), and higher current smoking (34.5 vs 17.4%). Yet, the NW resilient group had more prevalent T2D (16.7 vs 8.5%) than the NW low PRS group, despite similar estimates of central fat. Sensitivity analyses showed consistent effects across Caribbean vs Mainland ancestry.

**Conclusion:** Those resilient to obesity are more physically active, more likely foreign born, and spent fewer years living in the US. Although resilient individuals appear to be metabolically healthy, they have higher T2D prevalence. Identification and characterization of modifiable factors influencing resiliency to genetic risk may lead to changes in how we target, prevent and treat SevO.

## PgmNr 2799: Genome-wide polygenic risk scores for 23andMe phenotypes based on UK Biobank GWAS summary statistics.

### Authors:

W. Wang; S. Shringarpure; A. Auton

[View Session](#) [Add to Schedule](#)

**Affiliation:** 23andMe, Mountain View, California.

---

Polygenic risk scores (PRS) from large scale genome-wide association studies (GWAS) have been commonly applied to the prediction of risk of developing a complex disease. It is expected that larger datasets and improved statistical methodology will result in more accurate predictions, but it remains unclear how PRS generated in one large-scale dataset can be applied to another. For this reason, 23andMe's large-scale and diverse database that combines genotype data with self-reported phenotype data offers a great opportunity to obtain a more comprehensive assessment of PRS approaches.

We applied LDpred on UKBB GWAS summary statistics to construct polygenic risk scores in the 23andMe database and evaluated the performance of the risk prediction for potential prevention.

We constructed PRS with around 4.5 million genetic variants for over 100 phenotypes. We tested the prediction performance of the PRS in the 23andMe database by assessing the prevalence stratified by PRS. We undertook prospective validation on selected phenotypes to check the incidence rate across age based on genetic risk levels, using 23andMe health update data from health history survey where customers update their health status annually.

We assessed the prediction performance over 100 phenotypes, such as type 2 diabetes, deep vein thrombosis, gout, pulmonary embolism, high blood pressure, type 1 diabetes and heart diseases. For each 23andMe phenotype, the prevalence in the high risk group stratified by PRS which developed from UK Biobank GWAS is significantly higher than the prevalence of the rest of the population. For example, the prevalence of type 2 diabetes in the top 5% high risk group is 1.9 times higher than the rest. By checking the 1-year incidence rate of type 2 diabetes across age in 23andMe health update data based on different PRS levels, we found the cumulative 1-year incidence is 0.46% at age 60 and 0.9% at age 90 in the top 5% high risk group, compared to 0.21% at age 60 and 0.46% at age 90 for the remaining population. For the bottom 5% low risk group, the cumulative 1-year incidence is 0.05% at age 60 and 0.24% at age 90, compared to 0.24% at age 60 and 0.5% at age 90 for the rest of the population.

The polygenic risk scores developed from UK Biobank GWAS summary statistics show promise for predicting performance on 23andMe phenotypes. The progression analysis on 23andMe health update data highlights the potential for enhanced screening and prevention based on genetic risk.

## PgmNr 2800: Detection of copy-number duplication at 5q31.3 and its association with obesity in Arab population.

### Authors:

P. Hebbar <sup>1,2</sup>; R. Nizam <sup>1</sup>; S. Elsa John <sup>1</sup>; M. Melhem <sup>1</sup>; J. Pitkaniemi <sup>3</sup>; J. Tuomilehto <sup>3</sup>; F. Al-Mulla <sup>1</sup>; T. Alphonse Thanaraj <sup>1</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Genetics and Bioinformatics, Dasman Diabetes Institute, Shark, Kuwait city, Kuwait; 2) Doctoral program in Population Health, Department of Public Health, Faculty of Medicine, University of Helsinki, Finland; 3) Department of Public Health, University of Helsinki, Helsinki, Finland

---

**Aim:** Obesity is a growing health concern for the Arabian Peninsula. Yet, there is a lack of convincingly determined genetic risk variants - single nucleotide polymorphisms (SNP) and copy number variants (CNV) - for adult obesity in Arabs. In this study, we aimed at delineating copy number variations associated with quantitative traits relating to obesity in Arab population.

**Method:** We performed a genome-wide association analysis of CNVs identified from genome-wide genotyping data from 950 native Arab adult individuals from Kuwait and performed validation with whole-exome sequencing data from a cohort of 191 native Arab adult individuals. We used PennCNV program to call CNVs from genome-wide genotype florescent intensity signals and PennCNV-ExomeSeq to call CNVs from exome sequence read depths. We used ParseCNV suite to create individual files for Deletion and Duplication and then to perform statistical association tests using linear regression on quantitative phenotypes such as BMI, Weight, Waist circumference, Height.

**Results:** CNV discovery using genome-wide genotyping data delineated a duplication at genomic region chr5:140201219-140210616 comprising *PCDHA1-PCDHA6* genes. Further validation using exome sequencing data also confirmed CN-duplication at this region. Both genome-wide genotyping and validation using exome data showed consistency in CNV calls with 6% frequency for CN-duplication. Statistical association of CN-duplication showed that the CN-duplication associated with elevated levels of anthropometric traits such as BMI (beta=2.659; p-value=0.0006) and Weight (beta= 6.562; p-value=0.003).

**Conclusion:** The CN-duplication comprising protocadherin genes has been previously associated with childhood obesity and extreme obesity in Korean population. Our study further supports the involvement of protocadherin genes in obesity traits in Arab population.

## PgmNr 2801: Alterations in serum biomarkers and bioavailable testosterone are associated with loss of the Y chromosome in UK Biobank men.

Post-zygotic genetic alterations occur in hematopoietic stem cells and can lead to clonal mosaicism. Clonal mosaicism has been associated with increased risk of chronic diseases such as leukemia and cardiovascular disease; however, the biological mechanisms linking mosaicism to disease risk are largely unknown. Detected mosaicism could serve as a proxy of genomic maintenance or may reflect a cellular environment favorable for chronic disease onset. Mosaic loss of chromosome Y (mLOY) is the most frequently detected large mosaic copy number alteration with studies reporting frequencies of mLOY >20% in elderly men. We investigated potential associations between mLOY and serum biomarkers in UK Biobank men. After exclusion of men with cancer, the analytic cohort consisted of 208,775 men age 37 to 73 years old. We detected mLOY by scanning for deviations in the median log<sub>2</sub> R ratio (mLRR) of array probes in male-specific region of the Y chromosome. Blood biochemistry measurements were regressed against chromosome Y mLRR and related risk factors (age, ethnicity, smoking, alcohol consumption, body mass index, and disease diagnosis) to identify possible associations. Our analysis identified associations between mLOY and increased total testosterone, sex-hormone binding globulin (SHBG), high-density lipoprotein (HDL), apolipoprotein A (apoA) as well as decreased urate, triglyceride, low-density lipoprotein (LDL), cystatin C, cholesterol, and apolipoprotein B (apo B). We also performed analyses on the concentration and percentage of free and bioavailable testosterone and found lower levels of free and bioavailable testosterone in men with mLOY. To further investigate the association between mLOY and blood biochemistry measurements, we constructed a polygenic risk score (PRS) for mLOY based on 156 known SNPs associated with mLOY. Using this mLOY PRS, we found associations between mLOY and blood biochemistry panels persisted in apo B, cholesterol, LDL, SHBG, urate, free and bioavailable testosterone. Collectively, these results suggest modified sex hormone and serum biochemistry levels in men with mLOY. Further longitudinal studies are needed to disentangle whether these observations reflect a common cause between alterations in these serum biomarkers and mLOY or if alterations in these serum levels are potentially risk factors for or outcomes of mLOY.

## PgmNr 2802: Impact of reference panel choice for imputation on genome-wide association study results for type 2 diabetes in Arab population.

The prevalence of Type 2 Diabetes Mellitus (T2DM) varies substantially among ethnicities because of dissimilarity in lifestyle and genetic makeup. Genome-Wide Association Studies (GWAS) with T2DM have mostly been conducted in populations of European and Asian origin, and it remains to be confirmed whether they will be similar in the Arab population.

In this study, we conducted a GWAS for T2DM in a cohort of Kuwait-resident Arab population (498 cases and 1141 controls), genotyped on the Illumina HumanCardio-MetaboChip array. We evaluated the accuracy of imputation with Minimac3 and its impact on GWAS results using four reference panels: (1) 1000 Genomes Project data (1KG), (2) a public dataset of 108 healthy Qataris with Whole Genome Sequence (Q108), (3) the two previous datasets merged (1KG+Q108), and (4) a cohort of ~1000 Arab subjects, containing both healthy and T2DM patients, with Whole Exome Sequence.

Our preliminary results showed that the 1KG imputation generally led to the best performance across different Allele Frequency intervals. The Q108 imputation yielded similar performance to 1KG imputation for common variants despite its small size. Merging the two datasets decreased imputation performance.

For all imputations we performed, we confirmed two T2DM susceptibility genes, *TCF7L2* (Lead SNP was rs34872471, *P* value=9.58E-08, OR=1.6, 95% CI = [1.34,1.9]) and *GLIS3* (Lead SNP was rs10814915, *P* value 2.57E-05, OR =1.44, 95% CI = [1.22,1.71]). We also identified three genes, using 1KG imputation only, that could play a role in T2DM. These genes were *KCNE4*, *PTPRT*, and *PTRF*.

## **PgmNr 2803: Analyses of variants in GCK, RAPGEF, G6PC2, IGF, related genes for type 2 diabetes and fasting plasma glucose risk in Korean repeated community-based cohort.**

Type 2 diabetes mellitus (T2DM) is one of complex disease (T2DM). By association for various traits related to T2DM, important variations were reported consistently. In National Institution of Health in Korea, 10,038 participants were selected by the Korean Genome Epidemiology Study project (KoGES) and generated by the Korean Association Resource (KARE) through the Korean Genome Analysis Project (KoGAP). Type 2 diabetes was diagnosed based on the criteria of WHO.

We were analyzed genome-wide association for these traits like Type 2 diabetes mellitus, FPG(Fasting plasma glucose), BMI(body mass index), etc. and then also considering their relation. Moreover, Glycemic traits were used screening diabetes. We focused two traits (T2DM and FPG) in Korean repeated community based on cohort because FPG trait also diagnosed T2DM. We had analyzed clinical, epidemiological data that community based on cohort in two repeated (baseline and 12-year follow-up). We also genotyped and imputed using 1000 Genomes.

The association of each traits baseline and repeated were same tendency or effects in baseline and repeated (12-year follow-up).

The genes that had different aspects for FPG and T2DM were analyzed using linear regression adjust BMI (Body Mass Index). Especially, rs1799884 was significant for FPG in baseline and follow-up(P Value=5.37E-05, 2.97E-04) and also for T2DM(PValue=2.07E-08, 5.57E-05). Estimations of absolute beta had a tendency for increasing absolute beta estimates in follow-up data compare to baseline. Our results maintained even whenever variant is not significant in each trait (FPG or T2DM). Most studies that GCK gene is associated with T2DM or FPG. In Korean population had not reported the association for T2DM. However, we have got the results that association for FPG and T2DM but its results is significant. Our finding that rs1799884 is significant for two traits (FPG and T2DM) could help to identify high risk group of T2DM than any other locus.

**Acknowledgements:** This study was supported by intramural grants from the Korea National Institute of Health (2019-NI-097-00) and with bioresources from National Biobank of Korea, the Center for Disease Control and Prevention, Republic of Korea.

## PgmNr 2804: The functional impacts of rare coding variants in 46,000 individuals on 23 quantitative phenotypes.

---

While common variant genome-wide association studies (GWAS) have identified many complex trait-associated genetic loci, identifying causal genes and mechanisms remains a challenge. Through an analysis of 23 cardiometabolic quantitative traits (QTs) in 46,000 exome sequenced individuals from five ancestries, we ask to what extent can rare coding variants complement GWAS by providing insight into (a) effector genes that mediate GWAS associations and (b) specific molecular gene perturbations that impact disease risk. Exome-wide analysis indicated a total of 394 variant associations that were significant; nearly all are within 250 kb of known GWAS loci and collectively suggest >20 genes as novel effector candidates. Gene-level analyses of rare loss-of-function and damaging missense mutations produced 34 exome-wide significant associations; all are within 250 kb of known GWAS loci and one in particular suggests *ABCA6* as an effector gene which mediates an increase in LDL levels. We next evaluated whether rare coding variants could offer molecular insights even within genes that did not achieve exome-wide significance. First, for 18 QTs, we used the MAGMA gene-level analysis method to calculate gene-level GWAS association scores; the top 100 genes ranked by MAGMA had (collectively) a significant ( $p < 0.05$ ) excess of rare coding variant associations for six QTs and a near significant excess ( $p < 0.1$ ) for four QTs. Second, for six QTs, we curated gene-sets implicated in the trait by mouse knockouts and found that three had a significant excess of rare coding variant associations with another trait near significance. These results suggest that many disease-relevant genes harbor rare coding “allelic series” with varied molecular and phenotypic effects. In many cases, distinct allelic series exist for multiple traits; we find 56 genes in which distinct sets of variants associate with at least one QT below  $p < 1e-4$  and a second QT below  $p < 0.05$ . Such genes offer the potential to explore selective targeting of a gene as a means to affect one phenotype but not others; for example, within *SLC30A8*, a known type-2 diabetes (T2D) gene, we find three distinct allelic series for: T2D, fasting glucose, and fasting insulin/BMI/hip circumference. Collectively, these results confirm that rare coding variants offer a valuable resource for probing the molecular function of genes. Finally, we describe a public web-portal for viewing these data to assist with downstream functional analyses.

## PgmNr 2805: Building genetic risk scores with penalized regressions to infer whether an environmental factor attenuates or exacerbates the adverse influence of a candidate gene.

The detection of “gene-environment interactions” (GxE) is important and is even more challenging than the detection of genetic main effects. Although some gene-based GxE methods have been developed, very few GxE findings have reached the genome-wide significance level (i.e.,  $p < 2.5E-6$ , where  $2.5E-6$  is the commonly used significance level in genome-wide gene-based analyses). Most evidence of GxE was discovered from candidate gene analyses in which genome-wide association study (GWAS) hits were targeted. It is of interest to know whether an environmental factor (E) attenuates or exacerbates the adverse influence of a candidate gene. Different from most set-based gene-environment interaction tests, genetic risk score (GRS) approaches can not only provide a  $p$ -value for the significance of “gene-environment interaction” (GxE) but also guide inferences on how E modifies the effect of a gene. If E exacerbates the adverse influence of a gene, GRS constructed by the elastic net (ENET) or the least absolute shrinkage and selection operator (LASSO) is recommended. However, the performance of ENET or LASSO will be compromised if E attenuates the adverse influence of a gene, in which the sensitivity of selecting trait-associated SNPs is much lower than that in the exacerbation scenario. Instead, using the ridge regression (RIDGE) is more powerful in this situation. Applying RIDGE to 18,424 subjects in the Taiwan Biobank, we showed that performing regular exercise can attenuate the adverse influence of *the fat mass and obesity-associated (FTO)* gene on 4 obesity measures, including body mass index ( $p = 0.0033$ ), body fat percentage ( $p = 0.0097$ ), waist circumference ( $p = 0.0254$ ), and hip circumference ( $p = 0.0023$ ). Moreover, we replicated that *the fibroblast growth factor 5 (FGF5)* gene has a stronger effect on diastolic blood pressure with a higher BMI ( $p = 0.0106$ ). Our approaches provide an important inference on whether an environmental exposure attenuates or exacerbates the adverse influence of a candidate gene.

Complex traits and diseases are influenced by genetic factors, in part through altering gene expression. Leveraging existing reference panels, such as GTEx, the heritable component of gene expression can be imputed and tested for association with various traits. While these approaches have successfully identified new gene associations across a variety of traits, it remains unclear whether variant predictors derived from predominantly European descent reference panels can be used for discovery in more ancestrally diverse populations. The Population Architecture of Genetic Epidemiology (PAGE) study applied the PrediXcan approach to impute gene expression (GReX) based on models derived from the GTEx Consortium data using GWAS data from up to 49,781 ancestrally diverse PAGE participants (35% African American, 45% Hispanic/Latino, and 10% Asian) to identify 98 novel (>1MB from GWAS signals) genes associated (experiment-wide Benjamini-Hochberg FDR<0.05) with one or more of the 31 cardiometabolic traits evaluated in one or more relevant tissues. These findings include novel associations between QT-interval and *PCCB* GReX in whole blood, aortic, and atrial tissue (FDR= 0.006). *PCCB* encodes a subunit of PCC, for which deficiency causes long QT syndrome. Further, to assess the impact of ancestrally diverse samples, we compared the number of significant gene associations for height and BMI detected in PAGE to those detected in a subset of 50,000 participants from UK Biobank. In whole blood, we identified 82 height associated genes in UK biobank and 20 in PAGE with eight overlapping. For BMI we identified twelve genes in UK Biobank and three in PAGE, with two overlapping. Lastly, using principal component analysis in the PAGE dataset, we compared the extent of genetic differentiation of PrediXcan model variants to a set of control variants matched on various genomic features. We found that variants used for transcriptome imputation are less differentiated in terms of genetic ancestry than would be expected by chance. Collectively, these results suggest that while transcriptome imputation models derived from European-specific reference panels can be used for discovery, the potential gains from such approaches will be significantly diminished for populations with different ancestral backgrounds; therefore, further investment in multitissue transcriptomic data from ancestrally diverse samples is essential to equitable advance multi-omic research.

## PgmNr 2807: Distinct metabolomic signatures of central obesity in the Atherosclerosis Risk in Communities (ARIC) Study.

### Authors:

K.L. Young <sup>1</sup>; H.M. Highland <sup>1</sup>; B. Yu <sup>2</sup>; M. Grove-Gaona <sup>3</sup>; E. Boerwinkle <sup>2</sup>; K.E. North <sup>1</sup>

1) Department of Epidemiology, Univ North Carolina, Chapel Hill, North Carolina.; 2) University of Texas Health Science Center at Houston, Department of Epidemiology, Human Genetics and Environmental Sciences, Houston, TX, USA; 3) University of Texas Health Science Center at Houston, Human Genetics Center, Houston, TX, USA

While the prevalence of obesity has more than doubled in the US, not all obese individuals have the same risk for adverse health outcomes. As central obesity is more metabolically active, metabolites may provide insights into mechanisms leading to disease. We hypothesize that central obesity (measured as waist-to-hip ratio adjusted for BMI) has an identifiable metabolic signature distinct from metabolites associated with BMI. GWAS of obesity associated metabolites (mGWAS) can identify associations linked to metabolic transporters, regulators, or enzyme coding genes, allowing for discovery of the best biological candidates in known GWAS regions, as well as identifying novel central obesity genes. Our study leverages existing data in the Atherosclerosis Risk in Communities (ARIC) Study (N=4,032), a prospective, longitudinal cohort study of cardiovascular disease in European and African Americans (AA), to identify metabolomic signatures of central obesity.

We estimated associations between baseline natural log (ln) transformed WHRadjBMI and 245 baseline standardized serum metabolites, using ancestry and sex-stratified additive linear models, followed by meta-analysis in SAS 9.3. We identified 7 metabolites significantly associated with increased lnWHRadjBMI ( $p=2.04E-4$  (0.05/245\*2 traits) – including 1-stearoylglycerophosphoethanolamine – as well as 5 metabolites associated with decreased lnWHRadjBMI – including g-glutamylvaline and g-glutamylleucine. Notably, none of these metabolites were associated with BMI. All 7 metabolites positively associated with lnWHRadjBMI are lipids – supporting prior GWAS implicating lipid pathways, while 4 of the metabolites associated with decreased lnWHRadjBMI are amino acids or peptides.

Metabolites significantly associated with lnWHRadjBMI were carried forward for mGWAS ( $n=12$ ), followed by meta-analysis in METAL. An intronic variant in *ALDH1A2* is associated with increased 1-stearoylglycerophosphoethanolamine levels in all strata ( $\beta=0.24$ ,  $SE=0.03$ ,  $p=8.18E-22$ ,  $EAF=0.39$ ); this variant was previously associated with plasma lipid levels, including HDL and triglycerides. Two variants near *GGT1* are associated with  $\gamma$ -glutamylleucine ( $\beta=0.33$ ,  $SE=0.05$ ,  $p=6.23E-11$ ,  $EAF=0.82$ ) and  $\gamma$ -glutamylvaline ( $\beta=0.50$ ,  $SE=0.08$ ,  $p=6.55E-10$ ,  $EAF=0.93$ ) levels in AA only; *GGT1* codes for an enzyme involved in protein metabolism. These results highlight the potential for metabolomics to identify new central obesity signals and refine obesity phenotypes.

## PgmNr 2808: Investigating the use of machine learning methods to build risk prediction models for complex disease.

Large-scale population biobanks offer exciting opportunities to develop risk prediction models for complex diseases because of the availability of genetic data and extensive lifestyle and clinical information. Unlike traditional polygenic risk scores, machine learning methods can be utilised to build risk prediction models that include both genetic and non-genetic features, and interactions between them.

We have performed a simulation study to assess the utility of several machine learning methods (gradient boosting machines, deep learning neural networks, and random forests) to generate prediction models for type 2 diabetes (T2D), applied using the H2O package, using data from the UK Biobank. 20,000 participants were randomly selected according to their T2D status (10,000 cases and 10,000 controls). Five relevant clinical factors (age, sex, body mass index, diastolic blood pressure and systolic blood pressure) were selected for entry into the model alongside a set of 1-100 SNPs, simulated with varying minor allele frequency and relative risk of disease. Irrelevant clinical factors were also selected to assess whether the methods identify them as unimportant for disease prediction.

All methods successfully identified the most strongly associated genetic and non-genetic factors as the most important features for prediction, and assigned the least importance to the irrelevant factors. Results also indicated that the inclusion of strongly associated genetic variants increases the predictive accuracy of the model compared to using clinical factors alone, while the inclusion of more modestly associated variants does not appear to improve predictive power.

## PgmNr 2809: Type 2 diabetes and autonomic function: A bidirectional Mendelian randomisation study in the UK Biobank.

People with type 2 diabetes (T2DM) are at risk of vascular and neurological complications. The autonomic nervous system (ANS) controls metabolically relevant organs such as the liver, pancreas and adipose tissue. This study aims to explore the direction of causality between ANS function, using heart rate as a proxy, and T2DM.

Data from 400,000 Europeans in UK Biobank were used and T2DM status assigned using a validated algorithm. Mendelian randomisation analyses used an inverse-variance weighted (IVW) approach, and MR-Egger as a sensitivity analysis for horizontal pleiotropy. Independent variants ( $R^2 < 0.3$ ) from the latest genome-wide association studies were used as genetic instruments. Firstly, the causal effects of heart rate on T2DM status, overall obesity (body mass index-BMI) and central obesity (waist to hip ratio-WHR) were examined, using a genetic instrument with 14 variants. Secondly, to investigate the causal effect of T2DM, BMI and WHR on heart rate, 163, 899 and 366 genetic variants were used, respectively.

Using IVW, there was no evidence for a causal effect of heart rate on T2DM (OR [95%CI]: 0.998 [0.981, 1.016]), BMI ( $\beta$  [95%CI]: 0.003 [-0.015, 0.022]) or WHR ( $\beta$  [95%CI]: 0.017 [-0.014, 0.048]) and no evidence of horizontal pleiotropic effects ( $P_{\text{Egger intercept}} > 0.1$ ). However, there was a modest causal effect of T2DM and BMI on heart rate ( $\beta$  [95%CI]: 0.310 [0.171, 0.449] and 0.871 [0.601, 1.140], respectively) with no evidence of horizontal pleiotropy ( $P_{\text{Egger intercept}} > 0.1$ ). Although IVW suggested a causal effect of WHR on heart rate ( $\beta$  [95%CI]: 1.627 [1.208, 2.046]) there was likely to be unbalanced horizontal pleiotropy ( $P_{\text{Egger intercept}} = 0.026$ ).

Findings suggest that diabetes and obesity may cause autonomic dysfunction, with no evidence for the reverse direction. However, there is a need for better autonomic function genetic instruments to robustly study the effect of ANS dysfunction on diabetes and obesity.

## PgmNr 2810: Mendelian randomisation reveals that testosterone causally improves the metabolic profile of middle-aged men.

### Authors:

K. Kentistou<sup>1,2</sup>; P. Joshi<sup>1</sup>; P. Timmers<sup>1</sup>; J. Wilson<sup>1,3</sup>

---

**Motivation:** Androgens have been repeatedly shown to regulate fat mass and body composition in mammals. Several cardiometabolic diseases (CMD), such as heart disease, diabetes and dyslipidaemia are associated with a reduction in circulating levels of testosterone, while androgen supplementation has been shown to improve blood lipid levels and general metabolic health, in men. Observational studies report the opposite in women, whereby increased androgen levels increase abdominal adiposity and the risk for cardiovascular disease. This relationship between sex hormones and CMD is seen as cyclical, i.e. it is difficult to distinguish forward or reverse causality between them. Here, we use a mendelian randomisation (MR) approach to estimate the direct causal effect of testosterone on anthropometric and CMD traits.

**Methods:** A GWAS of testosterone was conducted in UK Biobank (n=278,405) and genetic instruments were created, by LD pruning of the summary statistics. Non-overlapping publicly available GWAS on cardiometabolic phenotypes were used as outcomes. These included sex-stratified measures of adiposity (BMI, WHR, etc.) and only sex-combined blood lipids and incidence of disease. Inverse variance weighted MR was used to determine the effects of the hormonal exposures on the outcomes.

**Results:** For anthropometric measures, where sex-stratified analyses were possible, we found an effect of testosterone on waist circumference of -0.08 (SE=0.03, P=5E-3) in men. This means that an increase in circulating testosterone of 4 nM, reduces waist circumference by 1 cm. This effect size is the same as the observational association, within UK Biobank. Due to moderate power, we were not able to preclude small deleterious effects in women, but any such effects appear to be smaller to the beneficial ones in men. In the sex combined analyses of blood lipid levels, testosterone causally decreased triglycerides (P=6E-9) and increased HDL cholesterol levels (P=3E-7), confirming a metabolically favourable effect.

**Conclusions:** Our results show a causal effect between testosterone and metabolic health in men, recapitulating the observational association between them and reinforcing intervention studies in the literature. Delineating the effect of testosterone and other sex-hormones on metabolic health and disease could lead to novel preventative insights.

## PgmNr 2811: Expression levels of *F13A1* transglutaminase in adipose tissue correlates with metabolic health in obesity and with genes linked to hypertrophic adipocyte phenotype.

---

Obesity increases the risk of developing debilitating and lethal comorbidities, however, it is estimated that 10-25% of obese humans remain healthy. This *metabolically healthy obesity* (MHO) has been speculated to arise from protection from development of insulin resistance and altered adipose tissue properties of individuals. To investigate adipose tissue-genes causative to obesity and metabolic health, Pietiläinen group examined genome wide gene expression in adipose tissue and adipocytes of monozygotic Finnish, BMI-discordant lean-obese twin pairs. The analyses identified 28 potentially causative genes in these pairs; out of which, the gene with strongest causative relation to obesity was *F13A1* (Factor XIII-a transglutaminase) which we have linked to metabolic health in mouse studies. It was also reported that the BMI-discordant monozygotic twins could be divided into groups that demonstrated metabolic differences; MHO-Group 1: insulin sensitive, low liver fat% in obese twin, and metabolically sick obesity MSO-Group 2: less insulin sensitive, high liver fat% in obese twin. Here we have used the twin GWA/Affymetrix mRNA and metabolic data to examine *F13A1* mRNA levels and correlation with possible markers of adipogenesis, tissue expansion and metabolic disturbances. The aim of this study was to examine expression levels of *F13A1* and its link to metabolic health. We performed statistical analyses of the data set (52 individuals, 26 twins) by means of regression, correlations, and descriptive statistics, in the MHO-Group 1 and MSO-Group 2. We report that *F13A1* mRNA levels are significantly higher in obese twins and highest in the obese twins of the MSO group. Conversely, lowest averaged levels were observed in the lean twins of MHO group. Adipose tissue cellularity in the MHO group was significantly higher compared to MSO where adipocyte size was significantly higher, suggesting different mode of expansion (hyperplasia vs. hypertrophy, respectively) that may be genetically regulated. Linear regression and clustering analysis between *F13A1* and expression of genes known to be highly produced in large-adipocytes showed strongest linear correlation to IL8 ( $R^2=0.81$ ), CXCL2 ( $R^2=0.62$ ) (inflammatory cytokines) and DCN ( $R^2=0.59$ ), (an extracellular matrix component). In summary, the data suggests that *F13A1* levels in adipose tissue link to metabolic health outcome of obesity and may be linked to adipose tissue capacity to expand and to respond to energy surplus.

## PgmNr 2812: Cross-phenotype association analysis identifies 62 adiposity-increasing loci that protect against cardiometabolic comorbidities.

---

**Background:** Some individuals remain cardiometabolically healthy despite being obese, the so-called metabolically healthy obese (MHO). The biological mechanisms that underlie MHO are poorly understood in current literature. In this study, we aim to 1) identify novel adiposity-increasing variants with protective cardiometabolic effects, 2) identify the tissues where these loci are enriched in, 3) find experimental evidence that links adipocyte function to these loci.

**Methods:** 1) We performed pairwise meta-analysis of adiposity and cardiometabolic traits from summary statistics of 11 GWAS using CPASSOC, including three adiposity traits (body fat percentage, BMI, and waist-to-hip ratio) and eight cardiometabolic traits (HDL-C, LDL-C, triglycerides, fasting insulin and glucose, and blood pressure levels, and incident coronary artery disease and type 2 diabetes). We searched for genome-wide significant associations ( $P < 5 \times 10^{-8}$ ) with any of the 24 trait pairs from one adiposity and one cardiometabolic trait. 2) We used DEPICT to perform tissue enrichment analysis on 62 loci and 3 gene clusters identified through K-means clustering. 3) We conducted *in vitro* experiments on human mesenchymal stem cells to ascertain functional role of the identified loci in adipocytes.

**Results:** 1) The meta-analysis identified 62 independent loci of which 32 are novel, several others reside in gene regions such as *IRS1*, *COBLL1*, *PPARG*, *TOMM40*, and *VEGFA*, which are previously reported MHO loci. 2) Tissue enrichment analyses implicate strongest enrichment in adipose tissue, adrenal cortex, adrenal gland, liver, and arteries. In cluster-specific analysis, we identified a cluster of 7 SNPs for which the BMI/BFP increasing alleles associated with protective effect on cardiometabolic outcomes, mediated through favorable fat distribution with lower WHR. Tissue enrichment analysis of this cluster shows a broad impact on adipose tissues, liver, digestive and cardiovascular systems. 3) We found evidence that the 62 SNPs are enriched for variants linked to differential gene expression in adipose tissue as well as in regulatory elements that gain activity during adipogenesis.

**Conclusion:** Our integrated approach using GWAS meta-analysis, computational tools, and *in vitro* experiments identified novel MHO loci and provided insight into biological pathways that may underlie MHO, and could shed light on future drug development targeting improvement in cardiometabolic profile of unhealthy obese individuals.

## **PgmNr 2813: Association of genetic risk scores for adiposity-related traits with body fat percentage and related phenotypes in the Jackson Heart Study.**

### **Background:**

Compared to European ancestry individuals, African ancestry individuals with comparable anthropometric measures have significantly lower abdominal adiposity deposits. Here we investigate the extent to which genetic risk scores for well-studied adiposity phenotypes, such as body mass index (BMI), also predict other adiposity measures, such as % body fat or visceral:subcutaneous (VAT:SAT) ratio, in order to better understand the genetic underpinnings of different patterns of adiposity.

### **Methods:**

Genetic risk score analyses for anthropometric measures were undertaken among 2420 African Americans aged 28-97 years from Jackson Heart Study (JHS). Anthropometric polygenic risk scores (PRS) for BMI, waist-hip ratio (adjusted for BMI), waist circumference (WC) (adjusted for BMI), and % body fat mass were calculated for each individual as the weighted sum of phenotype-increasing alleles. Genome-wide significant variants from prior studies using European or African ancestry individuals in the GWAS catalog were included. Associations between each PRS and inverse normally transformed adiposity measures were examined using multivariable linear regression models adjusted for age, gender, and up to 10 ancestry principal components.

### **Results:**

The BMI PRS was found to be a significant positive predictor of % body fat mass ( $\beta=0.005$  per allele,  $P=2.19\times10^{-3}$ ) and subcutaneous adiposity ( $\beta=0.004$ ,  $P=2.38\times10^{-2}$ ). The % fat mass PRS was significantly associated with subcutaneous ( $\beta=0.022$ ,  $P=1.70\times10^{-10}$ ) but not visceral adiposity ( $\beta=0.011$ ,  $P=5.64\times10^{-2}$ ). No significant associations were found between % fat mass PRS or BMI PRS with waist circumference, waist-hip ratio or VAT:SAT ratio. Likewise, the WC-PRS and WHR-PRS were not significantly associated with % fat mass.

### **Conclusion:**

These analyses suggest; (a) that genetically driven increases in percentage body fat mass strongly associate with subcutaneous adiposity but not with the more deleterious visceral adiposity; and (b) that percentage body fat mass is strongly associated with overall BMI associated genetic variants but not with variants associated with measures of central adiposity (WC and WHR). More study is needed to understand how genetic variants associated with these anthropometric traits may contribute to observed differences in adiposity patterns between African and European ancestry individuals.

## PgmNr 2814: A PheWAS and LabWAS approach in studying rs560887 SNP in the *G6PC2* gene using BioVU.

The glucose-6-phosphatase (G6Pase) enzyme system is located in the endoplasmic reticulum and catalyzes the hydrolysis of glucose-6-phosphate (G6P) to glucose and inorganic phosphate. G6Pase system is composed of a glucose transporter and a G6P/Pi transporter, encoded by the *SLC37A4* gene along with a catalytic subunit, which can be one of three isoforms, G6PC1, G6PC2 or G6PC3. *G6PC2* is expressed predominantly in pancreatic islet beta cells. G6Pase activity is abolished in *G6pc2*KO mice, which results in a leftward shift in the dose response curve for glucose-stimulated insulin secretion (GSIS) leading to a reduction in fasting blood glucose (FBG). Consistent with these mouse studies, genome wide association studies have linked the rs560887 SNP in the *G6PC2* gene to variations in FBG. Molecular studies have shown that the rs560887-G allele represents a gain of function that is associated with increased *G6PC2* RNA splicing which is predicted to lead to increased full length G6PC2 protein expression and elevated glucose cycling. Our aim here was to find other disease associations with rs560887-G allele. We performed a phenome-wide association study to examine the effect of this allele on 2000 different medical diagnoses present in the electronic health records (EHR) of 62,400 patients treated at Vanderbilt University Medical Center. The rs560887-G allele was significantly associated with acute pancreatitis (OR = 1.37,  $p = 1.75 \times 10^{-5}$ ) in patients without Type 2 diabetes, after adjusting for sex, genetic ancestry, age, and genotyping batch. We also conducted a Lab-wide association study including 272 heritable lab traits commonly measured in a clinical setting. We found rs560887-G allele to be significantly associated with decreased glucose ( $\beta = -0.049$ , SE = 0.005,  $p = 2.4 \times 10^{-22}$ ), which confirmed molecular studies in mice. The direction and magnitude of the associations were the same for both diabetic and non-diabetic patients but failed to reach statistical significance after correction for multiple testing in the Type 2 diabetic population. The rs560887-G allele was also significantly associated with decreased HbA1C ( $\beta = -0.045$ , SE = 0.011,  $p = 2.9 \times 10^{-5}$ ) in patients without Type 2 diabetes, which matches the GWAS data. Our future analysis will focus on studying how the SNP associates in populations with diverse ancestral backgrounds including African, Asian, and European ancestry.

## PgmNr 2815: A multivariate Bayesian genetic association analysis of a *CREBRF* variant and adiposity-related phenotypes.

While obesity has become a global epidemic, it is especially prevalent within the Samoan population. Over 80% of the Samoan adults are classified as either overweight or obese. It is therefore important to understand the interlinkages between genotypes and adiposity-related phenotypes. Previous studies have shown that a minor allele of *CREBRF* (encoding *CREB3* regulatory factor) rs373863828 (p.Arg457Gln) is strongly associated with BMI and reduced risk of type 2 diabetes in Polynesians. Although this variant is exceedingly rare in non-Polynesian populations, it is relatively common in the Samoan and Polynesian populations (MAF = 0.259); rs373863828 may have been subject to positive selection during historic periods of food scarcity on Polynesian islands.

The study population consisted of 1,810 unrelated Samoans from the Independent State of Samoa. We performed a Bayesian association test between rs373863828 and a panel of 10 anthropometric and lipid profile measurements – body mass index (BMI), fat mass index (FMI), fat-free mass index (FFMI), height, waist circumference, hip circumference, HDL cholesterol (HDL-C), LDL cholesterol (LDL-C), net triglycerides, and total cholesterol. The phenotype panel was quantile normalized to multivariate normality to reduce the risk of false positive associations due to influence of outlier observations. Analysis was carried out with mvBIMBAM, a Bayesian multivariate framework that has been shown to be more powerful than univariate association analysis. In addition to BMI, this variant has univariate associations with hip circumference, abdominal circumference, and height.

Under a  $\log_{10}$  Bayes factor threshold of 5.0, significant associations were found between rs373863828 and the overall phenotype panel ( $\log_{10}$  Bayes factor = 6.5), BMI (5.9), FMI (6.2), and abdominal circumference (5.2). There was evidence for a suggestive association with hip circumference (4.9) and a lack of evidence of association with FFMI (3.5), total cholesterol (1.4), net triglycerides (-0.2), LDL-C (0.8), HDL-C (-0.4), and height (0.1). The analysis, which accounts for multivariate correlation structures between phenotypes, provides further evidence for the association of rs373863828 with measures of total and regional adiposity while not supporting the previously observed univariate association with height. Furthermore, these results suggest that adipose tissue deposits as opposed

to fat-free mass increases potentially contribute to increases in BMI.

## PgmNr 2816: Homozygosity mapping of pulmonary and asthma-related phenotypes in minority populations in the US.

---

Homozygosity mapping has long been useful for identifying the genetic basis of recessive Mendelian diseases in inbred pedigrees. However, with increased density of genetic markers and improved methodology for detecting short autozygous segments, homozygosity mapping has become a viable approach for studying complex phenotypes in outbred populations. We use homozygosity mapping to investigate the genetic basis of asthma-related and lung function phenotypes in three minority populations in the US: African Americans, Puerto Ricans and Mexican Americans. Asthma is a chronic inflammatory disorder characterized by recurrent respiratory symptoms and reversible airway obstruction. It is the most common chronic childhood disease with variable prevalence across our study populations, with Puerto Ricans having the highest rates (36.5%), African Americans having intermediate rates (13.0%), and Mexican Americans having the lowest rates (7.5%).

We perform homozygosity mapping of both asthma status and an important measure of lung function, the forced vital capacity (FVC) of a patient's lungs. We find several population-specific homozygous regions significantly associated with these phenotypes, including several on or near genes previously associated with lung disease or lung function phenotypes. Many of these associations were found in the direction of a protective effect or increased lung function, suggesting that the underlying haplotypes in these associated regions may contain protective/beneficial variants related to asthma and lung function. Furthermore, these mapped regions did not appear significant when performing standard GWAS on the genotypes of these same samples, suggesting that our homozygosity mapping approach provides additional value over standard GWAS analyses.

## PgmNr 2817: Large scale GWAS of hypothyroidism and health risks in treated vs. untreated hypothyroidism.

---

The prevalence of overt hypothyroidism in Europe is between 0.2% and 5.3% and occurs more frequently in women, patients with autoimmune diseases, individuals >65, and whites. In iodine-sufficient areas, autoimmune thyroiditis (Hashimoto's disease) is the most common cause - though because of the lack of specific symptoms, there is up to a 5% rate of untreated hypothyroid disease. We undertook a combined meta-analysis of data from FinnGen (n=140,000) and UK Biobank (n=330,000) and found >50 independently associated loci. In addition to confirming previously documented hits (including PTPN22, SH2B3, FOXE1, IFIH1, TYK2) we identify about 40 novel hits including several corresponding to alleles specifically enriched through the founding bottleneck of the Finnish population. These include a missense variant in ZAP70, a gene in which recessive mutations cause immunodeficiency.

Using the results of this scan, as well as from a recent study of quantitative thyroid stimulating hormone (TSH) levels in the HUNT study and Michigan Genomics Initiative, we explore the impact of treated and untreated hypothyroidism on risk to all late-onset common diseases by utilizing polygenic risk scores (PRS) as a proxy for the severity of hypothyroidism in conjunction with the comprehensive national medication reimbursement data available nationwide since 1995 in Finland in the FinnGen cohort. With this approach, we can highlight specific instances where treatment for hypothyroid disease ameliorates downstream health consequences, reinforcing the importance of increasing the detection of untreated hypothyroid disease in the population

## PgmNr 2818: A new biomarker for idiopathic pulmonary fibrosis by combining Mendelian randomization and a metabolomics-based case-control study.

**Introduction:** Idiopathic pulmonary fibrosis (IPF) is a lethal disease with limited biomarkers and effective treatments. There is, therefore, an urgent need to find and validate biomarkers that could serve for diagnosis, prognosis, and/or as potential drug targets. We undertook combined genetic epidemiology and metabolomics studies to identify a metabolic biomarker for IPF.

**Methods and Results:** To identify potential metabolites associated with IPF, we looked for genetic markers jointly associated with blood metabolites levels and IPF risk using GWAS data for blood metabolites and IPF, respectively. Via this exploratory approach, we identified a shared genetic determinant near isovaleryl dehydrogenase (*IVD*) (SNP-metabolite association:  $-0.034$ ,  $p=1.87 \times 10^{-35}$ ; SNP-IPF risk association:  $OR=1.20$ , 95% CI: 1.12 to 1.28,  $p=7.4 \times 10^{-8}$ ). The known product of this gene is an enzyme whose inhibition is known to increase its substrate, the metabolite isovalerylcarnitine (IVC). Through two-sample Mendelian randomization (MR), we observed that genetically decreased IVC levels were strongly associated with increased risk of IPF ( $OR=12.13$ , 95% CI: 2.21 to 66.5,  $p=4 \times 10^{-3}$ ). We confirmed this result by using a different blood metabolomics GWAS in a second MR study ( $OR=2.91$ , 95% CI: 2.05 to 4.11,  $p=1.7 \times 10^{-9}$ ). We next found that the non-coding alleles from the two metabolite GWAS that were associated to decreased IVC blood levels increased *IVD* expression. Next we tested whether low IVC levels were associated with IPF risk in a study of 382 cases and 217 controls. We found that decreased blood IVC blood levels was associated with a 26% increase in IPF risk ( $OR: 1.26$  per 50 nM decrease, equivalent to an IQR drop in IVC; 95% CI: 1.00 to 1.60,  $p=0.048$ ). We are currently undertaking a replication case-control study.

**Conclusions:** IPF presents important unmet clinical needs. Building on strong complementary evidence from genetics and metabolomics data, we found that low IVC levels were associated with higher risk of IPF. IVC represents a novel biomarker and its enzyme, *IVD*, could represent an entirely novel IPF drug target.

## PgmNr 2819: Environment-dependent effect of *ALDH2* polymorphism on pediatric respiratory infections in Vietnam.

---

**Background:** Aldehyde dehydrogenase 2 (ALDH2) plays a key role in the degradation of ingested ethanol as well as the detoxication of environmental aldehydes. A variant allele of *ALDH2* locus, *ALDH2\*2*, encodes an inactive subunit of the enzyme with dominant-negative properties which is prevalently observed in Asian populations. Accordingly, the carriers of *ALDH2\*2* show ethanol intolerance and susceptibility to various diseases including esophageal cancer which are believed to be caused by toxic substance otherwise eliminated by active ALDH2. Acetaldehyde in cigarette smoke can induce tissue damages even in passive smokers, which in turn may enhance the susceptibility to respiratory infectious agents. In the present study, the effects of environmental tobacco smoke (ETS) exposure from parental habitual smoking and *ALDH2\*2* carriage on the risk of pediatric respiratory infections were assessed by a prospective cohort study. **Methods:** 1999 newborn babies, who were born at a single institution in Nha Trang City, Khanh Hoa Province, Central Vietnam in one-year period from May 2009 to May 2010, were enrolled to a longitudinal observational study after obtaining the parental informed consent. The history of hospital admission and that of exposure to ETS at home were collected at the age of 24 months. *ALDH2* genotype was determined using umbilical cord blood DNA. The incidence of respiratory infections requiring hospitalization was compared between subpopulations with/without risk factors. **Results:** Among 1494 children who were followed up for 24 months (74.7% of enrolled), 231 hospital admissions because of acute lower respiratory tract infections (LRTIs) were detected (71.6 events/1000PYO). Exposure to ETS increase the chance to be hospitalized (un-adjusted RR = 1.49, P = 0.017) as reported previously (Miyahara R, *et al.* Sci Rep 7:45481(2017)). The genotype frequencies of *ALDH2* in the children followed-up were \*1/\*1 : \*1/\*2 : \*2/\*2 = 0.69 : 0.28 : 0.03, which were not deviated from Hardy-Weinberg equilibrium. Carriers of *ALDH2\*2* exhibited a tendency of increased LRTI hospitalization (p = 0.07). Stratified population analysis revealed the effect of *ALDH* genotype was augmented in the children with exposure to ETS (RR = 1.80, p = 0.004) but not in those without. **Conclusion:** *ALDH2\*2* enhance the risk of acute LRTIs conferred by the exposure to ETS at home in infants under this epidemiological setting.

Bronchiectasis (BE) is a respiratory condition characterized by dilated bronchi, mucus hypersecretion, persistent lung inflammation, and chronic respiratory infection. Although BE can be caused by genetic disorders such as cystic fibrosis, primary ciliary dyskinesias, and immunodeficiencies (e.g. Activated PI3Kinase Delta Syndrome (APDS)), up to 50% of occurrences have no easily definable disease origin (idiopathic or post-infective). There are no licensed medicines specifically targeted for BE patients, presenting a need for deeper exploration into the genetic etiology of this disease and new therapeutic opportunities.

We performed whole exome sequencing of blood samples from 800 cases with idiopathic BE recruited from two respiratory clinics in the UK, and obtained exomes for 4,301 healthy donors from the UK Interval Cohort. We carried out single-variant and gene-based exome-wide association scans in a subset of unrelated individuals of European ancestry (743 cases and 3,992 controls) to estimate the aggregate burden of low frequency protein-altering variation in disease risk.

Of the 820,102 quality protein-coding sites identified, 2.6% are predicted high-confidence loss-of-function variants (stop-gained, splice site disrupting, frameshift), and 36.6% are predicted damaging missense variants (CADD>21 or MCAP>0.025). Single-variant association scans revealed exome-wide significant common variants (Firth logistic regression, MAF>1%) in two biologically plausible genes involved in epithelial cell function ( $P=7E-7$  and  $P=8E-7$ ), as well as rare variants (Fisher's Exact, MAF<1%) in two genes involved in adaptive immunity ( $P=5E-42$  and  $P=2E-23$ ). Notably, the combined burden of rare coding variants (SKAT-O, MAF<1%) resulted in exome-wide significant associations for three genes involved in epithelial barrier function ( $P=3E-32$ ), vesicular trafficking ( $P=4E-10$ ), and oxidative stress ( $P=3E-6$ ). The BE cohort is also composed of heterozygous carriers for 10 novel, potentially damaging missense variants in the *PIK3CD* and *PIK3R1* genes of the PI3Kdelta signalling pathway, as well as one carrier of the known APDS-causing *PIK3CD* E81K substitution (c.241G>A; p.Glu81Lys), subsequently confirmed by Sanger sequencing. Finally, we observe 30 heterozygous

carriers of at least 2 likely pathogenic coding variants in *CFTR*. These pathogenic variants in genes of immune and airway-related pathways identify novel mechanisms for disease susceptibility and guidance toward new drug targets.

## PgmNr 2821: Genome-wide gene-by-smoking interaction study of chronic obstructive pulmonary disease.

---

**Introduction:** Risk for Chronic Obstructive Pulmonary Disease (COPD) is determined by both cigarette smoking and genetic susceptibility, but little is known about gene-by-smoking (GxSmoking) interaction. Our study aims to identify novel genetic variants by accounting for potential interaction with smoking on COPD risk. **Method:** We analyzed 200,766 subjects with European ancestry including 179,689 controls and 21,077 COPD cases based on pre-bronchodilator spirometry for moderate airflow limitation from the UK Biobank study. We sought to replicate the significant results in 2,533 control and 2,809 case non-Hispanic white former and current smokers from the COPD Gene cohort, examining the marginal genetic effects. We considered 3 binary smoking variables (exposed/non-exposed): ever/never, current/non-current, and heavy ( $\geq 10$  pack-years)/non-heavy smokers in a genome-wide analysis. We used logistic regression with a 2-degree-of-freedom (2df) test considering both genetic main effects and GxSmoking interaction effects. We examined variants achieving genome-wide significance ( $P < 5 \times 10^{-8}$ ) in our analysis but conditionally independent ( $P < 1 \times 10^{-5}$ ) from previously described GWAS variants. **Results:** We identified 3 variants - rs11735046 near *GYP A*, rs56326741 in *TN X B* and rs2604894 in *EGL N 2* that are distinct from previously reported COPD or lung function variants. At known loci of COPD, 3 variants at 2 loci - *CH R N B 4* and *M E C O M* showed a statistically significant interaction with smoking. For these 6 variants, 1 showed a stronger association among the non-exposed group, while 5 among the exposed group. Five human leukocyte antigen (HLA) imputed markers were statistically significant for 1df interaction with GxEver-smoking. In the COPD Gene cohort, one of the variants at the previously described 19q13 loci - rs2604894 showed nominal significance ( $P = 0.02$ ) in a marginal association with COPD. Two known loci - *CH R N B 4* and *M E C O M*, showed a stronger association with longer smoking duration. **Conclusion:** Despite the strong relationship between genetic variants and smoking in COPD, a genome-wide GxSmoking interaction study did not identify new genome-wide significant loci. Interaction effects and secondary signals at previously described loci, however, may help elucidate biologic mechanisms.

---

Chronic obstructive pulmonary disease (COPD) encompassing chronic bronchitis and emphysema, is characterised by severe airflow obstruction and is a top contributor of worldwide mortality. Smoking is the biggest risk factor, whilst other environmental exposures also play a role such as air pollution, exposure to dust and previous chest infections. However, not all smokers develop COPD and around 20% of individuals with COPD have never smoked. Lung function measures used in COPD diagnosis have a strong genetic component, with 279 genetic signals identified to date. These signals are also associated with COPD risk. However, they only account for modest proportions of lung function heritability and have the same effects in ever and never-smokers. We hypothesised that there are additional genetic determinants of lung function and COPD that interact with cigarette smoking.

Presented here is the largest genome-wide gene-smoking interaction analysis in lung function to date, specifically for traits FEV<sub>1</sub> (forced expiratory volume in 1 second), FVC (forced vital capacity), the ratio of FEV<sub>1</sub>/FVC and PEF (peak expiratory flow). The analysis included 303,612 unrelated European individuals from UK Biobank. Phenotypes were inverse normalised adjusting for age, sex and height with 10 ancestry principal components and genotype array adjusted for during analysis. Interaction effect was determined using a gene-smoking interaction term in a linear regression model and a threshold of was used to identify discovery signals. Replication was sought using the SpiroMeta consortium consisting of 22 studies and up to 71,067 individuals.

Analysis of 8,647,748 variants identified 53 independent genetic signals at  $P < 5 \times 10^{-6}$ , none of which have previously been implicated for lung function or COPD. Twenty six signals were imputed with high quality in the SpiroMeta consortium (effective sample size  $> 50,000$ ), of which 11 had consistent direction of effect in ever and never-smokers. None reached a Bonferroni corrected threshold of for replication.

These 53 signals may influence estimates of relative and absolute genetic risk for poor lung function and COPD, and aid in the development of personalised medicine based on smoking behaviour. Larger sample sizes with denser imputation are however required to establish these signals as true positives.

## PgmNr 2823: Utilising human leukocyte antigen imputation to understand the role of genetic variation in immune system genes in a meta-analysis of idiopathic pulmonary fibrosis susceptibility.

---

Idiopathic pulmonary fibrosis (IPF), a rare interstitial lung disease of an uncertain cause with poor prognosis, is believed to be the result of an abnormal wound healing response to injury leading to large areas of scarring and inflammation of the alveolar wall. Genome wide association studies (GWAS) have reported 17 signals of association with IPF susceptibility from across the genome.

The human leukocyte antigen (HLA) region is one of the most complex and variable regions in the genome and is known to influence risk for multiple diseases (including respiratory disorders such as asthma and chronic obstructive pulmonary disease). The extreme genetic diversity of the HLA, with each HLA gene potentially encoding thousands of different proteins, challenges the interpretation of association studies in the region. Specific imputation strategies have been designed to capture classical HLA gene alleles and amino acid changes. Association of the classic *HLA-DQB1\*06:02* allele has been previously reported in a cohort of fibrotic idiopathic interstitial pneumonias (including IPF).

In this study, we combined the latest single variant imputation panel (Haplotype Reference Consortium) and a bespoke HLA classical allele and amino acid imputation panel (T1DGC). We tested the association of 37,212 SNPs, 424 HLA alleles and 1,276 amino acid changes across the HLA region (including *HLA-A*, *HLA-B*, *HLA-C*, *HLA-DQA1*, *HLA-DQB1*, *HLA-DPA1*, *HLA-DPB1*, *HLA-DRB1*) with IPF susceptibility in 2,769 IPF cases and 8,591 controls from 3 independent studies (UK [612 cases, 3,366 controls], Chicago [500 cases, 510 controls] and Colorado [1,515 cases, 4,683 controls]). Sex and 10 Principal Components were included as covariates.

Three independent signals passed a Bonferroni-corrected significance threshold of  $P < 2.8 \times 10^{-6}$  in a meta-analysis of the 3 studies. However, these three associations were not observed (at  $P < 0.05$ ) across all three contributing studies. The previously reported association of *HLA-DQB1\*06:02* was not replicated in this study.

To the best of our knowledge, we have undertaken the largest study of the role of HLA gene variation in IPF susceptibility to date, using a combination of dense SNP imputation and bespoke HLA allele imputation. No variants were consistently associated with IPF susceptibility in our data.

## PgmNr 2824: Comparisons between whole exome sequencing and whole genome sequencing in 25 individuals with autosomal recessive non-syndromic deafness.

We have compared output of whole-exome sequencing (WES) and whole-genome sequencing (WGS) in 25 unrelated probands with autosomal recessive non-syndromic deafness. Agilent SureSelect Human All Exon 50 Mb kits and an Illumina HiSeq2000 instrument were utilized for WES; we used Illumina HiSeq X Ten or BGISEQ-500 platforms for WGS. Sequencing data were analyzed at our in house bioinformatics pipeline. We then compared the coverage in the regions targeted by WES capture

We subsequently compared the coverage of 16 autosomal recessive non-syndromic deafness genes *CDH23*, *CLDN14*, *GJB2*, *GRAP*, *ILDR1*, *LOXHD1*, *MPZL2*, *MYO15A*, *MYO7A*, *OTOA*, *OTOF*, *PCDH15*, *SLC26A4*, *TMC1*, *TMPRSS3*, and *USH1C*. These genes were selected as mutations in them were found to be causative in multiple families in our previous studies. Out of the 25 samples, we identified 7 causative variants via WGS as opposed to 4 causative variants via WES. All 7 variants were confirmed with Sanger sequencing. While WES and WGS appear to have similar coverage for deafness genes, WGS appears to be superior as it provides more uniform coverage to detect deafness mutations scattered throughout the coding sequence. In addition, WGS provides data for non-protein coding regions, structural variants, and potentially better detection of copy number variants.

	mean	1X	5X	10X	20X	SNV	Indels
WES	69	99%	95%	88%	77%	134119	9790
WGS	45	99.90%	99.70%	99.20%	98.80%	119911	21641
WES_DeafGenes	97	99.70%	98.40%	96.80%	92.40%	160	8
WGS_DeafGenes	47.5	100%	99.90%	99.60%	97.60%	147	12

## PgmNr 2825: Genome-wide analyses using UK Biobank data provide insights into the architecture of chronic kidney disease and kidney function.

Chronic kidney disease (CKD), affects ~11% of the adult population in Europe and North America. It is associated with high morbidity and in the advanced stage requires life supporting treatment by renal dialysis or transplantation. CKD is defined as an irreversible reduction in glomerular filtration rate (GFR), which can be estimated by both serum creatinine (eGFR<sub>crea</sub>) and serum cystatin C (eGFR<sub>cys</sub>). Previous largest genome-wide association studies for these serum biomarkers were limited to ~ 110 thousands individuals. Thus, we aimed to perform genome-wide association studies for CKD-related quantitative biomarker traits both from serum and urine, using the UK Biobank data collected on more than 400,000 individuals.

We used the linear mixed model approach as implemented in the software BOLT-LMM to account for cryptic relatedness and potential population stratification. We inverse normalized all the biomarker measures, then took the residuals using covariates, including sex, age, age squared, assessment center locations, genome arrays and 10 principal components. We analyzed on serum levels of creatinine (N=437,653) and cystatin C (N=437,839) and urinary levels of sodium (N=445,081) in white individuals from the UK Biobank. Then we used FUMA, a web-based platform, to perform functional mapping and annotation for the genetic components associated with each genetic trait.

Our genome-wide association study demonstrated strong associations with CKD-related biomarkers. For example, we identified 93,501 and 87,815 significant SNP associations ( $P < 5 \times 10^{-8}$ ) with eGFR<sub>crea</sub> and eGFR<sub>cys</sub> at serum level, respectively. The top locus for eGFR<sub>crea</sub> included *SPATA5L1* locus (rs2433601,  $P=7.4 \times 10^{-246}$ ), which encoded a protein suspected to be related to creatinine production. The top SNP associated to eGFR<sub>cys</sub> was identified at *SHROOM3* locus (rs4859682,  $P=1.95 \times 10^{-296}$ ) which encoded a protein may be involved in cell development in kidney. For urinary sodium, we identified 4,659 significant SNP associations ( $P < 5 \times 10^{-8}$ ). The top locus was found at *FGF21* locus (rs838133,  $P=1.2 \times 10^{-28}$ ), which encoded fibroblast growth factor 21 and was noted to correlate with the severity of albuminuria and loss of GFR.

In summary, we identified common variants associated with kidney function in large population-based studies in both serum and urinary level. We further characterized the shared genetic architecture of these serum and urine biomarkers with CKD using 11,000 cases in UK Biobank cohort.

## PgmNr 2826: Genome-wide association study of autoimmune thyroid diseases detects nine novel risk loci.

### Authors:

**Introduction:** Autoimmune thyroid diseases (AITD) include Hashimoto's thyroiditis (HT) and Graves' disease (GD). The prevalence of HT and GD in the United States is about 5% and 0.5%, respectively. Both of these phenotypes are associated with papillary thyroid cancer in epidemiological studies. Genome-wide association studies (GWAS) have reported 32 genetic risk variants for HT and/or GD, with only one variant in HT alone.

**Methods:** A GWAS was performed in the UK Biobank (UKB) on 257 cases of HT and 541 cases of GD, with population-based controls matched 8 to 1. After imputation and quality control steps, 8.9 million autosomal single nucleotide polymorphisms (SNPs) with minor allele frequency greater than 1% were tested in logistic regression models for linear additive effects for each phenotype. SNP associations with p-value less than  $5 \times 10^{-8}$  were pruned by linkage disequilibrium (LD) to retain independent loci. SNPs were considered novel if they were not in LD with previously reported genome-wide significant SNPs ( $r^2 < 0.1$  within a 500-kb window).

**Results:** A locus on *PDXK* (chromosome 21) was associated with HT (lead SNP rs181726789; p-value =  $4.3 \times 10^{-8}$ ; odds ratio = 2.99, 95% confidence limits=2.02,4.42). This is a missense variant on a gene involved in vitamin B metabolism and which has not been associated with HT before. For GD, eight independent and novel loci were detected, seven located on chromosome 6. The lead SNPs for these seven loci were rs2523432, rs3132390, rs35744819, rs3130288, rs3130612, rs3094084, and rs2596474, of which the latter four are within the major histocompatibility complex (MHC). Another novel risk locus for GD was detected on chromosome 18 (lead SNP rs4239469 in an intronic region of *LINC01929*).

**Discussion:** This study contributes a known risk locus for HT and eight for GD. The analysis will be repeated in the full UK Biobank cohort (n=413,870 people).

## PgmNr 2827: High-sensitivity C-reactive protein and estimated glomerular filtration rate: A two-sample Mendelian randomization.

Chronic inflammation is thought to be a risk factor for kidney disease. However, the plentiful discussion of this topic was controversial whether inflammatory status is either a trigger or results of chronic kidney disease. We aimed to investigate the causal relationship between high-sensitivity C-reactive protein (hs-CRP) and kidney function using two-sample mendelian randomization (MR). We conducted a MR study to estimate the effect of inflammation on kidney function as a part of the Japan multi-institutional collaborative cohort (J-MICC) Study, one of the largest genome cohort studies in Japan. hs-CRP concentrations were measured using a latex-enhanced immunonephelometric assay. Estimated glomerular filtration rate (eGFR) was calculated based on serum creatinine, age, and sex using the Japanese equation. Due to the limited sample for measured hs-CRP ( $n = 2,524$ ), we created a non-overlapping dataset from the J-MICC Study ( $n = 7,186$ ), and applied two-sample MR method, an application of MR to the summary statistics in non-overlapping datasets. Four independent single nucleotide polymorphisms (SNPs) known to be associated with CRP (rs3093077, rs1205, rs1130864, and rs1800947) were used to construct the instrumental variables (IVs) based on previous GWAS in European populations. F-statistics of IVs was 10.5, which indicates the causal estimates were unlikely to be biased. In addition to the inverse-variance weighted (IVW) method, we applied the weighted median (WM) method and the MR-Egger method to estimate causal relationship even when some genetic variants violate the important assumptions.

The mean age (SD) in CRP and eGFR datasets were 54.9 (9.3) and 53.7 (9.5), respectively. In linear regression adjusted for age, sex, cohort and top five principal components, natural log-transformed eGFR was not significantly associated with increase in hs-CRP in all three approaches (IVW: beta per SD = 0.004;  $p = 0.74$ , WM: beta per SD = 0.003;  $p = 0.83$ , and MR-Egger: beta per SD = 0.005;  $p = 0.89$ ). In MR-Egger, the estimate of intercept was zero (intercept = 0.000;  $p = 0.97$ ), which indicates that all IVs and the estimates from IVW were valid and not biased. In conclusion, causal inference approaches using MR does not support a causal effect of inflammatory status on eGFR level in this population.

## PgmNr 2828: Circulating MiRNAs were differentially expressed in T2D patients with fatty liver disease.

### Authors:

T. Qiuxiang; Y. Jianli; W. Jianping; H. Chang; P. Xingchen; C. Peng

[View Session](#) [Add to Schedule](#)

**Affiliation:** Department of Genetics, College of Basic Medical Sciences, Jilin University, Changchun, China 130021

**Background:** Fatty liver disease (FLD) is a diabetes complication which can develop into liver fibrosis or liver cancer. The incidence of FLD in type 2 diabetes (T2D) patients was much higher than the general population. However, the effective biomarker for early prediction of fatty liver disease risk in T2D patients with acceptable accuracy is not available.

**Aims:** In this study, we intended to investigate the dysregulated circulating miRNAs in relation to FLD of T2D patients, in the hope of constructing an effective prediction model for FLD in these vulnerable people.

**Methods:** We conducted a two-stage case-control study, using peripheral blood serum samples from 33 FLD and 9 non-FLD T2D patients with retinopathy as discovery stage, and 42 FLD and 28 non-FLD T2D patients without retinopathy as replication stage. Differential abundance of circulating miRNAs was measured using next-generation sequencing. The participants in this study were of Chinese Han ethnicity. Moreover, the fragments per million (FPM) values were used to construct a FLD risk prediction model. Target genes of the dysregulated circulating miRNAs were curated and subjected to a tissue-specific expression analysis using FUMA.

**Results:** The differential expression in of 21 mature miRNAs were identified in our discovery cohort ( $p \leq 0.01$ ,  $LFC \geq 2$  or  $LFC \leq -2$ ), however, none of them remained significant after multiple testing correction ( $FDR\ p > 0.05$ ). Among these, miRNAs miR-4646-5p was also significant in our replication stage ( $\log_2$  fold change = -1.71,  $p = 5.7 \times 10^{-4}$ ). We employed miR-4646-5p as the only biomarker to construct a FLD risk prediction model and assessed its predictive power in our replication cohort. The result showed that our risk prediction model was of marginal clinical relevance ( $AUC = 0.788$ , specificity = 1.000, sensitivity = 0.485). In addition, the target genes of miR-4646-5p were significantly abundant liver ( $p = 1 \times 10^{-7}$ ), heart ( $p = 1 \times 10^{-5}$ ) and pancreas ( $p = 1 \times 10^{-4}$ ).

**Conclusion:** Circulating miRNA miR-4646-5p was differentially expressed in serum samples of T2D patients with FLD as compared to non-FLD. This miRNA may be indicating novel molecular mechanisms of FLD onset in T2D patients, hence could potentially serve as biomarkers for FLD risk prediction when T2D diagnosis is made. Our prediction model was not clinically actionable, but could be refined in future studies with a larger sample size.

## PgmNr 2829: The association between genetic risk score for age at menarche or menopause and women's reproductive health-related traits in the Study of Women's Health Across the Nation.

### Authors:

---

Genome wide association studies (GWAS) of age at menarche and age at menopause have identified hundreds of genetic risk loci associated with reproductive timing. In order to better understand the roles of genetic loci contributing to women's reproductive health, we constructed standardized genetic risk scores (GRS) for age at menarche and age at menopause using SNPs at least suggestively associated ( $p < 1e-04$ ) with each respective trait in the largest GWASs to date. We then evaluated their association with eight traits related to women's reproductive health in an independent multi-ethnic cohort, the Study of Women's health Across the Nation (SWAN). White (N=726), Black (N=348), Chinese (N=139) and Japanese (N=140) participants were genotyped using the Illumina Multi-Ethnic Global Array, and genotypes were imputed to the 1000G Phase 3 v5 reference panel. The traits we evaluated included age at menopause, age at menarche, reproductive lifespan, duration of perimenopause and reproductive hormone levels (estradiol (E2) and follicle stimulating hormone (FSH)) before and after menopause. We observed a significant association between the menarche GRS and age at menarche, and the menopause GRS and age at menopause in almost all ethnicities with the strongest associations observed in Whites (beta=0.41 year increase with each SD of GRS,  $p=6.9e-15$  for menarche; beta=0.56,  $p=4.95e-05$  for menopause). In Whites alone, we observed a significant association between reproductive lifespan and both the menarche (beta=-0.54,  $p=2.0e-04$ ) and menopause GRSs (beta=0.76,  $p=2.9e-07$ ), the duration of perimenopause and the menopause GRS (beta=0.58,  $p=1.9e-4$ ), and FSH level and the menopause GRS (beta=-0.15 IU/L increase with each SD of GRS,  $p=0.01$ ). In conclusion, this study validates the established roles of these genetic risk loci in age at menarche and menopause in populations of multiple ethnicities and suggests additional roles in other reproductive health related traits. However, there was heterogeneity among ethnicities regarding the effect sizes and the observed significant effects were most prominent in Whites. This may be due to lack of power (small sample size) in other ethnicities or because the effect sizes of the genetic loci were estimated through GWAS conducted in European ancestry samples. This suggests an urgent need for large scale GWAS on reproductive health-related traits in non-European populations to better understand these genetic effects in other ethnicities.

## PgmNr 2830: Increased burden of common risk alleles in children with a significant fracture history.

---

**Background:** Extreme presentations of common disease in children are often presumed to be of Mendelian etiology. However, the contribution of common risk alleles to presumed Mendelian presentations has not been fully explored. We therefore tested whether children with a significant fracture history but no evidence of osteogenesis imperfecta (OI) are at increased polygenic risk for fracture as measured through a polygenic risk score.

**Methods:** A childhood significant fracture history was defined as the presence of low-trauma vertebral fractures or multiple long bone fractures. We generated a polygenic risk score for quantitative ultrasound speed of sound, termed "gSOS", derived from common risk alleles in 341,449 UK Biobank participants. Low gSOS predicts adult osteoporotic fracture. We tested if individuals from three cohorts with a significant childhood fracture history and no OI had lower predicted gSOS. The Canadian cohort included 94 children with suspected Mendelian osteoporosis. Of these, 26 had a positive and 68 a negative OI gene panel. Two Finnish cohorts included 59 children recruited due to a significant fracture history and 25 children referred for suspected Mendelian osteoporosis, among which 5 had positive OI gene panel. 11 individuals of non-European ancestry and individuals with OI, or who failed genotyping were excluded. We computed gSOS estimates in the remaining individuals, standardized them, and compared their mean to that of a UK Biobank subset. We computed the number of individuals with significant fracture history and identified OI and compared it to that of children having gSOS below the mean in excess of what would be expected by chance alone.

**Results:** The average gSOS across all three cohorts (n= 131) was -0.47 standard deviations lower than that in UK Biobank (n=80,027,  $P= 1.1 \times 10^{-5}$ ). The gSOS of 78 individuals suspected to have Mendelian osteoporosis was even lower (-0.76 standard deviations,  $P$  for comparison with UK Biobank  $=5.3 \times 10^{-10}$ ). Among 108 individuals with fractures tested for OI, while 30 had a mutation in an OI-related gene, there were 23 more subjects with a gSOS below the mean than would be expected by chance alone.

**Conclusions:** Individuals with a significant childhood fracture history but not OI have an increased burden of common fracture risk alleles, compared to the general population. This suggests that patients with presumed Mendelian osteoporosis should be investigated for a polygenic etiology of fracture.

## PgmNr 2831: Interactions of genetic variants with physical activity associated with bone mineral density in Hispanic children: The Viva La Familia Study.

### Authors:

**Background:** Osteoporosis is a complex disease that is affected by both genetic and environmental factors. Physical activity is an important environmental factor affecting accumulation and maintenance of bone mass, particularly in children. However, it is unknown if the benefits of moderate to vigorous physical activity (MVPA) on bone mineral density (BMD) vary based on the genetic risk in Hispanic children.

**Objective:** Our aim was to investigate if MVPA interacts with BMD-related single nucleotide polymorphisms (SNPs) to influence BMD in Hispanic children (n=750, 4-19y) of the cross-sectional Viva La Familia Study.

**Methods:** Physical activity was measured by accelerometers for 3 consecutive days and MVPA was defined by physical activity ratio greater than 3.0 or energy expenditure greater than 0.04 kcal/kg per minute. Total body BMD and lumbar spine BMD were measured by dual energy X-ray absorptiometry. A genetic risk score (GRS) was computed based on significant SNPs associated with BMD in our study and from the published literature. The reference alleles were coded as 2 for homozygous alleles associated with greater risk of low BMD, 1 for heterozygous alleles and 0 for homozygous for alternate alleles.

**Results:** The children's mean age and BMI were  $11.0 \pm 4.1$  y and  $25.1 \pm 7.6$  kg/m<sup>2</sup>, respectively. We found evidence of statistically significant effects of interaction between the GRS and MVPA on total body BMD and lumbar spine BMD ( $p < 0.05$ ). Higher GRS was associated with a greater decrease in total body BMD in low MVPA group ( $\beta = -0.040$ ,  $p = 1.1 \times 10^{-5}$ ), as compared to high MVPA group ( $\beta = -0.015$ ,  $p = 0.02$ ). Higher GRS was also associated with a greater decrease in lumbar spine BMD in low MVPA group ( $\beta = -0.042$ ,  $p = 0.0016$ ), as compared to high MVPA group ( $\beta = 0.008$ ,  $p = 0.4$ ). Further analysis with individual SNPs included in the GRS showed evidence of statistically significant interactions between rs370055571 (*MAP4K3*), rs452369 (*SLC8A1*) and rs10953178 (*SEM1*), and MVPA in relation to total body BMD and lumbar spine BMD ( $p < 0.05$ ).

**Conclusions:** MVPA seems to benefit bone health in Hispanic children who are genetically susceptible to low BMD compared to children who are less prone to low BMD. Future independent replication studies of our findings and functional studies for biological mechanisms are warranted.

## PgmNr 2832: Effect of genetically raised serum calcium on bone mineral density and risk of fracture in the general population: A Mendelian randomization study.

---

**Importance.** Calcium supplementation in the general population is common and often intended to reduce risk of fracture. Yet, calcium supplementation has been associated with increased risk of coronary artery disease and protective effects on bone health are still unclear.

**Objective.** We therefore tested whether genetically increased serum calcium was associated with improved bone mineral density and a reduction in osteoporotic fractures.

**Methods.** We used a two-sample Mendelian randomization design. A genome-wide association meta-analysis of serum calcium levels in up to 61,079 individuals was used to identify genetic determinants of serum calcium levels. The UK Biobank study was used to assess the association of genetic predisposition to increased serum calcium with estimated bone mineral density (eBMD) derived from heel ultrasound in 426,824 individuals who had on average calcium levels in the normal range. We next performed a fracture genome-wide association meta-analysis comprising 24 cohorts and UK Biobank including a total of 76,549 cases and 470,164 controls, who on average also had calcium levels in the normal range.

**Results.** A standard deviation increase in genetically-derived serum calcium (0.13 mmol/L or 0.51 mg/dL) was not associated with increased eBMD (0.003 g/cm<sup>2</sup>, 95% CI: -0.059 to 0.066; P = 0.92) or reduced risk of fractures (OR = 1.01, 95% CI: 0.89 to 1.15, P = 0.85) in inverse-variance weighted Mendelian randomization analyses. Sensitivity analyses did not provide evidence of pleiotropic effects.

**Conclusions.** Genetic predisposition to increased serum calcium levels in individuals with normal calcium levels is not associated with an increase in eBMD and does not provide clinically-relevant protection against fracture. Whether such predisposition mimics the effect of short-term calcium supplementation is not known. Given that the same genetically-derived increase in serum calcium is

associated with increased risk of coronary artery disease, widespread calcium supplementation in the general population may provide more risk than benefit.

## PgmNr 2833: Multi-omics integration of the human gut microbiome and metabolome with applications to osteoporosis.

---

While a number of genetic factors have been implicated in the pathogenesis of osteoporosis, the influences of the gut microbiome and human metabolome remain largely unexplored. In this study we performed multi-omics integration analysis using metagenomic whole genome shotgun sequencing of stool samples, LC-MS untargeted metabolomics profiling, and DXA-derived bone mineral density (BMD) collected from 499 Chinese postmenopausal women. First, we developed a sparse canonical correlation analysis (sCCA) model using a lasso penalty to select the most highly correlated features between the multi-omics data that are also important for BMD. The performance of the model was evaluated through simulation, which revealed that the sCCA method is able to detect >95% of the correlated features while also maintaining a reasonable false positive rate under a variety of different scenarios. Next, the sCCA model was applied to the real data and the selected features were used as input to construct the Gaussian graphical model, where the significance of network edges was determined by the graph lasso penalty. We interrogated the partial correlation network to determine the hub microbes and metabolites with the most inter- and intra-omic connections. There were 20 features (16 microbes and 4 metabolites) with significant connections to BMD after adjustment for all other nodes in the graph. Finally, using structure learning algorithms we estimated the Bayesian network to identify the potential driver microbes and metabolites that may play key roles in the regulation of BMD. The findings provide novel insight into the biological mechanisms that may be involved in the development of osteoporosis and related phenotypes.

## PgmNr 2834: GWAS of copy number variations (CNVs) for cleft lip with or without cleft palate (CL/P) in a multi-ethnic study sample.

### Authors:

---

Orofacial clefts (OFCs) are the most common craniofacial birth defect in humans with a prevalence of 1 in 700 live births worldwide. Approximately 70% of cases with cleft lip with or without cleft palate (CL/P) are considered to be non-syndromic. Non-syndromic CL/P has been shown to have a strong genetic component and a number of risk variants across the genome have been identified by previous studies. The CL/P risk loci identified by GWASs thus far focus mainly on common single nucleotide variants. In our study, we investigate the contribution of copy number variations (CNVs) to the risk of developing OFCs in a large multiethnic study consisting of 2,863 European subjects, 4,513 Latino subjects and 2,000 Asian subjects. CNVs were identified on chromosomes 1-22 using the PennCNV software on a ~600K SNP genotyping array. Thereafter, we performed whole-genome association of CL/P using the CNV status (present/absent) of individuals at SNP positions that overlapped with one or more CNVs. In the Latino subgroup, significant associations were observed in 7p14.1, 16q21 and 19p13.3 in the genes *TARP*, *POLR2C* and *POLR2E* respectively. In the Asian subgroup, genome-wide significant associations were observed in 4p16.3, 11p15 and chromosome 21q22.3 spanning genes *TACC3*, *MRGPRG*, and *COL6A1* respectively. Further, the European subgroup showed a genome-wide suggestive association at 19q13.3 near the *ITPKC* gene. None of our significant loci replicate known OFC genes. However, two independent studies of OFCs have previously reported the involvement of CNVs near 7p14.1 (PMID 24528994) and 4p16.3 (PMID 26561393) respectively. Further, the region corresponding to the suggestive association in the European sample has been reported by linkage and association studies of CL/P (PMIDs 8751880, 9003487, 9722939). These previous studies were conducted on samples different from ours. The significantly associated SNPs are near or within active transcription sites and/or super-enhancer regions involved in craniofacial development. Our study shows promising evidence that structural variation within regulatory regions of craniofacial development may contribute to the formation of OFCs. This research is supported by NIH grants R01-DE016148, R03-DE026469 and X01-HG007485.

## PgmNr 2835: Using external controls to account for mating asymmetry in maternal genetic association: Application to orofacial cleft.

Mating symmetry is a frequent assumption made when using case-parent triad data to study the effects of maternal and child genes on the risk of a disease with early onset. Mating symmetry indicates that for any possible parental genotype pair, the frequency of a given mother-father genotype assignment in the population is equal to the reverse father-mother genotype assignment. The violation of this assumption (known as mating asymmetry) may result in confounding, leading to spurious maternal associations in studies utilizing case-parent triads. The hybrid design proposed by Weinberg et al., relies on the use of control-parent dyads to test and account for mating asymmetry (MA). However, parents of unrelated controls are not genotyped in most ongoing studies. In this study, we modified the hybrid design (HD) approach by using control parents from an external dataset. We first investigated the performance of the modified hybrid design through simulations, by considering different levels of MA and sample sizes ( $n$ ) of external control-parent dyads, to assess the effect on the type 1 error and power to identify maternal effects. Results from our simulation study showed that the type 1 error rate was around 5% when the MA in the external control-parent dyads was no more than  $\pm 0.15$  points from the MA in the case-parent triads. Power of the hybrid design using external controls was above 80% for most scenarios considered. Using this modified approach, we investigated how adjusting for MA with external control-parent dyads from the HapMap project would change previous maternal genetic associations observed for orofacial clefts using GWAS data on over 2000 case-parent triads from an international consortium accessed through dbGAP. Our findings show that, in some situations, the HD with external controls may account for MA and provide valid tests for maternally contributed genotype effects when the mating symmetry assumption fails.

## PgmNr 2836: A new summary-data-based statistical test for discovering genetic variants influencing two traits with an application to GWAS of clefts.

---

With a growing number of disease-/trait-associated genetic variants detected and replicated across genome-wide association studies (GWAS), scientists are increasingly noting the influence of individual genetic variants on multiple seemingly unrelated traits. Cross-phenotype association tests, applied on two or more traits, usually test the null hypothesis of no association of a genetic variant with any trait. Rejection of the null can be due to association between the genetic variant and a single trait, with no indication if the variant influences >1 trait.

We propose a new statistical approach, *metapleio2*, to discover genetic variants influencing two traits or phenotypic subgroups using GWAS summary statistics. The traits can be from two studies with/without overlapping samples. *metapleio2* gives an approximate asymptotic p-value for association with both traits and is computationally efficient to be implemented genome-wide. Our simulation studies show that *metapleio2* maintains appropriate type I error at stringent error levels when low-to-moderate sample size or effect size differences in the traits exist.

For an application, we chose non-syndromic orofacial clefts (OFCs)– a common human birth defect, which exhibits strong familial aggregation and has a complex etiology. OFCs are typically categorized as cleft lip with or without cleft palate (CL/P) and cleft palate alone (CP) based on epidemiologic and embryologic patterns. Historically, most studies of CL/P and CP have been analyzed separately. Evidence of shared genetic risk in *IRF6*, *GRHL3* and *ARHGAP29* regions exists, but no variant outside *FOXE1* has approached genome-wide significance in GWAS of CL/P and CP together. When applied to a multi-ethnic GWAS of 2847 CL/P and 611 CP case-parent trios, *metapleio2* identified 6 loci in or near recognized candidate genes: *PAX7* ( $p=7.3 \times 10^{-8}$ ), *IRF6* ( $p=4.6 \times 10^{-12}$ ), *DLG1* ( $p=5.6 \times 10^{-7}$ ), *LIMCH1* ( $p=5.2 \times 10^{-7}$ ), *SHROOM3* ( $p=8.5 \times 10^{-7}$ ) and *NOG* ( $p=6.3 \times 10^{-8}$ ), notably each significant variant appeared to increase risk for one cleft subgroup but decrease risk for the other. Additionally, we replicated known genetic variants in *FOXE1* ( $p=1.8 \times 10^{-7}$ ) and identified a locus in *RAB8A* ( $p=7.1 \times 10^{-7}$ ) that influence risk for both CL/P and CP.

In summary, *metapleio2* confirmed recognized genes and found evidence for new genetic regions exerting shared risk or with opposite effects on risk of CL/P and CP. It shows promise in providing

novel insights into the shared genetic architecture of traits.

## PgmNr 2837: Discovery of pleiotropic variants associated with multiple sclerosis and migraine.

---

Risk factors and symptoms of multiple sclerosis (MS) and migraine often overlap, and up to 69% of MS patients experience migraine. However, it remains unknown whether genetic risk variants are shared between the two disorders. We investigated whether genetic risk variants previously identified from GWAS of either condition could be contributing to both conditions (i.e., whether any variant exerted a pleiotropic effect). Data from 1,073 MS cases and 12,000 controls (white, non-Hispanic) from Kaiser Permanente Northern California were utilized. Migraine status was obtained through self-report and a validated electronic health record algorithm, and whole genome data were available. MS or migraine SNPs were identified from prior GWAS, and after quality control, 902 SNPs with MAF>1% were available for analysis. A method by Lutz et al. (2017) was used to identify pleiotropic SNPs in which observed *P* values were compared to genotype permuted *P* values for both phenotypes. SNPs significantly associated with MS and migraine were subsequently used in logistic regression models to estimate the association between each variant and phenotype, adjusting for ancestry. To account for ascertainment bias from obtaining a secondary phenotype (migraine) from a case-control study design that selected participants based on their MS status, the migraine model adjusted for a propensity score representing the probability of MS case-control status given covariates. Preliminary results showed five SNPs were significantly associated with MS and migraine: rs6677309, rs10801908, rs1335532, rs62420820, and rs17066096. Three were protective for MS (rs6677309, rs10801908, and rs1335532) and all increased odds of migraine. Implicated genes include *CD58*, which modulates regulatory T-cells, and several immune genes (*IL20RA*, *IL22RA2*, *IFNGR1* and *TNFAIP3*) within the 6q23 chromosomal region. Results illuminate the shared genetics of MS and migraine, and because several variants increase risk of migraine but decrease risk of MS, there are implications for targeted therapies.

## PgmNr 2838: Genetic variants from immune regulatory genes at MHC region predict *Clostridioides difficile* infection: A genome-wide association study using comprehensive electronic health records.

*Clostridioides difficile* (*C. difficile*), is a major cause of diarrhea following antibiotic treatment or after community contact with hypervirulent strains. Host genetic susceptibility to *C. difficile* infection (CDI) has not been studied on a large-scale with a non-hypothesis driven strategy. The purpose of this study is to identify common variants associated with CDI in a community population as well as antibiotic-treated subset. CDI cases and controls were identified by leveraging the comprehensive Geisinger Electronic Health Record (EHR) database. Geisinger PHASE I and II cohorts were genotyped separately. To account for the potential population structure and relatedness, a linear mixed model was selected for the genome-wide association study (GWAS). After meta-analysis of two GWAS data sets, rs115062572 ( $p=3.51E-06$ ), within the MHC region, was among the top tier signals associated with CDI. Robust evidence of functional impact on neighborhood genes was identified. Subset analysis of patients with notable antibiotic use prior to the index date was performed to characterize a high-risk cohort and the GWAS was reconducted. Subset analysis revealed that rs114751021 at the MHC region was the top signal with a genome-wide significant association with CDI (OR = 2.42; 95%CI = 1.84-3.11;  $p=4.50E-08$ ); while rs115062572 still demonstrated significant association with CDI in antibiotic-treated samples (OR = 2.29; 95%CI = 1.70-2.99;  $p=1.40E-06$ ). Since this locus can be enriched in this CDI high-risk cohort, fine mapping was implemented to identify the causal SNPs or genes. The subsequent eQTL analysis, transcriptomic imputation and association, colocalization testing, and PheWAS annotation, suggested that these SNPs serve as eQTL for NOTCH4 and pQTL for C4A/C4B, and also prioritized the causal SNPs/genes. Minor allele carriers with increased risk for CDI were predicted to have higher levels of NOTCH4 and C4A/C4B, suggesting increased inflammatory response to *C. difficile*. Known associations between IL-8 SNPs (rs4073 and rs2227306) and CDI were replicated ( $p_{\text{lowest}} = 0.036$  and  $0.017$ , respectively). No significant interaction between the top SNPs at the MHC region and other risk factors was identified in association with CDI. This study provides the first evidence that genetic variants at MHC region are associated with CDI, and that those variants significantly alter gene expression of NOTCH4, C4A/C4B, and some MHC molecules in disease-relevant tissues.

## PgmNr 2839: Epistatic combinations of multiple SNPs commonly confirmed in two different case-control studies of rheumatoid arthritis in Japanese populations.

Genome-Wide Association Study (GWAS) has played a great role as indicating the interaction between genetic variants, especially Single Nucleotide Polymorphism (SNP), and disease, phenotype and behavior for decades. Most of these studies have been conducted to detect association between one SNP and a disease; however, one SNP cannot cause complex diseases. This shortcoming leads to missing heritability problem in GWAS [1]. To overcome this problem, we have developed LAMP algorithm [2], a multiple testing method to detect combinatorial effect. This algorithm analyzes criteria whose frequency of appearance is small and does not change the probability of a false positive [3]. Using this approach in GWAS application, LAMPLINK [4] has become one of the tools that can detect combinations of SNPs that are statistically and significantly associated with the target phenotype.

In this study, LAMPLINK was applied to a case-control study of Rheumatoid Arthritis (RA) from Japanese population, involving 497,190 SNPs and 11,755 individuals, and 61 statistically significant combinations were detected in total. The reproducibility of the combinations was checked in another study of RA from Japanese population, involving 1998 individuals. We confirmed that some combinations consisting of 3 or more SNPs have adjusted p value less than 0.05 in the dataset, showing the common existence of the significant associations of the SNP combinations to RA at least in the independent Japanese populations. Interestingly, the combinations indicate high odds ratio while the independent SNPs in the combinations doesn't have high odds, suggesting the importance to check the combinatorial epistatic effects. Overall our results may provide new aspects for understanding combinations of SNPs.

Genome wide association studies (GWAS) have revealed numerous genetic loci associated with many heritable diseases. A key challenge in translating these findings into biological understanding is finding the tissues and cell types where these risk variants act. A number of gene expression datasets, including both bulk and single-cell RNA-seq (scRNA-seq) experiments, have been used to show interesting cell type enrichments in schizophrenia, Crohn's disease (CD) and other pathologies. There are also multiple statistical packages available for testing enrichment, as well as multiple techniques for detecting and scoring cell-type specificity of genes. Running these tests at scale can be computationally and logistically challenging, which makes finding the right test, and assessing how robust results are to test and parameter choice, difficult.

Here we present a new R package, GWASCellTyper, to efficiently test for enrichment of signal from GWAS summary statistics in cell types using a range of established tests, including LDSC, Magma and SNPsea. GWASCellTyper is designed in a modular fashion to allow flexibility of use. For example, users can enter clustered or unclustered scRNA-seq data, or use pre-computed gene sets to compute enrichment. The package is multithreaded to allow scalable computation, and can compare different techniques for selecting cell-type specific genes (e.g. differential expression vs specificity scoring).

We apply this package to data from a Crohn's disease GWAS using a range of bulk and scRNA-seq datasets. We demonstrate a consistent enrichment of CD risk loci in T cells across tests and datasets, particularly CD4+ memory cells, along with various myeloid cell types, particularly stimulated macrophages. We also find cell types specific to particular datasets or tests, including hematopoietic stem cells and gamma-delta T-cells. We find that enrichment tests that use quantitative gene expression levels generally identify more enriched cell types than tests that only use a discrete list of cell-specific genes. Finally, we show that single-cell datasets often lack power compared to cell sorted bulk datasets, likely due to greater measurement error, but that computational approaches to reduce measurement noise, such as metacell or index cell techniques, can partially restore this power.

We aim to introduce additional enrichment tests, other functional enrichment tests and increased portability into future versions of GWASCellTyper.

Tuberculosis (TB) is the leading cause of death from a single infectious agent. Although the bacillus responsible for disease, *Mycobacterium tuberculosis* (MTB), is estimated to infect 1.7 billion people worldwide, only a small portion of these people (5-10%) will transition from the latent disease state into active TB. Because only a small fraction of infected people develop active disease, we hypothesized that underlying host genetic variation associates with developing active disease. Variation in *CLEC4E* has been of interest in previous association studies with the same variant showing either no effect or protection from TB. One of the studies using a South African cohort theorized that *CLEC4E* contributes to susceptibility to TB but could not statistically support it, while a Northern Chinese study found it confers protection. For this study we assessed 60 SNPs in 12 immune genes, including *CLEC4E*, using a case-control study from Guinea-Bissau. The 289 cases and 322 controls differed in age, sex, and ethnicity all of which were included in adjusted models. Initial association analysis with unadjusted logistic regression revealed putative association with nine SNPs ( $p < 0.1$ ). Any SNP that was significant below a  $p$ -value of 0.05 was then assessed in an adjusted model. Of the six SNPs that remained significant, three of them were assigned to the *CLEC4E* gene (rs12302046, rs10841847, and rs11046143). Of these, only rs10841847 passed FDR adjustment for multiple testing. Based on these initial association tests, *CLEC4E* seemed to be the best single indicator of PTB risk in this population, thus a deeper analysis of the gene was completed. Haplotype analysis (2-SNP and 3-SNP windows) showed that minor alleles in segments including rs10841847 were the only ones to pass the threshold of global significance as compared to other haplotypes ( $p$ -value  $< 0.05$ ). Linkage disequilibrium patterns showed that rs12302046 exists in high LD with rs10841847 ( $r^2 = 0.63$ ), and all other SNPs lost significance when adjusted for rs10841847 effects. These findings indicate that rs10841847 in the *CLEC4E* is the single best predictor of pulmonary tuberculosis risk in our study population. These results provide experimental evidence for the hypothesis set forth by the study from South Africa.

## PgmNr 2842: Detecting and quantifying clonal expansions in immune repertoire sequencing data.

---

A key feature of the adaptive immune system is the ability of lymphocytes to bind non-self antigens, clonally replicate, and carry out effector functions. Immune repertoire sequencing of somatically rearranged T-cell and B-cell receptors (TCRs and BCRs) is a powerful and sensitive tool for measuring clonal population sizes. By tracking changes in clonal populations over time, repertoire sequencing can identify specific TCRs or BCRs that have expanded or contracted in response to perturbations of the immune system, such as the introduction of a pathogen. In this work, we propose and evaluate statistical methods for two related problems: identifying which clones have responded to a stimulus and quantifying the strength of a polyclonal immune response. A core challenge in developing these methods was to make them robust to the number of sampled lymphocytes, which can vary substantially across time points and individuals due to technical and biological processes. To demonstrate these methods, we analyzed peripheral blood from nine volunteers who received the YF-17D vaccine for yellow fever virus, with samples collected immediately before vaccination as well as 14 and 90 days after vaccination. We show that the number of expanded clones can be compared across individuals by correcting for sampling depth, and we describe a clonal expansion score that captures both the breadth and depth of an immune response.

## PgmNr 2843: *HLA B\*57:03* and *C\*03:02* are associated with slow pediatric HIV progression in Botswana and Uganda.

### Affiliations:

1) Medical Microbiology, Makerere University, Kampala, Central Region, Uganda; 2) Baylor-Botswana Children's Clinical Centre of Excellence, Gaborone, Botswana; 3) Baylor-Uganda Children's Clinical Centre of Excellence, Kampala, Uganda; 4) University of Botswana, Gaborone, Botswana; 5) University of Tennessee Health Science Center, Memphis, Tennessee, USA; 6) Baylor College of Medicine, Houston, Texas, USA; 7) MRC/UVRI and London School of Hygiene and Tropical Medicine, Entebbe, Uganda

### Background

HIV remains at epidemic proportions in sub-Saharan Africa especially in pediatrics, despite effective antiretroviral therapy (ART). HIV infected individuals characteristically progress to AIDS leading to mortality, however, 1-5% do not progress to AIDS for at least 10 years in the absence of ART. This restriction of HIV progression is determined by both host genetic and viral factors. The *human leucocyte antigen (HLA) class I* gene is strongly associated with long-term non-progression (LTNP) of HIV in adult Caucasians and Africans. However, *HLA* is highly variable and shows high geographical diversity. In this study we determine the class I *HLA* alleles associated with HIV disease progression in Botswana and Uganda.

### Methods

From a cohort of about 12,000 children enrolled into pediatric HIV care centers in Uganda and Botswana since 2003, 1,000 participants were retrospectively recruited using the electronic medical records. They were stratified equally into two groups of rapid progression and LTNP according to the WHO classification of HIV disease progression. Class I *HLA* typing was done using HLAreporter that derives high-resolution allelotypes from whole exome sequence (WES) data.

### Results

Of the 1,000, 850 participants had WES successfully done and class I *HLA* allele data was correctly typed for 800 participants. After adjusting for gender and country of origin, we identified *HLA-B\*57:03* (OR 3.21 95%CI 1.50-6.85, p=0.030) and *C\*03:02* (OR 4.49 95%CI 1.64-12.23, p=0.049) alleles that are associated with LTNP in children in Uganda and Botswana. In addition, we confirm earlier observations that *HLA-B\*15:10* (OR 0.46 95%CI 0.31-0.79, p=0.030) is associated with rapid HIV progression as seen in Caucasian populations.

### Conclusion

This study demonstrates the utility of whole exome sequencing to study the association of class I *HLA*

and HIV disease progression in African populations. Consistent with previous studies, we identified a major role of *HLA-B* in HIV disease progression, as well as an unreported, uncommon *HLA-C* allele associated with HIV restriction in African pediatric populations. We recommend studies to understand the functional mechanisms of these alleles that are potential targets for HIV immunotherapeutics and vaccines.

## PgmNr 2844: CNV calling from exome data using machine learning detects at least 90% of pathogenic CNVs detectable by microarrays.

---

The diagnosis of genetic diseases in clinical settings relies on performing several different assays, from karyotyping and array-based Copy Number Variant (CNV) detection approaches to whole genome or whole exome sequencing (WES). With the continuing decrease of sequencing costs it would be advantageous to determine all types of genetic variation from a single assay.

CNVs are an important class of disease associated variation. CNVs remain more difficult to call with high accuracy than single-nucleotide variants or short indels. Multiple methods and algorithms have been developed, but no large-scale assessment comparing the accuracy and sensitivity of array-based vs WES-based approaches has been performed. The Deciphering Developmental Disorders (DDD) study provides an ideal data set to test this because of its scale and large overlap of samples with both exon-resolution array-CGH and exome CNV calls.

We sequenced more than 32 thousand exomes from families of 13,462 patients with severe developmental disorders. For 6,832 probands both aCGH and WES data are available which makes it a unique data set to compare the characteristics of callsets obtained from the two platforms. To determine CNVs from the aCGH data we developed and applied an approach, CNsolidate, that integrates CNV calls from six different calling algorithms to give higher accuracy than is achievable with any one caller.

To determine CNVs from WES data, we evaluated four callers (XHMM, CONVEX, CLAMMS and CANOES). We show that sensitivity and specificity of all callers is low and that a Random Forest machine learning approach can be used to integrate the calls. The final callset performs better than any of the individual callers (as observed independently also by other groups).

We find that the Random Forest approach applied on WES data identifies at least 90% of pathogenic CNVs identified from the aCGH data. We note that aCGH arrays in DDD have considerably higher resolution than the arrays typically used in a clinical setting, and that the DDD study is impoverished for large pathogenic CNVs relative to a prospective clinical cohort, therefore the true sensitivity of the WES callset compared to standard clinical aCGH would be even higher.

We also analysed the parental origin of de novo CNVs and show that the proportion that are maternal in origin is significantly higher than for de novo SNVs.

## Introduction

Large-scale whole genome sequencing studies have enabled the analysis of rare variants (RVs) associated with complex human traits. Commonly used RV association tests (RVATs) have limited scope to leverage the functions of variants.

## Methods

We propose STAAR (variant-Set Test for Association using Annotation infoRmation), a scalable and powerful method to increase the power of RVATs by effectively incorporating both variant functional categories and multiple complementary functional annotations using a dynamic weighting scheme. For the latter, we introduce “annotation Principal Components” (aPCs), multi-dimensional summaries of *in-silico* coding and noncoding variant functional annotations. STAAR accounts for population structure and relatedness, and can be used for analyses of continuous and dichotomous traits. We highlighted STAAR-O, the omnibus test which aggregates multiple annotation-weighted tests including the burden test, SKAT, and ACAT-V in the STAAR framework. We focused on two types of WGS RV association analysis using STAAR-O: gene-centric functional element-based analysis by grouping variants into functional categories for each protein-coding gene and agnostic genetic region analysis using sliding windows. We applied STAAR-O to identify RV-sets associated with four quantitative lipid traits (LDL-C, HDL-C, TG and TC) in 12,316 discovery samples and 17,822 replication samples from the NHLBI Trans-Omics for Precision Medicine (TOPMed) program.

## Results

In RV gene-centric analysis, STAAR-O identified 25 significant associations with lipids traits. After conditioning on known lipids-associated variants, 13 out of the 25 associations remained significant and could be validated in replication phase, including the association between *NPC1L1* missense RVs and LDL-C, which was not detected by the conventional variant-set tests and has not been observed

in previous studies. In RV sliding window analysis, STAAR-O detected 59 significant 2kb sliding windows associated with lipid traits. 12 sliding windows remained significant after conditioning on known variants and could be validated in replication phase, including associations between an intergenic region near *APOC1P1* and LDL-C that were not detected using conventional tests.

### **Conclusion**

By incorporating multiple variant functional annotations via aPCs, STAAR-O empowers rare variant association analysis and detected novel rare variants association with lipid traits using the TOPMed WGS Freeze 5 data.

## PgmNr 2846: MetaPhat: Detecting and decomposing multivariate associations from univariate genome-wide association statistics.

---

Multivariate statistical tools that analyze jointly multiple genome-wide association studies have become widely-used due to the increased number of phenotypes gathered in biobanks. While these tools have been shown to considerably boost statistical power over univariate tests, a remaining challenge is to interpret which traits are driving the multivariate association and which traits are just passengers with minor contributions to the genotype-phenotype association.

MetaPhat is a novel computational tool to conduct genome-wide association studies of related multivariate traits based on univariate summary statistics and to decompose the significant multivariate associations into sets of statistically central traits. The decomposition is achieved by tracing the multivariate association p-value from testing on the canonical correlation value, beginning with the full model while traits are iteratively dropped. We use two new concepts to define the central traits. The *driver* traits are a small subset without which the association p-value does not reach the significance level. The *optimal* traits are a small subset of traits that together make the association statistic optimal.

Using univariate GWAS summaries for 21 heritable and correlated polyunsaturated lipid species from 2,045 Finnish samples, MetaPhat detected 7 independent significant SNPs ( $p\text{-value} < 5 \times 10^{-8}$ ). As an example, the missense variant rs7412 in the *APOE* gene, known to associate with low-density lipoprotein cholesterol, was detected in a multivariate analysis by MetaPhat, although the smallest p-value of rs7412 was found to be  $1.1 \times 10^{-4}$  from any univariate GWAS of the 21 traits. Our decomposition revealed that this association was driven by two polyunsaturated lipids with C20:4 acyl chain fatty acid properties. Learning this information without the systematic iterative procedure implemented in MetaPhat would have been infeasible, as it had required considering millions of possible subsets of the 21 traits. MetaPhat, instead, considers only a *few hundred subsets* of the 21 traits and completes decomposition of a variant association in just a few minutes.

MetaPhat is an open source application written in Python with built-in support for multi-processing, quality control, clumping and intuitive visualizations using R. The software is easy to use and suitable for cloud computing. The implementation is freely available under MIT license at <https://sourceforge.net/projects/meta-pheno-association-tracer>

## PgmNr 2847: Common genetic variation as a modifier of familial hypercholesterolemia in the Old Order Amish.

### Affiliations:

1) Regeneron Genetics Center, Tarrytown, NY; 2) Office of Research Affairs, University of Maryland School of Medicine, Baltimore, MD; 3) Department of Medicine, University of Maryland, Baltimore, MD; 4) Division of Endocrinology, Diabetes and Nutrition, University of Maryland School of Medicine, Baltimore, MD; 5) Program for Personalized and Genomic Medicine, University of Maryland School of Medicine, Baltimore, MD; 6) Geriatric Research and Education Clinical Center, Veterans Administration Medical Center, Baltimore, MD

Founder populations like the Old Order Amish (OOA) have a unique genetic architecture with a high representation of drifted alleles such as *APOB* p.R3527Q, a known familial hypercholesterolemia (FH) allele, present at a frequency of 6.5% in the OOA compared to only 0.06% in non-Finnish Europeans in gnomAD.

We assessed whether common genetic variation in the OOA modifies the effect of *APOB* p.R3527Q on LDL cholesterol (LDL-C) by performing genome-wide gene-by-gene interaction screens using merged exome and array genotyping data on 5,924 OOA individuals (768 of which carry at least one copy of *APOB* p.R3527Q). We utilized linear mixed models to account for relatedness and adjusted for sex, age, age<sup>2</sup> and study. *APOB* p.R3527Q was associated with an increase of 75.7 ( $\pm$  1.7) mg/dL in LDL-C per allele ( $p < 1 \times 10^{-303}$ ), but there were no genome-wide significant interaction effects with *APOB* p.R3527Q. We identified a nominal interaction effect of -0.31 SD in LDL-C ( $p = 1.02 \times 10^{-5}$ ) with rs6531176, located in a regulatory region 1.39 Mb upstream and in moderate linkage disequilibrium (LD) with *APOB* p.R3527Q.

Next, we evaluated the impact of a polygenic risk score (PRS) on LDL-C levels in the OOA. We generated a PRS for LDL-C using previously reported GWAS summary statistics from 188,577 European-ancestry individuals in the Global Lipids Genetics Consortium (GLGC). We pruned the PRS of any variants in LD with *APOB* p.R3527Q ( $r^2 \geq 0.1$ ) by removing a region of 22.8 Mb around *APOB* p.R3527Q from the GLGC source data and assessed the PRS effect on LDL-C in *APOB* p.R3527Q reference and heterozygous carriers. *APOB* reference individuals in the top PRS decile had LDL-C levels of 139.8 ( $\pm$  1.6) mg/dL, while *APOB* reference individuals in the lowest PRS decile had LDL-C levels of 103.5 ( $\pm$  1.2) mg/dL (a difference of 36.3 mg/dL). In comparison, *APOB* p.R3527Q heterozygous carriers in the top PRS decile had LDL-C levels of 211.2 ( $\pm$  4.8) mg/dL, while *APOB* p.R3527Q heterozygous carriers in the lowest PRS decile had LDL-C levels of 181.5 ( $\pm$  3.9) mg/dL (a difference of 29.7 mg/dL). These differences were associated with a nominal interaction effect between the LDL-C PRS and the *APOB* p.R3527Q allele with an effect size of -0.11 SD ( $p = 3.07 \times 10^{-3}$ ).

These results expand our understanding of the allelic architecture of LDL-C in the OOA, indicating that common genetic variation can modify LDL-C in individuals with monogenic FH, findings that are likely

generalizable to FH in other populations.

## PgmNr 2848: Evidence for a causal role of triglycerides in increasing blood pressure: A multivariable Mendelian randomization study of over 820,000 subjects.

Jebsen Center for Genetic Epidemiology, Department of Public Health and Nursing, NTNU, Norway; 2) MRC Integrative Epidemiology Unit, University of Bristol, UK; 3) Clinic of Thoracic and Occupational Medicine, St. Olavs Hospital, Trondheim, Norway; 4) Cardiovascular Epidemiology Unit, University of Cambridge, Cambridge, UK; 5) Department of Internal Medicine, University of Michigan, Ann Arbor, MI, US; 6) MRC Biostatistics Unit, University of Cambridge, Cambridge, UK; 7) Department of Endocrinology, St. Olavs Hospital, Trondheim University Hospital, Trondheim, Norway

**Background:** Higher low-density lipoprotein cholesterol (LDL-C), lower high-density lipoprotein cholesterol (HDL-C) and higher triglyceride (TG) levels have been associated with high blood pressure (BP) in observational studies.

**Aim:** To investigate the causal associations of serum lipid levels (LDL-C, HDL-C, and TG) with systolic (SBP) and diastolic blood pressure (DBP) using univariable and multivariable Mendelian Randomization (MR).

**Methods:** Using a two-sample MR, an instrument of 392 lipid-associated independent variants, selected from the Global Lipids Genetics Consortium (n=331,368) was examined for a causal association with SBP and DBP in 69,248 participants from the HUNT cohort and 757,601 participants from the combined UK biobank and International Consortium of Blood Pressure (UKB-ICBP) cohort. Estimates were meta-analyzed across cohorts. Besides inverse variance weighted (IVW) for univariable MR, multivariable MR was used to disentangle the independent effect of individual lipid traits on SBP and DBP. Evidence of pleiotropy was evaluated using MR-Egger. The estimates ( $\beta$ [95% CI]) represent the age- and sex-adjusted change in blood pressure (mmHg) per 1 standard deviation (SD) genetically attributed lipid level.

**Results:** For SBP, IVW meta-estimates in combined cohorts supported a meaningful change in SBP with HDL-C (-0.39[-0.64,-0.14],  $P=0.002$ ) and TG (0.63[0.11,1.16],  $P=0.02$ ), with comparable estimates in UKB-ICBP only. Multivariable meta supported substantial effect for TG (0.61[0.11,1.10],  $P=0.01$ ) only.

In both HUNT and UKB-ICBP cohorts, IVW estimates showed evidence for casual effect of HDL-C (-0.29[-0.55,-0.03],  $P=0.03$  and -0.26[-0.47,-0.04],  $P=0.02$ , respectively) and TG (0.53[0.22,0.84],  $P=7.7 \times 10^{-4}$  and 0.59[0.35,0.82],  $P=1.2 \times 10^{-6}$ , respectively) with DBP with consistent estimates from meta-analysis (HDL-C: -0.27[-0.43,-0.11],  $P=0.001$  and TG: 0.57[0.38,0.76],  $P=3.2 \times 10^{-9}$ ). Multivariable MR along with its meta estimate supported only the independent casual association of TG

(0.53[0.18,0.88],  $P=0.003$  and 0.64[0.36,0.91],  $P=5.7 \times 10^{-6}$ , 0.60[0.38,0.81],  $P=6.3 \times 10^{-8}$ , HUNT, UKB-ICP, Meta respectively) with DBP. MR-Egger regression provided little evidence of pleiotropy.

*Conclusion:* In our cohorts, univariable MR provided evidence for the causal association of multiple lipid traits with blood pressure traits. However, multivariable MR only supported the independent causal role of TG in increasing blood pressure.

## PgmNr 2849: Multi-trait genome-wide multivariate polygenic risk score improves disease prediction of complex traits.

---

Polygenic prediction has been extensively used to identify individuals with elevated risk in a given population. Albeit advancements in modern high-dimensional statistics, most of the genetic risk score models are built on a stepwise procedure for each trait, independently: clumping and thresholding based on the significant associations from univariate marginal GWAS summary statistics, limiting the incorporation of informative alleles with modest effect for single or multiple traits and the overall predictive performance. To address this, we built genome-wide multivariate penalized regression models and their corresponding polygenic risk scores (PRSs) using batch screening iterative lasso (BASIL) algorithm implemented in R snpnet package across 94 phenotypes in UK Biobank, including 38 biomarkers and 46 cancer phenotypes. Among the improved predictive performance, we found our model explains 56% of the variance in Lipoprotein (a) levels and predicts prostate, skin, and breast cancers with ROC-AUC of .64, .61, and .59, respectively, using the features in the array-genotyped data alone. To investigate and summarize correlated predicted disease risks across traits, we applied an unsupervised statistical learning approach and characterized latent components of PRSs (multi-PRS LCs). By quantifying phenotype pairwise similarities within multi-PRS LCs, we found the 22 distinct phenotype pairs with more than .5 of absolute value of similarity score within the biomarker PRSs: creatinine and eGFR ( $< -.999$  cosine similarity), LDL and Apolipoprotein B ( $> .990$ ), and HDL cholesterol and Apolipoprotein A ( $> .0.985$ ), all of which are consistent with coherent variant selection in the penalized multivariate Lasso regressions. Using multi-PRS LCs, we further identified outlier individuals and characterized the directions (i.e. the composition of multi-PRS LCs) and magnitude of the elevated genetic risks. We found a set of outlier individuals who have elevated risks for creatinine, cystatin-C, and Urea. Together, our results highlight the benefit of genome-wide characterization and integrative analysis of PRSs across correlated traits. The resource made available with the study, which includes the weights of the individual trait-specific polygenic risk scores from the penalized Lasso regression models and combined multi-PRS LC scores, will accelerate further investigation of PRSs and pleiotropic effects of complex traits.

Transcriptome-wide association studies (TWAS) have identified thousands of genes whose *cis*-regulated expression levels associate with a host of complex traits and diseases. In this study, we devised an integrative framework that combines TWAS with probabilistic fine mapping across multiple large-sized cohorts. We performed TWAS using S-PrediXcan on summary-statistics of lipid traits - high-density lipoprotein (HDL), low-density lipoprotein, total cholesterol and triglycerides (TG). Analyses were performed using 31,838 European American (EA) adults from electronic Medical Records and Genomics (eMERGE) network Phase III, 76,627 Non-Hispanic EA adults from Genetic Epidemiology Resource on Adult Health and Aging (GERA), and 188,578 predominantly EA individuals from Global Lipids Genetics Consortium (GLGC). We used tissue-specific weights (~8300 genes) derived from Genotype Tissue Expression Project v7 for adipose subcutaneous (AS), adipose visceral omentum, liver, small-intestine terminal ileum (SI), and whole blood. We identified 375 Bonferroni-significant genes (137 novel and 238 previously known). 42 of the novel genes “replicated” (same direction of effect for the same trait-tissue pair) in at least two cohorts and had an FDR-adjusted gene expression prediction accuracy p-value < 0.05. After conditioning on independently associated SNPs at a locus (GCTA-COJO), we conducted statistical colocalization analyses in each of five tissues (coloc) and filtered out LD-contaminated genes (probability of independent GWAS and eQTL signals > 0.5). We subsequently performed probabilistic fine mapping of causal gene sets (FOCUS) and identified 29 genes that had posterior inclusion probabilities > 0.5 in at least two cohorts for the same trait-tissue pair. We also estimated local SNP heritability for all four lipid traits (HESS). Some of our novel genes replicated in all three cohorts for the same trait-tissue pair (*TRIM74*: AS-HDL, *ZSWIM1*: AS-TG, and *MT3*: SI-HDL) and one replicated in two cohorts for all five tissues (*RP11-109L13.1*: TG).

*RP11-109L13.1* was in a 1.3 MB region that includes *APOC3/A1/A4/A5*; this region explained 2.2%

(GERA) and 1.3% (GLGC) of variation in TG. We are using data from Million Veteran Program, Penn Medicine Biobank, and the UK Biobank as additional replication cohorts and are also running S-PrediXcan “phenome-wide”. We demonstrate the power of this framework over standard GWAS to identify novel genes that have strong evidence for causality.

## **PgmNr 2851: Uncommon, non-coding variants in the *APOE* region are associated with Alzheimer's disease risk, independent of the *APOE* $\epsilon 2/\epsilon 3/\epsilon 4$ alleles.**

### **Authors:**

E.E. Blue <sup>1</sup>; A.Q. Cheng <sup>2</sup>; C.E. Yu <sup>3,4</sup>; Alzheimer's Disease Genetics Consortium

---

The two single nucleotide polymorphisms (SNPs, rs429358 and rs7412) defining the *APOE*  $\epsilon 2/\epsilon 3/\epsilon 4$  alleles are the most well-established genetic loci for the risk of Alzheimer's disease (AD). Other SNPs in the *APOE* region have also been associated with AD risk, including rs2075650 in the intron 2 of *TOMM40* and rs4420638 located 3' of *APOC1*. It has been difficult to determine whether these associations are independent of the strong *APOE* effect, as both rs2075650 and rs4420638 are in linkage disequilibrium (LD) with  $\epsilon 4$  and each other ( $0.30 \leq r^2 \leq 0.65$  in the 1000 Genomes Europeans). Using the Alzheimer's Disease Genomics Consortium (ADGC) genotype data near *APOE* ( $\pm 500$ kb; imputed with 1000 Genomes reference) among subjects with European ancestry, we tested for association between SNPs (minor allele frequency, MAF,  $\geq 0.01$ ) and AD disease status with four mixed models adjusting for sex, population structure, and relatedness: model 1 (N=18,770) without *APOE* adjustment, model 2 (N=18,770) adjusted for the count of *APOE*  $\epsilon 2$  and  $\epsilon 4$  alleles, model 3 (N=8,878) restricted to *APOE*  $\epsilon 3$  homozygotes, and model 4 (N=1,503) restricted to *APOE*  $\epsilon 4$  homozygotes. We find stronger LD between rs429358, rs2075650, and rs4420638 in ADGC data relative to the 1000 Genomes Europeans ( $0.50 \leq r^2 \leq 0.83$ ). As expected, rs2075650 and rs4420638 are strongly associated with AD without *APOE* adjustment (model 1; p-value  $\leq 3.19 \times 10^{-228}$ , odds ratio, OR,  $\geq 2.59$ ). While rs2075650 is significantly associated with AD risk among the *APOE*  $\epsilon 4$  homozygotes (model 4; p-value = 0.0468, OR = 1.33) and trends towards significance under models 2 and 3 (p-value < 0.10), rs4420638 is no longer associated with AD after *APOE* adjustment or stratification. Among the other SNPs near *APOE*, we find significant association between rs192879175 and AD among the *APOE*  $\epsilon 3$  homozygotes (model 3; p-value =  $8.30 \times 10^{-6}$ , OR = 0.50) and suggestive association between 12 additional SNPs and AD after correcting for the estimated number of independent tests (p-value <  $4.74 \times 10^{-5}$ ). These 13 SNPs are uncommon among the *APOE*  $\epsilon 3$  homozygotes (MAF < 0.10), and most are non-coding SNP estimated to have a protective effect for AD. Over half of these 13 SNPs were nominally associated with AD risk in the model with *APOE* adjustment (model 2; p-value < 0.05), with the same direction of effect across models. Together, these results suggest that uncommon, non-coding variants in the *APOE* region also contribute to AD risk independent of the *APOE*.

## PgmNr 2852: Detectable chromosome X mosaicism is rare in peripheral leukocytes of UK Biobank men.

---

Genetic mosaicism is the presence of clonal populations of cells harboring post-zygotic mutations that are absent in inherited germline DNA. Age-related mosaicism of the sex chromosomes occurs more frequently than autosomal mosaicism, with detectable mosaic Y loss affecting up to 20% of elderly men and base pair adjusted rates of mosaicism on the female X chromosome observed at 4 times the rate of the autosomes. To our knowledge, the frequency of large structural (>2 Mb) mosaicism on the X chromosome has not been investigated in male populations. We characterize the frequency of genetic mosaicism of the male X chromosome in 196,219 men from the UK Biobank. We systematically scanned for deviations in median log R ratio (mLRR) data of chromosome X probes extracted from Affymetrix UK BiLEVE and UK Biobank Axiom genotyping arrays of blood-derived DNA. We detected 12 (0.01%) men in the UK Biobank with deviations in chromosome X LRR suggesting potential chromosome X mosaicism ( $|\text{mLRR}| \geq 0.15$ ), including 1 man with a potential mosaic gain on Xq and 11 men with gains spanning the whole X chromosome. Only 2 men with mosaic whole chromosome X gains surpassed the median  $\text{mLRR} \geq 0.25$  threshold, suggesting a high proportion of cells in these men are affected by mosaic X events. We did not detect evidence for mosaic losses in UK Biobank men. There was no evidence in the UK Biobank suggesting detected X mosaicism is age-related. We also detected 24 (0.01%) males in the UK Biobank with constitutional XXY (Klinefelter syndrome). The rarity of chromosome X mosaicism in males relative to females likely reflects the importance of the genetic content of the X chromosome for cellular growth and survival. Whereas in females the loss or gain of an inactivated copy of the X chromosome may be tolerated, clonal loss or gain of the X chromosome in males is rare.

## **PgmNr 2853: Direct-to-consumer genetic testing data identified the possible risk markers associated with the oral cavity health among Japanese subjects.**

---

[Background and Objective] The importance of oral cavity, an organ required for ingesting food, has been increasingly appreciated in parallel with the growing concerns on healthy longevity. However, only a few studies have been conducted to understand the genetic background of oral cavity health, particularly among the Japanese. Thus, to gain new insights about the genetic background of oral cavity health, we conducted the present study to identify the risk markers associated with oral diseases and problems.

[Method] We performed a genome-wide association analysis of more than 10,000 Japanese participants recruited via the direct-to-consumer genetic testing service in Japan. Their genomic DNA was extracted from saliva and was genotyped for about 300,000 single nucleotide polymorphisms (SNPs) using SNP array. We conducted web-based questionnaires about the oral cavity of the subjects. Some examples of the questions asked in the questionnaire are as follows; "Have you (or your relative) ever been diagnosed with periodontal disease by your doctor? (yes/no)", "Have you (or your relative) ever been diagnosed with dental decay by your doctor? (yes/no)", and "Are you worried about bad breath? (yes/no)". The genome-wide association analysis was performed on the acquired data by logistic regression model adjusted for age and sex using PLINK software, and P-value  $< 5 \times 10^{-8}$  was regarded as being genome-wide significant and P-value  $< 1 \times 10^{-5}$  was regarded as being genome-wide suggestive. To evaluate the associated SNPs, we performed mediation and stratified analyses.

[Results and Discussion] We identified some genome-wide suggestive SNPs ( $p < 1 \times 10^{-5}$ ) that were associated with periodontal disease and bad breath. These SNP loci were previously reported in non-Japanese population studies focused on the oral cavity. In conclusion, we identified the candidate risk makers associated with oral cavity health. However, further studies are required to examine the reliability of these markers owing to the low sample size and moderate p-values in our current study. Our findings may provide new clues to understand the underlying mechanisms that influence oral cavity health, and are expected to be exploited as biomarkers for personalized oral cavity treatments.

## PgmNr 2854: Association analysis of handgrip strength in targeted loci from GWAS using longitudinal measures and whole-genome sequence data from the Trans-Omics for Precision Medicine (TOPMed) Program.

**Background:** Low or declining handgrip strength, a widely used proxy of muscular fitness and a marker of frailty, predicts a range of morbidities and all-cause mortality. We performed association analyses of handgrip strength in 16 targeted GWAS loci (Willems et al, 2017) using longitudinal handgrip measurements and whole-genome sequence data from the Trans-Omics for Precision Medicine (TOPMed) program.

**Methods:** We analyzed 12,342 ethnically diverse participants from six cohort studies (Amish, ARIC, CHS, FHS, HyperGEN, and WHI) who had between two and six handgrip measures per exam, from one to nine separate exams over time. We selected the maximum observation per participant at each exam and used all exams per participant, totaling 32,266 observations. We conducted association analyses with GMMAT using linear mixed models adjusted for age, sex, height, BMI, study, age×sex, BMI×sex, study×sex, and 11 ancestry principal components. We included random effects for study, kinship and participant to account for correlation of measures across exams. We also performed stratified analyses in European (EA) and African (AA) ancestry ( $N_{EA}=9,538$ ;  $N_{AA}=2,663$  participants). We defined loci using a 500kb window around the lead 2017 GWAS variants.

**Results:** Participants had a mean age of 66.6 years (SD: 13.8) and a mean handgrip of 29.4 kg (SD: 10.8). We detected a significant ( $P \leq 6.9 \times 10^{-6}$ ) 17q21 association (lead TOPMed variant rs4793937,

MAF=0.18,  $P=1.9\times 10^{-7}$ ,  $P_{EA}=4.2\times 10^{-6}$ ,  $P_{AA}=0.003$ ) in the homeobox B3 (*HOXB3*) gene. The association of the lead 2017 GWAS variant (rs2288278, MAF=0.34) was restricted to EA and modest in our sample ( $P_{EA}=0.005$ ), which may be due to the younger age of the 2017 GWAS participants (mean age (SD): 56.8 years (8.0)). The association of rs4793937 remained significant after conditioning on rs2288278 ( $P=2.1\times 10^{-6}$ ), suggesting two distinct signals. The correlation between rs4793937 and rs2288278 was higher in EA ( $r^2=0.41$ ) than in AA ( $r^2=0.11$ ), which may explain why the 2017 GWAS identified only one signal in *HOXB3*. Using GTEx and FUSION quantitative trait loci (QTLs) results of expression (eQTLs) and DNA methylation (mQTLs) in human skeletal muscle tissue, we found that both variants are eQTLs of *HOXB3* and mQTLs of *HOXB3* CpG sites.

**Conclusion:** Leveraging multi-ethnic populations along with longitudinal data can help identify additional signals in GWAS loci associated with complex traits. Further investigation of the function of *HOXB3* in muscle cell is needed.

## PgmNr 2855: Predicting physiological aging rates from quantitative traits using machine learning methods.

### Authors:

It is widely thought that individuals age at different rates. A method that measures physiological age independently of chronological age could therefore be a first step to understand relevant mechanisms; but searches for individual biochemical markers of physiological age have had limited success. In this study, we assessed the extent to which an individual's physiological age could be determined as a composite score inferred from a broad range of biochemical and physiological trait data. Data were collected in population studies in Sardinia ("SardiNIA") and Tuscany ("InCHIANTI"). We used machine learning strategies on data for ~6,000 Sardinian participants, who ranged in age from 12 to 81. The best predictive models were determined from combinations of dimensionality reduction, classification, and regression algorithms. They reached very strong correlations ( $R > 0.9$ ) between predicted and actual ages. However, some individuals showed differences between predicted and chronological age, which were maintained in repeated visits. Similar results were also seen for participants in the InCHIANTI study. We then defined an Effective Rate of Aging (ERA) for each participant, a continuous trait measured as the ratio of an individual's predicted physiological age to his/her chronological age. The inference that individuals have characteristic rates of aging is supported by findings that in the SardiNIA cohort, values of ERA showed genetic heritability of 40%. Thus, young individuals already showed a rate of aging, and its heritability was sufficient to sustain a genome-wide association study. It pointed to genetic variants influencing the rate of aging in genes that affect telomere length and metabolic activity.

## PgmNr 2856: Assessing age, BMI, and genetic effects on serum IGF-1 in the long life family study.

---

Serum levels of insulin-like growth factor 1 (IGF-1) decrease with increasing age and are associated with susceptibility to age-related diseases. Measures of adiposity, such as body mass index (BMI) also are associated with susceptibility to age-related diseases. Previous reports of the relationship between IGF-1 and BMI ranged from positive to negative to no relationship, perhaps because previous reports studied different age cohorts. Using data on 4270 participants (aged 24-110 years old [yo]) from the Long Life Family Study (LLFS), we investigated the relationship between IGF-1 and BMI overall and by age groups, and also estimated heritability, and performed linkage analyses on IGF-1. IGF-1 and BMI were positively correlated in the total sample ( $\beta=0.161$ ,  $r^2=0.0038$ ,  $P<0.0001$ ). However, further analyses revealed that the relationship between IGF-1 and BMI varied by age quartile: in the 1st quartile (24-58 yo) the relationship was negative ( $\beta=-0.204$ ,  $r^2=0.011$ ,  $P=0.0008$ ); in the 2nd quartile (59-66 yo) the relationship was negative but non-significant ( $\beta=-0.069$ ,  $r^2=0.0012$ ,  $P=0.28$ ); in the 3rd quartile (67-86 yo) the relationship was positive but non-significant ( $\beta=0.106$ ,  $r^2=0.002$ ,  $P=0.13$ ); and in the 4th quartile (87-110 yo) the relationship was positive ( $\beta=0.388$ ,  $r^2=0.019$ ,  $P<0.0001$ ). This pattern did not differ by sex. We also detected a similar age-related pattern between IGF-1 and BMI using an independent dataset, NHANES III. In LLFS, after adjusting for age and sex, the estimated residual heritability of IGF-1 was 0.40 ( $P<0.0001$ ). Multipoint linkage analysis of IGF-1 (using maximum likelihood methods) revealed a potentially novel quantitative trait locus on chromosome 11 at 78 cM (maximum LOD-score=3.48). In summary, we find age-group effects that may clarify some of the inconsistency in previous literature about the relationship between IGF-1 and BMI. In addition, we identified a possible novel locus for IGF-1 levels. Additional studies of IGF-1 and adiposity measures, as well as additional genetic studies of IGF-1, are needed to better understand the underlying mechanisms involved.

## PgmNr 2857: Heritable determinants of mitochondrial heteroplasmy.

### Authors:

---

Mitochondrial (Mt) heteroplasmy, or the existence of multiple mitochondrial sequences within an individual, is frequently identified in mitochondrial sequencing. For pathogenic variants, the severity of associated symptoms correlates well to the degree of heteroplasmy. Heteroplasmy can be *de novo* or inherited, and inherited heteroplasms can quantitatively shift during mother-to-child transmission. Our goal was to evaluate heteroplasmy and identify its underlying genetic determinants in the 23andMe database. Our large sample size and the high density of mitochondrial variants on the most commonly used 23andMe array allow us to quantify heteroplasmy and identify nuclear genes in which variation is associated with appreciable statistical power.

We performed Mt variant-level quality control in a subset of 278,196 unrelated European-ancestry samples, which consisted of discarding (1) variants with a high proportion of samples with low intensity, and (2) variants for which we observed extensive heteroplasmy, including those in hypervariable regions of the mtDNA. We retained 327 variants for downstream analyses. As described in previous work (Sondheimer et al. HMG 2011), we computed heteroplasmy from the allele-specific intensity ratios for each of these variants, and to validate the observed heteroplasmy in our data, we compared these variants' intensities in maternal-child pairs and noted a high correlation. Next, to quantify heteroplasmy per-individual and at a large scale, we considered both the mean and the maximum values across this high-quality set of variants as quantitative traits in approximately 1 million unrelated 23andMe European-ancestry samples. Preliminary GWAS of both heteroplasmy definitions identified multiple genes of interest, including the mitochondrial transcription factor *TFAM*, and the mitochondrial deacetylase *SIRT3*. Additional work will be carried out to replicate these findings in other data and also to further study the physical location, potential consequences, and prevalence of heteroplasmy across the Mt genome in the large-scale 23andMe dataset.

## PgmNr 2858: Incidence estimation of monogenic disorders caused by *de novo* variants.

**Purpose** Epidemiological disease estimates are not available for the vast majority of rare single-gene disorders due to phenotypic heterogeneity and the absence of nation-wide genomic screens. Here, we use a genetic data based statistical method to predict the incidences of all *de novo* variant-associated, rare, and severe single-gene disorders.

**Methods** We used a well-established mutational model to calculate *de novo* variant rate and predict incidence in 100,000 births for all selected rare single-gene disorders.

**Results** We predicted the disorder incidence for 103 known and 3,104 variant intolerant putative *de novo* variant associated genes. Greater predicted incidences correlated with larger numbers of pathogenic variants annotated in patient variant databases for 1,108 known and putative single-gene disorders ( $p\text{-value} = 7.2 \times 10^{-06}$ ), supporting the validity of the incidence prediction. Furthermore, our predicted incidence rates were in the range of reported epidemiological estimates identified in the literature for 86% (six out of seven) *de novo* variant associated single-gene disorders (*SCN1A*, *SLC2A1*, *SALL1*, *TBX5*, *KCNQ2*, and *CDKL5*).

**Conclusion** In the absence of epidemiological data, our catalog of incidence estimates for 103 established and 3,104 putative *de novo* variant associated single-gene disorders can guide patient advocacy groups, clinicians, researchers, and policymakers in strategic decision making.

## PgmNr 2859: Imputed gene expression identifies significant contribution of common regulatory variants to congenital malformations in a medical biobank population.

---

Congenital malformations (CM) are structural defects present from birth. CM are detected in 3% of births and are the leading cause of infant mortality; however, studies suggest that a large number of CM cases go undetected by medical professionals. Most defects arise due to genetic variation, in combination with environmental exposures, nutritional deficiency, and parental age. Identifying the genetic risk factors, and the individuals at greatest risk for CM, could provide insight into the prevention or treatment of these disorders. In this study we demonstrate the utility of medical biobanks paired with imputed gene expression to identify the genetic and phenotypic correlates of CM.

We set out to test the hypothesis that genetic variation in the regulatory regions of known CM genes is associated with congenital outcomes in a biobank population. We tested this prediction across 23,000 individuals of European ancestry in the de-identified electronic health record-linked biobank at Vanderbilt University, BioVU. In addition to the rich phenotypic information, genotyping data on these individuals gave us the opportunity to assess genetic variation in regulatory regions of the genome through imputed gene expression. Models for gene expression were built using the large eQTL dataset, GTEx. We find that imputed gene expression of known CM genes is significantly associated with congenital phenotypes in the BioVU population (DNMT3B (DNA Methyltransferase-3 Beta) with congenital anomalies of esophagus  $p = 9.51e-7$ , POLR1A (RNA Polymerase I Subunit A) with chromosomal anomalies  $p = 9.60e-6$ ). Additionally, we generated a phenotype risk score (PheRS) for CM and performed a transcriptome-wide association study to identify all imputed genes correlated with the CM PheRS. This approach resulted in the confirmation of known congenital genes (DHODH (Dihydroorotate dehydrogenase)  $p = 2.27e-11$ , and UBE2W (Ubiquitin Conjugating Enzyme E2 W)  $p = 8.39e-18$ ).

This study examined the effects of regulatory variation on CM phenotypes in a large biobank population. We find that common genetic variation in known CM genes results in imputed gene expression that is significantly correlated with both individual CM phenotypes and the CM PheRS. These results suggest that genomic and phenomic tools paired with large biobank datasets provide an opportunity to confirm known CM genes, in addition to identifying new CM genes and pathways.

## PgmNr 2860: Noninvasive prenatal screening of uniparental disomy.

### Authors:

H. Xu; Y. Guan

[View Session](#) [Add to Schedule](#)

**Affiliation:** Department of Biostatistics and Bioinformatics, Duke University School of Medicine, Durham, NC.

Uniparental disomy (UPD) is the inheritance of two copies of a chromosome from one parent and no copy from the other parent. Its prevalence is estimated to be one in 2000 births. UPD may cause imprinting disorders or recessive diseases. Current available methods to detect fetal UPD are invasive, requiring chorionic villus sampling or amniocentesis samples. Here we present a noninvasive method that can reliably detect fetal UPD (isodisomy) and its parental original, which can be an add-on item for noninvasive prenatal screening (NIPS).

We obtain both cell-free DNA (cfDNA) and white blood cell DNA (wbcDNA) from peripheral blood of a women at early pregnancy (gestation age 9-12 weeks) and perform whole genome sequencing for each DNA sample at a depth of about 1X. We define read heterozygosity at SNPs covered by two reads such that AB is read heterozygosity. If fetus has maternal UPD, the read heterozygosity is smaller than that when fetus is normal. If fetus has paternal UPD, the read heterozygosity is larger than that when fetus is normal. This difference depends on fetal fraction, the amount cfDNA that is of fetal origin.

To demonstrate the power of our method, we simulated data of 4 UPD syndromes using 1000 Genome Project genotypes. For fetal fraction as 0.04, 0.06, 0.08, 0.10, the power of maternal UPD7 is 0.934, 0.995, 1.000 and 1.000 (at the type I error rate of 0.001), the power of maternal UPD14 is 0.696, 0.968, 1.000 and 1.000, the power of paternal UPD15 is 0.379, 0.570, 0.899 and 0.931, the power of paternal UPD6 is 0.626, 0.915, 0.983, 0.995. Our simulations suggest that the power of our method critically depends on chromosomal size and fetal fraction.

Our method for noninvasive prenatal screening of uniparental disomy has several merits. First, it is effective screening; Second, it can easily be integrated into the routine NIPS, with no additional experimental cost; Third, our method can directly infer the parental original of UPD, a critical information that affects the clinical consequences of UPD. For example, maternal UPD7 causes Silver-Russell syndrome, but paternal UPD7 is clinically unapparent.

## PgmNr 2861: Gut microbiome and virome profiles associated with lean mass traits among menopausal women.

**Background** Sarcopenia, the age-related loss of muscle mass and strength, is a major health problem with the rapid growth of the aging older population. Increasing evidence suggested that gut microbial dysbiosis might contribute to the development of sarcopenia. Here, we investigated the relationship between human gut microbiome and virome, and their associations with lean mass among menopausal women.

**Methods** We conducted a metagenome-wide association study for lean mass in 497 Chinese women, aged 41-65 years. Lean mass for arms, legs, trunk and the total body were measured using dual-energy X-ray absorptiometry. Shotgun metagenomics sequencing was performed on the HiSeq 4000 platform (Illumina), targeting ~7.6 Gb of raw reads per sample. After filtering the raw reads and sequence quality check, we measured the taxa of human gut microbiome and virome using software Centrifuge, and aligned the entire NCBI nonredundant nucleotide sequence database. The taxa present in > 10% samples were subjected to further analysis. We estimated the alpha diversity using Shannon index and performed Spearman's rank correlation tests between each microbial taxa and lean tissue mass. Multiple hypothesis testing was adjusted using the false discovery rate method, with a q value < 0.2 as the significant level.

**Results** We found 24 of the 434 microbiome species to be associated with various lean mass traits, and 2 of the 40 virome species to be associated with trunk lean mass. Of specific note, we identified *Enterobacteria phage P4* (Spearman correlation coefficient SCC = 0.12, q = 0.14) and *Sfi* (SCC = 0.12, q = 0.14) to be positively associated with trunk lean mass, while *Enterobacteria phage P4* was significantly associated with its host *Escherichia coli* (SCC = 0.23, p =  $2.4 \times 10^{-7}$ ) and *Escherichia virus P2* (SCC = 0.21, p =  $1.6 \times 10^{-6}$ ).

**Conclusion** We identified microbiome and virome species which were significantly associated with body lean mass traits and the potential interaction between microbiome and virome. These findings suggested novel biological mechanisms underlying the regulation of human muscle mass.

## PgmNr 2862: Dissecting polygenic risk score for Alzheimer's disease by pathway.

---

Alzheimer's disease (AD) is the most common form of dementia and is responsible for a huge and growing health care burden in the developed and developing world. Majority of drugs development have been focused on the amyloid cascade hypothesis based on implication of APP metabolism and A $\beta$  production in the etiology of the disease. So far clinical trials for this hypothesis have been unsuccessful showing far more complex nature of the disease. Genome wide, exome and genome sequencing studies have implicated with varying degrees of confidence lipid metabolism, the innate immune system and endosomal vesicle recycling gene networks in disease pathogenesis. Gene networks construction is an imperfect art both because of the knowledge base used in the generation of the pathways and because proteins may have more than one function in more than one cell type. Polygenic Risk Score (PRS) analysis has been successfully applied to different case-control AD datasets in order to predict individual risk of developing AD. This study exploits PRS analysis further to divide polygenic risk by the most recently published biologically relevant gene-sets that were identified as associated with AD.

We examine association of gene-sets polygenic risk scores in ADNI dataset (Alzheimer's Disease Neuroimaging Initiative) comparing a) AD cases to controls (174/224), b) samples with cognitive impairment (MCI) which is pre-clinical stage of AD to controls (344/224) and c) individuals with positive amyloid deposition to amyloid negative individuals (357/304).

This study is important because in terms of modeling the disease through iPSC technologies one might like to assign high or low risk by gene-sets and, eventually, it is possible that one might wish to tailor therapies to gene-sets deficits. Therefore in these analyses we grasp the nettle of dissecting gene-sets analyses to the prediction of disease risk in the largest publicly available dataset with extensive phenotypic data: (ADNI).

---

IGAP meta-analyses of genome-wide association studies (GWAS) have previously identified 30 susceptibility LOAD loci in addition to *APOE*, the majority common (minor allele frequency (MAF)>0.02). To identify novel rare variant, gene, and pathway associations, IGAP consortia used using Minimac3 on the Michigan Imputation Server to impute variants of MAF>0.0008 in 42 GWAS datasets (24,466 cases /39,951 controls) to the Haplotype Reference Consortium (HRC) r1.1 reference panel (64,976 haplotypes/39,235,157 SNPs) (MAF>0.0008) for discovery association testing. For variants with MAF>0.01, logistic regression was performed using imputed genotype probabilities in SNPTEST (generalized linear mixed model in R for family-based variants) and fixed-effects meta-

analysis performed using METAL. Variants with  $MAF \leq 0.01$  were meta-analyzed using score-based tests with the program SeqMeta/R. Both analyses adjusted for age, sex, and population substructure. Gene-based and pathway associations were examined using VEGAS2. Analyses of ~39.2M genotyped or imputed SNVs confirmed single variant associations in 26 of 30 known IGAP LOAD loci at suggestive levels of significance ( $P < 10^{-5}$ ), with 12 known loci attaining genome-wide statistical significance ( $P < 5 \times 10^{-8}$ ). Newly observed associations included variation at *APP* (rs112547745, OR[95% CI]=1.10 [1.06, 1.14],  $P=8.70 \times 10^{-7}$ ), an early-onset AD gene; variants in genes associated with cardiovascular traits [*IGSF5* (rs16998166, OR[95% CI]=0.74 [0.65-0.84],  $P=4.23 \times 10^{-6}$ ), *ACE* (rs116112765, OR[95% CI]=1.28 [1.15-1.42],  $P=2.95 \times 10^{-6}$ ), *LIPG* (rs2156500, OR[95% CI]=0.94 [0.91-0.96],  $P=2.59 \times 10^{-6}$ ), and *SCARB1* (rs12229555, OR[95% CI]=0.93 [0.90-0.96],  $P=5.28 \times 10^{-6}$ ), which encodes an HDL cholesterol receptor]; and variants in genes involved in neurodegenerative processes, like *TRIT1* (rs61781270, OR[95% CI]=1.08 [1.04-1.11],  $P=3.54 \times 10^{-6}$ ), encoding an amyloid fiber-forming protein. Gene-based analyses identified several genes involved in innate immunity, including *BTRC* and *DCUN1D5* (both  $P < 10^{-6}$ ). Pathway analyses implicated neuronal development [GO:0030182 ( $P_{\text{empirical}}=10^{-6}$ ) and GO:0048666 ( $P_{\text{empirical}}=1.20 \times 10^{-5}$ )]. Replication of these signals is ongoing. Several novel LOAD candidate loci, including those with prior associations with cardiovascular traits and early-onset AD, were identified using high-quality imputation of rare and low-frequency variants in IGAP, highlighting a multitude of genetically-influenced pathologic processes in LOAD development.

## PgmNr 2864: Genetics of handedness in Alzheimer's disease.

---

The skewed distribution of handedness, or laterality, with 87-90% of individuals favoring their right hand for complex manual tasks and 10-13% favoring their left hand, is believed to be a product of differences in brain morphology, and several studies have suggested that lefthandedness (LH) correlates with elevated risk of Alzheimer's disease (AD) and earlier onset of cognitive deficits, while others have suggested a protective effect of lefthandedness against AD and slower disease progression. In this study, we examined handedness in individuals with and without AD to identify genetic contributors to handedness which may affect Alzheimer's disease risk. We tested genome-wide association (GWA) with handedness in 7,541 Caucasian subjects in the AD Genetics Consortium (ADGC) (3,553 cases/3,988 controls) with genotyping imputed to the HRC r1.1 panel (~39.2 million SNPs) and available handedness and AD data; primarily analyses adjusted for population substructure and AD case-control status; secondary control-only analyses examined handedness in a sample more representative of the general population. Examining LH vs. righthandedness (RH), multiple variants upstream the chromosome 7q32.1 gene *TSPAN33* (encoding tetraspanin 33) demonstrated genome-wide significant association (GWS;  $P < 5 \times 10^{-8}$ ), including rs112574546 (minor allele frequency (MAF)=0.047; OR[95% CI]=2.21 [1.76, 2.77],  $P = 9.78 \times 10^{-12}$ ). Associations near GWS were also observed upstream of the 7q11.23 gene *HIP1* (encoding huntingtin interacting protein 1) and the 12q21.31 genes *SLC6A15* (encoding a solute carrier family 6 transporter protein) and *TSPAN19* (encoding tetraspanin 19). Secondary analyses using only cognitively normal controls also observed the regional LH association with *TSPAN33* (OR[95% CI]=2.29 [1.69, 3.10],  $P = 7.07 \times 10^{-8}$ ), although similar evidence for association was not observed for *HIP1*, *SLC6A15*, or *TSPAN19*. Similar patterns of association were observed in analysis comparing those with LH or ambidexterity (AMBI) against RH. *TSPAN33* is a member of the TspanC8 group of tetraspanins that have been shown to regulate *ADAM10* (encoding a disintegrin and metalloprotease 10), which cleaves amyloid precursor protein and is known to affect AD risk. Additional analyses, including polygenic risk score and Mendelian randomization analyses are on-going. This work suggests that genetic contributors to handedness may also influence the pathology of and affect risk of Alzheimer's disease.

Individuals of African American (AA) ancestry are more likely to develop Alzheimer's disease (AD) compared to those of non-Hispanic white (NHW) ancestry. However, AA remain underrepresented in genomic studies of the etiology of AD.

To begin addressing this we have assessed whole-exome sequencing (WES) data of 3,810 unrelated AA individuals (1,715 AD cases and 2,095 controls) obtained from the Alzheimer's Disease Genetics Consortium (ADGC) and the Washington-Heights/Inwood Columbia Aging project (WHICAP). To our knowledge, this is the largest WES-AD study in AA to date.

Cases and controls were at least 60 years old. Cases met NINCDS-ADRA criteria for AD on clinical assessment or presence of AD upon neuropathological exam. We conducted single-variant (with PLINK) and gene-based (with SKAT-O) association analyses, adjusting for population substructure (PC1, PC2 and PC3), age and sex covariates.

Our results confirmed the association of AD with variants in *APOE* and *ABCA7* genes and in the *APOE* region two previously identified risk factors in AA. Two new variants, rs41267647, an intron variant in the *PHF1* gene and rs79808124, an intron variant in the *SLC25A39* gene were significantly associated with AD but not genome wide ( $p < 1.00E-5$ ). Suggestive odds ratios and 95% CI were 0.4771 (0.351-0.647) and 1.637 (1.316-2.036) respectively.

Recent experiments revealed that mutations in the *SLC25A39* Drosophila homolog resulted in accumulation of reactive oxygen species, mitochondrial dysfunction, and neurodegeneration. rs41267647, located in the *PHF1* gene exerted a protective effect in AD. This gene encodes a protein involved in epigenetic regulation of gene expression. rs41267647 is also a strong eQTL for *CUTA*, a

gene that affects A $\beta$  generation through beta-secretase 1-mediated *APP* processing. In summary, our study suggests two new variants associated with AD in AA that have not been detected in NHW.

# PgmNr 2866: Polygenic risk scores as screening tools for Alzheimer's disease clinical trials.

## Authors:

C. Whelan; S. Bian; J.Z. Liu; C.Y. Chen; W. Wang; M.D. Laloti; F. Gao; H. Runz; for the Alzheimer's Disease Neuroimaging Initiative (ADNI)

---

## Background

Polygenic risk scores (PRS) can be used to predict the diagnosis of Alzheimer's disease (AD), yielding predictive area under the ROC curve (AUC) estimates of 0.8+, even after accounting for *APOE* e4. PRS may also serve as a useful screening tool for AD clinical trials, enhancing the prediction of pathological beta-amyloid ( $A\beta$ ) levels prior to screening via CSF lumbar puncture or PET imaging. Here, we aimed to retrospectively investigate the utility of PRS as a screening tool for ENGAGE and EMERGE, two large-scale Phase III trials of aducanumab, an  $A\beta$ -targeting therapeutic candidate for AD.

## Methods

We stratified samples from the Alzheimer's Disease Neuroimaging Initiative using the screening protocol for ENGAGE/EMERGE (<https://clinicaltrials.gov/ct2/show/NCT02484547>). Samples were further stratified by  $A\beta$  pathology, defined by a PET SUVR  $>1.11$ , or CSF phospho-tau/ $A\beta$ 42 ratio  $>-3.6$ . In total, we included 678 prodromal AD patients (268  $A\beta$ -negative, 410  $A\beta$ -positive) and 69 mild AD patients (7  $A\beta$ -negative, 62  $A\beta$ -positive). PRS were constructed using summary statistics from the most recent GWAS of clinically-confirmed AD (Kunkle et al., 2019), applying LD clumping ( $r^2$  cutoffs 0.2, 0.5 and 0.8) and the PRS-CS algorithm (shrinkage parameters of 0.01, 0.0001 and auto-select) to genome-wide SNPs. PRS distributions were compared between  $A\beta$ -positive and  $A\beta$ -negative individuals using logistic regressions in R.

## Results

In mild AD, prediction accuracy was moderate in a model using weights derived via auto-selected parameters (AUC = 0.80; 95% CI = 0.64-0.97), and lower after *APOE* exclusion (AUC = 0.49; 95% CI = 0.22-0.75). In prodromal AD, the best prediction accuracy for  $A\beta$ -positivity was achieved using auto-tuned parameters (AUC = 0.67; 95% CI = 0.62-0.72), which lowered when *APOE* was excluded (AUC = 0.54; 95% CI = 0.48-0.60). Prodromal AD patients with a PRS of  $\geq 0.02$  (representing 12% of all prodromal patients) had a 3.3 fold increased likelihood of PET- or CSF-defined amyloid positivity compared to patients with a PRS  $<0.02$ .

## Conclusion

The predictive power of PRS for  $A\beta$  positivity in AD is moderate when scores are constructed from genetic studies of AD susceptibility, and currently uninformative when *APOE* is removed. Construction of PRS using alternative training data (such as GWAS of PET- or CSF-defined  $A\beta$ /tau load), integration of exome sequencing data, and combination with blood biomarkers should be considered to further evaluate the clinical utility of PRS.

## PgmNr 2867: Genome-wide linkage analysis of African-American Alzheimer disease families.

---

Genetic studies of African-Americans (AA) with late-onset Alzheimer's disease (LOAD) have been limited, despite evidence suggesting an increased risk for Alzheimer disease (AD), and differential genetic effects across ancestral populations. In this study, we assessed 44 multi-generational AAAD families from the Research in African American Alzheimer Disease Initiative (REAAADI) and LOAD using genome-wide linkage analysis to prioritize regions containing risk or protective genes for AAAD. As part of REAAADI and LOAD, genotype data were generated for 44 families (137 affected and 282 unaffected) and whole genome sequence data for 33 families. We performed linkage analyses in 44 families using genotype data. Three models were assessed using Merlin software: 1) two-point parametric dominant affected-only and age-dependent penetrance models 2) multipoint parametric dominant affected-only dominant model (MPT-AO) and 3) Non-parametric linkage (NPL) multipoint. WGS data were used to prioritize variants in the consensus regions based on segregation with disease among affected individuals, rarity, and annotation for putative function. The MPT-AO model had 4 peaks over an HLOD of 1.2 with the strongest peak seen on Chromosome 7 (HLOD 2.49, four families contributing >0.58). Family specific peaks over 1.4 were seen in two families in MPT-AO model. The strongest signal localized to a region on Chromosome 12 (LOD=3.18) in the parametric dominant model. This overlaps with a previously reported linkage peak in Non-Hispanic White (NHW) families in (Scott et al., 2000) and in the ADSP Linkage analysis (Beecham et al., 2019). The region on chromosome 12 includes *LRRK2* and *CNTN1* genes. Missense mutations in *LRRK2* reported as a major cause of inherited and sporadic Parkinson disease, and *CNTN1* identified as a new candidate locus for Lewy Body dementia. However, in the segregation analysis using WGS data we didn't observe any variants in *LRRK2* and *CNTN1* genes that segregate with the disease in the family that support linkage peak. Linkage analysis of AA families confirmed a previously identified family specific peak on chromosome 12. Our results didn't show any risk variants in known dementia genes such as *LRRK2* and *CNTN1*. The overlapping of the linkage peak on chromosome 12 with previously reported linkage peaks and known dementia genes emphasize the need for additional studies of all genes at the region by using segregation analysis and bioinformatics tools.

## **PgmNr 2868: Developing statistical models to study gene-gene interactions underlying autism spectrum disorder.**

**Authors:**

Q. Li

[View Session](#) [Add to Schedule](#)**Affiliation:** 2500 University Dr NW, Calgary, AB, Canada

---

Through many years' efforts, thousands of genes are identified to be associated with the Autism Spectrum Disorder (ASD). However, the interpretation of the genetic variants tailoring to specific molecular mechanism is largely unsolved, leaving gaps between the statistical association and functional follow-ups. This is partly due to that fact that the current statistical methods do not integrate biological knowledge and the statistical learning and the biological interpretation are done sequentially. So, the development of statistical models specific to molecular mechanics is urgently needed to bridge this gap. In this project, as a proof-of-concept, we have developed a novel statistical model leveraging information of 3-D genomic conformation assessed by Hi-C experiments and the power of machine learning algorithms to further elucidate the genetic underpinning of complex behaviors of ASD. By applying the novel model on benchmark datasets of more than seven thousand individuals from the MSSNG consortium, we have identified interesting results indicating the association between the 3-D structure and ASD risk. The outcome is naturally interpretable by default as the 3-D genomic conformation is driven by the design of the statistical models. This project can further basic understanding of 3-D genetics of diseases and provide a new way to understand the pathology of other diseases.

## PgmNr 2869: Transmission patterns of ultra-rare variants in autism spectrum disorder.

---

Autism spectrum disorder (ASD) is highly heritable but genetically and phenotypically heterogeneous. Although *de novo* mutations (DNMs) and copy number variants (CNVs) have a well-known role in ASD pathogenesis, collectively these mutations are estimated to account for only 19-30% of cases. To further understand the heritability of ASD we combined whole-exome and whole-genome sequencing data from 9,309 families with ASD from five distinct studies and identified over 2.9 million private, coding variants (heterozygous single-nucleotide variants and indels observed only once across all families and transmitted to at least one affected or unaffected child). Using aggregate burden tests we find an increased burden of private, likely-gene disrupting variants in probands as compared to siblings for genes showing an enrichment of DNMs in autism individuals (OR = 4.93,  $p = 8.24e^{-3}$ ). Previous analyses by our group found that private variant burden increases with increasing gene constraint. When we exclude known DNM-enriched genes from this analysis, we find that at least 92.3% of the burden remains and the percent of remaining burden increases with gene constraint, suggesting that private variants are acting on a distinct set of genes that have not yet been identified by DNM enrichment analyses. Although still underpowered to identify specific genes, we developed a gene-specific binomial testing framework and have identified a dozen high-likelihood candidates. As a group, we confirm that these genes are more intolerant to mutation (OR = 6.47,  $p = 4.24e^{-3}$ ). Modeling the relationship between private variants, DNMs, CNVs, as well as common risk variants, we find an inverse relationship between *de novo* and private mutations versus common variant burden among individuals with ASD, pointing to a highly complex genetic model of autism with multiple sources of disease etiology.

## PgmNr 2870: Genome-wide association analysis demonstrates that the genetic risk burden for multiple sclerosis confers earlier onset.

---

**Objective:** To characterize the genetic component of age of onset (AOO) in person with multiple sclerosis (MS).

**Background:** AOO is a strong predictor of MS evolution independent of disease duration. Factors influencing AOO are not well known though *HLA-DRB1\*15:01* (DR2; the primary genetic risk factor), female sex, and relapsing subtypes confer earlier onset.

**Design/Methods:** We conducted a genome-wide association meta-analysis and evaluated the narrow-sense heritability ( $h^2$ ) of MS AOO in cases of European ancestry. The meta-analysis (N=2,376) included the Accelerated Cure Project (ACP1; N=1,076), ACP2 (N=191), and Vanderbilt University Medical Center BioVU (N=1,109) cases. There were  $1.6 \times 10^6$  SNPs in  $\geq 2$  datasets (MAF  $\geq 0.01$ , HWE  $p > 0.0001$ ). A tagging SNP rs3135388A determined DR2. A genetic risk score (GRS) was constructed based on 200 risk SNPs outside 6p21 where DR2 resides. Linear regression analyses were conducted adjusting for ancestry and sex using PLINK v1.9. Meta-analyses were conducted using METAL weighting by standard errors.  $h^2$  was estimated using GCTA, partitioning by MS risk and non-risk loci.

**Results:** The 6p21 locus was the most significant region associated with AOO ( $p < 3 \times 10^{-6}$ ). MS cases homozygous for DR2 were 2.6 years younger at onset compared to non-carriers ( $p = 0.0008$ ). The largest impact on AOO was a splice donor *SCN7A* (a voltage-gated sodium channel protein) variant ( $\beta = -7.5$  years,  $p < 3 \times 10^{-6}$ ). Additional top ranking associations ( $p < 4 \times 10^{-5}$ ) were observed for variants in *MTG2*, *SLC30A10*, *MIR548H4*, *STXBP6*, *PDE11A*, *PLAR2R1*, *CPAMD8*, *A2ML1*, *PLXDC2*, *MMP7*, and *CIITA*.

10% of MS risk SNPs outside 6p21 were associated with AOO ( $p < 0.05$ ), including the *CLEC16A-CIITA* variants. Increases in GRS was associated with earlier onset across datasets ( $p < 0.05$ ). Furthermore, AOO  $h^2$  ranged between 21-26%, and established MS risk loci explain a portion of this heritability. Exploratory analyses in ACP1 showed, the predicted AOO was 3.8 years earlier for DR2 carriers with the highest GRS quantile burden (30.5 years) versus DR2 non-carriers with the lowest GRS quantile burden (34.3 years).

**Conclusions:** The MS genetic risk component significantly predisposes susceptible individuals for earlier onset, reducing the time from initiation of pathogenetic processes (particularly those

associated with DR2 and DR2 regulation [*CIITA*]) to the appearance of clinical symptoms. Replication analyses are ongoing in Biogen Phase 3 trials (N=1,702; ADVANCE, ASCEND, and DECIDE).

## PgmNr 2871: Pharmacogenetic analysis of known variant associated with IFN- $\beta$ -induced liver injury replicated in African Americans with multiple sclerosis.

---

Multiple sclerosis (MS) is a debilitating disease characterized by the demyelination of the axons of the central nervous system. Disease-modifying therapies (DMT), such as interferon- $\beta$  (IFN- $\beta$ ), have been successfully used to reduce relapses, but its use has been observed to induce liver damage in some patients. rs2205986 has previously been associated with IFN- $\beta$ -induced liver injury in cohorts of MS patients of European ancestry ( $P = 2.3 \times 10^{-8}$ ). The aim of this study was to replicate this result in a cohort of MS patients of African American ancestry. Of the 691 African American MS patients in Vanderbilt University Medical Center's BioVU database, 151 had genotyping information available for analysis. Manual review of these patients' electronic health records (EHR) identified 82 patients with clearly defined IFN- $\beta$  treatment periods. Laboratory values for liver enzymes alkaline phosphatase (AlkP), bilirubin, aspartate aminotransferase (AST), and alanine aminotransferase (ALT) that were recorded within the IFN- $\beta$  treatment period were extracted from the patients' EHRs using R v3.4.3, leaving 68 patients for the final analyses. The liver enzyme values for each test were normalized to the upper limit of normal. One patient was excluded from the analyses for AST and ALT values exceeding three standard deviations from the mean. A linear regression analysis was performed using PLINK v1.90 with age, sex, and first four principal components included as covariates. No significant associations were identified between rs2205986 and elevated AlkP, bilirubin, and AST levels ( $P = 0.634$ ,  $P = 0.701$ ,  $P = 0.197$ ). However, rs2205986 was significantly associated with elevated ALT levels ( $P = 0.015$ ,  $\beta = 3.61$ ). Additionally, results for each test trended in the direction with those previously reported. A genome-wide association study was performed for each liver enzyme. Four SNPs of genome-wide significance were identified. rs77134863 ( $P = 6.01 \times 10^{-10}$ ,  $\beta = -3.80$ ), rs58470026 ( $P = 3.93 \times 10^{-9}$ ,  $\beta = -3.75$ ), and rs200464088 ( $P = 5.97 \times 10^{-9}$ ,  $\beta = -3.75$ ) were associated with decreased levels of ALT, indicating a reduced risk for IFN- $\beta$ -induced liver injury. By contrast, rs254276 ( $P = 2.56 \times 10^{-8}$ ,  $\beta = 1.17$ ) was associated with increased levels of AST, indicating an elevated risk for IFN- $\beta$ -induced liver damage. These results may prove valuable in informing MS clinicians and patients about specific risks associated with IFN- $\beta$  use and guide treatment to suit the needs of the individual patient.

## PgmNr 2872: Sex-specific genetic drivers in common diseases with susceptibility sex bias: The case of multiple sclerosis.

---

**Background:** Several common diseases exhibit sex bias, i.e. differential risk between females and males. The sex bias can be evident in any facet of a given disease, among which disease susceptibility is of upmost importance, since we can translate genetic knowledge into potentially actionable prediction models. Multiple sclerosis (MS) is a common neurodegenerative inflammatory disease that exhibits a well-described sex bias. Females are two-fold or higher risk to develop MS with little understanding of the drivers. We have recently compiled the genetic map of MS, describing 32 genome-wide associations ( $p\text{-value} < 5 \times 10^{-8}$ ) in the major histocompatibility complex (MHC) region, 200 within the autosomal non-MHC, and one in chromosome X. Overall, we can explain almost half of MS's heritability. In this study, we aimed to identify any genetic drivers of the susceptibility's sex bias in MS and develop a framework of in-depth investigation that can be applied to any common disease.

**Methods:** We leveraged data from 15 genome-wide associations studies (GWAS) that included overall 42,575 individuals: 10,966 female MS cases and 14,262 female healthy controls, and 4,266 male MS cases and 13,081 male healthy controls. We applied the same quality check pipeline and imputed all data with the most recent version of 1,000 Genomes. We meta-analyzed post-imputation probabilities across the 15 GWAS genetic variants with minor allele frequency (MAF) of at least 1% and imputation quality score of at least 0.5.

**Results:** We analyzed 8,456,964 genetic variants that fulfilled all inclusion criteria. Applying our sex-specific framework, we identified a total of 508 autosomal non-MHC and 1,445 MHC sex-specific effects ( $p\text{-value} < 10^{-4}$ ). These putatively sex-specific variants represented at least 81 autosomal non-MHC sex-specific loci, and 3 MHC loci. We further dissected our sex-specific findings to 10 categories based on magnitude and direction of effects. Most strikingly, we identified that 55 out of 81 autosomal non-MHC loci predisposed males to MS, among which 27 were protective in female, and 25 had no effect in female ( $p\text{-value} > 0.05$ ). Pathway analysis of the sex-specific variants identified 148 pathways at a  $p\text{-value} 0.05$ , the vast majority of which were immune-related pathways.

**Discussion:** We developed a framework for in-depth investigation of sex-specific genetic associations in common diseases and applied it in MS, identifying several sex dimorphic genetic variants.

## PgmNr 2873: Epilepsy and epilepsy subsyndromes: Findings from the Epi25 Consortium GWASs.

---

Genome-wide association studies (GWAS) in epilepsy and the two largest clinical subgroups - genetic generalized epilepsy (GGE) and focal epilepsy - have had only limited success in identifying risk loci. The largest GWAS in epilepsy up to date, comprising 8,696 individuals with epilepsy and 26,157 controls, identified two susceptibility loci shared by all epilepsies, one susceptibility locus for genetic generalized epilepsy, and no association signal for focal epilepsy. Here we report a new large-scale genome-wide meta-analysis in epilepsy in the largely independent Epi25 cohort, currently the largest sequencing project in the epilepsies, with 14,671 sequenced and genotyped epilepsy samples. In the European subsample of the Epi25 cohort comprising 10,497 individuals with epilepsy and 15,610 controls, we replicated the susceptibility locus for all epilepsies at 4p15.1 in proximity to *PCDH7* (rs4692500,  $P=2.2 \times 10^{-11}$ ), and a previously replicated susceptibility locus for GGE at 2p16.1 in a 706kb region encompassing *VRK2* and *FANCL* (rs2717004,  $P=2.0 \times 10^{-9}$ ). In addition, we identified three credible new susceptibility loci at 5q22.1 near *NREP* (rs112832534,  $P=4.2 \times 10^{-8}$ ), 16p12.1 near *TNRC6A* (rs2112783,  $P=1.7 \times 10^{-8}$ ), and 19q13.33 near *GLTSCR1* (rs2914006,  $P=2.2 \times 10^{-8}$ ). Subgroup analysis identified two new susceptibility loci for GGE at 2q12.1 in proximity to *TMEM182* (rs1379430,  $P=7.7 \times 10^{-12}$ ), and at 12q13.13 near *ACVR1B* (rs114131287,  $P=1.6 \times 10^{-12}$ ). Consistent to previous results, no genome-wide significant association signal could be observed for focal epilepsy. Our study provides further insights on the shared etiology of all common epilepsies, despite clinically different manifestations. We further provide additional evidence for a significant genotypic and phenotypic heterogeneity of the focal epilepsies, and a challenge for improvement of the actual clinical classification.

## PgmNr 2874: Evidence supports causal association between genetic variation in vitamin D binding and susceptibility to multiple sclerosis.

---

There is strong evidence for a causal association between 25-hydroxyvitamin D (25OHD) serum levels and multiple sclerosis (MS; MIM 126200) susceptibility, but the mechanisms underlying these associations are unknown. It is well established that 25OHD signals through the nuclear vitamin D receptor (VDR), a ligand-regulated transcription factor. Testing for associations between VDR binding and traits can be difficult; however, single nucleotide polymorphisms (SNPs) associated with VDR binding can be used as instrumental variables for Mendelian Randomization (MR) studies. These SNPs must be independent of confounders, and can only influence the trait via the exposure. Pleiotropy can violate this last assumption and bias MR estimates. To address this, we used a weighted genetic risk score (wGRS) for 25OHD levels, a proxy for vitamin D bioavailability, as a second instrumental variable. Observed interaction between VDR binding and the wGRS would provide evidence that the association between VDR binding and MS is not entirely due to pleiotropy, and is causal. Data from an international cohort of MS cases and controls from the US and Sweden (7,881 cases, 16,069 controls) were studied. Genome-wide genetic data were subjected to QA/QC protocols prior to analysis. All participants were of European ancestry. VDR binding variants (VDR-BVs) were previously identified using ChIP-exo data from 16 calcitriol-stimulated Lymphoblastoid Cell-Lines followed by Allele-seq. VDR-BVs were regressed against ChIP-exo read counts; 305 were significant ( $p < 0.05$ ) and used as VDR binding instruments. Associations from these regressions were used as weights. 136/305 VDR-BVs were present in the data after QA/QC. The wGRS for 25OHD level was comprised of 6 SNPs identified through recent GWAS. Logistic regression was used to estimate associations between each VDR-BV instrument and MS susceptibility, and interaction between each VDR-BV instrument and

25OHD wGRS. Analyses were adjusted for genetic ancestry. Four VDR-BVs (rs17160772, rs1011817, rs4047774, and rs4413108) were independently associated with MS after multiple testing correction ( $q < 0.05$ ). There was also evidence for interaction between 4 VDR-BVs (rs9493768, rs3793786, rs7309003, and rs13098781) and 25OHD wGRS ( $p < 0.05$ ). rs17160772 is in an enhancer region for *ZC3HAV1*, a zinc finger protein that may help prevent infection by retroviruses. This study is the first to provide evidence that VDR binding contributes to MS susceptibility.

## PgmNr 2875: Genetics of multiple sclerosis disease severity.

**Introduction:** Numerous genetic variations have been linked to Multiple Sclerosis (MS) risk, but the genetic contribution to highly variable disease progression rates and severity is undefined. Rate of brain atrophy and level of serum neurofilament light (sNfL) have been independently linked to progression rates and/or disease severity. The goal of this study is to evaluate the impact of common genetic variants on sNfL levels and rate of brain atrophy in MS patients from randomized controlled trials (RCTs).

**Methods:** We performed genome-wide association studies (GWAS) of percent brain volume change (PBVC) in each of six RCTs enrolling MS patients (N=3,389): Biogen RCTs ASCEND (secondary progressive MS [SPMS]), ADVANCE (relapsing MS [RMS]), and DECIDE (RMS); and Roche RCTs OPERA1 (RMS), OPERA2 (RMS), and ORATORIO (primary MS [PMS]). Annualized PBVC from baseline to last time point was analyzed as a continuous trait. Each GWAS was adjusted for age, sex, genetic ancestry and treatment. Mean follow-up was 2 years (range 1.7-3 years). We also performed GWAS of cross-sectional sNfL levels at baseline in two Biogen RCTs (N=974): ASCEND (SPMS) and ADVANCE (RMS), adjusting for age, sex and genetic ancestry. For each trait (PBVC and sNfL), GWAS were pooled together in a meta-analysis across RCTs.

**Results:** For PBVC, a region near *RAB4A/SPHAR/CCSAP* on chromosome 1 ( $p=7.8 \times 10^{-8}$ ) approached genome-wide significance. For sNfL levels, we found genome-wide significant loci on chromosomes 17 near *MEOX1* and 18 near *RPRD1A* ( $P_{\text{meta}}=1.7 \times 10^{-8}$ ,  $2.4 \times 10^{-9}$ , respectively). Thus far, we have not found overlap in signal between MS susceptibility, sNfL and brain atrophy.

**Discussion:** We identified several genetic regions of potential interest in two measures of MS progression, sNfL and PBVC. We will expand our sNfL GWAS by adding Roche RCTs (N=1,056) to our meta-analysis. To identify causal genes and potential mechanisms, we are conducting systematic colocalization analysis across our sNfL and PBVC results, along with other phenotypic traits (e.g. MS risk) and molecular traits (e.g. gene or protein expression). We will perform additional analysis of brain atrophy in the placebo subset (N=518) to separate treatment effect from disease severity. Our results represent a step toward using objective, quantitative traits to examine the genetics of MS progression.

## PgmNr 2876: Genome-wide association analyses of progressive supranuclear palsy identifies novel loci.

---

Progressive supranuclear palsy (PSP) is a rare neurodegenerative disease characterized by tau protein aggregation in the brain and clinical features including increased frequency of falls, postural instability, and supranuclear ophthalmoplegia. While this disease shares some features with other well-studied neurodegenerative diseases, including Alzheimer's and Parkinson's diseases, unlike those diseases much of the underlying genetic component of the disease remains to be identified. To identify novel common and rare variant associations, we imputed genome-wide genotyping on 2,238 PSP cases and 3,228 controls to the Haplotype Reference Consortium (HRC) r1.1 reference panel (64,976 haplotypes/39,235,157 SNPs) (MAF>0.0008) for discovery association testing using Minimac3 on the Michigan Imputation Server. For variants with MAF>0.01, logistic regression was performed using imputed genotype probabilities in PLINK. Variants with MAF≤0.01 were analyzed using score-based tests with the program SeqMeta/R. Analyses adjusted for population substructure and genotyping platform. We confirmed known genome-wide significant (GWS;  $P<5\times10^{-8}$ ) associations on chromosome 17q21.31 near *MAPT* and *KANSL1*, and the top signals correlated with associations in the H1/H2 haplotype (lead SNP rs9468, OR[95% CI]=4.96 [3.95, 6.22],  $P=9.37\times10^{-44}$ ). GWS associations were also observed at variants in *STX6* (SNP rs9468, OR[95% CI]=1.51 [1.32, 1.72],  $P=1.79\times10^{-9}$ ), which encodes the syntaxin 6 gene previously shown to be associated with PSP. Additional associations were observed at *TOM1* (lead SNP rs138760, OR[95% CI]=1.49 [1.28, 1.74],  $P=1.88\times10^{-7}$ ) and *PTPRS* (lead SNP rs73919781, OR[95% CI]=1.73 [1.41, 2.14],  $P=2.08\times10^{-7}$ ). Although these associations did not attain GWS, these genes are strong biological candidates: *TOM1*, which encodes a target of the v-myb oncogene, has recently been shown to regulate neuronal accumulation of beta amyloid oligomers in Alzheimer's Disease whereas *PTPRS*, which encodes protein tyrosine phosphatase receptor type S, has been implicated in axon guidance during embryogenesis and molecular control of adult nerve repair. Replication of these associations is ongoing. In a GWAS case-control analysis of the largest collection of PSP cases to date, we confirmed associations at several known loci and identified novel associations at several potential biological candidate genes, helping to further illuminate the complex genetics of neurodegeneration.

## PgmNr 2877: Metabolome-wide association study identifies altered cerebrospinal fluid metabolites in Alzheimer's disease.

---

**Background:** Despite progress in understanding the etiology of Alzheimer's disease (AD), an effective treatment remains elusive. One source of novel biomarkers and potential therapeutic targets is the cerebrospinal fluid (CSF) metabolome. However, the invasive procedure used to acquire CSF samples makes large-scale, direct study of the CSF metabolome difficult. Here, we demonstrate the use of genetic prediction models trained on a smaller set of CSF samples from the Wisconsin Registry for Alzheimer's Prevention (WRAP) cohort to conduct a study of CSF metabolites in AD that leverages the sample sizes from large-scale AD GWAS consortia.

**Methods:** Data for 338 metabolites were measured in CSF samples from 136 cognitively healthy adults (ages 45-74) with genotype data in the WRAP cohort. We conducted a genome-wide association study (GWAS) to identify predictive single nucleotide polymorphisms (SNPs) for each CSF metabolite and replicated our findings in 156 cognitively healthy adults (ages 55-86) from the Wisconsin Alzheimer's Disease Research Center (W-ADRC) study.

Using the GWAS results in WRAP, we trained a polygenic score (PGS) predictive model for each CSF metabolite and assessed the performance using the W-ADRC samples. These models were used with the BADGERS method to conduct a CSF metabolome-wide association study (MWAS) for AD using three independent GWAS data sets: the International Genomics of Alzheimer's Project (N = 54,162), an independent subset of the Alzheimer's Disease Genetics Consortium (N = 7,050), and the UK Biobank (parental AD diagnosis; N = 114,564).

**Results:** At the Bonferroni-corrected significance threshold ( $P < 1.5e-4$ ), we identified 19 AD-associated CSF metabolites in the MWAS meta-analysis, of which 13 associated metabolites were lipid-related. The most strongly associated metabolite was 1-palmitoyl-2-arachidonoyl-GPC (16:020:4n6;  $P = 9.13e-9$ ), a lipid from the phosphatidylcholine pathway.

**Conclusion:** Taken together, these findings provide novel biological insights into the genetic regulation of the CSF metabolome, demonstrate the utility of genetic prediction models in studying metabolome-disease associations in rare sample sources like the CSF, and add to the growing literature implicating altered lipid metabolism in AD. We believe the CSF MWAS framework developed in our study will have wide applications in genetic studies of neurological disorders.

---

Huntington's disease (HD) is a dominantly inherited neurodegenerative disease, caused by an expansion of unstable CAG trinucleotide repeat in *HTT*, which encodes huntingtin. HD involves various neurological changes (such as motor, cognitive, and psychiatric), whose onset ages can be largely accounted for by CAG repeat size, but the substantial residual variance in age-at-onset of HD symptoms shows heritability. Our recent HD genome-wide association study (GWAS) revealed that age-at-onset in HD is determined by the length of the uninterrupted CAG repeat and is modified by numerous genes involved in DNA maintenance processes. Here, we performed an X chromosome-wide association study (XWAS) to supplement the GWA analysis which had focused on autosomal SNPs. We imputed SNPs on the X-chromosome for approximately 8,900 HD subjects with European ancestry using Haplotype Reference Consortium data as the reference panel, and subsequently analyzed residual age-at-onset as the phenotype to evaluate genetic association. In single SNP association analysis, no variant revealed genome-wide significant association with residual age at onset, but two loci (including Xq12) showed suggestive significances. In gene-based analysis, genes in the Xq12 region generated false discovery rate significant association, suggesting a potential role for Xq12 in modifying HD age-at-onset. Genetic association analysis of the X-chromosome is challenging due to its inactivation in females and haploidy in males. Thus, it may require a large sample size to achieve genome-wide significance in genetic association analysis. Nevertheless, our data suggest a potential role for variants on the X-chromosome in modifying the course of HD, and additional genetic analysis with increased power may reveal a new avenue for therapeutic development.

## PgmNr 2879: Colocalization analysis of genes linked to Huntington's disease age at onset and disease progression.

---

Huntington's disease (HD) is a Mendelian disorder, however other genetic loci also influence the disease trajectory. GWAS have identified loci that modify the age at onset (AAO) and the rate of disease progression (DP) of HD. Taking a list of genes of interest derived from these GWAS findings, we performed colocalization analysis to assess which genes causally influence these HD phenotypes. Colocalization tests whether the exposure and outcome share a common genetic effect, rather than the association being due to linkage disequilibrium.

We applied three methods to test for colocalization of gene expression with AAO and DP: coloc, SMR/HEIDI and S-PrediXcan. Each method has different limitations hence we used multiple methods and compared the results. We also performed 2-sample Mendelian randomization (MR) of gene expression levels on AAO and DP. We studied gene expression in blood and brain tissues, using expression data from GTEx (whole blood, brain caudate basal ganglia and brain cortex), eQTLGen (whole blood) and Brain-eMeta (meta-analysis of brain tissues).

Our coloc results found that DP colocalized with *DHFR* in blood, caudate and cortex, and AAO colocalized with *MSH3* in blood. In our Brain-eMeta coloc results, DP and AAO both colocalized with *FAN1* but not *DHFR* or *MSH3*, perhaps due to the Brain-eMeta sample including other brain tissues. Results from SMR/HEIDI suggest that AAO colocalizes with *DHFR* in blood and DP colocalizes with *MSH3* in brain. Our S-PrediXcan results suggest that AAO colocalizes with *MSH3* in blood and DP colocalizes with *DHFR* in blood and brain and *MSH3* in brain cortex.

MR analysis of genetically predicted gene expression on AAO estimated that AAO decreases by 1.13 years (95%CI=0.53-1.74,  $p=2.5 \times 10^{-4}$ ) per unit increase in *MSH3* expression in blood (measured in Transcripts Per Million) when using eQTLs from GTEx, and by 0.78 years (95%CI=0.34-1.23,  $p=6.1 \times 10^{-4}$ ) when using eQTLs from eQTLGen. MR analysis of genetically predicted gene expression on DP estimated that the HD DP score increases by 0.20 (95%CI=0.14-0.27,  $p=4 \times 10^{-9}$ ) per unit increase in *DHFR* expression in blood (using GTEx eQTLs), by 0.18 (95%CI=0.09-0.26,  $p=3.5 \times 10^{-5}$ ) in blood (using eQTLGen eQTLs), and by 0.13 (95%CI=0.08-0.18,  $p=1.2 \times 10^{-7}$ ) in brain cortex (using GTEx eQTLs).

Overall, our results imply that *MSH3* expression colocalizes with AAO and *DHFR* expression colocalizes with DP. Increased *MSH3* expression predicts a lower AAO, and increased *DHFR* expression predicts faster DP.

## PgmNr 2880: An exon deletion polymorphism in the haptoglobin (HP) gene influences neurocognitive impairment in people with HIV infection.

---

Haptoglobin (HP) captures free hemoglobin and delivers it to degradation. We previously reported that higher cerebrospinal fluid (CSF) HP levels confer an increased risk of HIV-associated neurocognitive impairment (NCI). Beyond that, the *HP* gene contains a common copy number variant—deletion of two exons—that separates the two alleles: *HP1* (deletion) and *HP2* (normal). It also influences the multimerization of the encoded HP protein. These *HP* alleles are not captured by typical genome-wide arrays and their impact on NCI in people living with HIV is unknown. To assess this, we imputed the *HP* deletion in a large, observational neuroHIV study--CHARTER, using experimentally validated reference panels and IMPUTE2 in 558 European- and African-descent samples. CSF (n=202) HP levels were quantified by immunoassay. Within each subpopulation, *HP* genotypes were examined for associations with CSF HP levels and NCI, assessed by the global deficit score (GDS), with adjustments for age, sex, neuro-influential comorbidity, plasma viral load, nadir CD4+ T-cell count, and ancestry-based principal components. Increasing *HP* deletions were associated with progressively higher CSF ( $p=1.22e-5$ ) HP levels. The *HP1/HP2* heterozygous group has the lowest GDS values (multivariable-adjusted  $\beta=-0.1314$ ,  $p=0.006$ ) and a 2.13 times lower risk of NCI (defined by a  $GDS \geq 0.5$ ;  $p=0.0013$ ). Although the significance of the effects decreased when adjusted for CSF HP levels, an *HP*-by-CSF-HP interaction showed no statistically significant effect suggesting the impact is not through HP protein levels. Moreover, when involving apolipoprotein E (APOE), having one *APOE4* allele increases 0.34 in GDS ( $p=0.027$ ,  $n=202$ ) in the *HP2* homozygous group compared to *HP1* homozygous and it is predominantly driven by the African-descent population. Given prior reports that HP is involved in *beta*-amyloid aggregation and acts as an anti-oxidant of APOE, and that all three proteins co-immunoprecipitate, our findings implicate the *HP* deletion variant may result in abnormal protein processing in the brain and play a role in the development of NCI in people living with HIV. While the mechanisms remain to be clarified, the multimeric structural change of HP protein complex influenced by the *HP1* is likely to disrupt its function, potentially also altering the amyloid processing and clearance together with APOE in people

living with HIV.

## PgmNr 2881: Analysis of interaction and association of genetic variants with ischemic stroke risk in five Brazilian cities.

Stroke is a severe disorder with high morbidity, mortality and disability-adjusted life years rates, which is considered a major healthcare problem and a worrisome economic burden. In Brazilian population, the adjusted annual incidence rate of IS ranges from 62 to 92 per 100,000 inhabitants, with a mixed pattern of cardiovascular risk factors, due to the high prevalence of cardiovascular diseases, dyslipidemia, hypertension, and diabetes. Risk factors have been associated with IS, including advanced age, hypertension, diabetes mellitus, smoking, and dyslipidemia. However, around 10% of IS events remain unclassified, which had reinforced to the hypothesis of a multi-factorial model disease, including genetic and small-effect environmental risk factors and even possible interactions among them. We aimed demonstrated the genetic association and genetic variants interaction for large- artery atherosclerosis and cardioembolic ischemic stroke. Were genotyped common genetic variants in individuals from five Brazilian regions: Campo Grande, Central region (774,202 inhabitants), Canoas, outh region (323,827 inhabitants), Joinville, South region (515,288 inhabitants), Sertãozinho, South-east region (101,784 inhabitants) and Sobral, North-east region (147,135 inhabitants), distributed in Large Artery Atherosclerosis Ischemic Stroke and Cardioembolic Ischemic Stroke (only for group from Joinville, SC – Brazil) and healthy controls. Genetic variants previously described in association with stroke were selected to this work: rs2107595 (NC\_000007.13:g.19049388G>A) and rs2383207 (NC\_000009.11:g.22115959A>G) for LAAS-IS, and rs879324 (NC\_000016.10:g.73034779G>A), rs1396476 (NC\_000005.10:g.60100815T>C), rs2910829 (NC\_000005.10:g.60174072G>A), rs966221 (NC\_000005.10:g.60206693A>G), rs6843082 (NC\_000004.11:g.111718067G>A), and rs152312 (NC\_000005.10:g.60491989G>A) for CE-IS. We reported a significant association of *rs2383207* genetic variant localized near *CDKN2B* gene with the susceptibility to Large Artery Vessel Ischemic stroke in Brazilian population *rs2383207*\*A allele [OR 2.35 (95% CI= 1.79 - 3.08)  $p=4.66 \times 10^{-10}$ ]. In addition, the genetics variants investigated for CE-IS, were not demonstrated significative association with CE-IS. The genetic contribution of stroke risk is not clear until, however studies of gene-gene and gene-environmental interactions may be elucidated the genetic role in pathogenesis of stroke

## PgmNr 2882: Variant prioritization by pedigree-based haplotyping: method characterization using simulation data.

Rare genetic variants have recently been implicated in the genetic basis of complex diseases. It has been suggested that multiple rare, rather than common, variants might play a role in the etiology of complex diseases and that these rare variants could account for the “missing” heritability of diseases. Population-based association analyses are underpowered to detect disease-associated rare variants of small size effects. On the other hand, multipoint linkage analysis is one of the best approaches for localizing trait loci that segregate rare variants associated with complex diseases. The presence of large numbers of variants within linkage regions however complicates the identification of disease-associated variants. To begin to address the problem of prioritizing these variants, we developed a pedigree-based haplotyping method and applied it to a real-data situation. We assumed that the key rare variants should have originally occurred on a single risk haplotype thus reducing the number of variants under consideration to <0.25% in the region of interest.

To validate our method further, we now use a 52-member pedigree with simulated chromosomal descent patterns based on different reduced-penetrance trait models. We randomly assigned phased real WGS data to founders and, using simulated chromosomal descent patterns in the rest of the pedigree members, dropped the individual WGS alleles through the pedigree. Following identification of a linkage signal for the simulated trait, we are performing pedigree-based haplotyping to identify the risk-haplotype responsible for the linkage signal, as well as the subjects who carry vs. those who do not carry this haplotype. As before, our goal is to determine boundaries of the risk-haplotype and to identify rare variants that are unique to the risk-haplotype. The performance of our method will be characterized by accuracy of (1) detection of boundaries of a risk haplotype within the linkage region, (2) identification of subjects carrying at least one copy of the risk haplotype, and (3) determination of the phase of variants relative to the risk haplotype. Based on previous application of this method to real data, pedigree-based haplotyping with subsequent identification of a haplotype driving a linkage signal may be a useful tool for WGS variant prioritization and for follow up in other samples.

---

**Background:** Polygenic risk scores (PRS) have been shown to efficiently sum weighted risk loci identified via genome-wide association analyses (GWAS) and improve predictive models. However, until recently, GWAS have been focused on individuals of European ancestry (EA), bringing in to question the generalizability of a PRS to non-Europeans. A recent study found that a PRS constructed using EA GWAS data for Hispanics/Latinos (HL) can vary in performance (Grinde et al.). We present a PRS in a South American Parkinson's disease (PD) cohort constructed using EA summary statistics in order to determine if an EA-based PRS is associated with PD in a HL cohort.

**Methods:** PD GWAS summary statistics originate from a meta-analysis of EA cohorts (Chang et al.), with a total of 9,830 variants. We estimated local heritability using HESS with an effective sample size of 77,195. The LARGE-PD cohort consists of 808 cases and 691 controls. Subjects were genotyped using the MEGA chip with standard quality control steps. Imputation was performed using Beagle 5.0 and a custom reference panel comprised of 1000 Genomes subjects and Native Americans from the Peruvian Genome Project. The PRS was calculated using R and PLINK 1.9's clump procedure. The PRS was tested via logistic regression, adjusting for age, sex, and the first five PCs; associations with age at onset were similarly tested using linear regression. PRS parameters were evaluated using AUC,

Nagelkerke's pseudo R<sup>2</sup>, and cross-validation (CV) error.

Results: The PRS calculated from EA GWAS was significantly associated with PD status across all PRS parameters. The PRS calculated with an R<sup>2</sup> of 0.8 and a 1E-04 p-value threshold had the strongest association with PD status (5.0E-17) and an AUC of 0.721, a 7% improvement over the base model. The PRS explained 7% of the trait variance as compared to the 8.7% estimated from the summary statistics. The PRS calculated with parameters of 0.2 and 0.01 had the strongest association with age at onset (1.8E-04), suggesting differences in trait architecture.

Conclusion: Without a second independent HL cohort, we are limited to CV. Nevertheless, the results here indicate that a EA-derived PD PRS performed reasonably well. This finding suggests that the genomic architecture of PD is similar in EA versus HL cases; the extent of this similarity warrants further study. Greater diversity in PD cohorts is needed to elucidate this question and improve the predictive power of the PRS in Latinos.

## PgmNr 2884: Mutation burden and oligogenic inheritance in a large inherited axonopathy cohort.

---

Inherited axonopathies include the clinically distinct phenotypes, Charcot-Marie-Tooth (CMT) and Hereditary Spastic Paraplegia (HSP), which both cause slowly-progressing, length-dependent axonal degeneration. Both phenotypes are genetically and phenotypically diverse with close to 100 Mendelian genes involved for each thus far. Whole-exome sequencing of axonopathy patients may identify more than one rare variant within known disease genes. Occurrence of additional rare variation, also referred to as a 'mutation burden', has been reported in two independent CMT cohorts (n £40) supported by functional zebrafish assays. The data indicate that mutation burden may influence clinical heterogeneity and severity of disease. We sought to replicate a mutation burden across inherited axonopathies in a WES cohort 10-fold larger than the original observations (CMT cases = 357, HSP cases = 515, controls = 931). We tested the mutation burden in cases compared to controls for both non-synonymous and loss-of-function variants at ExAC MAF £0.1% and 1%. For each tested variant set, cases harbored a higher average number of qualifying variants (Mann-Whitney, p-value £0.05). The significance of this difference was further evaluated by permutating case/control status over 10,000 iterations (p-value £0.05). Next, we evaluated the possibility of di- and oligogenic inheritance within each cohort. Cases carrying a qualifying variant in <sup>3</sup>2 genes were classified as di/oligogenic and in <sup>3</sup>3 genes as oligogenic. We observed a difference in the proportion of cases and controls carrying variants for both di/oligogenic and oligogenic inheritance for non-synonymous variation (Chi-squared, p-value £0.05). Neither HSP nor CMT showed evidence of oligogenic inheritance for loss-of-function variation; however, HSP cases were enriched for digenic inheritance (Chi-squared, p-value £0.05). In this study, we provide further evidence of a mutation burden in CMT cases, demonstrate a mutation burden in HSP cases, and explore potential oligogenic inheritance patterns in a large cohort.

## PgmNr 2885: P-value combination methods for integrative meta-analysis of genome-wide associations.

Many summary data of genome-wide association studies are publicly available now. They contain p-values of SNPs from various genotyping platforms (array or sequencing technologies), studies, and phenotypes. The combination of these data together provides large sample size, high density SNPs, and a systematic view of multiple related phenotypes of a disease. For best mining the rich data to detect novel disease genes we desire 1) statistical tests that are optimal to various signal patterns; and 2) strategies that fully incorporate correlation information due to LD, shared samples, phenotypic similarity, etc.

We provide a general framework of combining SNP p-values by two families of tests that are optimal for addressing a broad spectrum of signal patterns. The first family, referred as the gGOF, is a generalized goodness-of-fit tests, which take the supremum of the contrasts between ordered p-values and their null expectations. The gGOF is optimal for detecting weak and sparse signals. The second family, referred as the tFisher, which is a general Fisher type cumulation of p-values with proper truncation and weighting of them. The tFisher is optimal for both sparse and dense signals. Data-adaptive omnibus tests in both families can automatically select the best test statistics for given data. We developed analytical calculation for controlling the type I error under correlations. We also studied linear transformations of data in order to increase the signal strength of true genes for more powerful detection.

To illustrate the application of these tests, we analyzed big genetic data of Osteoporosis (GEnetic Factors for OSteoporosis Consortium) and ALS (ALS Variant Server). We combines p-values and incorporate correlations at three levels 1) SNP sets; 2) meta studies; 3) phenotypes. Promising novel genes for these diseases were found and reported.

## PgmNr 2886: Transparent deep learning incorporating causal inference for genomic disease risk prediction.

Deep learning, a rapidly resurged subfield of machine learning, outperforms many classical ML approaches and is emerging as a major analytic platform in machine learning. Deep learning with massive amounts of computational power has produced a revolution in driverless cars, speech recognition and imaging analysis, and demonstrated great potential for diagnosis and risk prediction of complex diseases. There is a growing interest in application of deep learning to healthcare and medicine. Despite its great progresses in computer vision, natural language processing, control, decision making, diagnosis and early detection of complex diseases, deep learning is also well known as a 'black box' due to its low interpretability to humans and still has a serious opacity problem. Overcoming the limitation of the lack of transparency and interpretation remains a great challenge for deep learning. In this talk, we develop a novel general framework that integrates deep learning and causal inference for disease classification. We will arrange millions of SNP and other genomic data into imaging-like two dimensional or three dimensional data structures. Therefore, all machine learning methods for imaging classification can be applied to SNPs data for disease risk prediction. The new framework for genomic disease risk prediction consists of two stages: (1) develop deep convolutional neural networks (CNN) to classify disease status based on genomic data and use occlusion map to find SNPs that are most distinctive for disease status and (2) the state-of-the-art causal inference tools to determine if the identified genetic variants are causal for complex diseases. Specifically, the convolutional neural network (CNN) model VGG (Visual Geometry Group) that won the first and the second places in the localization and classification tracks, respectively, in the ImageNet Challenge 2014 was chosen for disease risk prediction. Prediction difference analysis for visualizing the response of CNN to a specific input was used to select genetic variants for disease risk prediction. Wasserstein conditional generative adversarial networks (WCGAN) will be used to discover causal relationships between the genetic variants and diseases. The proposed algorithm is applied to the Alzheimer's Disease Neuroimaging Initiative (ADNI) dataset with 2379855 SNPs typed in 498 individuals. The results show that the intelligent algorithms substantially outperform the state-of-the-art methods.

## PgmNr 2887: Transcriptome-wide transmission disequilibrium analysis identifies novel risk genes for autism spectrum disorder.

---

Large-scale genetic studies have identified numerous point mutations and copy number variants (CNVs) implicating risk of autism spectrum disorder (ASD). However, these genetic variations are only found in a moderate proportion of ASD probands. Recent advances in consortium-scale genome-wide association studies (GWAS) have highlighted the critical involvement of common genetic variants in the etiology of ASD, but our understanding of their mechanistic roles is far from complete. Here, we introduce a novel statistical framework to quantify the transmission disequilibrium of genetically regulated transcriptomic activities from parents to offspring. We generate three pseudo-sibling controls for each proband based on phased parental genotypes, apply genetic prediction models to impute gene expression levels and alternative splicing events in each tissue, and use conditional logistic regression to identify over- or under-transmission of imputed molecular activities. We applied our method to conduct a transcriptome-wide association study (TWAS) in 11 brain tissues using 7,805 ASD proband-parent trios from the Autism Genome Project, Simons Simplex Collection, and Simons Foundation Powering Autism Research for Knowledge, and replicated our findings using independent samples from the iPSYCH project (N=35,740). We identified significant transmission disequilibrium of *POU3F2* and *MSRA* (splicing) in the discovery stage and replicated both associations in iPSYCH ( $P=2.1e-7$  and  $5.7e-9$ , respectively). Meta-analysis identified 16 additional transcriptome-wide significant associations. No associations were identified in 3,245 unaffected sibling-parent trios, suggesting a well-controlled type-I error rate in our approach. Among the identified genes, transcription factor *POU3F2* is a master regulator of a brain gene expression module associated with psychiatric disorders. *SOX7* and *NKX2-2* ( $P=4.7e-6$  and  $1.5e-10$ ) are two transcription factors involved in the regulation of embryonic development. We also identified the tau protein *MAPT* ( $P=3.6e-7$ ) and amyloid precursor protein secretase *CTSB* ( $P=1.5e-6$ ), both of which are critical genes for Alzheimer's disease. The identified genes showed minimal overlap with loss-of-function intolerant genes or known ASD genes enriched for pathogenic mutations, hinting at distinct biological processes underlying common and rare genetic variations in ASD. These results provide fundamental new insights into the genetic basis of ASD.

## PgmNr 2888: Determining the clinical epidemiology and genetic architecture of psychogenic nonepileptic seizures.

### Authors:

---

Psychogenic nonepileptic seizures (PNES) are characterized by episodes clinically similar to epileptic seizures. 80% of PNES patients are initially misdiagnosed with epilepsy. PNES do not arise due to aberrant brain electrical signaling but are psychology- or stress- related. PNES patients have higher rates of psychiatric disorders and obesity, and 75% of patients with PNES are females. PNES are understudied and studying PNES using electronic health records (EHR) is difficult because there is no International Classification of Diseases (ICD) code for PNES. Nothing is known about the genetic contribution to PNES. The goal of this project was to characterize the clinical and genetic characteristics of PNES in a hospital population.

We identified 4,267 PNES cases in the VU-EHR out of 2,346,808 people (prevalence 0.18%) in the Vanderbilt University EHR (VU-EHR) by developing an algorithm using convulsion ICD codes and natural language processing of keywords in patient charts. 205 of these were genotyped. We performed chart review on 50 identified cases along with a clinical neurologist.

We characterized the pattern of comorbidities associated with PNES across the lifespan. We identified VU-EHR cases of 13 common psychiatric disorders using ICD codes, and tested them for comorbidity with PNES within males and females using the Phi correlation coefficient. We then compared the likelihood of association in females vs. males using odds ratios. We found associations with PNES in a host of psychiatric disorders confirming previous reports. We found that several of these psychiatric disorders were more likely to be comorbid with PNES in females vs. males (e.g. PTSD, OR 2.72). Other phenotypes in the VU-EHR associated with PNES case/control status were determined using a Phenome Wide Association Study. Notably, cerebrovascular disease was associated with PNES (OR 1.08,  $p = 6.8 \times 10^{-19}$ ).

We determined which disorders shared underlying genetic architecture with PNES. We calculated polygenic risk score (PRS) for PNES cases ( $n = 205$ ) and controls ( $n = 48492$ ) using GWAS summary statistics for commonly comorbid psychiatric phenotypes, epilepsy, and type 2 diabetes. To determine variables' contribution to the variance in PNES case/control status, we ran a multivariable logistic regression using the PRSs. The PRS for T2D ( $p = 0.0033$ ), suicide attempts ( $p = 0.0021$ ), focal epilepsy ( $p = 0.036$ ), and insomnia ( $p = 0.037$ ) were significantly correlated with PNES case/control status.

## PgmNr 2889: Tractor: A framework for well-calibrated genomic analysis of complex traits in admixed individuals.

---

Admixed individuals are routinely removed from medical genetic studies due to the paucity of methodological approaches that account for their genomic complexity such that population substructure can infiltrate analyses and bias results. Admixed populations, including African American and Latino individuals, make up more than a third of the US populace yet face severe disparities in medical research and treatment due their underrepresentation in genomic studies.

Here we present a novel analytical framework, distributed as a software package named '*Tractor*,' which precisely accounts for subtle differences in admixture at the genotype level, allowing admixed samples to be readily included alongside homogenous ones in statistical genomics efforts. Our pipeline incorporates local ancestry in addition to global, which takes into account subtle differences in individual-level admixture patterns that may differ among case and control cohorts even if their global ancestry fractions are the same. *Tractor* further leverages the information in ancestral chromosome painting to correct phase errors and recover long-range haplotypes in admixed individuals, which we find to be severely disrupted by statistical phasing.

We test our framework in simulation modeling off of African American cohorts from the Psychiatric Genomics Consortium PTSD working group as well as apply it to empirical data from African-descent individuals of the UK Biobank. We observe a significant gain in power to detect risk loci across sample sizes and disease prevalences using the *Tractor* framework, which incorporates a novel local-ancestry aware GWAS method, compared to the traditional GWAS model. We further demonstrate that this framework gives increased fine-mapping precision by leveraging the disrupted linkage disequilibrium blocks visible with ancestral chromosome painting in recently admixed groups and boosts signal to discover GWAS loci across genetic and demographic contexts.

This framework could be applied to solve the statistical issues related to admixture across many medical and population genetics activities, such as evolutionary studies using genome-wide selection scans or in the construction of polygenic risk scores. *Tractor* dramatically advances the existing methodologies for studying admixed individuals and allows for significantly better calibrated study of the genetics of complex disorders in underrepresented populations.

## PgmNr 2890: A novel statistical method to identify susceptibility genes from copy number variations.

For over a decade, genome-wide association studies (GWAS) have been the main strategy to uncover genetic architecture of complex diseases. GWAS typically focus on single nucleotide polymorphisms (SNPs). Despite its success in a wide range of disease applications, SNPs thus discovered explain limited heritability in cognitive disorders such as Schizophrenia (SCZ). Copy number variations (CNVs), on the other hand, are believed to play a critical role in complex disease etiology. CNVs are large genomic duplication or deletion events. Previous studies have suggested that CNVs are an important source of genetic variation affecting many neurodevelopmental disorders. However, since CNVs often span multiple genes, distinguish susceptible gene(s) from other genes in the same CNV event is difficult. Results of CNV associations are thus difficult to interpret. This hurdles the use of CNV data to unravel the genetics of complex diseases.

To address the challenge we developed a new approach that exploits large-scale genome-wide CNV data in case-control studies to map genes. It is inspired by statistical fine-mapping of causal variants in linkage-disequilibrium blocks from GWAS. Unlike existing approaches that directly test for CNV associations, our method seeks to identify in CNV events true susceptible genes in a rigorous statistical framework. Genome-wide CNV data are first clustered into disjoint analysis blocks, i.e. no CNV spans between any two blocks. For genes within a block we test for disease associations while accounting for correlations among genes induced by CNV in the same block. We accomplish this by extension of a recently developed Bayesian variable selection method, SuSiE (Wang et al 2018). Our method thus selects a small number of putative risk genes among multiple correlated ones that best explain the CNV-phenotype data. Furthermore, we leverage knowledge of known biological pathways to set prior probabilities of genes in CNV events to increase power. Our model estimates posterior probabilities of all putative risk genes as well as 95% credible sets (i.e. the set of genes that cover all risk genes with high probability). Using this new approach we perform gene-level analysis in several case-control CNV datasets in SCZ. Since our method reports the statistical confidence of genes, it can be integrated with other gene-level datasets, e.g. results from exome-sequencing studies. This provides a powerful strategy to integrate data from independent sources.

## PgmNr 2891: Most rare and high-risk CNV carriers do not have major health, cognitive, or socioeconomic consequences.

---

CNVs are associated with syndromic and severe neurodevelopmental and psychiatric disorders (SNPDs), such as intellectual disability (ID), epilepsy, bipolar disorder (BD), and schizophrenia (SZ). Although considered high-impact, CNVs exist in the general population as well. This presents a diagnostic challenge in evaluating their clinical impact. To estimate the impact of CNVs to general health and well-being, we analyzed CNV burden alongside three genome-wide Polygenic Risk Scores (PRS; IQ, Educational Attainment [EA], and SZ) in a Finnish working-age population (FINRISK, n=23,053).

In carriers of high-risk CNVs (Susceptibility CNV, Risk Gene Deletion, or Large [ $>1\text{Mb}$ ] CNV), 96.1% (537/559) had no SNPD diagnosis. The remaining 3.9% (n=22) had been diagnosed with ID (4/22, 18%), Schizophrenia (4/22, 18%), Epilepsy (13/22, 59%), Bipolar Disorder (3/22, 14%), and Behavioral and Emotional Disorders (1, 5%). ID in particular was associated with Large Deletions (OR=7.2 [1.7-31]), Large Duplications (OR=5.4 [1.2-23]), ID Gene Deletions (OR=11.9 [1.5-91]), and Susceptibility CNVs (OR=13.4 [1.7-102]). In comparison, the 559 individuals with the highest PRS<sub>SZ</sub> were enriched for Schizophrenia (OR=6.1 [3.3-12]), ID (OR=2.9 [1.1-7.6]) and Bipolar Disorder (OR=2.6 [1.2-5.3]).

We hypothesized that even if CNV carriers might not have a diagnosed SNPD, some of them might have subclinical features that could be associated with their general health, well-being or socioeconomic status. In individuals without SNPD (n=22,210), we observed lower educational attainment in individuals carrying Susceptibility CNVs (1.5 years [0.4-2.6]), Large Deletions (0.7 years [0.1-1.3]), and High pLI Gene Deletions (0.6 years [0.1-1.0]). In the 559 lowest PRS<sub>EA</sub> individuals, the effect was more severe (1.9 years [1.6-2.2]) than any high-risk CNV type. The 559 lowest PRS<sub>IQ</sub> individuals had 1.2 years [0.8-1.5] lower EA.

Household income was impacted by large deletions (ordinal logit OR=0.52 [0.37-0.72]) and High pLI Gene Deletions (OR=0.69 [0.54-0.86]). Subjective Health was lower in individuals harbouring ID Gene Deletions (OR=0.37 [0.19-0.68]).

Our analyses indicate that high-risk CNVs contribute to risk for developing SNPDs. Despite this, the vast majority of working-age individuals carrying high-risk CNVs have no disease. High-risk CNVs other than large duplications are associated with lower subjective health, educational attainment, or income, yet no more than common variation as measured by PRS.

## PgmNr 2892: GWAS of alcohol consumption in the UK Biobank identifies variants that affect tissue-specific alcohol disease.

### Authors:

---

**Introduction:** Alcohol consumption is associated with a wide range of human diseases and is a significant contributor to worldwide morbidity and mortality via alcohol use disorder (AUD), psychiatric disorders, and liver/pancreas-related sequelae. The genetic contributions to these traits is not fully known.

**Methods:** To better understand the etiology of alcohol use, we performed a genome-wide association study of self-reported alcohol intake (N=288,919) and alcohol-related sequelae (N=407,713) in > 390,000 Caucasian ancestry individuals from the United Kingdom (UK) Biobank. Genome wide significant SNPs were assessed for effects on targeted alcohol related diseases and traits with effects that reached an FDR < 5% reported.

**Results:** After conditional analyses adjusting for previously identified loci, we identified 2 novel and independent loci associated with alcohol consumption via fine mapping: rs109536-C, an expression quantitative trait locus (eQTL) variant for BRD3 and LINC00094 (B=0.018 and Pconditional=1.77'10-8) and rs13066050-T, an intergenic SNP 213kb downstream of GBE1 (B=0.022 and Pconditional=2.92'10-10). Analyses of the effects of genome-wide significant variants for alcohol-intake on alcohol related sequelae identified variants at GCKR and ADH1B that associated with AUD, delirium secondary to alcohol withdrawal, and alcoholic hepatitis and/or cirrhosis.

**Conclusions:** These results further elucidate and refine the genetic architecture of alcohol intake and its sequelae.

## PgmNr 2893: Testing gene-environment interactions without measuring the environment.

Both genetic variations and environmental factors play key roles in shaping the etiology of complex disease. Dissecting the interplay between genetics and environmental factors may provide new insights into disease development and progression and shed light on prevention and treatment strategies. However, studies on gene-environment (GxE) interactions have only had limited success to date. This is in part due to a lack of large datasets that provide all the components required in a successful GxE study: genome-wide genetic data, robust measurements of environmental risk factors, and a sufficient number of cases for the disease of interest. We propose a novel statistical framework to test GxE interactions by using polygenic score (PGS) as a proxy for the environmental factor. PGS has quickly gained popularity in GxE research in the past few years. In fact, most recent GxE studies used PGS as the 'G' component. Through theoretical derivations and numerical analyses, we demonstrate that the inference of interaction effect remains statistically valid using our method. We use extensive simulations to show that our method provides accurate estimates for GxE effects without inflating the type-I error. In addition, our method can be applied to diverse types of GxE study designs. We applied our method to three large, independent genetic datasets for autism spectrum disorder (ASD), i.e. the Autism Genome Project (AGP; n=2,188 probands), Simons Simplex Collection (SSC; n=1,794 probands), and Simons Foundation Powering Autism Research for Knowledge (SPARK; n=3,823 probands), to investigate the interaction effect of genetic variants and birth weight on ASD risk. We used a PGS based on a GWAS conducted on the UK biobank (n=205,475) as the genetic proxy for birth weight in our analyses. Meta-analysis of three independent datasets revealed a significant negative interaction between the PGS of ASD and the PGS of birth weight ( $p=4.64E-4$ ), suggesting that a higher birth weight may buffer the genetic risk of ASD. As a negative control, we also applied the same approach to 3,243 unaffected siblings of ASD probands from SPARK and SSC cohorts and did not identify any interaction ( $p=0.65$ ). Our novel approach makes it possible to perform rigorous GxE inference on large GWAS datasets even if the environmental factor is not directly measured. We believe this method has great potential for accelerating findings in GxE research and advancing our understanding of complex disease.

## **PgmNr 2894: Model-based assessment of replicability of association signals: Application to genome-wide association meta-analysis of smoking and drinking phenotypes in 1.2 million individuals.**

Genome-wide association meta-analysis (GWAMA) is an effective approach to enlarge sample size and empower association studies. However, as current GWAMA often aggregate all available datasets, it becomes impossible to find a large enough independent dataset for replication. Un-replicated signals are much more likely to be false positives, and although some ad-hoc procedures may be applied to examine the validity of the signals, e.g. whether the signal is supported by multiple studies, they are often based upon heuristics and hard to be interpreted and generalized.

To overcome this limitation, we developed MAMBA for assessing the "posterior-probability-of-replicability" (PPR) for identified associations. MAMBA is a two-level mixture model which leverages both the strength and consistency of association signals between contributing studies. We model the genetic effects distribution as a mixture of normally behaving SNPs and outlier SNPs with inflated effect sizes. By fitting the model to genome-wide SNPs, the model will assign PPR to each SNP, measuring how likely the SNP has real non-zero effects. To facilitate the comparison with frequentist methods, we also developed a bootstrap procedure to calculate p-values.

We compared MAMBA with fixed effect, random effect, RE2 (a more powerful random effect method under genetic heterogeneity), and binary effect meta-analysis. We showed through extensive simulations that MAMBA is robust to the presence of outlier studies, and is almost always the most powerful or close to the most powerful even when the data is generated to favor alternative methods.

We also applied MAMBA to a meta-analysis of smoking/drinking phenotypes in 1.2 million individuals. Using 23andMe dataset as an independent replication, we observed that MAMBA yielded considerably higher p-value correlation and effect size correlation between discovery and replication estimates across all phenotypes, particularly for rare variants (e.g. for cigarettes per day phenotype, the correlation of effect sizes for rare variant association goes from .05 for fixed effect meta-analysis to .33 for MAMBA). Combining the discovery and replication datasets, we identified multiple novel rare coding variants for smoking traits with high PPR. These associations point to novel immunity or cancer related genes, including GZZM, SPOCK3, SLC7A9. We expect our method will be highly valuable for assessing the replicability of association signals in large GWAMA.

## PgmNr 2895: *In silico* enhanced GWAS for schizophrenia.

---

Schizophrenia (SCZ), affecting ~1% of the world population, is a highly heritable, debilitating psychiatric disorder associated with high morbidity, mortality, personal and public health costs. The largest SCZ genome-wide association studies (GWAS) published to date have revealed the polygenic genetic architecture underlying SCZ, identifying >140 genome-wide significant loci with 40,000 cases and 100K controls. Taken together with earlier GWAS, these studies indisputably demonstrate the value of increased sample sizes for genetic dissection of SCZ. However, unlike many other complex diseases and traits, it is challenging to increase the sample size for SCZ GWAS by another order of magnitude. Therefore, enhanced GWAS on existing samples via computational approaches may be particularly valuable for SCZ research.

Here, we attempt to enhance power of uncovering SCZ risk loci by leveraging GWAS summary statistics from the largest published GWAS for SCZ (discovery  $n = 35476$  cases + 46839 controls), as well as brain related functional genomic information. Specifically, we train models to predict SCZ associated genetic variants via multiple statistical or computational methods including classic statistical (logistic regression), machine learning (random forest, and XGBoost) and deep learning (deep neural network) methods. Applying the trained models to GWAS summary statistics from the largest published GWAS, we performed an enhanced GWAS for SCZ and compared with our latest/unpublished results with  $n = 40675$  cases + 64643 controls (treated as the truth). Our preliminary results from chromosome 6 showed that our enhanced GWAS improved sensitivity by 20% (from 75.6% to 95.6%), at the cost of a 0.0018% false positive rate. Our enhanced GWAS also revealed 3 novel loci not detected in the large published GWAS. Our study suggests a powerful new paradigm for genetic studies of SCZ and other disorders for which necessary increases in sample sizes are difficult or expensive to attain in practice.

## PgmNr 2896: Longitudinal variant-set retrospective association test.

**Authors:**

W. Wu; Z. Wang

[View Session](#) [Add to Schedule](#)**Affiliation:** Department of Biostatistics, Yale School of Public Health, New Haven, CT.

---

Set-based tests have become popular for the identification of rare genetic variants that are associated with disease traits. Burden test and variance component test are two widely used set-level tests for single time measurement. Longitudinal repeated measures have been increasingly used in genome-wide association studies. The repeated measures provide an opportunity to study the temporal development of traits and also increase the statistical power in association tests. Most of the existing variants-set association tests are based on a population model in which ascertainment is ignored. Prospective inference with longitudinal traits and rare variants can have inflated type I error when the trait model is misspecified. Here, we propose LSRAT (Longitudinal variant-Set Retrospective Association Tests) and RSMMAT (Retrospective variant-Set Mixed Model Association Tests), two groups of retrospective variant-set tests that are constructed based on the genotype model given the phenotype and covariates. RSMMAT can be viewed as a retrospective version of the recently proposed variant-set mixed model association tests (SMMAT) and the LSRAT tests are derived under the generalized estimation equation framework. These tests have several advantages: (1) they are robust against trait model misspecification; (2) they are able to adjust both static and time-varying covariates; (3) they allow for related subjects and account for population structure; and (4) they are computationally more efficient than existing prospective approaches. Simulation studies showed that our proposed tests are robust to the trait model misspecification and gain power compared to SMMAT. We illustrated our method in the Veterans Aging Cohort Study to evaluate the association of repeated measures of cocaine use with rare variants.

## PgmNr 2897: Gene-based association testing for GWAS summary data using the general optimally weighted combination method.

---

To identify genetic susceptible variants for complex traits and disease, genome-wide association studies (GWAS) have been widely performed with immense, publicly available summary data. However, the identified genetic variants can only explain a small fraction of the overall heritability for most complex traits and disease. To explain the missing heritability for complex traits and disease, powerful statistical methods need to be developed to utilize GWAS summary data to identify novel disease susceptible genes. The power of different gene-based tests rely on the sample size and the underlying genetic architecture, which can differ in number, effect size, and effect direction of the causal variants in different genes. A statistical challenge is that, due to unknown true association patterns, there is no uniformly most powerful test to detect traits and/or disease susceptible genes; an association test may perform well for one dataset, but not necessarily for another. In this study, we propose an optimal weighted combination (OWC) test which is a general weighted combination framework utilizing GWAS summary statistics. Some popular methods including burden tests, the weighted sum of squared score (SSU), weighted sum statistic (WSS) and score test are special cases of OWC. We analytically prove that aggregating the variants in one gene is the same as using the weighted combination of Z-scores for each variant based on score test. Extensive simulation studies indicate that the type I error rates of the OWC are well controlled in different scenarios. We also numerically illustrate that our proposed test outperforms other several comparable methods through extensive simulation studies. Further, the application of the OWC and other comparison methods on two schizophrenia GWAS datasets obtained from the Psychiatric Genomics Consortium demonstrates that the new method can identify more biology plausible genes than the comparison methods. We identified that genes affecting music-related creative behavior are associated with schizophrenia. Also, our results support that schizophrenia is caused by a combination of multiple genetic factors, with each showing a relatively small effect size. Although our application was focused on schizophrenia, the proposed method is quite general and applicable to other traits and/or diseases based on either individual-level or summary GWAS data. In addition, we have made the R program of OWC freely and publicly available.

## PgmNr 2898: No causal effect of alcohol and coffee consumption on perceived stress: A Mendelian randomization study.

---

The few cohort studies that examined association between alcohol consumption and the risk of depression produced inconsistent results. Therefore, we undertook the present study to confirm causal effect of alcohol consumption on perceived stress, instead of depressive symptoms, using a Mendelian randomization (MR) approach. Perceived stress contributes to the development of depressive disorders, and substantial genetic overlap was observed between perceived stress and depressive severity: the genetic correlation between them was 0.78 in a twin study [Rietschel L 2014]. In previous studies, the variant, rs671 in ALDH2 revealed a strong genome-wide association for alcohol consumption, coffee consumption and serum uric acid (SUA) in East Asians [Jorgenson E 2017, Nakagawa-Senda H 2018, Nakatochi M 2019]. Therefore, if this variant was used for an instrumental variable, horizontal pleiotropy was a particular concern. To address this highly probable problem, we employed a multivariable MR framework, where multiple exposures can be incorporated. We conducted the present study using a general population sample of 13,618 Japanese participated in the Japan Multi-Institutional Collaborative Cohort (J-MICC) Study.

Since SUA was not associated with perceived stress in a linear regression analysis, horizontal pleiotropy via the uric acid pathway was unlikely. In previous cohort studies, coffee consumption showed a protective effect for depression. Therefore, we incorporated alcohol consumption (g/day) and coffee consumption (cups/day) as exposure variables in a multivariable MR. For the analysis, we used nine SNPs reported to be associated with alcohol or coffee consumption as instrumental variables (rs671, rs1229984, rs1957553, rs17685, rs4410790, rs12094032, rs1260326, rs6265, rs573194563) based on three analysis methods: a two-stage least-squares regression, an inverse-variance weighted (IVW) and MR-Egger methods. In the MR-Egger analysis, the intercepts were not statistically different from zero, which means that the average horizontal-pleiotropic effect across the genetic instruments were likely to be null. Then, both the two-stage least-squares regression and IVW analysis revealed no significant causal effect of alcohol consumption ( $P$ -value = 0.246 and 0.107) and coffee consumption ( $P$ -value = 0.970 and 0.716) on perceived stress, respectively. Thus, the present MR study confirmed that alcohol and coffee consumption have no influence on perceived stress.

## PgmNr 2899: A phenome-wide association study identifies the consequence of smoking derived methylation changes.

### Authors:

---

The tobacco epidemic is one of the biggest public health threats. As the leading cause of disease and death in the US, smoking accounting for about 1 in 5 deaths. Studies have supported that smoking affects DNA methylation, and these effects may contribute to the development and progression of various diseases. In the current study, we systematically scanned the phenotypic consequences of smoking-induced methylation changes in an EHR-based dataset BioVU (~23,000 EA samples). The methylation level and gene expression level were not directly measured in BioVU samples. Instead, we used common variants to mimic the effect of smoking derived methylation changes on gene expression. We first identified regions in which smoking significantly affected methylation status at sites that are variably methylated (Joehanes et al 2016 Circ Cardiovasc Genet). In independent data, we identified genes in which measured expression was significantly affected by methylation status at the previously identified regions (Liu et al 2013 Hum Mol Genet). For each of the genes, an expression prediction model was trained from the GTEx reference panel (Gamazon et al 2015 Nat Genet). PheWAS was performed for the predicted score aggregated from affected genes for each individual in BioVU. In brain tissues (frontal cortex BA9, anterior cingulate cortex BA24), we observed an increased risk of addiction-related phenotypes, consistent with the hypothesis that smoking-induced methylation changes may work within reward system pathways to reinforce nicotine addiction. *FCRLB* (Fc Receptor-Like B) is the leading gene for the association. Increased risk of multiple sclerosis, PTSD, primary pulmonary hypertension, etc. was also observed to be associated with the smoking-associated methylation and expression changes. Taking advantage of the wealth of traits from an EHR-linked biobank, the current study extends our understanding of the phenome-wide consequences of methylation-induced, potentially long-term consequences of smoking.

## PgmNr 2900: Inferring causal effects of neuroproteins on psychiatric disorders.

---

Protein quantitative trait loci (pQTL) are essential tools to study the molecular basis of complex diseases, as they provide insights on the role of genetic variation in determining the protein levels that modulate the metabolic state of an individual. We quantified 184 proteins involved in neurological processes in the Olink (c) Neuro-exploratory and Neurology panels in 1070 individuals of the Orkney Complex Disease Study (ORCADES), for whom we had genotypic information (350k genotyped SNPs on the Illumina Hap300 and Omni panels, and data imputed to the Haplotype Reference Consortium panel 11 million SNPs). For each protein, we performed a genome-wide association analysis (GWAS) looking for loci associated with protein levels, both in the proximity of the protein coding gene (using gene position plus and minus 50kb in cis) and distantly (1mb in trans).

We discovered 48 cis- and 59 trans-pQTL for 95 of these neuroproteins. We performed enrichment analyses on level of expression of these proteins in different tissues, and show that the neuroproteins with cis-pQTL display enriched expression in the brain. We subsequently investigated the potential causal effect of variation in proteins levels on different psychiatric disorders, including Depression, Schizophrenia, and Bipolar Disorder for the proteins with cis-pQTL. For example, using our pQTL study and GWAS summary-level data for major depressive disorder (Wray et al, 2018), we discovered 12 additional loci associated with major depressive disorder. Two of these 12 loci we uncovered were also discovered in the latest 2019 meta-analysis for major depression, confirming our results. Further investigation of the role of the remaining 10 novel loci in depression and neural functions (including functional validation) is required, but our study highlighted novel loci with potentially relevant roles in psychiatric disorders.

## PgmNr 2901: Challenges of predicting health outcomes from gene expression levels in individuals with anorexia nervosa.

---

Anorexia nervosa (AN) is a heritable psychiatric disorder characterized by low body weight and a fear of gaining weight. Individuals with AN at critically low weight are often hospitalized for medical stabilization and to promote weight gain. Repeated hospitalizations are a major concern: over 20% of patients are re-hospitalized within one year. Improved prediction of clinical outcomes post-discharge are needed to facilitate earlier, more personalized interventions.

Subjective behavioral, social, and psychological factors vary in their ability to predict weight change post-discharge or rehospitalization. Furthermore, no robust, biological predictors of these outcomes exist. Our goal is to identify genes whose expression levels in blood may be predictive of weight change post-hospital discharge. To do so, we collected clinical, demographic, and biological information at admission, discharge, and 3 months post-discharge from 41 females with AN at the UNC School of Medicine.

Previous studies have focused on predicting body mass index (BMI) post-discharge. However, an individual's change in BMI over time also impacts rehospitalization. We found that BMI at discharge is strongly correlated with BMI post-discharge (Pearson's  $r = 0.60$ ,  $P < 0.01$ ), but not with rate of BMI change ( $r = 0.19$ ,  $P = 0.29$ ). Therefore, we attempted to predict both outcomes from discharge gene expression levels. For each outcome, we identified 1000 genes with the most highly associated expression levels and 8 covariates, and then trained a support vector machine. The training set comprised 29 individuals (for whom we had information at multiple timepoints post-discharge). Since an independent set was not available, the test set was comprised of the additional 12 individuals in our study. We could not reliably predict either outcome in the test set ( $R^2 < 0$ ).

This study highlights the clinical and logistical challenges of predicting treatment response in individuals hospitalized for AN. For example, further characterization of outcome—including how BMI and rate of BMI change influence rehospitalization—is needed. Additionally, future studies must collect substantially larger cohorts and include an independent replication set. Power analyses will allow us to estimate a lower bound for the number of individuals needed to predict these types of outcomes. Overall, our pilot study will guide the design of future studies predicting treatment response in individuals with AN.

## PgmNr 2902: Prediction of pathological gambling and problematic gambling behaviours by Bipolar Disorder and Parkinson's disease: A polygenic risk score analysis.

### Authors:

P.A. Lind <sup>1</sup>; A. Campos <sup>2</sup>; L. Colodro-Conde <sup>1</sup>; S.E. Medland <sup>1</sup>; W.S. Slutske <sup>3</sup>; N.G. Martin <sup>2</sup>

---

Increasing evidence has emerged that there is (i) an increased prevalence of problem gambling in individuals with Bipolar Disorder (BP); and (ii) a subset of Parkinson's disease (PD) patients who are at higher risk for developing pathological gambling when they undergo dopamine agonist and/or dopamine replacement therapy. We examined the extent to which individual differences in the age of gambling initiation (Initiation), gambling versatility (Versatility), DSM-IV pathological gambling (PG), and severity of problematic gambling (Severity), can be predicted by a polygenic risk scores (PRS) derived from the latest Psychiatric Genomics Consortium BP (leave out QIMR; Stahl et al 2019) and International PD Genomics Consortium (leave out 23andMe; Nalls et al 2018) analyses. Gambling data and genotyping were available for ever gamblers in the 25UP (N=1644) and GA (N=1948) studies undertaken at QIMR. In the GA study, Severity was calculated as the number of DSM-IV PG and South Oaks Gambling Screen symptoms endorsed (30-point scale; N=1948). In the 25UP study, Severity was calculated as the Problem Gambling Severity Index score (27-point scale; N=555). Initiation and Versatility (a 13-point scale of the number and types of gambling activities engaged in) were available for N=3,592. PRS were calculated using the PLINK profile score method for clumped SNPs. Linear and logistic regressions on the profile scores were performed, controlling for relatedness, ancestry, sex, age and age<sup>2</sup> at survey time, sex\*age, cohort and imputation status. Between 2.2% and 3.2% of GA subjects were diagnosed with DSM-IV PG or as probable pathological gamblers respectively. Around 7% of 25UP subjects screened positive for problem gambling. After correcting for multiple testing, genetic risk for Parkinson's disease predicted DSM-IV PG and Severity (all PRS calculated from  $p \leq 0.05$  to  $p \leq 1$ ; explaining ~0.5% of variance). There was no evidence that the genetic risk for Bipolar Disorder predicted DSM-IV PG or Severity. Genetic risk for Parkinson's disease and Bipolar Disorder did not predict Initiation or Versatility. These preliminary findings suggest a possible shared genetic aetiology between pathological gambling and Parkinson's disease. Furthermore, the development of pathological gambling risk prediction models that incorporate genetic information from future gambling GWAS could enable us to identify at-risk PD patients undergoing dopamine agonist and/or dopamine replacement therapy.

## PgmNr 2903: A new robust method uncovers significant context-specific heritability in diverse polygenic traits.

Gene-environment interaction (GxE) is a conjectured source of substantial heritability and can be fundamental in applications ranging from functional genomics to precision medicine. However, unbiased methods to profile GxE genome-wide are nascent and, as we show, cannot accommodate general environment variables, heterogeneous noise, or binary traits. To address this gap, we propose a simple, unifying mixed model for gene-environment interactions (GxEMM). Our scalable approach identifies changes in both genetic and environmental variance, and is implemented in the LDAK software package.

In simulations and theory, we show GxEMM can dramatically improve estimates and eliminate false positives when the assumptions of existing methods fail. We then apply GxEMM to a range of human and model organism data sets and find broad evidence of context-specific genetic effects. First, in a major depression (MD) cohort, we find Bonferroni-significant evidence for genetic heterogeneity across several measures of lifetime adversity; in particular, this directly implies the existence of polygenic MD subtypes. Second, we examine psychiatric disease-specific functional genomic architecture in prefrontal cortex and find substantial signal, both on average across the transcriptome (e.g. ~20% increase in heritability in schizophrenia) and at 9/63 known candidate genes. Finally, we analyze 115 traits in outbred rats and find clear evidence of sex-specific genetic and non-genetic variability in many traits at Bonferroni thresholds, including bone density and glucose tolerance. These results can help pinpoint the mechanisms underlying sexual dimorphism in complex traits. Overall, GxEMM is broadly useful for quantifying genome-wide genetic interactions, which can be useful for explaining heritability and is invaluable for determining biologically relevant environments.

## PgmNr 2904: Genome-wide causation studies of complex diseases.

---

The mainstream of research in genetics and epigenetics data analysis focuses on statistical association or exploring statistical dependence between variables. Despite significant progress in dissecting the genetic architecture of complex diseases by genome-wide association studies (GWAS), the signals identified by association analysis can only explain a small proportion of the heritability of complex diseases. A large fraction of risk genetic variants is still hidden. Finding causal SNPs only by searching the set of associated SNPs may miss many causal variants. Using association analysis as a major analytical platform for the complex data analysis is a key issue that hampers the theoretic development of genomic science and its application in practice. Causality shapes how we view and understand mechanism of complex diseases.

To shift the current paradigm of genetic analysis from association analysis to causal discovery, we develop novel causal inference methods for genome-wide causal studies (GWCS). Permutation is used to calculate the P-values of the causal tests. Large simulation studies show satisfactory Type I error rates and high power of the proposed method in four scenarios: no association and no causation, having association but no causation, no association but having causation, having both association and causation. Excitingly, linkage disequilibrium has little impact on identification of causal SNPs.

The proposal methods have been applied to CATIE-MGS-SWD schizophrenia dataset with 8,421,111 common SNPs typed in 13,557 individuals for GWCS of schizophrenia. At the significance level of , 245 SNPs show causation. Among them, 62 causal SNPs can be confirmed from the literature and four of them are on the typical 108 schizophrenia-associated genetic loci (Nature, 511 (2014), pp. 421-427). We also conduct GWAS for this dataset. A total of 5,917 SNPs are associated with SCH at the significance level of and only 89 of them show causation.

## PgmNr 2905: An implementation of adaptive p-value thresholding to improve power in detecting bipolar disorder and schizophrenia associations.

The continual growth of “omics” technologies creates exciting opportunities to merge information from multiple studies to enhance power to understand the etiology of disease. Yet, such explorations are challenged by the need to limit detection of false positives and spurious biological conclusions, while maintaining power. Classical approaches for addressing this challenge rely on simple, albeit many hypothesis tests; recent methodologies, however, can improve power by enabling exploration of auxiliary information to weight hypotheses while retaining statistical guarantees. Such approaches can utilize prior research results and provide insights into key biological processes. We illustrate an approach, called adaptive p-value thresholding (AdaPT; Lei and Fithian, 2018) for false discovery rate (FDR) control, by analyzing bipolar disorder (BD) and schizophrenia (SCZ) genome-wide association studies (GWAS) results from the Psychiatric Genomics Consortium (PGC). Specifically, we apply AdaPT to both the BD and SCZ p-values from a set of eSNPs (gene expression single nucleotide polymorphisms) identified from the recent BrainVar study (Werling et al., 2019), which uses human dorsolateral prefrontal cortex samples across a developmental span from 176 individuals. Analyzing this set of candidate eSNPs, we demonstrate an improvement in power by exploring multiple types of information external to the specific GWAS results for the disorder: (1) due to the genetic correlation between BD and SCZ, we use independent GWAS tests from one phenotype to inform the other; (2) we explore how estimated eQTL slopes inform BD and SCZ discoveries; (3) using eSNP-gene pairs and gene-gene coexpression, we determine if module assignments from weighted gene co-expression network analysis are informative; and (4) we utilize additional SNP information gleaned from PsychENCODE. How can we use such diverse sources of information? Within the AdaPT framework, we use this auxiliary information in the context of flexible gradient boosting trees to model conditional local FDR. This analysis yields a substantial increase in the number of discoveries with each additional piece of information; for example, revealing BD and SCZ enrichment for particular gene modules. Importantly, the process underlying this analysis can be implemented for many different settings to improve power and by utilizing a variety of complementary data sources.

## PgmNr 2906: Using Mendelian randomization to evaluate the causal relationship between serum C-reactive protein levels and age-related macular degeneration.

### Authors:

---

Serum C-reactive protein (CRP), an important inflammatory marker, has been associated with age-related macular degeneration (AMD) in some observational studies; however, the findings are inconsistent across studies. Genetic studies have the potential to shed light on this but studies to date find no evidence for the association between genetic variants in the CRP gene and AMD risk. It remains unclear whether elevated circulating CRP levels are causally related to AMD risk. We used recently released UK Biobank (UKBB) CRP data to dramatically expand our understanding of CRP genetics, allowing powerful Mendelian randomization (MR) analysis to evaluate the potential causal relationship between genetically predicted elevated serum CRP levels and the risk of AMD.

Two-sample MR analyses were performed using data from UKBB and the International AMD Genomics Consortium (IAMDGC). We derived 526 (nearly all novel) independent lead variants (genetic instruments) for serum CRP levels in 418,642 participants of European descent from UKBB. We conducted a genome-wide association study (GWAS) for 12,711 advanced AMD cases and 14,590 controls of European descent from IAMDGC. Genetic variants which predicted elevated serum CRP levels were associated with advanced AMD (odds ratio [OR] for per standard deviation [SD] increase in serum CRP levels: 1.31, 95% confidence interval: 1.19 to 1.44,  $P = 5.2 \times 10^{-8}$ ). Our results were unchanged in sensitivity analyses using MR models which make different modelling assumptions. Our findings were broadly similar across the different forms of AMD (intermediate AMD, choroidal neovascularization, and geographic atrophy). We used multivariable MR to adjust for the effects of other potential AMD risk factors including smoking, body mass index (BMI), systolic blood pressure (SBP), high-density lipoprotein cholesterol (HDL-C), and glycated haemoglobin (HbA1c); this did not alter our findings.

Our study provides strong genetic evidence that higher circulating CRP levels lead to increases in risk for all forms of AMD. This finding highlights the potential utility for using circulating CRP as a biomarker in future trials aimed at modulating AMD risk via systemic therapies.

## PgmNr 2907: Linkage analyses of Midwest Amish families uncover novel loci for age-related macular degeneration on chromosomes 8q21 and 18q21.

Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, Florida

---

Age-related macular degeneration (AMD) is the most common cause of blindness in adults over 60 in the developed world. Although many common genetic risk variants are associated with AMD, a few rare variants also contribute to disease risk. The Amish have a lower genetic burden from known AMD variants than the general population, which suggests that rare variants may be contributing to their AMD risk. We genotyped 175 Amish individuals from Ohio and Indiana for the Illumina HumanExome panel, including 86 AMD cases, 77 controls, and 12 related Amish individuals with unknown AMD diagnosis. We determined that these individuals are interrelated through a 2,118-person pedigree and therefore were well-suited for discovery of novel rare genetic loci for AMD. Because analyzing large complex pedigrees for linkage is computationally intractable, we divided this pedigree into 16 sub-pedigrees and performed multipoint linkage analyses of 5,668 autosomal variants passing extensive quality control. We utilized affecteds-only dominant and recessive models (disease allele frequency = 0.10) allowing for locus heterogeneity. We found significant evidence of linkage ( $HLOD > 3.6$ ) on chromosomes 8q21 (maximum recessive  $HLOD = 4.03$ ) and 18q21 (maximum dominant  $HLOD = 3.87$ ; maximum recessive  $HLOD = 4.27$ ). These are independent of susceptibility loci identified by the International AMD Genomics Consortium and other previous AMD linkage screens. To determine whether genes in the 1-HLOD support intervals of our significant loci are functionally related to one another, we performed gene ontology (GO) enrichment analyses with ClueGO in Cytoscape. *P*-values were calculated with right-sided hypergeometric tests and corrected using the Benjamini-Hochberg method. The 1-HLOD support interval of our chromosome 8 peak ( $n = 80$  genes) is enriched (corrected  $p < 0.0005$ ) in genes involved in lipid catabolic processes and fatty acid binding, and the support interval of the chromosome 18q21 locus under the dominant model ( $n = 102$  genes) harbors genes that contribute to the positive regulation of epithelial to mesenchymal transition and endopeptidase regulator and inhibitor activities. The 1-HLOD support interval of our chromosome 18 peak under the recessive model contains 46 genes that are not overrepresented in GO terms. Our results implicate novel AMD loci in the Midwest Amish and highlight the power of investigating genetic polymorphisms for a complex trait, like AMD, in an isolated population.

## PgmNr 2908: Variation in *GSAP* identified as a novel risk factor for pigment dispersion syndrome and pigmentary glaucoma.

---

Pigmentary glaucoma (PG) is an uncommon form of open angle glaucoma that can result in irreversible blindness. The average age of onset for PG is much younger than other forms of glaucoma, meaning it has a high burden of disease. Pigment dispersion syndrome (PDS) is a precursor and cardinal characteristic of PG. Although PG and PDS have a significant genetic component, to date only rare risk variants have been identified in familial studies. We performed a genome-wide analysis to identify genetic risk present at the population level.

We conducted separate GWAS using Firth logistic regression in two cohorts with PG cases (cohort 1: N cases=227, N controls=291; cohort 2: N cases=66, N controls=50,821), and one with PDS cases (cohort 3: N cases=137, N controls=1370), all of European ancestry. An inverse variance meta-analysis of these cohorts was just underpowered to identify genetic variants with genome-wide significant association, but did identify some strongly suggestive loci. Results from the meta-analysis were used to perform a gene-based analysis in S-Predixcan to identify association between gene expression and PDS.

After strict Bonferroni-adjustment for all gene-tissue pairs, statistically significant association was identified with *GSAP* ( $p=2.48 \times 10^{-7}$ ) which encodes the gamma-secretase activating protein. Gamma-secretase is a protease that has been shown to regulate the trafficking of TYR and TYRP1 in melanosomes. Mutations within both *TYR* and *TYRP1* are both responsible for ocular pigment defects (oculocutaneous albinism), and DBA/2J mice with *Tyrrp1* mutations present with PG. The gamma-secretase complex also eliminates the C-terminal fragment of the premelanosome protein (PMEL) and mutations within *PMEL* have been recently shown to be associated with PG in a familial study. This study identifies a novel association between *GSAP* and PDS that is present at a population level. Not only is this result compatible with previously published data, but it identifies a common pathway that accounts for the locus heterogeneity seen between familial studies.

## PgmNr 2909: GWAS-based machine learning approaches for predicting AMD progression.

Recent advances in machine learning have made extraordinary achievements in establishing flexible and powerful prediction models. The genome-wide association study (GWAS) of Age-related Macular Degeneration (AMD), a polygenic and progressive eye disease, is the first and most successful GWAS research among many diseases, where the massive GWAS data provide unprecedented opportunities to study disease risk and progression. Motivated by the need to establish a flexible and reliable prediction model for AMD progression, such as the progression-time-to-late-AMD, we developed a novel framework, which builds deep neural networks on time-to-event outcomes (referred as “NNsurv”) to effectively extract features from the wealthy GWAS data. Using data from two large randomized clinical trial on AMD progression, Age Related Eye Disease Study (AREDS) and AREDS2, we applied our method to develop and evaluate three machine-learning-based prediction models, including the NNsurv, Cox Lasso and random survival forest, to predict the risk of progression to late-AMD given the patient’s clinical and genetic profiles. The c-index on the independent test data from these three methods ranged from 0.74 to 0.77, implying satisfactory prediction performance. Time-dependent ROC curves from all prediction models were provided. Furthermore, the prediction model under NNsurv was able to classify patients into different progression risk categories based on their genetic and clinical characteristics. The result provides valuable insights for early prevention and clinical management of AMD.

---

Age-related macular degeneration (AMD) is a leading cause of blindness in the elderly with multifactorial etiology. Genome-wide association studies (GWAS) have identified > 50 independent risk variants for AMD but nearly half the heritability remains to be explained. To identify additional variants, we meta-analyzed four European ancestry GWAS, totaling 40,952 cases and 247,517 controls, using samples linked to electronic health records or ocular fundus examination from the Million Veteran Program (MVP) ( $n = 157,750$ ), the International AMD Genomics Consortium (IAMGDC) ( $n = 33,976$ ), the Genetic Epidemiology Research on Adult Health and Aging (GERA) Cohort ( $n = 28,588$ ) and the UK Biobank ( $n = 68,155$ ). Genotypes were imputed to the 1000 Genomes Phase 1 or Phase 3 reference panel. Fixed-effects and random-effects meta-analysis were conducted, combining GWAS results from logistic regression, adjusting for age (except MVP), sex and principal ancestry components.

GWAS results from 10,158,774 autosomal variants with minor allele frequency  $\geq 0.004$  revealed 54 genome-wide significant (GS) loci (index  $p < 5e-08$ ), 16 of which meeting genome-wide significance for the first time. Conditional association analysis revealed 72 independent GS variants. A total of 12,711 markers with  $p < 5e-08$  included 181 nonsynonymous and two stop-gain variants, with 47 coding variations classified as deleterious by SIFT or Polyphen score. The MVP also offered the ability to examine these loci in African Americans (AA, 1,247 AMD cases, 26,720 controls) and Hispanic

Americans (HA, 544 cases, 7,425 controls). While none of these loci met genome-wide significance in the GWAS of AA and HA, notably the *CFH* and *ARMS2* loci, 54% and 78% of the index markers showed consistent effect estimates in AA and HA, respectively.

Rare-variant analysis of the MVP cohort demonstrated that coding variants in the complement system occur more frequently in Europeans, whereas mutational profiles in AA and HA are not as strong for complement but do highlight new loci. Thus, our results were dominated by deleterious variants in complement genes in European ancestry individuals, but the two new ethnic groups provided novel insights into AMD biology.

This effort is the largest multi-ethnic genetic analysis for AMD. In summary, we have revealed fundamental differences in genetic architecture across different ethnic populations of US Veterans, a finding of potential clinical significance.

## PgmNr 2911: Novel score test to increase power in association test by integrating external controls.

**Authors:**

Y. Li; S. Lee

[View Session](#) [Add to Schedule](#)**Affiliation:** Department of Biostatistics, University of Michigan, Ann Arbor, MI.

---

Recent advances in genotyping and sequencing technologies have enabled genetic association studies to leverage high-quality genotyped data to identification of variants accounting for a substantial portion of disease risk. However, identifying potentially pathogenic less common variants requires a large sample size. The usage of external controls, whose genomes have already been sequenced and are publicly available, could be a cost-effective approach to increase the power of association testing. There has been a recent effort to integrating external controls while adjusting for possible batch effects. For example, the integrating External Controls into Association Test (iECAT) method, which uses an empirical Bayesian approach to combine external controls, has been shown to improve power while controlling type I error rates. The original iECAT test, however, cannot adjust for covariates such as age, gender, etc. Hence, based on the insight of iECAT, we propose a novel score-based test that allows for covariate adjustment and constructs a shrinkage score statistic that is a weighted sum of the score statistics using exclusively internal samples and using both internal and external control samples. Similar to the original iECAT test, we assess the existence of batch effect at a variant by comparing control samples of internal and external sources. We show by simulation studies that our method has increased power over the original iECAT while controlling for type I error rates. We present the application of our method to the association studies of age-related macular degeneration (AMD) utilizing data from the International AMD Genomics Consortium (IAMDGC) and Michigan Genomics Initiative (MGI). Through incorporation of the score test approach we extend the use of iECAT to adjust for covariates and improve power, further honing the statistical methods needed to identify disease-causing variants within the human genome.

Numerous susceptibility genes have been associated with the three most common allergic diseases (asthma, allergic rhinitis, eczema) but these genes explain only a part of the heritability. In the vast majority of genetic studies, complex phenotypes, such as the co-occurrence of at least two of these diseases in the same subjects (comorbidity), has not been considered. This may explain the missing heritability.

Our goal was to identify genetic variants specifically associated with the comorbidity of asthma plus eczema.

In a first step, we conducted a meta-analysis of four GWAS of the combined asthma plus eczema phenotype based on the Illumina 610K chip (total of 8807 European-ancestry subjects of whom 1208 subjects had both asthma and eczema). To assess whether the association with SNP(s) detected at the first step (threshold  $P=10^{-4}$ ) was specific to the asthma/eczema comorbidity, we conducted at a second step, a meta-analysis of homogeneity test of association according to disease status (presence of the two diseases "asthma plus eczema" versus the presence of only one disease "asthma only or eczema only"). On another hand, we used a joint test by combining the two test statistics from the disease-SNP association meta-analysis and the phenotypic homogeneity meta-analysis. Altogether, these analyses detected nine SNPs (of which seven were independent) showing significant association ( $P<3.10^{-7}$ , the significance threshold after correction for multiple testing).

These SNPs were located in seven genes, not previously detected for asthma or eczema. The most significant SNP ( $P=8.10^{-9}$ ) was located in *TBC1D14* associated with monocyte, leucocyte and eosinophil counts by previous GWAS. Moreover, eQTL data showed strong association between this SNP (and proxies) with *TBC1D14* expression in the blood, the skin and the esophagus mucosa.

We identified a SNP located in *TBC1D14* specifically associated with the comorbidity of asthma plus eczema. This gene is involved in both immune response and epithelial barrier mechanisms. Our study underlies the importance of studying sub-phenotypes as the comorbidity to detect new susceptibility genes.

## PgmNr 2913: Genome-wide association study of fluorescent oxidation products in asthma-ascertained families of the French EGEA study.

---

Oxidative stress is a major pathophysiological mechanism involved in asthma. Fluorescent oxidation products (FIOPs), a global and stable biomarker of damage due to oxidative stress, are of interest for epidemiological studies. Recently, they were found to be associated with expression and poor control of asthma in adults from the French Epidemiological study on the Genetics and Environment of Asthma (EGEA) (Andrianjafimasy et al, ERJ 2017). To date, no genetic study of FIOPs has yet been published.

The aim of the present study was to identify genetic loci associated with FIOPs.

We conducted a GWAS of FIOPs levels based on the Illumina 610 Quad array (Illumina, San Diego, CA) in 1216 adults (mean age 43 years old, 51% women, 37% with current asthma) from the second survey of the EGEA cohort study. FIOPs levels (geometric mean (Q1-Q3) = 92 (80-105) RFU/mL) were log-transformed and adjusted for age, sex and smoking prior to the GWAS. Association analysis between adjusted-FIOPs and SNPs used a generalized linear model to take into account the EGEA family structure; principal components to capture population ancestry were included in the model. This analysis was conducted in the whole sample and by stratifying according to asthma status (current asthma vs non-asthmatic).

In the whole sample, the two SNPs that showed the strongest associations, although not reaching the significance threshold of  $2.10^{-7}$ , were located in *BMP6* on chromosome 6 ( $P=3.10^{-6}$ ) and in *BMPER* on chromosome 7 ( $P=9.10^{-6}$ ). Interestingly, both genes were found to be strongly associated with lung function in previous GWAS and to interact with each other in a functional study. In the stratified analyses, among the top 10 SNPs showing suggestive evidence for heterogeneity according to asthma ( $P=9.10^{-6}$ ), two variants were located in *RRM2B*, a gene involved in the 'Response to oxidative stress' pathway. This gene has been previously associated with chronic obstructive pulmonary disease.

Overall, this first GWAS of FIOPs suggest promising genetic determinants previously associated with respiratory outcomes. Further replication is needed to confirm these findings.

## **PgmNr 2914: Integrated analysis of GWAS and mRNA expression array identified IFNG and CD40L as the most significant upstream-regulators in primary biliary cholangitis.**

Genome-wide association studies (GWAS) in European descents and East Asian populations have identified more than 40 disease-susceptibility genes in primary biliary cholangitis (PBC). However, the disease-pathways and their upstream-regulators remain to be elucidated. The aim of this study is to computationally identify the disease-pathways and their upstream-regulators in PBC by integrated analysis of GWAS and mRNA microarray in the Japanese population. Disease-pathways and their upstream-regulators were analyzed by Ingenuity Pathway Analysis (IPA) using the dataset 1 of GWAS (1920 PBC cases and 1770 controls) which included 261 annotated genes derived from 6760 SNPs ( $p$ -value<0.00001), and dataset 2 of mRNA microarray of liver biopsy specimens (36 PBC cases and 5 normal controls) which included 1574 genes with fold expression change>2 as compared to controls ( $p$ <0.05). Hierarchical cluster-analysis was also performed using dataset 2. There were 27 genes, 10 pathways, and 149 upstream regulators that were overlapped between the datasets 1 and 2. All of these 10 pathways were immune-related and the most significant common upstream regulators that are associated with disease-susceptibility to PBC were identified as IFNG and CD40L followed by B2M, SPIB, and FASL. The hierarchical cluster-analysis of dataset 2 revealed the presence of two distinct groups of PBC patients depending on their disease-activity, and the most significant upstream regulators that are associated with disease-activity were identified as IFNG and CD40L followed by IL6 and CC chemokine ligands and receptors. Our integrated analysis using GWAS and microarray datasets predicted that IFNG and CD40L are the most significant upstream-regulators in PBC. Further studies focusing on IFNG – and/or CD40L – pathways are needed to identify the new molecular targets for PBC patients.

## PgmNr 2915: Can you clap to the beat? Findings from the first genome-wide association study of rhythm in 606,825 individuals.

### Affiliations:

1) Vanderbilt University Medical Center, Nashville, Tennessee.; 2) 23andMe, Inc; 3) Max Planck Institute for Empirical Aesthetics, Frankfurt; 4) Center for Science and Society, Columbia University; 5) Department of Psychology, Michigan State University; 6) Department of Neuroscience, Karolinska Institute, Sweden; 7) Department of Biological Sciences, Vanderbilt University; 8) Department of Otolaryngology, Vanderbilt University Medical Center

**Background:** Over the last decade moderate heritability estimates for various measures of musical ability have been established, but the human genome variations underlying such traits are not yet well-defined. Obtaining a better understanding of the biological underpinnings forming causal influence from genes to brain function to musical behavior may result in significant clinical-translational applications, in light of recently amplified interest in music and health.

**Methods:** We conducted the first genome-wide association study (GWAS) to identify common genetic variants associated with a musical rhythm phenotype, i.e. “Can you clap in time with a musical beat?”, collected from 606,825 individuals participating in research with 23andMe, Inc. We also examined whether there was a shared genetic susceptibility of rhythm with other traits with publicly available GWAS as well as whether these associations were causal.

**Results:** 68 independent Single Nucleotide Polymorphisms (SNPs) reached genome-wide significance ( $p < 5 \times 10^{-8}$ ) and the observed SNP heritability was 0.05 (s.e.=0.0002). Integration of association results with GTEx gene expression across 30 tissue types showed that SNP associations were significantly enriched in the brain tissue and pituitary gland tissue gene set. There were 31 statistically significant genetic correlations between rhythm and other traits estimated from publicly available GWAS summary statistics. For example, increased genetic predisposition towards rhythm was correlated with greater hand grip strength ( $rg(\text{left})=0.18$ ,  $se=0.02$ ,  $p=3.6 \times 10^{-16}$ ,  $rg(\text{right})=0.16$ ,  $se=0.02$ ,  $p=6.91 \times 10^{-15}$ ), faster processing speed ( $rg=-0.16$ ,  $p=3.22 \times 10^{-13}$ ) and evening chronotype ( $rg=0.09$ ,  $p=3.8 \times 10^{-5}$ ). We partitioned heritability by functional annotation and found enrichment in many functional categories including regions conserved in humans and also in functional categories involved in acetylation of histone H3 at lysine 9 (H3K9ac), monomethylation of histone H3 at lysine 4 (H3K4me3) as well as intron annotations from Refseq gene models obtained from the UCSC Genome Browser

**Discussion:** Our study is the first to examine the genetic architecture of rhythm ability. Taking into account that the biological foundations of rhythm are deeply ingrained in humans, as is language, our

study paves the way for future research into the neurobiological pathways of this universal behavioral trait.

## PgmNr 2916: Does the size matter? Telomere length distribution in Italian isolated populations.

Whole genome sequence (WGS) data represent a valuable source of information in terms of genetic characterisation of an individual: it can be reliably used to identify both SNP variations and Structural Variations (SV), and also provide better resolution to study Copy Number Variations (CNV). Recently, computational methods have been developed to estimate the mean telomeric length (MTL) from WGS data. MTL is a highly heritable phenotype that has been associated with a wide range of phenotypes (from lifespan to age-related diseases and cancer) and with population ancestry.

This study aims to exploit high coverage WGS data to provide information on MTL distribution in different isolated populations from the North-East Italy, where several phenotypes, including age-related ones, are available.

The 'computel' software was used to generate preliminary data on a subset of 400 samples on genome-wide MTL. MTL measurements ranges from 1,186 kb to 6,410 kb (mean=2,563 kb; sd=0,808 kb), with a negative correlation (Pearson correlation coefficient  $R=-0.31$ , p-value=  $2 \times 10^{-11}$ ) with samples' age, as expected. Moreover, on a subset of 131 samples, where sensory phenotypes are available, logistic or linear regressions (sex and age adjusted) were applied to verify the association between MTL and age-related phenotypes. The MTL resulted a significant predictor for the capacity to discriminate following odours: peppermint (p-value=0.041), lemon (p-value=0.034), rose (p-value=0.0036) and fish (p-value=0.0040). In addition, MTL showed a suggestive p-value (=0.063) when the association with smell impairment (defined as the total number of errors in odours discrimination) was tested.

Since the ageing process is strongly related to sensory decay, the study on MTL can contribute to a better understanding of this phenotype as well as relationships with other age-related traits and diseases. This approach could also help to define an "optimal" MTL length, which strikes a balance between the advantages and disadvantages of having long vs short telomeres.

## PgmNr 2917: Back to the future: Advancing disease mapping through efficient use of founder effects.

Large biobanks coupled with technology advances allow for a new era in disease mapping through implicit shared haplotypes. Founder effects are well-known, but have been little-used for disease gene mapping. They can be used within the framework of population-based linkage analysis to identify shared genomic segments between apparently unrelated individuals. However, its broader use requires crucial progress in analytical efficiency. We have recently developed TRUFFLE (Dimitromanolakis et al., AJHG 2019) for fast and accurate identification of shared genomic segments, suitable for studies with hundreds of thousands of individuals. TRUFFLE does not need phased data, and a built-in error model corrects for segment break-ups that occur because of genotyping errors.

Rarely was information from haplotype sharing across families used to map genes in which variants cause simple Mendelian diseases, due to the low resolution of genotyping and low frequency of founder variants. As proof-of-principle for disease mapping we revisited the extent of haplotype sharing for a classic autosomal recessive Mendelian disease, cystic fibrosis, which is caused by mutations in the Cystic Fibrosis (CF) transmembrane conductance regulator (*CFTR*) and was originally fine-mapped using haplotypes. We applied TRUFFLE to Illumina 660 GWAS data from 2,436 individuals with CF from the Canadian CF Gene Modifier study where CF-causing variants were not genotyped. We varied the length of segments (from 700 kb to 5 Mb) to detect IBD segments around *CFTR* to determine the likely optimal size of shared haplotypes. At lengths of <2 Mb we see evidence for excess sharing around *CFTR*, and this becomes stronger and narrower as we reduce to 700 kb. Even at this length, we do not see excess sharing at other regions in the genome, except at HLA. Since a single common variant (rs113993960, deltaF508) accounts for the majority of disease causing variants at *CFTR*, we also examined sharing patterns in the subset of individuals with this variant. We see a stronger and narrower signal at *CFTR* when the analysis is restricted to individuals carrying the variant allele at rs113993960. As expected, other *CFTR* disease-causing variants show different lengths of shared segments due to their different ages and recombination histories. Founder effects are typically only discovered after the disease gene have been identified. The proof of principle that we present here suggests that it could enable disease gene mapping.

## PgmNr 2918: Understanding the role of gene expression in multiple tissues in stratifying blood protein levels.

More and more studies are relying on integrating transcriptomics data, in the form of eQTLs, in order to provide more power for the discovery of causal loci and provide evidence of biological function. However, despite their use in examining differential expression there is increasing evidence that eQTLs do not predict translated protein levels effectively. This is believed to be due to the many layers of control that exist between transcription and protein translation. This includes multiple splicing variants, the existence of *trans*-eQTLs, mRNA half-life, and the rate of translation which can be influenced by a number of factors. Another possibility is that the protein levels in specific tissues may be modulated by exportation of proteins from one tissue to another. To test this hypothesis we first created *cis*-expression polygenic scores (*cis*-PGS) for each gene in each tissue utilising GTEx eQTL data and verified their ability to predict circulating protein levels for approximately 1000 proteins measured in ORCADES. In order to maximise our prediction ability we first compared two methods for creating *cis*-PGS: PrediXcan and LDpred. This analysis had mixed results and shows that the two methods perform equally well. Then when comparing the predictive scores for specific tissues, the whole blood eQTLs only best predicted the blood proteins in 6% of genes suggesting that the source of most circulating proteins needs to be sought elsewhere. We then created a “multi-tissue” model by fitting a multivariable model which included all *cis*-PGS for each gene using the blood protein as the outcome and evaluating prediction through cross validation. The multi-tissue model had a higher predictive power in 54% of the 711 tested genes suggesting that in many cases the circulating protein levels are the result of the production of several different tissues. In conclusion we have shown that LDpred and PrediXcan have similar performances in creating *cis*-PGS suggesting that LDpred can be used without requiring raw data. Moreover, we have shown that in many cases using a multi-tissue approach seems to improve prediction of circulating protein levels and may at least partly explain the relatively low predictive power of *cis*-eQTLs.

## PgmNr 2919: Methods for analysis of inheritance of multiple complex diseases in families.

Families often suffer from a collection of common conditions, some of which may be due to shared environments and some of which due to shared genetics, i.e. pleiotropic genetic effects. In contrast to studies that seek to identify within individual pleiotropy, we are interested in identifying pleiotropic relationships within families using family health histories (FHH). Standardized collection of FHH in primary care represents a source of pedigrees well suited for exploring clusters of common complex diseases.

The web-based FHH collection tool, MeTree®, was used to collect FHH for two patient cohorts: Dataset 1 (DS1) with 1608 primary care patients for 44 conditions and Dataset 2 (DS2) with 1889 primary care patients for 91 conditions. In DS1 and DS2 respectively, patients averaged 25 and 13 relatives per family, 2.4 and 2.1 conditions for themselves, and 0.78 and 1.12 conditions per relative. We estimated the risk to first-degree relatives (FDR) for pairs of conditions by modeling disease A in the FDRs (within family counts/proportions) with disease B in the proband using nonparametric rank correlation (NP) and two parametric models: Bayesian generalized linear models with logit (BLGLM) and Poisson (BPGLM) links, adjusted for family size, age, sex, and race. The BPGLM and BLGLM results were concordant in DS1 but not in DS2. When disease A (FDRs) and disease B (proband) are the same, we expect significant positive associations in disease presence, due to heritability. In the DS1 and DS2 BPGLM results, respectively, 40 of 44 and 84 of 91 diseases were significantly, positively associated. In the DS1 and DS2 NP results, respectively, 43 of 44 and 90 of 91 diseases were significant. In the disease combinations for which disease A and B were different, there were 59 of 2068 and 194 of 8645 significant disease pairs in the BPGLM results. The NP findings had a number of significant discordant disease pairs (55 of 2068 and 272 of 8645, DS1, DS2, respectively). Within disease associations were detected by all methods, however the higher number of diseases detected by the NP approach may be due confounding (e.g. age, race); the two parametric approaches yielded consistent results in DS1 but not DS2. These suggest that FHH clustering analysis is robust to method selection for high heritability conditions, is sensitive to method selection for lower heritability conditions and/or noise, and can be used to study familial pleiotropy in high heritability conditions.

## PgmNr 2920: Modifying sample splitting in ComPaSS-GWAS for improved performance on rare SNP applications.

**Authors:**

J.A. Sabourin; A.F. Wilson

[View Session](#) [Add to Schedule](#)

**Affiliation:** Genometrics Section, Computational and Statistical Genomics Branch, NHGRI, NIH, Baltimore, MD

---

ComPaSS-GWAS [Sabourin et. al., 2019] is a method that uses repeated sample splitting to identify SNPs that are corroborated across random splits as an approximation to replication when appropriate replication data are not available. However, for rare or very rare SNPs, sample splitting can by chance, leave too few (or no) subjects with the minor allele in one of the sample splits to allow for corroboration, reducing the SNPs score. This reduces both the type I error rate and power to detect rare SNPs with ComPaSS-GWAS. In this study we present a modification to ComPaSS-GWAS, ComPaSS-rare, that replaces sample splitting with the use of complementary random weights, motivated by the weighted likelihood bootstrap. In ComPaSS-rare, the two halves determined by complementary weights are not independent and the theoretical squaring of  $\alpha$  can't be applied, so the parameter value ( $\alpha$ ) for ComPaSS-rare must be appropriately adjusted.

Two simulation studies were performed. In the first, the rare variant modification (ComPaSS-rare) was applied to the common variant simulation model from the previous study [Sabourin et al 2019] which was based on a typical GWAS on SNPs with  $MAF \geq 0.01$ ; causal SNPs had MAFs of 0.05. In the simulations for common variants, there was consistent performance for type I error and power for traditional GWAS, ComPaSS-GWAS and ComPaSS-rare, suggesting that the modification for rare SNPs does not significantly change the performance of the method for common SNPs. The second simulation was based on the GAW19 whole exome sequencing data that focused on rare SNPs with MAF between 0.0025 and 0.05 with causal SNPs having MAFs of 0.005. Under this model, the traditional GWAS with critical value of  $5 \times 10^{-8}$  showed inflated type I error rates on SNPs with  $MAF < 0.01$  and ComPaSS-GWAS had reduced power and type I error rates for rarer SNPs due to sample splitting issues. However, ComPaSS-rare had type I error and power consistent with the traditional GWAS over all MAF ranges. Based on these results we believe the modified procedure, ComPaSS-rare, is appropriate for analysis of both common and rare SNPs, and has improved performance for analysis of rare SNPs that are more prevalent in association studies with sequencing data.

## PgmNr 2921: Mediation analysis of high-dimensional phenotypes.

---

A variety of statistical methods exist for testing global association between a genetic variant (or set of variants) and a collection of correlated phenotypes, in order to leverage pleiotropy for more powerful gene mapping. However, if such a test is significant, there is subsequent interest in assessing whether the cross-phenotype effect is due to biological pleiotropy or mediation pleiotropy. Given a significant cross-phenotype association between a SNP and two phenotypes (P1 and P2), biological pleiotropy implies that the SNP has direct effects on both P1 and P2. Mediation, on the other hand, considers the possibility that P1 lies in the pathway between the SNP and P2 so that part of the association between SNP and P2 can be indirectly explained by the direct relationship with P1. Here, we propose novel kernel-based methodology to identify whether an observed association between a variant (or a group of variants within a gene) and possibly high-dimensional phenotype data is completely or partially mediated by a different set of high-dimensional phenotypes. Our mediation-based approach is novel in that it can handle high-dimensional genetic data, mediators, and outcome variables. The method further adjusts for covariates. We show that our method controls for type I error and is powerful to detect a variety of mediation scenarios in simulated data. We further apply our mediation technique to multivariate symptom data from the Beck Depression Inventory (BDI) that were collected as part of the Grady Trauma Project GWAS. We show that initial cross-phenotype associations between a candidate risk locus and the 21-item multivariate BDI outcome can be partitioned into 3 symptoms directly associated with the locus while the remaining 18 symptoms are only indirectly associated.

## PgmNr 2922: A cross-trait genetic risk prediction framework leveraging biobank-scale GWAS summary statistics.

---

Polygenic risk score (PRS) methods have quickly gained popularity in human genetics research due to its simplicity and robustness. However, despite recent advances in the estimation of variant effects and variant prioritization using biological annotation information, PRSs for most complex traits remain only moderately predictive. It has been demonstrated that jointly modeling multiple traits could effectively improve the predictive power of PRS. However, existing methods can be applied to only a small number of traits. Therefore, summary statistics from large-scale biobanks cannot be effectively utilized. Here, we introduce a principled framework to jointly model thousands of GWASs from large biobanks to improve the prediction accuracy of PRS. We adaptively prioritize thousands of traits in the UK biobank based on their genetic correlations with the phenotype of interest, jointly model each selected trait and the main phenotype to re-estimate variant effects, and compute a re-weighted PRS that combines information across many genetically correlated traits. Through extensive simulations, we demonstrate that our method provides significantly increased prediction accuracy compared to state-of-the-art single- and multi-trait PRS models, especially under sparse genetic architecture. We applied this framework to breast cancer (BC), celiac disease (CEL), Crohn's disease (CD), rheumatoid arthritis (RA), and type-II diabetes (T2D), and evaluated the predictive performance of our method using external cohorts independent from the input GWAS. For each disease, we integrate the GWAS summary statistics with more than 4,000 traits from the UK biobank. We show that our method substantially outperforms single-trait methods including standard PRS with fine-tuned p-value cutoffs and LDpred, and multi-trait methods such as PleioPred. Furthermore, we illustrate that weighing PRSs based on the level of genetic similarity could further strengthen predictive power. In particular, as we adopt a more stringent trait-selection criterion based on genetic correlation, our method produces consistently more predictive risk scores for multiple diseases. Finally, our method does not include tuning parameters and is computationally efficient. We believe this method could have wide applications in genetic prediction applications.

## PgmNr 2923: Genome-wide mapping for palpebral fissure inclination.

Palpebral fissure inclination (PFI; i.e., eye inclination), defined as the angle between the line connecting the medial and lateral canthi and the horizontal plane, varies remarkably in humans based on age, gender, and ethnicity. Additionally, genetic disorders often present with extreme PFI. However, there is limited information about the genetic basis of normal PFI variation. We aimed to identify genetic variants for three PFI measures (right eye angle, left eye angle, and combined angle) in a sample of 2210 healthy individuals of European ancestry using three complementary genetic approaches: (1) Genome-wide association study (GWAS), testing common variants (MAF > 5%); (2) Genome-wide gene-based association analysis of low-frequency variants (MAF < 5%) in aggregate; and (3) *In silico* candidate gene study based on the published literature of genetic disorders that often present with extreme PFI (e.g., CHARGE syndrome, Glass syndrome) and prioritizing putatively functional variants. Participants were genotyped on the Illumina (San Diego, CA) HumanOmniExpress+Exsome v1.2 array. No genome-wide significant associations were observed ( $p < 5E-8$ ). However, several suggestive signals ( $p < 1E-5$ ) were observed near genes with potential biological roles in facial morphology, such as *TENM2*, *CHD9*, *SLC23A2*, *CNTN1*. Results for low-frequency variants and candidate genes will be presented. Understanding the genetic architecture of PFI may yield insights into the mechanisms impacting facial morphology and aid in the assessment of facial dysmorphology in the clinical setting.

## PgmNr 2924: A SVM-based ancestry inference method for large-scale genetic data.

---

Ancestry inference in genetic studies has been routinely performed for the purpose of quality control and reduced population stratification effects in association analyses. We present our integrative implementation of a support-vector-machine (SVM)-based method to identify the most likely ancestral group(s) for an individual by leveraging known ancestry in a reference dataset (e.g., the 1000 Genomes Project data). Our method involves first projecting each study sample to the principal component (PC) space of a reference dataset, followed by training and classifying the ancestry of each study sample using an SVM algorithm. This algorithm has been well integrated in the computationally efficient tool, KING. To evaluate the performance of our ancestry inference method, we conducted a simulation study using simuPOP, a forward-time simulation tool. For 9 simulated HapMap populations, our SVM-based tool had 100% accuracy in classifying ancestry. To further investigate the performance of our SVM-based ancestry inference method as implemented in KING, compared to peddy, another SVM-based method, we analyzed 13,181 participants who were genotyped with the Illumina HumanCoreExome array (with GWAS backbone) as well as the Illumina ImmunoChip (a custom fine-mapping array covering 186 loci). The inferred ancestry is identical in 95.4% (N=12,574) of subjects across 3 different analyses: 1) HumanCoreExome array data with KING; 2) ImmunoChip array data with KING; and 3) HumanCoreExome data with peddy. The consistency in our ancestry classification suggests that the example data consists of EUR (78.6%), AFR (9.3%), AMR (6.1%), SAS (3.4%), and EAS (2.6%) ancestry samples. In comparison, the ancestry inference from ImmunoChip array data using peddy is substantially less reliable than the three other inference approaches: 15.3% of these 12,574 subjects are inferred as unknown, and another 16.4% are inferred as AMR, instead of EUR as consistently inferred by all three other inferences. This analysis demonstrates that the KING implementation of the SVM-based ancestry inference method can provide accurate and consistent inference across different genotyping platforms. Further, the implementation of the approach in KING is orders of magnitude faster than existing methods and is scalable to large datasets with sample size beyond one million subjects (17 minutes to classify ancestry for all subjects in a dataset consisting of 1 million samples on our server with 96 CPU cores).

---

**Introduction:** Polygenic scores (PGS) aggregate the effects of hundreds-to-millions of variants across the genome into a single score and have been shown to have predictive value for many common diseases and traits. Studies have shown that PGS (e.g. for Coronary Artery Disease; CAD) can provide independent risk stratification when included into models with traditional risk factors (age, smoking, cholesterol, etc.) and family history. PGS are actively being translated into the clinic; however, adoption has been hindered by inadequate annotation and availability, variable or incomplete benchmarking of multiple PGS for the same disease, and variable performance in diverse populations.

**Objective:** A complete understanding of each PGS and its predictive value is necessary for its application; however, no central resource of consistently annotated PGS exists. In collaboration with the NHGRI-EBI GWAS Catalog, we are developing the PGS Catalog to increase the transparency and reproducibility of PGS by distributing the information necessary for both research and translational uses of PGS for a wide range of diseases and traits.

**Methods:** Initially, we have focused on cataloging PGS that have been developed for five well-studied traits (CAD, diabetes (types 1 and 2), obesity/BMI, breast cancer, and Alzheimer's) based on their potential clinical utility and public health burden of the disease.

To populate the PGS Catalog we reviewed the literature for purpose-built PGS developed after 2010. We have defined and extracted metadata describing each PGS (e.g. SNP rsID, effect allele, effect size), as well as how it was developed and applied. This includes direct links to the GWAS Catalog study (sample size, ancestry, cohorts) used to develop the score, characteristics of the training and

validation cohorts, and reported accuracy of the PGS.

**Results & Future Directions:** We have developed a framework to consistently summarise and represent PGS, to be housed in a publicly accessible database. The pilot PGS Catalog currently contains over 100 consistently extracted PGS for our five disease areas. We seek community feedback and are inviting PGS researchers to submit their PGS to increase coverage and maximize the utility of their scores. With the PGS Catalog, we intend to provide a complete picture of the predictive accuracy of all available PGS in external population cohorts and distribute directly comparable performance metrics between scores as part of the complete Catalog.

## PgmNr 2926: Whole exome sequences reveal rare and common variants associated with 1102 plasma proteins.

---

Proteins are major drivers of all biological processes. Blood plasma proteins reflect the proteomes of a wide variety of cells, providing an insight into physiological processes occurring in diverse biological systems. Therefore, they are potentially useful biomarkers of various diseases. Combining proteomics with protein-altering variation captured by whole exome sequencing provides an opportunity for a more direct insight into mechanisms behind complex traits and diseases.

We performed exome-wide association analysis of 1,102 proteins measured using OLINK proximity extension assays in plasma from 1059 individuals from the genetically isolated ORCADES cohort (Scotland) and whole exome sequencing (WES) generated by the Regeneron Genetics Center. We found 3,545 significant ( $p \leq 4.5 \times 10^{-11}$ ) associations between 374 proteins and 968 genes mapping to 377 genomic regions, where a region was defined based on all significant associations within 1Mb from the strongest association in the region. 5% of associations were with low frequency variants (MAF<0.05). Of the 374 proteins, 237 (63%) had *cis* associations only, 88 (24%) *trans* only and 49 were associated with two loci - 26 (7%) *cis* and *trans*, 23 (6%) *trans*. Overall, 171 sentinel variants are missense, with 5 resulting in gained or lost stop or start codons. 136 of our sentinel pQTL variants were in high LD ( $r^2 \geq 0.8$ ) with disease-associated variants. Association of very rare variants was assessed using aggregate tests and revealed further loci influencing the proteome.

Given the direct role of proteins in various biological processes and more interpretable functional consequence of WES variants, genetic associations of a large number of proteins and protein-altering variants provide not only a basis for understanding mechanisms behind complex traits and diseases, but also provide a framework for assessment of causality of individual biomarkers.

# PgmNr 2927: A method for rare variant burden analysis using case-only exome data.

---

## Background:

Rare variants have been shown to contribute to many sporadic genetic disorders, motivating systematic genome-wide sequencing studies for complex traits. The standard designs include family-based trios for the analysis of *de novo* mutations (DNMs), or case-control (CC) cohorts. A main challenge in DNM and CC analysis is the necessity for availability of family members or controls matched for ethnicity and sequence coverage respectively.

## Hypothesis:

Based on the assumption that ultrarare variants are likely to be recent DNMs, we developed a statistical framework for performing a burden analysis of rare variants with case-only dataset.

## Methods:

Exome sequencing: Genomic DNA was captured using Roche or IDT kit, sequenced on Illumina platforms. Variants were called using GATK.

Identification of rare variants: We identified very rare qualifying variants (gnomAD MAF < 10<sup>-5</sup> and internal cohort MAF < 10<sup>-3</sup>).

Mutational model: We calculated mutation rates based on both sequence context and genomic features according to mutation type considering 7-mer sequence context.

Adjustments to the mutational model: We calculated mutation rates per gene using the estimated mutation rates while adjusting for the observed coverage, deleteriousness of missense variants and regional intolerance to mutation.

Modelling rare variant events: We modelled the observed number of variants per gene using a Poisson distribution, with the expected number of variants per gene calculated based on the fitted values from a polynomial regression model.

## Results:

As a proof of concept, we applied this statistical framework to detect rare mutations in a published cohort of 553 patients with chronic kidney disease that had been analyzed under a CC design. We recovered all the top genes from the CC analysis such as *PKD1*, *PKD2* and *COL4A5* analysis. In addition, we detected several suggestive candidate genes not previously identified in the CC collapsing analysis - *PKD1L2* (P=2.19E-03; Deleterious Missense), *COL27A1* (P=2.84E-03; Non-benign Missense) and *COL6A3* (P=3.60E-03; Non-benign Missense). We are now extending this analysis to other published datasets to validate the approach.

## Conclusions:

The current statistical model based on the probabilities of mutation of rare variants extends the conceptual framework of DNM and CC analysis and provides a robust and cost-effective approach for rare variant burden analysis by utilizing case-only exome data when family member or control samples are not available.

## PgmNr 2928: Genetic variants and candidate genes for nonsyndromic cleft palate detected by whole-exome sequencing.

### Authors:

### Objective:

Genetic factors modifying the nonsyndromic cleft palate only (NSCPO) have been investigated through genome-wide association studies (GWAS) of common genetic variants. However, these variants explain only a fraction of NSCPO heritability.

### Methods:

We conducted a whole-exome sequencing study of common, low-frequency and rare variants to associate genetic variations with NSCPO in 126 cases and 2,827 controls. Single-variant association analysis were performed using a logistic regression model. Burn tests were carried out for coding variants with a minor allele frequency less than 0.01. Pathway enrichment analysis were based on KEGG database. Associated genes were tested for pathway enrichment using Kyoto Encyclopedia of Genes and Genomes (KEGG) database.

### Results:

Twenty-five SNPs reached the genome-wide significance ( $P < 5E-08$ ) and exhibited  $P < 0.05$  after Bonferroni correction. Gene-based analysis revealed that *APOE?KLHDC9?KIF1A* might account for the association with NSCPO risk ( $P < 1E-04$ ). Pathway enrichment analysis indicates that protein digestion and absorption pathway ( $P = 2.31E-03$ ), dilated cardiomyopathy ( $P = 6.03E-03$ ), arrhythmogenic right ventricular cardiomyopathy (ARVC) ( $P = 6.28E-03$ ), and hypertrophic cardiomyopathy (HCM) ( $P = 4.21E-02$ ) reached the thresholds of adjusted  $P$  value  $< 0.05$ .

### Conclusion:

Our results highlight the important role of common and low-frequency variants play in NSCPO susceptibility and indicate that candidate genes and pathways are potentially biologically relevant to NSCPO.

## PgmNr 2929: Integrating eQTLs to identify SNP associations in whole-genome sequencing association studies: A genetic study of platelet aggregation.

---

GWAS studies have successfully identified thousands of SNPs associated with complex traits, however identifying the functional elements through which these genetic variants exert their effects remains a critical challenge. Recently, there is increasing evidence that SNPs associated with complex traits are more likely to be expression quantitative trait loci (eQTLs). Thus, incorporating eQTL information can potentially improve power in highlighting causal genes. Our goal was to investigate the potential to detect novel risk loci among eQTLs only. Our data was comprised of nine platelet aggregation traits from the GeneSTAR family-based study, with whole genome sequencing (WGS) data in European Americans (EA) and African Americans (AA). RNA-seq data were generated from extracted non-ribosomal RNA from 185 (84 AA, 101 EA) iPSC derived megakaryocyte cell lines and 290 (110 AA, 180 EA) platelet samples. We fit a linear mixed model for genetic association within each racial group, including age, sex, principal components for ancestry and random effects from genetic relatedness. We conducted fixed effects meta-analysis using summary statistics in the EA and AA groups. Since eQTLs typically exhibit very strong patterns of linkage disequilibrium, we performed permutation analysis using 1000 permutations for all nine traits to obtain family-wise error rates for eQTL SNPs, substantially lowering the genome-wide significance threshold compared to standard Bonferroni threshold. Our analyses confirmed known platelet aggregation loci such as PEAR1, ADRA2A and ARHGEF3. A number of novel genetic loci were also identified: ADAM22, APIP, ARAP2, BANF2, C6orf195, CBLN2, CEP68, CTNNA1, GPR98, GTF2IRD1, HIVEP2, IMPG2, LOC642236, MACROD2, NT5C1B-RDH14, PI4KAP1, RAB1A, RPTOR, SENP7, SLC1A4 and TMEM120B. Our future work entails exploring Bayesian GWAS by incorporating eQTL information to detect novel risk loci. Our study has the potential of identifying associated SNPs that underlie biological control of gene expression and genes involved in platelet aggregation.

# PgmNr 2930: Multivariate generalized Levene's test for detecting latent gene-gene or gene-environment interactions.

---

**Introduction:** Complex traits are influenced by a combination of multiple genes and environmental factors, including gene-gene (GxG) or gene-environment (GxE) interactions. Current multi-SNP GxE tests (e.g. iSKAT of Lin et al. 2016) consider a single environmental factor and assume that the exposure data have been collected. However, relevant exposures may be unmeasured.

**Methods:** Here, we extend the generalized Levene's scale test (Soave and Sun 2017) to jointly study the potential latent interaction effects between multiple SNPs and one (or multiple) environmental factor(s) using a two-stage regression approach. The first stage models the main effects of a set of SNPs on a complex trait and obtains the residuals. The expected values of the absolute residuals from the first-stage are related to phenotypic variances, while in the presence of un-modeled, latent multivariate GxE interactions, the phenotypic variances differ between genotype groups. Thus, the second stage regresses the absolute residuals on this set of SNPs again and tests for the association, for example, using the classical F-test or variance-component type of tests.

**Results:** Simulation studies confirm that our method, the multivariate generalized scale test (MGS), has good power when the environmental factor is not available; and it outperforms direct GxE interaction tests when there are measurement errors in the environmental factor. We also identified type 1 error issue in several direct GxG or GxE interaction tests under the empirical null simulation design as opposed to the theoretical null design (Zhang and Sun 2018), while MGS maintains a correct type 1 error control.

**Conclusion:** The proposed multivariate generalized scale test can potentially serve as a useful tool to identify if any GxE or GxG interaction effects exist, and to identify phenotype-associated genetic variants that might have been missed if the interacting exposure variable(s) were not collected or measured with errors.

## PgmNr 2931: A genome-wide meta-analysis identifies novel loci associated with NSCL/P in Asian population.

Nonsyndromic cleft lip with or without cleft palate (NSCL/P), which is one of the most common human birth defects, involves complex etiologies including genetic and environmental factors. So far, previous genome-wide association study (GWAS) research has found considerable loci with significant genetic significance. However, known variants account for a small percentage of the estimated heritability in risk to these craniofacial birth defects. We performed meta-analysis using four GWAS research databases about Asian population, including two case-control studies from our previous research and two case-parent trio subgroups analyzed by transmission disequilibrium test (TDT) from dbGaP. Fourteen loci reached genome-wide significance, of which six loci have been reported previously, while eight loci (rs6016400, rs9891446, rs6686599, rs1209515, rs9530361, rs1685144, rs596731, rs4751616) were novel. To evaluate the genetic effect of eight loci in NSCL/P risk prediction, we constructed the weighted genetic risk score (wGRS) model, which showed higher wGRS in cases than that in controls among Hua Xi case-control study ( $P=1.56 \times 10^{-13}$ ). It was also confirmed that these eight loci would improve the ability of risk prediction ( $AUC_{6\text{loci}}=0.630$ ,  $AUC_{14\text{loci}}=0.652$ ,  $P=0.011$ ) in the same cohort. In conclusion, This study indicated eight novel loci for NSCL/P susceptibility in Asian population, which can serve as a general and useful reference for further genetic research.

## PgmNr 2932: Ancestry mapping across known primary open-angle glaucoma loci.

---

Primary open-angle glaucoma (POAG) is a leading cause of blindness worldwide; it is a complex disease with known risk factors including age, race/ethnicity, and genetics. Of >100 risk loci for POAG and/or related endophenotypes, most were found in European-descent samples, despite the fact that POAG risk is >2x higher in those of African descent. To increase diversity of POAG-focused genetic studies, we evaluated ancestry differences in known POAG loci in a small sample of African Americans. DNA samples were obtained and extracted by standard methods from 236 African Americans previously recruited in Cleveland, Ohio with glaucoma evaluation. Samples were genotyped on the Illumina Infinium® Expanded Multi-Ethnic Genotyping Array. Excluding individuals with genotyping rates <98%, sex discrepancies, estimated African ancestry <20%, and related individuals, 190 remained for analysis. Variants with a minor allele frequency (MAF) >0.05, Hardy-Weinberg Equilibrium p-value >0.0001, and missingness <1% were retained, resulting in 689,084 variants with genotyping rate =0.9995. Phasing was performed with Eagle 2.3 (1000 Genomes Phase 3 reference [1000G3]) and merged with 1000G3 CEU and YRI subpopulations. Across 267,317 variants with reference MAF >0.05 and  $F_{ST}$  >0.1 between CEU and YRI, RFMix was used to estimate local ancestry inference (3 EM iterations, node size 2, window size 0.2cM). The expected number of YRI alleles were estimated from RFMix forward-backward probability estimates. Global ancestry was estimated by summing the expected number of YRI alleles weighted by distance between markers divided by 2. Admixture mapping tests were limited to known POAG loci  $\pm$ 50kb. Associations were estimated with logistic regression models adjusted for global African ancestry proportion. *COL8A2*, *AXTN2*, and *FERMT2* had p-values <0.05. Within *COL8A2*, the strongest positive association between YRI ancestry and affected status had  $\log(OR)=0.832$ ,  $SE=0.410$ ,  $p=0.0423$ . *AXTN2* and *FERMT2* were negatively associated with YRI ancestry with  $\log(OR)=-0.635$ ,  $SE=0.317$ ,  $p=0.0450$  and  $\log(OR)=-1.141$ ,  $SE=0.529$ ,  $p=0.0309$ , respectively. A negative association was also detected in an intergenic region near *SPTSSA* at chr14:34774848,  $\log(OR)=-1.073$ ,  $SE=0.508$ ,  $p=0.0348$ . We aim to use this project as a catalyst for understanding the genetic difference that specifically increases POAG risk in individuals of African ancestry.

## PgmNr 2933: Genome- and environment-wide study of red meat consumption in 23andMe research participants.

### Authors:

B. Cameron; Y. Huang; K. Fletez-Brant; R. Gentleman; S. Aslibekyan; 23andMe Research Team

**Affiliation:** 23andMe, Mountain View, CA.

A large body of evidence links red meat consumption to increased risk of chronic diseases and all-cause mortality. Dietary habits cluster in households, but known sociodemographic factors explain only a modest fraction of red meat intake variation. Notably, the genetic basis of red meat intake has never been comprehensively assessed. The 23andMe research database provides a rich opportunity to characterize both genetic and environmental contributions to red meat intake.

In the present study, we conducted the first genome-wide association study of red meat intake in 23andMe research participants of European descent. Red meat intake was separately assessed by the 23andMe Health Profile survey (N=2,135,523) and the NHANES dietary screener (N=420,037, non-overlapping). Linear regression models adjusted for age, sex, age\*sex interaction, ancestry principal components, and genotyping chip. We identified 126 independent hits ( $P < 5 \times 10^{-8}$ ) for red meat consumption in the Health Profile data. Reproducibility was defined as  $P < 0.05/126 = 0.0004$  with consistent direction of effect across data sets for the same variant. Under that definition, we replicated 38 of 126 hits in the smaller NHANES sample. Furthermore, in the UK Biobank data (N~360,000) we replicated 15 hits for processed meat, 14 for beef, 6 for lamb, and 6 for pork intake. Top replicated hits included rs35866622, a coding variant in MAMSTR ( $\beta = -0.017$ ,  $P = 2.9 \times 10^{-33}$ ), rs276454 in CCDC171 ( $\beta = -0.017$ ,  $P = 1.5 \times 10^{-31}$ ), rs429358, a coding variant in APOE ( $\beta = 0.02$ ,  $P = 1.6 \times 10^{-23}$ ), and rs537249739 in HIST1H2BD ( $\beta = -0.015$ ,  $P = 7.8 \times 10^{-21}$ ); all four peaks listed above were robust to additional adjustments for BMI.

We also tested associations between 685 lifestyle, clinical, and socioeconomic phenotypes and red meat intake in 23andMe research participants. Environment-wide models adjusted for age, sex, age\*sex, ancestry principal components, and cohort entry time. The strongest associations (all  $P < 10^{-300}$ ) were identified between red meat intake and other dietary variables (e.g.  $\beta$  per SD of fast food exposure=0.25), health habits (e.g.  $\beta$  per SD of packs smoked/day=0.09), fertility (e.g.  $\beta$  per SD of number of children=0.07), and obesity (BMI > 30;  $\beta$  per SD=0.13). Our findings provide novel insights into dietary behavior of US consumers, informing future causal (e.g. instrumental variable) studies of red meat in disease etiology and highlighting potential intervention targets.

Recent work has highlighted the need to evaluate the impact of environmental factors in complex traits with uncertain genetic aetiology. AncestryDNA has the largest genomic database in the world, with more than 15 million customers genotyped, many of these individuals participating in our Personal Discoveries Project® (PDP), a survey platform. The survey data collected from customers who have consented to participate in scientific research include responses about traits with low heritability (i.e. liking to sing and dance) and more heritable traits, such as eye color or hair color, for which environmental influences may outweigh genetics. These environmental influences among individuals can be characterized by demographic factors such as age, birth, cultural factors, and current geographic locations. Genetic ancestry and genetic communities, or groups of individuals identified to be more genetically similar than others in our database and representing a more recent fine-scale population structure, may also have an impact on these complex traits. Collaborative filtering methods were used to investigate whether the similarities between individuals' genetic information and shared environmental factors are related to the similarities of their survey responses. Here we present a novel approach to assessing the impact of shared environment in complex traits. Results suggest similarities across consistencies between survey responses and genetic information for these individuals, but the levels of consistency vary between traits with low heritability and more heritable traits.

1) Research Unit, Centro de Educación Médica e Investigaciones Clínicas-Consejo Nacional de Investigaciones Científicas y Técnicas (CEMIC-CONICET), Buenos Aires, Argentina; 2) Estudio Colaborativo Latino Americano de Malformaciones Congénitas (ECLAMC), CEMIC-CONICET, Buenos Aires, Argentina; 3) Instituto Nacional de Genética Médica Populacional (INAGEMP), CEMIC-CONICET, Buenos Aires, Argentina; 4) Department of Neonatology, Instituto de Maternidad y Ginecología Nuestra Señora de las Mercedes (IMGNSM), Tucumán, Argentina; 5) ECLAMC, IMGNSM, Tucumán, Argentina

Preterm birth (PTB) is defined as birth before 37 gestation weeks. It is the leading cause of perinatal morbimortality worldwide. It is estimated that 9,60% of all births in the world are preterm. Due to spontaneous PTB etiological heterogeneity, previous epidemiological genetic studies suggest their discrimination by clinical subtypes: preterm labor leading to PTB (PTB-I) and premature rupture of membranes (PTB-PPROM). The aims of this study is to evaluate the fetal and maternal haplotypes effects on spontaneous PTB occurrence by clinical subtype.

This study included families of neonates born between 2005 and 2010 in the Instituto de Maternidad y Ginecología Nuestra Señora de las Mercedes (Tucumán, Argentina). Inclusion criteria were singleton neonates delivered at less than 37 weeks of gestational age. Neonates were excluded for: congenital anomalies, multiple gestation, or maternal age less than 14 years. Of the 1290 families recruited, 436 (210 PTB-I and 226 PTB-PPROM) families was selected and 24 SNPs from 18 candidate genes of mother, father and child were genotyped. Genotyping quality controls were performed. Haplotypes were defined from protein interactions with a score greater than 0,7 in String database. Eighteen fully connected groups of 2 and 3 proteins were used. To estimate maternal and fetal haplotypes effects, and interaction effects between haplotypes and clinical subtypes, a log-linear additive model of Haplin R package was used.

In the PTB-I subtype, a fetal haplotype generated with the *IL1B-FN1-IGF1* genes presented a double dose Relative Risk (RR) (respect to reciprocal reference) greater than 3. On the other hand, in the PTB-PPROM subtype, fetal haplotype generated with *IGF1R-FN1* genes showed a RR greater than 4. The 95% confidence interval lower end of these RRs was greater than 1 (p-value < 0,01 and q-value < 0,1); the haplotype population frequency was greater than 0,2.

The interaction between clinical subtypes and fetal haplotypes of *IGF1R-FN1* and *TIMP2-FN1* genes presented a RR greater than 3 (calculated as RR PTB-PPROM over RR PTB-I). While the interaction between clinical subtypes and maternal haplotype of *IL1B-FN1* genes showed a RR greater than 2. The p-values of these RR were less than 0,06 and q-values were less than 0,15.

Results suggest that fetal and maternal haplotypes effects would contribute differently to spontaneous PTB risk according to clinical subtype.

## PgmNr 2936: A genome-wide association study of the age-of-onset of idiopathic pulmonary fibrosis.

### Affiliations:

1) Department of Health Sciences, University of Leicester, Leicester, UK; 2) GlaxoSmithKline, Stevenage, UK; 3) Section of Pulmonary, Critical Care, and Sleep Medicine, Department of Medicine, Yale School of Medicine, Yale University; 4) Medical Research Council Centre for Inflammation Research at the University of Edinburgh, Edinburgh, UK; 5) National Institute for Health Research, Leicester Respiratory Biomedical Research Centre, Leicester, UK; 6) National Institute for Health Research, Nottingham University Hospitals, Nottingham, UK; 7) Division of Respiratory Medicine, University of Nottingham, Nottingham, UK; 8) National Institute for Health Research Respiratory Biomedical Research Unit, Royal Brompton Hospital, London, UK; 9) National Heart and Lung Institute, Imperial College, London, UK

**Rationale:** Idiopathic pulmonary fibrosis (IPF) is characterised by progressive scarring of the lungs, predominantly affects people above the age of sixty and has a poor prognosis. The precise age-of-onset of IPF is difficult to determine as early disease is likely to be asymptomatic or may present with similar symptoms to other more common respiratory diseases. Previous genome-wide association studies (GWAS) have identified 17 genetic signals associated with IPF susceptibility but ours is the first to investigate the genetic determinants of the age-of-onset. Identifying genetic determinants of disease can improve our understanding of underlying mechanisms and highlight important pathways for future drug targets.

**Objectives:** To investigate whether there is a genetic component to the age-of-onset of IPF by performing the first GWAS for age-of-diagnosis as a proxy for age-of-onset in IPF.

**Methods:** We performed a discovery GWAS in 465 subjects with IPF from the PROFILE study, assuming an additive genetic model and adjusting for sex, smoking history and the first 10 genetic principal components. Genetic variants which showed suggestive statistical significance ( $P < 1 \times 10^{-5}$ ) in the discovery were followed-up in two additional independent cohorts; the Trent Lung Fibrosis study ( $n=210$ ) and UK Biobank ( $n=98$ ). The results from all three cohorts were then meta-analysed. Genetic signals were defined as genome-wide significant if they reached  $P < 5 \times 10^{-8}$  in the meta-analysis.

**Results:** The genome-wide analysis was performed on 10,858,143 genetic variants. There were 14 independent genetic signals that showed suggestive statistical significance in the discovery analysis. In the meta-analysis there were no genetic variants which reached genome-wide significance but four variants did display suggestive statistical significance ( $P < 1 \times 10^{-5}$ ), with three of these variants displaying a consistent direction of effects across the three cohorts. The most significantly associated variant was rs75681116, which is located on chromosome 8 between the genes *LZTS1* and *RNU3P2*, where each copy of the risk allele was associated with a 9 month earlier age-of-onset of IPF (95% CI [6 months, 12 months],  $P = 2.2 \times 10^{-7}$ ).

**Conclusion:** Our results suggest that there could be a genetic component to the age-of-onset of IPF and highlight four signals of potential interest that require further investigation. We will seek

additional support for the four novel signals in additional independent data sets.

## PgmNr 2937: The association of *APOL1* genotype and pathological factors with preeclampsia risk in Black women.

---

Black women in the United States and Africa are at an increased risk for preeclampsia. Previous research has shown that genetic variants in apolipoprotein LI (APOL1, SNPs rs717185313, rs73885319, rs60910145) increase the risk for kidney disease in black populations. Human placentas express APOL1, and although APOL1 is uniquely found in primates, transgenic mice expressing human APOL1 develop preeclampsia. Additionally, previous studies report that the fetal- not the maternal- APOL1 mutation increases the mother's risk of preeclampsia in a recessive inheritance pattern. By further understanding the association of APOL1 variants and preeclampsia, targeted interventions may be developed to improve pregnancy outcomes. The association of fetal APOL1 variants with preeclampsia was evaluated in a case-control study of deliveries from black women at the University Hospitals Cleveland Medical Center (282 controls and 395 cases). We used logistic regression to assess the association between APOL1 variants and preeclampsia and also evaluated associations between APOL1 and several pathological features within several case definitions based on prematurity and severity of preeclampsia using uncomplicated term pregnancies as controls. In logistic regression models adjusted for maternal age, gravidity, and overall villous architecture maturity, a significant association was found between APOL1 genotype and preeclampsia. The association varied by assumed mode of inheritance in all cases: additive 1.22 (95% CI 0.97, 1.54 p = 0.0973), recessive 1.17 (95% CI 0.74, 1.88 p = 0.5071), and dominant 1.40 (95% CI 1.01, 1.94 p = 0.0422). APOL1 genotype was not associated with any pathological feature e.g. villous infarcts, placental weight, and maternal vascular malperfusion. Further studies are needed to increase confidence in the mode of inheritance as our results indicate a different mode of inheritance compared to prior work and to assess whether APOL1 genetic testing can predict risk for preeclampsia.

## PgmNr 2938: Genetic association testing with multivariate outcomes: Comparing statistical methods with application to cognition and eye disease.

---

There is growing evidence that some complex traits are caused by overlapping biological mechanisms and thus under common genetic influences. In addition, complex traits are often measured by multiple correlated phenotypes. Analyzing the different related traits in multivariate analyses could provide increased power to detect genetic associations, but is especially challenging with both discrete and continuous phenotypes. Retinal diseases (like age-related macular degeneration (AMD) and glaucoma) and cognitive decline are thought to share biological mechanisms. In addition, cognitive function can be measured by several related cognitive tests. To study the effect of different genetic variants on retinal diseases and cognition, we analyze data from 312 Caucasian participants recruited from the Ophthalmology clinics of the Maisonneuve-Rosemont Hospital (Montreal, Canada). Variables collected included 6 continuous cognitive phenotypes, 2 discrete eye-disease phenotypes (AMD or Glaucoma vs. normal vision), 39 candidate genetic variants and covariates like age and sex. We first used univariate and multivariate regression to assess genetic associations within subsets of multivariate outcomes. SNPs rs1061170 and rs10808746 were found to be associated with glaucoma based on the univariate logistic regression analyses. These two SNPs also showed nominal significance with cognitive phenotypes in multivariate linear regression analyses. Using simulations based on our data, we assess the performance of different methods that can accommodate both discrete and continuous phenotypes in multivariate analyses, including MARV (Multi-phenotype Analysis of Rare Variants; Kaakinen et al., 2017) and GAMuT (Gene Association with Multiple Traits; Broadaway et al., 2016). We apply these methods to our data.

## **PgmNr 2939: An empirical comparison of multivariate and univariate methods for detection of cross-phenotype associations: An example using asthma and body mass index.**

---

Myriad univariate and multivariate approaches can be used to screen for cross-phenotype associations in genetic epidemiologic studies. Although multivariate methods provide distinct statistical power advantages, they remain underutilized in genome-wide association (GWA) studies. However, this will likely change as multivariate datasets and population-wide biobank data become more readily available for research use. To inform future investigations, we empirically compared the two classes of methods by applying them to a search for cross-phenotype associations and pleiotropy for two positively-correlated phenotypes, asthma and body mass index (BMI). We conducted GWA analyses among 305,945 UK Biobank subjects using univariate regression, MV-PLINK, and MultiPhen, and searched for signals elevated to genome-wide significance ( $p < 5 \times 10^{-8}$ ) in the multivariate analyses, relative to the univariate analyses. Overall, the multivariate approaches detected an additional ten independent genetic loci displaying cross-phenotype associations with asthma and BMI that were not detected by the univariate approach. Among these loci was *RERE*, which harbors variants with the same direction of effect on both phenotypes. To provide more robust statistical evidence of pleiotropy at *RERE*, we dissected the cross-phenotype association using mediation analysis, and show that it remains after accounting for the asthma-BMI relationship in our study population. Our results suggest that *RERE* has pleiotropic effects on asthma and BMI and demonstrate that multivariate methods can improve discovery of cross-phenotype associations and pleiotropy, even though they are not specifically optimized to detect these phenomena.

## PgmNr 2940: Testing 15 billion cis-eQTL associations: Fine-mapping and multivariate methods.

Contemporary genetic association analyses are typically performed on millions of variables (SNPs) over thousands of phenotypes, for tens of thousands of samples. Phenotypes of interest range from complex traits to molecular features such as gene and protein expression in different tissues or cell types. However, due to the presence of Linkage Disequilibrium (LD), localizing non-zero effect SNPs for these phenotypes from many other correlated neighboring SNPs is a hard problem. In particular, when SNPs are observed to have non-zero effects across phenotypes, it is both interesting and challenging to distinguish true pleiotropic effects from LD induced confounding. It is therefore desirable to perform multi-phenotype fine-mapping in genetic association studies. However, currently few tools are available for the task. This is due in large part to the computational challenge in simultaneously evaluating association between large number of SNPs and phenotypes.

We have previously developed a Sum of Single Effects (SuSiE) model and an efficient Iterative Bayesian Stepwise Selection algorithm for variable selection in regression (Wang et al 2018). The method has several attractive properties for single phenotype genetic fine-mapping. We have recently extended it to fine-map multiple phenotypes. The new method exploits our earlier work on an empirical Bayes approach to multivariate association testing, which models arbitrary correlations of multi-phenotype genetic effects to increase power (Urbut et al 2019). Patterns of effect correlations are first identified across genome via Multivariate Adaptive Shrinkage (MASH), then used as prior covariances to fine-map across phenotypes (MV-SuSiE). This method, called M&M, is therefore capable of rapidly performing multivariate fine-mapping while revealing effect size heterogeneity across phenotypes. We illustrate features of M&M through extensive simulations using GTEx genotypes, under different multi-phenotype effects models. M&M outperforms MV-SuSiE when naive prior effects are used. Compared to the state-of-the-art multivariate fine-mapping method MT-HESS (Lewin et al 2016), M&M is magnitude faster and significantly more powerful. When applied to detecting cis-eQTL across 49 GTEx tissues, M&M is capable of jointly analyzing ~10,000 SNPs under 5 minutes on a desktop computer. We show that M&M elucidates genetic architecture of eQTL in human tissues, and has great potential in large-scale multi-trait GWAS analyses.

## PgmNr 2941: A scalable method for genetic fine-mapping using summary statistics.

Genome-wide association studies (GWAS) have successfully identified many genomic regions associated with complex diseases and traits. To gain more precise biological understanding of these associations, researchers have turned to fine-mapping methods to help pinpoint the causal variants contributing to these diseases and traits. The most successful approaches to fine-mapping are based on Bayesian variable selection methods, which quantify uncertainty in the causal genetic variables by taking into account patterns of Linkage Disequilibrium (LD). However, current Bayesian variable selection methods rely on computationally intensive procedures to make posterior inferences (e.g., exhaustive enumeration, stochastic search). We have recently developed a method, “Sum of Single Effect Regression” (SuSiE), for Bayesian variable selection. SuSiE is computationally efficient and provides a simpler way to summarize fine-mapping results. However, SuSiE requires individual-level genotype and phenotype data, which prevents this approach from being applied to data sets where only summary-level data are available. Here, we extend the SuSiE approach so that it requires only summary statistics (z scores and an LD reference panel). This approach enjoys all of SuSiE’s advantages, including computational complexity that is lower than comparable methods. Additionally, in numerical experiments we show that misspecification of the LD panel can lead to unreliable inferences, and we describe an approach for correcting inconsistencies to improve performance. In simulation studies using data from the Genotype-Tissue Expression (GTEx) project, we show that our method works as well as currently available fine-mapping methods, and provides well-calibrated posterior probabilities. Further, we show that our method has the potential to be robust to misspecification of the LD matrix. Finally, we apply our method to fine-map associations for height and bone mineral density in the UK Biobank data with about 500,000 individuals.

## PgmNr 2942: Improving efficiency of polygenic risk score by leveraging graphical structures among genetic variants and functional annotations.

---

Polygenic risk scores (PRS) was proposed to aggregate genetic effects across a large number of variants that do not individually achieve statistical significance. The original approach to calculating risk scores demands linkage disequilibrium (LD) -based pruning of SNPs and further thresholding based on marginal p-values of individual SNPs. An increasing number of literatures have demonstrated that modeling the inherent correlations between genetic variants can improve power of PRS. However, optimal approaches to exploit the (diverse) correlation structures have not been sufficiently studied. In addition, performance of PRS can be further improved by incorporating external variant-specific functional information. In this work, we propose a summary-statistic based linear mixed effect model to leverage the graphical structures among genetic variants and functional information simultaneously. Benefiting from the sparse graphical structures described by the conditional correlations among genetic variants, the proposed method is capable of estimating the structure via a tuning-robust penalized procedure designed for graphical model from a reference panel. Without access to individual-level data, the proposed framework can integrate variant-specific functional information with ease. A test statistic is established by jointly testing the fixed effect and one-sided random effect (variance component) based on the proposed mixed-effect regression model. The one-sided test for the random effect is proposed to address the boundary issue in terms of type I error control for variance component test. The asymptotical null distribution of the proposed test statistic is investigated, and an efficient p-value calculation approach is developed for finite samples. Empirical evidences from simulation studies and applications will be provided.

## PgmNr 2943: For what sets of variants can array genotyping and imputation with large reference panels replace deep genome sequencing?

### Authors:

S. Hanks <sup>1</sup>; C. Pato <sup>2</sup>; M. Boehnke <sup>1</sup>; L.J. Scott <sup>1</sup>; C. Fuchsberger <sup>3,4</sup>

### Affiliations:

1) Department of Biostatistics and Center for Statistical Genetics, University of Michigan School of Public Health, Ann Arbor, MI; 2) State University of New York Downstate Medical Center College of Medicine, Brooklyn, NY; 3) Division of Genetic Epidemiology, Department of Medical Genetics, Molecular and Clinical Pharmacology, Medical University of Innsbruck, Innsbruck, Austria; 4) Institute for Biomedicine, Eurac Research, Affiliated Institute of the University of Lübeck, Bolzano, Italy

Genome-wide association studies (GWAS) have identified thousands of genetic variants associated with hundreds of human traits, with recent studies beginning to leverage sequencing data to detect associations across the full allele frequency spectrum. Deep whole-genome sequencing (WGS) is the current gold standard for capturing genetic variation, particularly rare and structural variants. However, array genotyping followed by imputation is currently ~20 times less expensive than WGS and, as reference panel size and diversity increase, allows for analysis of increasingly lower minor allele frequency variants in samples with diverse ancestry. Our goal is to determine the extent to which variants seen in European and African ancestry WGS studies can be accurately imputed using large haplotype reference panels.

We performed WGS of 3,074 Finns and 7,718 African Americans from the METSIM and InPSYght studies at average depth of 24X and 27X, respectively. For each study, we subsetting the markers from WGS to those included on the Illumina Infinium OmniExpress array. We imputed each array with 1000 Genomes, HRC, and TOPMed reference panels. We calculated the observed Pearson correlation ( $r^2$ ) between the imputed gene dosages and the WGS variant calls for all biallelic SNVs for each imputed dataset. We assigned  $r^2=0$  for any variants not present in a reference panel. We evaluated each WGS study and imputation panel based on the percentage of study-specific WGS SNVs that were well imputed ( $r^2>0.8$ ) within different allele frequency bins.

For METSIM, we found that 90-95% of 5.9M common ( $MAF>5\%$ ), 68-87% of 3.7M low frequency ( $0.5\%<MAF<5\%$ ), and 9-24% of 16.9M rare ( $MAF<0.5\%$ ) variants were well imputed depending on reference panel choice. Only 3-11% of 8.4M singletons were well imputed, and between 86-89% of poorly imputed variants ( $r^2<0.3$ ) had  $MAF<0.1\%$ . The TOPMed and HRC reference panels gave the greatest percentage of well imputed variants for this study.

Our results from METSIM indicate that while imputation with large reference panels is sufficient to capture the large majority of common and low frequency SNVs, deep WGS is still needed to accurately capture most rare variants. We are in the process of assessing imputation quality in InPSYght and considering structural variants and the effect of genomic position on imputation performance in both studies.

## PgmNr 2944: Identifying and exploiting disease-relevant tissues using penalized eQTL enrichment analysis.

### Authors:

Y. Gautam; T.B. Mersha

[View Session](#) [Add to Schedule](#)

**Affiliation:** Cincinnati Children's Hospital Medical Center, Department of Pediatrics, University of Cincinnati, OH, 45229, USA

---

Genetic variants discovered from the genome-wide studies are independent of tissue types. However, the biological role of such variants have tissue specific effects. The studies of expression quantitative trait loci (eQTLs) link the disease associated variants with the gene expression in the cell-type specific and thus providing the basis of understanding the biological effects of the genetic variants. Existing functional annotation tools provide tissue-enrichment analyses for a given set of genes without accounting the underlying eQTL associations. Identifying tissues or cell types enriched for the disease associated eQTLs may be helpful to prioritize disease-relevant tissues and develop useful tissue-specific hypotheses of functional mechanisms. In this study, we present a novel approach of *cis*-eQTL-specific tissue scoring analysis using a functionally prioritized set of genome-wide variants. Our approach is carried out in two steps. First, we identified prioritized set of disease associated variants from NHGRI GWAS Catalog including variants in linkage disequilibrium using a composite functional annotation score (cFAS). cFAS integrates multiple functional and regulatory annotations from the transcription start site, regulatory elements in the intergenic regions of the genome. Second, eQTL linked with genetic variants were identified across 48 different tissues from the GTEx project. We developed a tissue scoring approach that penalize the distribution of eQTL signals across different tissues. The null distribution of the score was estimated using a bootstrapping approach. We applied our approaches to multiple allergic diseases - asthma, atopic dermatitis (AD), allergic rhinitis, food allergy, and Eosinophilic esophagitis. Our results unravel tissue enriched for eQTLs for the allergic diseases. Skin was identified as the most enriched tissue for the AD-associated variants, while lung and bloods were ranked among the top scored tissues for asthma. Our enrichment analysis approach could lead to discovery of tissue-specific gene regulations affected by the genome-wide variants and biological insights into various complex diseases including asthma and other allergic diseases.

## PgmNr 2945: Genome-and environment-wide study of sleep quality in 23andMe research participants of European descent.

### Authors:

Y. Huang; S. Aslibekyan; R. Gentleman; 23andMe Research Team

[View Session](#) [Add to Schedule](#)

**Affiliation:** Research, 23andMe. Inc, Mountain View, California.

Previous research has indicated that sleep-related traits, including disturbance and duration, are influenced by both genetic and environmental factors. The genetic basis of overall sleep quality and its non-genetic determinants are not well understood.

In this study, the Pittsburgh Sleep Quality Index (PSQI), a validated measure of overall sleep quality, was used to investigate the genetic and environmental contributions to sleep quality. It is created by summing values on 7 subscores that represent different aspects of sleep quality. A total of 340,195 23andMe research participants of European descent were included.

We first conducted 8 genome-wide association studies (GWAS) using linear regression separately with PSQI global score or its components as the dependent variable. Covariates included age, sex, age\*sex, 5 ancestry principal components, and genotyping chip. 13 loci surpassed the genome-wide significance threshold ( $P=5 \times 10^{-8}$ ) for the PSQI global score. Of those, 4 replicated in the UK Biobank data (<http://www.nealelab.is/uk-biobank/>), including *rs12468708* (the strongest hit, near *FANCL*,  $\beta = -0.012$ ,  $P=1.2 \times 10^{-13}$ ) and *rs9815484* (near *IGSF11*,  $\beta = 0.014$ ,  $P=1 \times 10^{-10}$ ) for “insomnia”, *rs34291892* (*FOXP2*,  $\beta = -0.010$ ,  $P=2.7 \times 10^{-10}$ ) for “sleep duration” and “being a morning person”, and *rs704633* (*NAV1*,  $\beta = 0.010$ ,  $P=4.7 \times 10^{-9}$ ) for “having sleep problems”. When considering components separately, 43 loci surpassed the genome-wide significance threshold, including 10 for duration, 2 for efficiency, 15 for onset latency, 4 for disturbance, 15 for sleep medication, 2 for self-rating sleep quality, and 4 for daytime dysfunction. Genetic correlations calculated using LD score regression between PSQI and its components ranged from 0.67 to 0.93 (all  $P < 4 \times 10^{-186}$ ).

We also systematically evaluated associations between 681 other lifestyle, clinical and socioeconomic phenotypes and PSQI using linear regression models adjusted for age, sex, age\*sex, cohort entry time and ancestry. Effects were expressed per standard deviation of exposure to facilitate comparisons across phenotypes. After adjusting for multiple comparisons, the strongest predictors (all  $P < 10^{-300}$ ) were mental health and stress (e.g.  $\beta$  per SD of perceived stress = 0.27) and health conditions (e.g.  $\beta$  per SD of back pain frequency = 0.15). Our findings advance the understanding of both genetic and environmental sleep quality determinants in the European population and lay the groundwork for future interventions.

## PgmNr 2946: First GWAS on transferrin N-glycans: One step closer to understanding the genetics of protein glycosylation.

---

Glycomics, the study of the collection of glycans in biological systems, is an emerging field among omics data. Despite glycans being involved in the aging process and in a wide variety of diseases (including cancer, immunological and autoimmune diseases, diabetes and congenital disorders), the genetic regulation of glycosylation is not fully understood.

To partly address the knowledge gap regarding genetic regulation of glycosylation, we focused on transferrins, blood plasma glycoproteins regulating iron's level in body fluids. This is the first study integrating genomics and transferrin glycomics, thus allowing us to investigate genetic regulation of transferrin N-glycosylation and whether the same or distinct genes are involved in the N-glycosylation of different proteins. Accordingly, we compared results obtained for transferrin N-glycans to state-of-the-art knowledge about genetic regulation of immunoglobulin G (IgG) N-glycosylation.

We performed genome-wide association study (GWAS) of 35 transferrin N-glycans, using data collected on 948 samples from the CROATIA-Korcula cohort, a genetic isolate characterized by high kinship. This dataset features UPLC-quantified N-glycan traits and genetic data imputed to the Haplotype Reference Consortium.

We identified 778 genome-wide significant loci (p-value < 5-e08/35 traits), mapping in genes encoding glycosyltransferases (*MGAT5*, *FUT6*, *FUT8*, *ST3GAL4*, *B3GAT1*), genes potentially related to the glycosylation process (*MSR1*, *TUSC3*) and transferrin (*TF*), or genes previously associated with N-glycosylation of IgG (*NXPE1*, *NXPE4*). Some of these genes (*TF*, *MSR1*, *TUSC3*) have not previously been associated with glycosylation.

We thus suggest that while some genes are responsible for regulating the N-glycosylation of both transferrin and IgG proteins, others instead appear to control N-glycosylation of only one of these proteins. Our findings shed light on the complex mechanisms regulating protein N-glycosylation and also corroborate the notion that while some genes are specific for a restricted number of proteins, others instead affect the N-glycosylation of multiple proteins.

When conducting genome-wide association studies (GWAS), model selection is critical to identify and adjust for confounding factors, while permutation testing enables an empirical assessment of statistical significance. In conducting GWAS within a large cohort comprised of AncestryDNA customers, who have consented to participate in scientific research, we performed logistic regression on binary outcomes collected from self-reported survey data. We regressed on predictors including genotype, age, biological sex and principal components within a cohort comprised of European-ancestry individuals. Using this approach, we were able to replicate previously identified loci from GWAS literature. To conduct these analyses on well-studied traits with known genetic architectures and also to extend this work to previously unpublished traits, it was essential to assess whether we had sufficiently controlled for confounding factors, especially European population substructure. In an example GWAS on a previously unpublished trait, we observed substantial genomic inflation. We looked at top signals for evidence of population stratification, examining allelic differentiation across Northern and Southern Europeans, both in frequencies from 1000 Genomes, and also within our European ancestry cohort. Furthermore, we observed differences in prevalence of traits between largely unadmixed European-ancestry groups in the AncestryDNA cohort. These findings led to evaluating various approaches to account for population substructure. We also used permutation testing in order to empirically set a threshold of significance for these GWAS. We tested setting significance thresholds by permuting naively, permuting by conditioning on binary covariates, and permuting by conditioning on all covariates jointly. We found increased value in the conditional methods compared to the naive approach. In conducting a GWAS in previously unexplored traits, we show that model selection and empirical significance thresholds are study and trait-specific.

## PgmNr 2948: Genome-wide association study of human milk oligosaccharides in lactating mothers and interaction effects on lung health among infants in the CHILD Study.

---

Human milk oligosaccharides (HMOs) are complex carbohydrates found uniquely in human breast milk and absent in formulas<sup>1</sup>. HMOs shape the growth of infant gut microbiota and contribute to immune system development<sup>2</sup>. While genetic variants in *FUT* genes have been correlated with HMO secretion, it remains to be determined if other genetic factors modulate HMO concentrations in breast milk<sup>3</sup>. This is the first genome-wide association study (GWAS) of HMOs among lactating mothers. Moreover, we tested the interaction effects of HMO exposures with asthma risk variants on respiratory outcomes among infants of these mothers. Breast milk samples were collected 3-4 months postpartum from 980 lactating mothers recruited in the Canadian Healthy Infant Longitudinal Development (CHILD) birth cohort. A total of 19 HMOs were analyzed by high-performance liquid chromatography. Genotyping data from the mothers and their children were obtained using the Illumina HumanCoreExome BeadChip and imputations were performed using the Haplotype Research Consortium data on the Michigan Imputation server. In addition to GWAS of maternal HMO concentrations, we computed genetic risk scores correlated with recurrent wheeze, asthma diagnosis and lung function at age 5 in their children using summary statistics from the largest published GWAS study of asthma<sup>4</sup>. Our results indicate that multiple loci in chromosome 19 (*FUT2* & *FUT3*) were correlated with HMO concentrations. In addition, several novel loci on chromosome 3 were correlated with 6'-sialyllactose ( $P = 3.92 \times 10^{-9}$ ) and disialyllacto-N-hexose ( $P = 1.51 \times 10^{-8}$ ); the most significant variant located 3' of the *ST6GAL1* gene. Interestingly, children exposed to high concentrations of sialylated HMOs had reduced prevalence of recurrent wheeze between ages 2-5. These results were

significant among children with high genetic risk of developing wheeze and asthma. In conclusion, our study replicated previous genetic associations with HMO secretion but also identified several novel loci. Furthermore, our results demonstrated protective effects of specific HMOs on risk of respiratory outcomes including recurrent wheeze and asthma during early childhood.

**Background.** n-3 and n-6 long chain polyunsaturated fatty acids (LC-PUFAs) play critical roles in many physiologic and pathophysiologic processes. We investigated the association of common genetic variation with eight major LC-PUFAs through genome-wide association studies (GWAS) in African American [AfAm] and Hispanic American [HisAm] cohorts from the CHARGE Consortium.

**Methods.** Circulating n-3 (eicosapentaenoic acid [EPA], docosapentaenoic acid [DPA], docosahexaenoic acid [DHA], alpha-linolenic acid [ALA]) and n-6 (arachidonic acid [AA], gamma-linolenic acid [GLA], dihomo-γ-linolenic [DGLA], linoleic acid [LA]) PUFAs were measured in participants from three population-based cohorts (the Multi-Ethnic Study of Atherosclerosis [MESA] (AfAm: n=1462 and HisAm: n=1218), the Cardiovascular Health Study [CHS] (AfAm: n=425) and the Framingham Heart Study [FHS] (AfAm: n=203 and HisAm: n=211)). Genome-wide analysis was carried out separately in each cohort with covariate adjustment for age, sex, study site and principal components of ancestry. For each genetic variant and fatty acid trait, cohort-specific GWAS results were filtered using EasyQC based on MAC > 6 and imputation R-squared > 0.3. Cohort-specific GWAS results were combined by inverse-variance weighted meta-analysis in METAL.

**Results.** After filter on effective heterozygosity > 60, we confirmed genetic loci in *FADS1/2* and *ELOVL2*, previously reported in European-ancestry based GWAS in CHARGE. We further identified novel genome-wide significant ( $P < 6.25 \times 10^{-9} = 5 \times 10^{-8} / 8$  traits) loci (4 in AfAm and 7 in HisAm) across

the LC-PUFA traits. In AfAm, significant associations were identified for DPA (*CASC15*, rs717894,  $P = 3.302 \times 10^{-9}$ ) and EPA (*MGAT5*, rs112877348,  $P = 4.624 \times 10^{-10}$ ; and *MRVI1*, rs16908026,  $P = 1.812 \times 10^{-9}$ ). In HisAm, we observed significant associations for AA (*TPCN2*, rs3750967,  $P = 6.436 \times 10^{-9}$ ; *PHF21A*, rs76595296,  $P = 3.026 \times 10^{-11}$ ; and *KDM2A*, rs77988791,  $P = 1.527 \times 10^{-11}$ ), DGLA (*PDXDC1*, rs4985128,  $P = 1.178 \times 10^{-9}$ ), EPA (*OR5B3*, rs17152659,  $P = 2.594 \times 10^{-9}$ ; *SLC22A25*, rs75269907,  $1.316 \times 10^{-11}$ ), GLA (*LOC107986082*, rs55918609,  $P = 2.788 \times 10^{-9}$ ) and LA (*NUDTB*, rs145834191,  $5.536 \times 10^{-11}$ ; and *PHF21A*, rs76595296,  $1.627 \times 10^{-9}$ ).

Conclusion. Next steps will include replication of the identified variant associations and eQTL colocalization analyses. The results of our study may be useful in defining future targeted recommendations for LC-PUFAs intake in the African American and Hispanic population.

## PgmNr 2950: Quantifying pairwise trait co-regulation through modeling individual genetic correlations.

One major goal in quantitative and medical genetics is to determine how gene networks drive individual variation and establish when their dysregulation may lead to disease emergence. To that end, correlation patterns between genes or metabolites are frequently used to assemble co-expression networks, under the well-supported assumption that correlation often implies co-regulation. However, whether correlation networks vary across individuals is largely an open question. We still have a poor understanding of how genetic variation, environmental perturbations, or disease states can modify essential patterns of co-regulation.

Correlations are generally estimated as the property of a population, not an individual. This is a key limitation because it does not allow for the investigation of individual-specific factors that may influence variation in co-regulation. One solution is to gather multiple observations per individual (for example over time), thus allowing us to view correlation between traits as a property of an individual. This shift in focus from a population to an individual estimate, enable us to address new questions: 1) Does the correlation between genes or metabolites vary between individuals? 2) Are the patterns of correlation heritable? 3) Are certain disease states characterized by a change in correlation pattern?

In order to tackle these questions, we developed a mixed linear model that accommodates intra individual correlation through a random slope. When decomposing individual correlations into an environment and genetic components, a polygenic random slope quantifies the degree of correlation between traits. We show through extensive simulations, how this statistical framework can to be used to distinguish between three different phenomena that may lead to correlation between traits: i) additive genetic effects on each trait independently, ii) genetic effects on the correlation between traits (i.e. a correlation QTL), and iii) pleiotropic effects (i.e. a given variant affects multiple traits). We show that this approach can estimate the heritability of correlation in an unbiased fashion - provided repeated measures for a given individual. We apply this approach to longitudinal data from medical records with the goal of identifying the genetic basis of co-regulation and find cases where a change in the degree of correlation between traits (e.g. metabolites) may reveal the loss of homeostasis and potentially disease emergence.

# PgmNr 2951: An evaluation of the frequency of Intron 1 and 22 inversion and the clinical characterization of haemophilia A in Nigeria.

**Background:** Haemophilia A(HA) is an X-linked recessive disorder. Its aetiology is founded on mutations within the *F8* gene which result in reduced or absent circulating levels of the F8 protein being produced. The mutational mechanisms include inversions, deletions, point mutations, missense etc. This study focussed on the detection of 2 of the most recurring mutations, intron 1 and 22 inversions of the *F8* gene. Intron 1 and 22 inversions are responsible for 1-7% and 40-50% of the mutations in Haemophilia A. The clinical characteristics and inhibitor screen were also assessed in this study.

**Materials and Methods:** 76 Haemophilia A patients registered with the Haemophilia Foundation of Nigeria were enrolled in the study. Their clinical characteristics, FVIII concentrations, inhibitor status and mutation types were assessed. Coagulometry involved clot-based assays via semi-automated coagulometer. The Inverse-Shifting PCR protocol was used for detection of the inversion mutations. IS-PCR protocol is designed to be able to detect inversions, duplications and deletions within intron 22.

**Results:** 75% (57/76) of the participants were found to have severe Haemophilia A( FVIII level < 1%) while 25% were of moderate severity with FVIII level 1-5%. The most frequent presentation was joint bleed with a frequency of 60% and 20% of patients had developed significant disuse atrophy. Of the 76 subjects, 27 had inversion mutations; 2 with intron 1 inversion and 25 with intron 22 inversions. Intron 1 and 22 inversions were documented in 2/57(3.5%) and 19/57(33.3%) of severe HA respectively. Twenty-nine of 76 subjects were positive for FVIII inhibitors. No significant associations were found when the mutations were matched against the clinical characteristics, FVIII levels and inhibitor status.

**Conclusion:** This study documented the prevalence of severe HA among Nigerian subjects with diagnosed haemophilia to be 75%. Inversions of introns 1 and 22 occurred in 3.5 and 33.3% of the severe haemophiliacs. FVIII inhibitors were found in 38.2% of Nigerian haemophiliacs.

## PgmNr 2952: Severity of TB associated with eQTL regulatory variants in two independent cohorts from Kampala, Uganda.

Several studies have demonstrated human genetic susceptibility for tuberculosis (TB), but few have examined TB severity. We assessed genetic association with TB severity in our household contact study in Kampala, Uganda. We analyzed genotype and severity in 148 HIV-infected TB cases (Cohort 1). We sought to replicate our findings in Cohort 2, 198 independently collected HIV-uninfected TB cases. We analyzed only SNPs available in both cohorts. The two cohorts were similar with respect to mean age, distribution of sex, and distribution of TB severity. We modeled TB severity using the TBscore by Wejse et al., which ranges from 1-13, incorporating clinical symptoms present. It has previously been associated with risk of mortality as well as important biomarkers in TB patients. We modeled severity as a function of host SNP genotype, analyzing 214,070 SNPs in both cohorts derived from an exome chip. We observed association between TBscore and numerous eQTL SNPs in Cohort 1 that replicated in Cohort 2, including multiple SNPs in linkage disequilibrium and regions with multiple significant SNPs in the same gene. In total, 67 SNPs were associated with a combined  $p\text{-value} < 10^{-4}$  and only 12% of these were exonic. The strongest association was found for rs10176270 in the combined analysis ( $\beta=0.82$  and  $p=1.17 \times 10^{-6}$ ), an eQTL that maps to the HEATR5B gene on chromosome 2. HEATR5B is ubiquitously expressed in human tissues and is involved in endocytosis, protein localization, and retrograde transport to the Golgi apparatus. Because of the large proportion of non-exonic localization of associated SNPs, we used FUMA GWAS and HaploReg v4.1 to annotate SNP functionality. We observed that many of these SNPs had potential regulatory influences on TB immune cells. For example, we determined that rs10176270 has been identified as an enhancer and promoter that is associated with differential expression of HEATR5B in human whole blood, lymphoblastic, and CD14+ monocyte cell lines. The importance of this SNP in monocytes is especially important, as these cells are precursors to tissue macrophages, which are intracellularly infected by *Mycobacterium tuberculosis* and thought to be the primary facilitators of the host immune response to TB infection. Further, rs10176270 is in LD ( $r^2 > 0.8$ ) with other SNPs that have previously identified in the GWAS catalog to be significantly associated with red cell distribution width, hematopoiesis, and regulation of T cells.

## PgmNr 2953: Evaluation of the host genetic effects of tuberculosis-associated variants among patients with type 1 and type 2 diabetes mellitus.

---

**Background:**As the global burden of non-communicable diseases continues to expand, the public health importance of understanding the link between tuberculosis (TB) and diabetes is increasing. Genetic association studies have identified numerous host genetic variants linked to TB. However, to date, host genetic mechanisms linking TB and diabetes remain unknown.

**Methods:**We conducted a genetic association study to evaluate the effects of seven previously reported TB-related host genetic variants (genome-wide significant associations from published studies) in patients with diabetes using genetic and phenotypic data from the UK Biobank. The study included 409,692 adults of European ancestry including 13,976 type-2 diabetes (T2D) cases and 2,177 type-1 diabetes (T1D) cases defined by ICD-10 diagnosis codes.

**Results:**Out of seven TB-associated SNPs, four were associated ( $p < 0.05$ ) with T2D and one with T1D ( $p < 0.05$ ), after adjusting for age, sex, BMI, smoke, alcohol use and population structure. After correction for multiple testing, the C allele of SNP rs3135359 (*BTNL2* gene on HLA-A) was significantly associated with increased prevalence of T2D (OR 1.06, 95% CI 1.025-1.096), and increased prevalence of T1D (OR 1.72, 95% CI 1.57-1.88). The rs3135359 association with T2D diminished after further exclusion of probable T1D cases defined by ICD-10 codes. The SNP rs3135359 was also strongly associated with thyroid disease and additional autoimmune diseases including multiple sclerosis and rheumatoid arthritis. SNPs rs12680942 (OR 1.03, 95% CI 1.00-1.06) and rs4733781 (OR 1.03, 95% CI 1.00-1.06) on chromosome 8 (*ASAP1* gene) were associated with T2D after exclusion of T1D cases.

**Conclusion:**Our findings suggest that host genetic effects may partially explain observed associations between TB and T2D. Our analyses demonstrated common genetic factors underlying TB and non-communicable disease, particularly via immune functions of the HLA region.

## PgmNr 2954: Genotype-phenotype correlation in lysosomal storage diseases detected by newborn screening in Mexico.

### Authors:

The goal of newborn screening is an early detection of inborn errors of metabolism diseases. In Mexico we began newborn screening since 1977 with very few inborn errors of metabolism such as phenylketonuria, galactosemia, congenital hypothyroidism, sickle cell anemia and cystic fibrosis. (1) Petróleos Mexicanos is a big governmental institution with approximately ten thousand workers and their families. Since 2005 a larger screening has been done to all newborns in this institution through all the country.

We test for most aminoacidopathies; since August 2012 we included primary immunodeficiencies, Gaucher disease, Niemann-Pick (A/B) disease, Pompe disease, Krabbe disease, Fabry disease, and MPS1.

We analyzed our results from August 2012 to December 2018 , we have found 5 newborns with Fabry disease confirmed with enzyme activity and molecular analysis; and 6 patients with Pompe disease, three were pseudodeficiencies. one was a late onset presentatio; one patient with MPS I homozygous and one Gaucher patient.

These findings give us the opportunity to make genotype-phenotype correlation for the early treatment of lysosomal storage diseases. This early detection will allow us to make a close follow up of these patients; and through a study of their genealogy detect other Family members with the disease.

## PgmNr 2955: Genetic risk factors for recombination-related maternal chromosome 21 nondisjunction.

### Authors:

---

Nondisjunction in oocytes is the leading cause of pregnancy loss, as well as intellectual disabilities and birth defects among pregnancies surviving to term. In addition to increasing maternal age, altered patterns of meiotic recombination are a known risk factor for nondisjunction. Specifically, errors in meiosis I (MI) and meiosis II (MII) are each associated with distinct “susceptible” patterns, suggesting their etiologies may differ. For MI nondisjunction of chromosome 21 these include a lack of recombination on the chromosome or a single, telomeric exchange; MII errors are associated with exchange near the centromere.

Previous genome-wide association studies have found associations between common variants and recombination phenotypes (e.g., global recombination rate, recombination outside of hotspots). Our own previous and ongoing work also suggests that common genetic variants may contribute to the risk of nondisjunction of chromosome 21, with some variants conferring risk for nondisjunction in just one stage and others conferring risk in either stage. Here we extend that work by analyzing the relationship between common variation and the occurrence of susceptible recombination patterns.

A set of 2,186 study participants was genotyped on the HumanOmniExpressExome-8v1-2 array. These included 749 live birth offspring with maternally-derived standard trisomy 21 and 1,437 of their parents. We developed methods for determining the stage of meiosis in which nondisjunction occurred and for locating recombination events on chromosome 21 in these parent-child trios and dyads. We then analyzed recombination patterns in two ways. In one group of analyses, susceptible recombination patterns were treated as phenotypes for GWAS and candidate-gene testing. In the other, we performed stratified GWAS of nondisjunction. Finally, we performed age-stratified analyses of nondisjunction.

**Background:** The plasma proteome and blood transcriptome are potential sources of therapeutic targets. Genetic studies of these molecular traits enable systematic comparison of genetic architecture between protein and gene expression; and estimate causal associations of these traits on human diseases.

**Methods:** Here, we estimated the effects of 1,740 plasma proteins and 16,058 blood transcripts on 576 phenotypes in Europeans using two-sample Mendelian randomization (MR) followed by single and multi-trait colocalization (coloc/moloc). We report the findings of 9.46 million gene-phenotype associations in an accessible database: EpiGraphDB ([www.epigraphdb.org/xqtl/](http://www.epigraphdb.org/xqtl/)).

**Results:** We compared 4,094 cis/trans pQTLs and eQTLs associated with the same gene (1,194 genes). Only 317 (7.7%) of the pQTLs and eQTLs were in LD ( $r^2 > 0.1$ ), of which 314 were in the cis region. Although the pQTLs and eQTLs differed, their estimated causal effects on the disease were highly correlated ( $r = 0.98$ ) for the 29 associations with strongest MR and colocalization evidence from pQTL and eQTL ( $P_{MR} < 5.3 \times 10^{-9}$ , coloc probability  $> 0.8$ ). We found 6 associations with multi-trait coloc evidence, including an approved drug target (PLAU) with a novel indication (Crohn's disease). Mediation analyses of these 6 findings suggest that PLAU gene expression influenced PLAU protein expression, ultimately affecting susceptibility to Crohn's disease. Of 1,718 protein-phenotype associations with MR evidence, 1,215 (70.7%) had coloc evidence. Of 19,775 gene expression-phenotype associations with MR evidence, 12,787 (64.7%) had coloc evidence. This work improves on previous omics studies by making careful use of multiple cis and trans instruments and identifying additional gene-phenotype associations. Retrospective evaluation of 268 developed drugs (Pharmaprojects) showed that target-indication pairs with proteomic MR and

coloc support were more likely to succeed (OR=26.4; 95%CI=4-580). Further, we validated 8 marketed drugs, prioritised 8 targets in current drug trials, and identified 53 repurposing opportunities.

**Conclusions:** This is the first systematic MR and coloc analysis of the plasma proteome and blood transcriptome. Our results suggest that genetic confounding due to LD may be widespread in phenome-wide association studies of molecular traits. We identified novel gene-phenotype associations and provide evidence that proteomic MR/coloc support of drug targets increases probability of success for drug discovery.

## PgmNr 2957: Shrinkage methods utilising the estimation of error quantity to improve GWAS and polygenic risk score.

---

GWAS have been used as a tool to discover the associated loci of polygenic traits and empowered downstream analysis such as Polygenic Risk Scores (PRS) to further investigate the aetiology. The effect size estimates of GWAS can be influenced by 'Winner's Curse' especially the top SNPs, which are more likely to be included in PRS calculation and other analyses. The widely-used methods utilise Bayesian approaches, LASSO etc. to generate a posterior distribution of effect sizes. Here, we developed a set of novel shrinkage methods that estimate error quantity in the observed effect size estimates from a null effect size distribution generated by permuting raw phenotype data ('Permutation Shrinkage') or order statistics ('Order Statistics Shrinkage') and subtracted the estimated null effects from the observed estimates. We tested our methods, 'Permutation Shrinkage' and 'Order Statistics Shrinkage', with quantitative traits in UK Biobank. Our methods lead to an average 35% relative increase of PRS  $R^2$ .

## **PgmNr 2958: 16S rRNA analysis of 17<sup>th</sup> and 18<sup>th</sup> century New York African burial ground grave soil samples to detect human microbiome signatures and infectious disease pathogen.**

In 1991, in Lower Manhattan, during the construction of a federal building the 400- year old New York African Burial Ground (NYABG) was unearthed. This cemetery is the largest and oldest site of free and enslaved African remains. Four hundred and four individuals were excavated and analyzed using archaeological, skeletal biological, and historical methods, then reburied at the historical site. At the time of excavation cadaver-associated soil samples were also retrieved creating the NYABG grave soil collection, currently maintained at Howard University. This investigation observes the bacterial community diversity of 74 unique burials from multiple body regions compared with 8 non-burial controls from Lower Manhattan. Comparing burial vs non-burial samples, we see increased detection of species abundance in the Firmicutes phylum indicating a pronounced signature for human microbiome. In addition, this investigation identifies bacterial disease pathogen associated with specific burials suggesting that the individual suffered from this infection in life and it may have contributed to their death. For example, bacteria genera associated with *Shigella* (dysentery), *Blautia* (present in the GI tract of cholera patients) and *Legionella* (Legionnaires disease) have been detected in burials 277, 245, and 230 respectively. These findings give profound insight to the quality of life and possible cause of death of NYABG inhabitants. Consequently, we are able to deduce information about living conditions of Africans in Lower Manhattan in the 17<sup>th</sup> and 18<sup>th</sup> centuries. This project helps us to learn more about the lives of free and enslaved Africans and the occurrence of pandemic outbreaks in the New York City area.

## **PgmNr 2959: A powerful microbial group association test based on the higher criticism analysis for sparse microbial association signals.**

**Authors:**

H. Koh; N. Zhao

---

The microbial group association analysis has been widely conducted to evaluate the association between microbial group (e.g., community or clade) composition and a host phenotype (or any other health/disease-related factor) of interest. In response, a variety of microbial group association tests have been proposed while incorporating the unique features of the microbiome data (e.g., high-dimensionality, compositionality, phylogenetic relationship). These tests generally fall in the class of aggregation tests which amplify the overall group association by combining all the underlying microbial association signals; as such, they are powerful when many microbial species are associated (i.e., low sparsity). However, in practice, the microbial association signals can be highly sparse, and this is especially the situation where we have a difficulty to discover the microbial group association. Hence, here we introduce a powerful microbial group association test for sparse microbial association signals, namely, microbiome higher criticism analysis (MiHC). MiHC is a data-driven optimal test taken in a search space spanned by tailoring the recent higher criticism test to incorporate phylogenetic information and/or modulate sparsity levels. Our simulations show that MiHC maintains a high power at different phylogenetic relevance and sparsity levels with correct type I error controls. We also demonstrate the use of MiHC with tree real data applications to test the disparity in respiratory-tract microbiome by smoking status, the disparity in infant's gut microbiome by delivery mode and the disparity in gut microbiome by type 1 diabetes status. In summary, MiHC is attractive because of its high adaptivity to diverse phylogenetic relevance and sparsity levels, which are usually unknown in practice.

## PgmNr 2960: Comparison of imputation quality for an Arab population using different references and methods.

---

There has been a significant gap between research on European genetics and that of other ancestries. The ExAC dataset is 54.97% European and the Telenti et. al 10,000 deeply sequenced genomes are 78.55% European. There are efforts underway to address this data bias, e.g. the work of the Consortium on Asthma among African-ancestry Populations in the Americas, the Personal Genome Project's 10,000 Korean genomes goal, etc. Despite these, there has been a relative dearth of data and analysis of Middle Eastern populations. Here we attempt to identify which methods, reference panels and Genome-Wide Association Study (GWAS) SNP arrays that perform well for a Qatari cohort.

We used a public set of 108 Qatari Whole Genome Sequences (WGSs). We formed three GWAS arrays by keeping only the SNPs present in two GWAS panels from Illumina: (1) The Multi-Ethnic AMR/AFR-8 Kit (AMR\_AFR), and (2) Infinium Multi-Ethnic EUR/EAS/SAS-8 Kit (EUR\_EAS\_SAS) panels, and (3) we also considered selecting SNPs at random. Two imputation methods were performed on each GWAS data, Minimac and the recent Positional Burrows-Wheeler Transform (PBWT) using two reference populations, 1KGP3 (1000 Genomes Phase 3) and Haplotype Research Consortium (HRC). We find that our best results are achieved using the 1KGP3 reference with the EUR\_EAS\_SAS GWAS panel and Minimac. Minimac combined with the 1KGP3 reference performed particularly well, and Minimac was consistently the better imputation method. The EUR\_EAS\_SAS panel did slightly better than the AMR\_AFR panel, but the random SNP selection performed worse than either panel. Rare SNPs were imputed markedly well.

## PgmNr 2961: Quantifying the loss of accuracy in trans-ethnic genetic prediction.

---

Polygenic risk scores (PRS) have been widely used to predict genetic component of complex traits or risk of diseases using variants identified from genome-wide association studies (GWASs). However, to date, the predictive performance of PRS has predominantly been evaluated in populations of European ancestry. The prediction accuracy of PRS has been found to be substantially reduced when the target population has a different genetic background from the GWAS discovery population. Here we derive a theoretical model to quantify such a loss of accuracy (LOA) of PRS and then use simulation studies and real data analyses to evaluate the model. We assume that: 1) the causal variants are shared, and 2) their allele substitution effects ( $\alpha$ ) are constant between populations. The model is a function of population genetic parameters including  $S$  measuring the relationship of  $\alpha$  and minor allele frequency (MAF), linkage disequilibrium (LD) correlations between the observed SNP markers and the causal variants, and MAF of the observed SNP markers and the causal variants between populations. It only requires summary statistics from GWAS and a reference panel to calculate the LD correlations and MAFs. All the analyses are conducted using the real genotypes of UK Biobank, including unrelated participants from four homogenous populations, namely, self-reported British ( $N = 323,284$ ), South Asian ( $N = 9,448$ ), East Asian ( $N = 2,257$ ) and African ( $N = 7,015$ ). A subset of 10,000 British individuals are randomly sampled as a target population. We perform simple linear association tests on  $\sim 0.98$  Million HapMap3 SNPs in the remaining 313,284 British and apply “LD clumping” algorithm to select approximately independent genome-wide significant SNPs, which are used to build the genetic predictors in all target populations. In simulations we vary trait heritability, the number of causal variants and  $S$ , and show that the LOA in non-European descents can be accurately predicted by our theory when ethnically-diverse populations differ in LD structure and MAF. In the analysis of height and BMI, we find that more than half of LOA (58% and 65%, respectively) in African can be explained by our theory. Our results highlight the necessity of collecting large scale of genome-wide data across different ancestries to achieve a complete understanding of such a LOA in transeethnic prediction; moreover, to fulfil the potential and equitable use of PRS in the precision medicine era.

## PgmNr 2962: Localization of rare variants in loci previously identified in aggregate rare variant testing.

Studies that examine the role of rare variants in both simple and complex disease are increasingly common. Though the usual approach of testing rare variants in aggregate sets is more powerful than testing individual variants, it is of interest to identify the variants that are plausible drivers of the association. We present a novel method for prioritization of rare variants after a significant aggregate test. Our approach leverages quantification of the influence of the variant on the aggregate test of association. In addition to providing a measure used to rank variants, we use outlier detection methods to present a computationally efficient approach to identify a subset of variants that is driving the disease association. We evaluated several outlier detection methods that vary based on the underlying variance measure: interquartile range (Tukey fences), median absolute deviation and standard deviation. We performed 1000 simulations for each region and compared the true and false positive rates. All outlier detection methods observed higher sensitivity to detect uncommon variants ( $0.001 < \text{MAF} < 0.03$ ) compared to very rare variants ( $\text{MAF} < 0.001$ ). For uncommon variants, the inner Tukey had the highest median true positive rate of 0.60 (IQR: 0.51, 0.87) compared to the standard deviation having a median of 0.30 (IQR: 0.10, 0.59). We compared our method using the inner Tukey to two existing methods: adaptive combination of p-values (ADA) and a Bayesian hierarchical model (BeviMed). For uncommon variants, the inner Tukey observed a lower median false positive rate of 0.10 (IQR: 0.06, 0.18) compared to the ADA, which observed a median false positive rate of 0.23 (IQR: 0.18, 0.36). ADA and the inner Tukey had significantly higher true positive rates than that observed for BeviMed. Finally, we applied this method to data from our targeted resequencing study in idiopathic pulmonary fibrosis (IPF). Within two aggregate sets including 100 rare variants, we identified six variants with the greatest evidence for influencing the association with IPF. In summary, our localization methods to classify risk variants obtain a high true positive rate while maintaining a low false positive rate. This work provides an approach to obtain greater resolution of the rare variant signals within significant aggregate sets; this information can provide an objective measure to prioritize variants for follow-up experimental studies and insight into the biological pathways involved.

## PgmNr 2963: Admixture mapping of lung function in Puerto-Rican Islanders.

---

In the U.S., asthma disproportionately affects urban minority populations, with Puerto Ricans showing the highest asthma prevalence 16.1%. However, what causes high asthma prevalence among the Puerto Ricans is not very well understood. The varying proportions of African, European, and Native American genetic ancestry in Puerto Ricans can be leveraged to identify genetic determinants of clinically significant measures and outcomes such as lung function and asthma severity. We have previously demonstrated that genetic ancestry is associated with lung function.

In this current study, we sought to discover potential causal genes that may be associated with lung function in Puerto Rican islanders by applying admixture and fine mapping methods. A genome-wide admixture mapping study of lung function was conducted in 843 Puerto Rican children with and without asthma, who were recruited from Puerto Rico. After mapping admixture segments, we fine-mapped the genomic region using whole genome sequencing data. Functional annotation was then used to elucidate underlying biologic links between genetic variants and lung function.

The association test between local genetic ancestry and forced expiratory volume in 1 second (FEV<sub>1</sub>) identified a strong admixture mapping peak on chromosome 1q32, indicating that a one percent increase in African ancestry was associated with 0.13 liters decrease in the volume of exhaled air [95%CI: -0.07 to -0.18, p-value=1.3×10<sup>-6</sup>]. Variants identified from the fine-mapping analysis were associated with the inflammation-related genes (*INAVA* and *NEK7*). The minor allele of the intron variant associated with *NEK7* gene (rs111428936) tracks with European ancestry and is associated with well-controlled asthma and better lung function, whereas the major allele had the opposite effect.

The results from admixture mapping and functional annotations point a potential enhancer variant for the *NEK7* gene. It is possible that *NEK7* may be involved with inflammasome activation in the lung, which may influence the lung function and asthma severity of Puerto Ricans.

## PgmNr 2964: Correcting gene expression batch effect in single-cell RNA sequencing.

Single-cell RNA-sequencing (scRNA-seq) enables unbiased measurement of gene expression in individual cells, and provides unprecedented opportunities to characterize cell types and cellular heterogeneity. The continuously decreasing cost of scRNA-seq has made it possible to profile the transcriptomes of hundreds to thousands of cells simultaneously. Unfortunately, scientific discoveries from these abundant data are hampered by technical artifacts and inherent biological heterogeneity in the data. The former is usually termed “batch effects,” referring to systematic differences in gene expression from one batch to the other, and the latter is often modeled by different cell types. Batch effects are inevitable, particularly in human tissues, because samples have to be processed quickly, making it impossible to randomize the samples and cells in the experiment. Additionally, different laboratories might use different cell dissociation protocols, library preparation kits, or sequencing platforms. All of these could lead to unwanted technical differences across batches. Failure to remove batch effect will obscure downstream analysis and lead to erroneous findings. To correct for batch effect, a common strategy is to merge all scRNA-seq data together first, and then use regression models to regress out batch effect. After batch effect is removed, further analyses, such as cell type clustering and differential expression, can be performed. However, this global batch effect correction procedure may not be ideal for scRNA-seq data, because some cells are more vulnerable to batch effect than others. The global batch effect correction approach may over correct for some cells but less effective for other cells. To address this limitation, we propose a new procedure that distinguishes the cell types first, and then performs batch effect correction for each type of cells. Our simulation results demonstrate that this new procedure outperforms the traditional global batch effect correction approach. We show that it has well controlled type I error rates and high sensitivity in downstream differential expression analysis under a wide range of scenarios. With the growing popularity of scRNA-seq, we believe our procedure will offer a valuable tool for proper analysis of scRNA-seq data and aid scientific discoveries.

## PgmNr 2965: Graphical analysis using genetic variables for phenome-level causal discovery in population-scale biobanks.

Availability of large genetic databases has led to the development of powerful causal inference methods that use genetic variables as instruments to estimate causal effects. However, such methods were developed for analysis of a selected exposure-outcome pair and are limited when performing a phenome-level analysis (e.g., sensitive to biases and assumptions). Here, we present cGAUGE, a new pipeline for causal Graphical Analysis Using GEnetics that analyzes the genetic variables and many traits jointly to find patterns that carry causal information. Specifically, cGAUGE utilizes conditional independence (CI) tests to either filter out associations that are not likely to represent direct causation or to detect unique combinatorial patterns that serve as evidence for causal links that are justifiable even if the underlying causal diagram has cycles. Using these analyses, cGAUGE finds valid genetic instruments, directly searches for cycles in the underlying causal diagram, and detects cases where Mendelian Randomization (MR) can be performed with minimal risk of horizontal pleiotropy bias. For the best of our knowledge, cGAUGE is the first algorithm to detect such patterns. Moreover, for MR analysis cGAUGE scores the reliability of the causal link using a simple Bayes false discovery rate statistic. We present theoretical justification, simulations, and apply our pipeline to 96 complex traits from 337,198 subjects from the UK Biobank. We illustrate how CI filters remove around 40% of the GWAS results, highlighting genetic variants that are more likely to be proper instruments for MR. Our MR-based results cover 121 causal links supported by at least 10 instruments and detected at 1% FDR. Many of the links expected causal links, some of which are missed by extant methods, but also new associations previously speculated to be causal such as detrimental effects of depression on kidney and liver function, and a protective effect of immune system activity in prostate cancer. Our results also recapitulate a refined structure of the underlying causal diagram and highlight central hubs, such as sleep duration, that indirectly affects many biomarkers, traits, and diseases.

## PgmNr 2966: Dealing with confounding in causal network inference for biological data.

### Authors:

M.B. Badsha; A.Q. Fu

[View Session](#) [Add to Schedule](#)

**Affiliation:** Department of Statistical Science, Center for Modeling Complex Interactions, Institute for Bioinformatics and Evolutionary Studies, University of Idaho, Moscow, ID 83844-1104

It is a challenge to reliably infer causal relationships among multiple molecular phenotypes (such as gene expression) when many other variables (demographic and hidden variables) may bias the inference. When genotype data are available, we can employ the principle of Mendelian randomization (PMR) for causal inference. As a randomization principle, the PMR assumes that the alleles of a genetic variant (which is an instrumental variable) are randomly assigned to individuals in a population, analogous to a natural perturbation experiment, which helps establish causality.

We take a graphical model approach to causal inference. Our method, namely MRPC, learns a causal network from integrating genotype and molecular phenotype data at the individual level, where directed edges indicate causal directions. MRPC implements an online false discovery rate (FDR) control method to control the overall error rate and incorporates the PMR (Frontiers in Genetics, 2019; arXiv, 1806.01899). It can capture a wide variety of causal relationships, beyond the canonical causal model ( $V \rightarrow X \rightarrow Y$  in which  $V$  is a genetic variant,  $X$  a regulator, and  $Y$  a target).

With a graphical model, we can explicitly include confounding variables as additional nodes into the network, without making assumptions on how they affect the variables of interest. This implies that we can check whether the conditions in the PMR are satisfied while performing causal inference when other methods often assume these conditions to be true. If a large number of confounding variables are present, we derive lower-dimensional surrogate variables (e.g., top principal components of the entire gene expression matrix and demographic variables) as composite confounding variables.

We took this approach to dissect direct and indirect targets among multiple genes associated with the same eQTLs. The GEUVADIS consortium has identified 62 eQTLs in LCLs to be associated with more than one gene. We applied MRPC to each eQTL-gene set and incorporated the top principal components into the analysis. We identified 10 types of causal networks between the eQTL and its associated genes. The presence of confounding variables did not alter the inference. Among these eQTL-gene sets, 46 also had data in the GTEx LCL samples and the causal networks inferred for 30 of them were replicated in GTEx.

## **PgmNr 2967: Wilson-interval corrected population frequency estimates for reduced-coverage areas in population reference databases.**

**INTRODUCTION:** Population-frequency criteria are frequently used to target disease causing variants in clinical genome and exome datasets. A common approach removes variants above a defined cutoff, for example 1% frequency, based on a hypothesis that a severe, rare, highly-penetrant Mendelian disorder will be unlikely to be caused by more frequent variants derived from a generally healthy population. Variant frequencies vary by population. Evidence that a variant is overly frequent may be derived from a population with relatively few genotyped individuals. We hypothesized that the frequency of a minority of potentially clinically-relevant DNA variants is overestimated in available population databases, thereby causing them to be excluded from analysis. We further hypothesized that adjusting the frequency to include these variants would increase the sensitivity of potentially pathogenic variant identification in our genetic data analysis procedures.

**METHODS:** We obtained frequency data from the widely used gnomAD database (Lek, et al 2016, PMID: 27535533). A Wilson score interval was used to generate a frequency-estimate confidence interval for areas with a low number of genotyped alleles. The Wilson score interval (Wilson, 1927, DOI: 10.2307/2276774) is a statistical tool designed to find the interval that is likely to contain the true mean given number of observations and number of successes. It is particularly suited to cases with few observations (Newcombe, 1998, PMID: 9595616). Frequency estimates from gnomAD were compared with estimates based on the lower frequency bound from the Wilson calculation.

**RESULTS:** In regions with less than 300 observed alleles, there were 187,258 variants with a 1% allele frequency or less according to the Wilson interval. The gnomAD allele frequency at this level of observation shows 171,385 variants. The difference between these groups (17,313 variants) represent variants that would have been discarded using a 1% frequency threshold based on the reported gnomAD frequency.

**DISCUSSION:** Population frequencies are a powerful means of focusing attention on a subset of important variants during clinical genomic analysis. We present a procedure for revising frequency estimates that may be inappropriately high given the underlying number of successfully genotyped alleles. The presented data will further explore the overlap between the set of revised alleles and datasets identifying known pathogenic variants.

## PgmNr 2968: Visualization of relationship inference in large-scale genetic studies.

### Authors:

Relationship inference is fundamental to genetic data and analyses. Recent advances in computational algorithms have made it feasible to infer relatedness in > 1 million samples, *e.g.*, using our software tool KING. Here we present visualization techniques to facilitate and enhance relationship inference in large-scale genetic studies. The concept underlying the visualization of relationship inference is that the inferred relationships can be displayed in undirected graphs, with nodes representing samples, and colored edges representing different types of relationships (*e.g.*, using the R package igraph), with the resulting pedigree evaluation visualized in classical pedigree structure (*e.g.*, using the R package kinship2). Our visualization processes are as follows: 1) To visualize pedigree errors in a family, we display documented relationships in a classic pedigree structure, next to inferred relationships in an igraph plot, with inconsistent relationships highlighted; 2) To visualize a summary of all documented and cryptic relationships, we utilize the powerful igraph operations on subgraphs (*i.e.*, families) and visualize all unique family configurations (such as sib pairs, trios, *etc.*) in one graph, together with the counts of each configuration; 3) Reconstructed families are visualized in classic pedigree structures; 4) Clustered families are visualized in igraph plots; 5) Genomes that contain runs of homozygosity are visualized using the ggplot routines; 6) To visualize potential sample swaps for a set of samples that are genotyped or sequenced with multiple platforms/technologies, we use a directed igraph to connect samples with identical genomes but different names. The visualization of mismatch patterns in a directed igraph provides additional information regarding the possible error mechanisms (*e.g.*, sample switch in pairs, one sample shift, *etc.*). All visualization techniques are implemented in R and integrated in KING *via* the “rplot” option. Further, our efficient implementation in KING makes all of the described visualizations feasible for biobank-scale data. We demonstrate various visualization techniques in several large-scale datasets. Data visualization in KING is also detailed in the KING tutorial at <http://people.virginia.edu/~wc9c/KING/KINGvisualization.html>. These newly implemented visualization algorithms allow KING to communicate results more effectively with the software users, providing a better understanding of their genetic data.

## PgmNr 2969: Improving polygenic risk prediction by incorporating LD information from multi-ethnic Biobank data.

Although various polygenic risk prediction methods have been put forward in recent years, most available methods are inadequate for genetic risk prediction for complex traits or diseases in non-European populations because they utilize only a single population, mostly European ancestry, for both training and validation datasets. Here, we introduce a novel penalized regression based polygenic risk prediction method for cross-ethnicity studies. We introduce a new penalty function to incorporate the different LD structure across multiple ethnicities and evaluate the predictive performance using the Lasso and the minimax concave penalty (MCP) to induce a sparsity solution. These functions can improve the prediction accuracy for complex traits of non-European ancestry (primary ethnicity) using European ancestry (secondary ethnicity) in large sample size. Our novel implementation of a parallel computing algorithm makes it feasible to apply our method to biobank-scale multi-ethnic GWAS data. Furthermore, they can take advantage of the secondary ethnicities based on summary statistics and thus have the potential to utilize information from most published GWAS summary statistics. We illustrate the method using Chinese GWAS datasets with 1000 Genomes imputation through collaboration with Tongji Medical College, including: training (N=7,417) and testing (N=1,452). We also picked 7,417 individuals from UK Biobank as training set. LD score (LDSC) were estimated using 1000 Genomes EUR and EAS populations. LDD (LD difference) is defined as  $LDSC_{EUR} - LDSC_{EAS}$ . We first simulated SNPs with relatively small LD difference between the UK and Chinese populations. We sampled 5000 SNPs (2K with LDD >0.02, 2K with LDD < -0.03 and 1K in middle). 1,000 causal SNPs (20%) were randomly selected from the 5,000 SNPs and SNP-heritability was set to 50%. We then simulated SNPs with larger LD difference between the UK and Chinese populations. We sampled 5000 SNPs (2K with LDD >0.03, 2K with LDD < -0.05 and 1K in middle). The simulation results clearly shows the advantage of using a cross-population penalty over a single population method. When LD difference is relatively small, UK trained model + China summary statistics even outperform trained models based on Chinese individual data.

## PgmNr 2970: Methylome-wide association study identifies CpG sites associated with 30 complex traits.

Transcriptome-wide association studies (TWAS), in which gene expression is imputed from SNP genotypes and then tested for association with a trait of interest, have become a popular post-GWAS approach for elucidating the role of gene expression in complex traits. This methodology can also be extended to other complex biological intermediates, such as CpG methylation. Here, we explored how well CpG methylation can be predicted from SNP genotypes, and conducted a methylome-wide association study (MWAS) of 30 complex traits.

Using data from the Avon Longitudinal Study of Parents and Children (ALSPAC), we investigated how well three penalised regression methods - ridge regression, elastic net and LASSO - predicted CpG methylation from local SNP genotypes. Methylation was poorly predicted at most CpG sites (150,661 of 173,769 CpGs showed prediction  $R^2 < 0.1$ ), although for a small subset, it was relatively well predicted (2486 CpGs showed  $R^2 > 0.5$ ). Elastic net and LASSO performed similarly, both outperforming ridge regression, indicating a potential sparse underlying genetic architecture of CpG methylation.

Following identification of CpGs that can be predicted well enough from SNP genotypes, we then constructed prediction models for 65,853 CpG sites (showing  $R^2 > 0.01$ ) and applied them to publicly available genome-wide association study (GWAS) summary data for 30 complex traits in an MWAS. We identified 7214 predicted methylation - trait associations at 4269 unique CpGs, including CpGs that tag known GWAS risk genes. To further elucidate the function of these CpGs, we tested association between imputed methylation levels and imputed expression of nearby genes, finding 101 associations between 64 CpGs and 34 genes, providing insight into the interplay between CpG methylation, gene expression and complex traits.

We conclude that MWAS represents a powerful method for investigating the role of CpG methylation in complex traits, and that further application and integration with other data (including gene expression) may help improve understanding of the biological mechanisms underlying GWAS signals.

## PgmNr 2971: Rare variant association analysis for studies with rich phenotyping subject to missingness.

Many large-scale genome-wide association studies, such as TOPMed, pair rich phenotyping with whole genome sequencing; however, not all phenotypes are measured in all studies or for all individuals. Existing rare variant association methods only allow for the use of completely observed phenotyping, and therefore do not take full advantage of studies with broad but incomplete phenotyping. We propose kernel association tests based on a multivariate regression framework to test for multi-phenotype associations and phenotype-specific associations. We consider jointly modeling related phenotypes in a multivariate linear model adjusting for population structure for quantitative phenotypes, which is extended to a mixed model to account for relatedness using a sparse genetic relatedness matrix. We allow for missing data in phenotypes by considering the likelihood contribution of all observations, given that any of the modeled phenotypes are observed. We specifically allow for the use of all available data by performing estimation through the expectation conditional maximization algorithm. We demonstrate in simulation the Type 1 error rates and power of the proposed tests and compare them to existing rare variant association methods that only allow for complete phenotype data. We simulate settings with different proportions of missingness and correlation structures between phenotypes. We further apply our methodology to large-scale sequencing efforts to study related pulmonary phenotypes that have been incompletely observed. Pulmonary traits have been shown to have shared genetic architecture among common variants, high statistical correlation, and related biological mechanisms. We model pulmonary and related traits jointly and test for trait-specific and multi-trait associations. Our methods allow for the complete use of all available data to empower statistical tests for rare variants by better purposing the available data, rather than relying exclusively on growing whole genome sequencing study sample sizes to improve power.

## PgmNr 2972: Increased *SLC6A14* expression is associated with reduced cystic fibrosis lung function mediated by increased susceptibility to *P.aeruginosa* infection.

Progressive lung disease, the major concern for morbidity and mortality in cystic fibrosis (CF), results from cycles of infection and inflammation and is modulated by genes in addition to the CF transmembrane conductance regulator (*CFTR*). A genome-wide association study (GWAS) by the International CF Gene Modifier Consortium (ICFGMC) identified a CF lung disease locus on chromosome X between *SLC6A14* and *AGTR2* (Corvol, *et al*, 2015). We sought to understand how the associated non-coding SNPs contribute to CF lung disease.

First, we established that human primary nasal cells (HNE) are a suitable airway model to study lung disease modifiers in CF by comparing RNA-seq of HNE to the gold standard human primary bronchial (HBE) model from 13-paired CF samples. We observed a strong correlation in gene expression between the two airway models. Notably, the correlation patterns of *SLC6A14* expression with apical constituents (including *CFTR*) that were considered relevant epithelial factors were consistent between HNE and HBE ( $p=2.4E-5$ ). *AGTR2* showed no expression in either cell type.

We then conducted expression quantitative trait loci (eQTL) analysis using RNA-seq of HNE from 70 Canadian individuals with CF. The *SLC6A14* eQTL pattern co-localized with the ICFGMC GWAS lung disease results using the *Simple Sum* colocalization method ( $p\text{-value}=9.5E-9$ ; Gong *et al*, 2019). The finding supports that the associated SNPs impact lung disease through the expression of *SLC6A14* with increased *SLC6A14* expression corresponding to reduced lung function.

The expression of *SLC6A14* and *CD45* from the HNE were correlated ( $\text{corr}=0.68$ ,  $p=7.2E-10$ ). *CD45* is a marker of immune cell composition in RNA-seq of HNE (Polineni *et al*, 2018) and thus its strong correlation with *SLC6A14* suggests increased *SLC6A14* expression may be associated with susceptibility to bacterial infections. We carried out an association analysis between age of first *P. aeruginosa* (PsA) infection and variants at the ICFGMC lung disease GWAS locus in 1,522 CF Canadians and observed an association pattern similar to the lung disease GWAS. A mediation analysis demonstrated that the age of first PsA is a significant mediator ( $p=0.007$ ) between the top *SLC6A14* eQTL and lung disease, corresponding to 34% of the total effect.

Together, this study suggests that increased *SLC6A14* expression results in reduced lung function in CF patients that manifests with earlier onset of PsA infection.

## PgmNr 2973: Leveraging genetic ancestry for new insights into complex traits in admixed populations.

---

Genetic studies in multi-ethnic cohorts offer great potential to elucidate the genetic factors influencing complex traits. A variety of statistical methods have recently been developed to overcome special challenges for whole genome association analysis of complex traits in large-scale multi-ethnic cohorts. With existing methodology, however, genetic ancestry differences among sampled individuals are often treated as a confounder to be adjusted for in an analysis to protect against spurious association. Leveraging genetic ancestry can provide improved complex trait mapping in multi-ethnic populations, such as African Americans and Hispanic/Latino populations, who have admixed ancestry derived from multiple continents. We have developed mixed effects models for admixture mapping that incorporate both local and global ancestry for the identification of genetic loci influencing complex traits. The proposed mixed model admixture mapping methods have been developed for continuous and dichotomous traits, and are completely applicable to large-scale whole genome studies with multi-ethnic samples from a variety of study designs. We demonstrate the utility of leveraging genetic ancestry for complex trait mapping in applications to the Hispanic Community Health Study / Study of Latinos (HCHS/SOL) to elucidate the genetic determinants of glomerular filtration rate (GFR), a trait associated to chronic kidney disease. The genome-wide admixture mapping was performed on 12,702 samples using our proposed linear mixed model with a joint test for the local ancestry count from all European, African and Native American ancestries. We identified a significant signal on chromosome 15 ( $p\text{-value} < 5.7 \times 10^{-5}$ ) in an admixture-linkage disequilibrium block of 37 variants in the *RYR3* gene, a gene implicated in cellular calcium signaling. Single tests into each ancestral group separately showed that this signal is driven by the African ancestry. The genome-wide association mapping on about 2,5 million SNPs using a similar linear mixed model was able to capture significant association signals in three chromosomes, but not in chromosome 15. These results emphasize the great potential of admixture mapping as an alternative approach to the traditional genome-wide association studies for the genetic mapping of complex traits in multi-ethnic population.

**Introduction:** For complex traits such as lung disease in Cystic Fibrosis (CF), Gene x Gene or Gene x Environment interactions can impact disease severity but these remain largely unknown. Unaccounted-for genetic interactions introduce heterogeneity in the variance of the quantitative trait across the genotypic groups (Pare et al., 2010); thus, a GWAS using variance testing can identify variants putatively involved in genetic interactions. Joint tests of both mean and variance (or full distributional differences) across genotype groups can account for unknown genetic interactions and increase power for gene identification. Aschard et al. (2013) proposed a variant of the Kolmogorov-Smirnov test but its computational requirements limit implementation genome-wide. Parametric joint tests that assume a Gaussian trait under general models (joint location-scale test (JLS); Soave et al., 2015) or under additive assumptions (heteroskedastic linear model (HLM); Yonge et al., 2018) are accessible for GWAS, but under departures from normality, these can suffer from type I error inflation or be inefficient, even after normalization.

**Method:** Here, we overcome previous limitations by developing a quantile regression-based JLS method (qJLS) without any distributional assumptions, is robust to outliers, detects linear and non-linear changes in mean and variance and in the shape of the distribution and is computationally efficient for GWAS. A simulation study compares the statistical power of qJLS to the JLS and HLM methods, investigating the effect of varying interaction magnitudes and phenotypic distributions including skewed, heavy-tailed and count data. We apply the qJLS in a GWAS of CF lung disease in the Canadian CF Gene Modifier consortium (n=2,835).

**Results:** The simulation study shows that qJLS is more powerful than JLS and HLM with skewed or heavy-tailed distributions, even with a quantile normalization. Under the Gaussian trait scenario for which the JLS and HLM were designed, JLS and HLM are more powerful. Type I error was well-controlled for all methods; without normalization, JLS and HLM showed inflated type I error under non-normality.

**Discussion:** The qJLS statistic for GWAS is an alternative to conventional mean-based tests in the presence of unknown or unmeasured genetic or environmental interactions, is applicable and more powerful for non-normal phenotypic distributions (e.g. those that are skewed or heavy-tailed) and in the presence of outliers.

## **PgmNr 2975: Meta-prediction of gene expression levels from genotypes across multiple tissues and datasets using summary-level data.**

Transcriptome wide association studies (TWAS) is a powerful method to interpret the underlying biological mechanisms underlying GWAS loci by mapping gene expression levels with phenotypes. In TWAS, gene expression is often imputed from individual-level data trained from external resources, such as GTEx, and several approaches shared the prediction models as a summary-level data (e.g. eQTLs and effect sizes). Because the eQTL discovery can be limited by the sample size, which in turn, limits the power of the downstream TWAS, we developed an integrative approach to leverage the abundance of prediction models trained from multiple tissues and datasets. Here, we propose SWAM (Smartly Weighted Averaging across Multiple datasets), a meta-prediction method to improve prediction accuracy by integrating relevant models across tissues and datasets. Instead of training directly from a single reference data, SWAM aggregates existing prediction models, calculating expression using an optimal linear combination of tissues for each gene. As a result, tissue-specific expression calculated from SWAM is not limited by the sample size of the target tissue but leverages summary-level information from multiple datasets without requiring raw data.

To demonstrate the improvement in prediction accuracy, we applied our method to predictDB's single-tissue lymphoblastoid cell line (LCL) prediction model to obtain meta-LCL model. We then used our meta-LCL model to impute tissue-specific expression for 344 European samples from the GEUVADIS consortium. Overall, we were able to predict 2,948 genes at a false discovery rate (FDR) < 0.05, a significant improvement over the 1,809 genes from the prediXcan single-tissue model. SWAM also outperformed another cross-tissue model UTMOST, which requires raw data, and found 2,373 predictable genes at the threshold. We also extend our method to TWAS, using metaXcan and summary GWAS statistics for many traits, including HDL, LDL from GLGC. We found that for most tissues, there was a 1.5~4 fold increase in the number of significant signals using SWAM compared to single-tissue models, even after accounting for stricter transcriptomic-wide threshold. For example, the liver tissue from GTEx which has small sample size, SWAM detected 71 genes compared to 16 using single-tissue liver. Our results demonstrate that meta-prediction from summary-level data can substantially improve the power of TWAS compared to using a single trained model.

## PgmNr 2976: A Bayesian graphical model approach to inferring gene regulatory networks.

**Introduction:** Gene regulatory networks have been studied extensively in genomics to understand the relationship among genes. In a gene regulatory network, a directed edge between two gene nodes may be interpreted as a causal (i.e., regulatory) relationship. Many methods have been developed to infer regulatory networks directly from genomic data. However, due to noise in the data not all edges in the inferred network have the same level of confidence and none of the existing methods quantify such uncertainty. Additionally, existing methods often ignore potential confounding variables. **Methods:** We have developed a novel Bayesian approach for gene regulatory network inference. Our method, baycn, estimates the posterior probability of the state (presence/absence and direction) for each edge and provides a coherent framework to account for confounding variables. We develop a Markov Chain Monte Carlo algorithm for inference that accepts a candidate graph as input, which helps reduce the search space to a more manageable size. The candidate graph may be inferred by another, much faster, network inference method and may contain false edges or undirected edges. We incorporate into the algorithm the Principle of Mendelian Randomization (PMR), which is a randomization principle that helps establish causality from observational genomic data. To do so, we impose the constraint that genetic variant nodes are always parents of gene expression nodes. We further include confounding variables as nodes in the network to examine whether the conditions of the PMR are satisfied. **Results:** We performed extensive simulations under multiple networks with varying sizes and structures of the network, variable types (e.g., genotype and gene expression) and types of confounding variables. Posterior probabilities for these networks are close to what we would expect accounting for Markov equivalence, which means that multiple graphs of the same likelihood may exist. Our method can also identify false positive edges and performs well in the presence of multiple confounding variables.

## PgmNr 2977: Effects of reference panel composition on genotype imputation quality in founder samples.

---

Genotype imputation, the process of leveraging haplotypes observed in a reference panel to infer unobserved genotypes in other samples, is widely used in genetic studies. The performance of imputation depends on the representativeness of haplotypes present in the reference panel, which is a function of the number and diversity of haplotypes in the reference panel. In this study we evaluate imputation quality for DNA samples from a founder population (Amish) as a function of the relative mix of founder and nonfounder haplotypes in the reference panel.

We evaluated imputation performance using 3 different imputation reference panels for 6,153 Amish individuals genotyped on the Illumina Global Screening Array. Genotypes were imputed using the TOPMed reference panel that included 1,025 Amish whole genome sequences (n=54,035 subjs; TOPMed-global), or the one excluding the Amish (n=53,010 subjs; TOPMed-noAmish), or the one with Amish only (n=1,025; Amish-only). We evaluated imputation performance and quality across the 3 reference panels by comparing the number of imputed SNPs across panels and assessing concordance of imputed genotypes with genotypes obtained using whole exome sequencing (n=5,317).

All 3 panels imputed approximately the same number of common (MAF>5%) SNPs. Far more rare SNPs (MAF<0.5%) were imputed using the TOPMed-noAmish reference panel (n=1,929,020) than the Amish-only (n=126,510) and TOPMed-global (n=392,323) panels. Imputed genotypes from the TOPMed-noAmish panel also had much lower non-reference allele concordance rates compared to Amish-only and TOPMed-global (88.6% vs. 95.7% and 94.9% respectively for MAF 0.5 to 5%). These results suggest that the use of a cosmopolitan panel without a representation of the founder population could overcall false-positive rare variants (i.e., impute genotypes that may not exist) and support the further development of whole genome sequence reference panels for founder populations.

## PgmNr 2978: A unified framework for gene-based and multi-trait colocalization testing: Application to cystic fibrosis.

1) Department of Statistical Sciences, University of Toronto, Toronto, Ontario, Canada; 2) Program in Genetics and Genome Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 3) Division of Biostatistics, Dalla Lana School of Public Health, University of Toronto, Toronto, Ontario, Canada

To understand the mechanism by which genome-wide association study (GWAS) loci contribute to disease and to assess their contribution across traits demands integration of omics data from several sources. For example, integration of GWAS summary statistics with expression quantitative trait loci (eQTL) can inform whether a GWAS locus is driven by variation in gene expression and can pinpoint the responsible gene and tissue.

We previously developed a colocalization test, the *Simple Sum* (SS; Gong et al, 2019), that assesses pattern similarity between GWAS and eQTL statistics. The SS is of the form  $Z'AZ$ , with Z containing the GWAS statistics and matrix A incorporating eQTL or other omics data; p-values of SS can be computed analytically. When A is the identity matrix, the test statistic simplifies to a gene/set-based test. When A represents GWAS statistics for a second phenotype, the SS measures genetic correlation between phenotypes.

However, in a given GWAS region with significant association but, for example, no eQTLs, the SS could have type I error inflation, thus we previously restricted SS analyses to regions with sufficient eQTL evidence. To facilitate genome-wide implementation of SS as a general integration tool, here we propose an adaptive shrinkage method in the SS (*SS-shrink*) that is similar to the weighted lasso (Bergersen et al. 2011).

Simulation shows that *SS-shrink* has correct type I error control for all settings and improved power in the presence of linkage disequilibrium (LD) and allelic heterogeneity when compared to *COLOC* (Giambartolomei et al. 2014) and *eCAVIAR* (Hormozdiari et al. 2016). Several analyses in the International Cystic Fibrosis Gene modifier cohort (ICFGMC; n>6,500) demonstrate the effectiveness of *SS-shrink*. For example, three intestinal obstruction associated GWAS loci previously colocalizing with eQTLs in the pancreas using the SS (Gong et al. 2019) continue to do so with *SS-shrink* (p=3.10E-8, p=9.89E-10 and p=6.33E-5 at *ATP12A*, *SLC6A14* and *SLC26A9* respectively). While integration of lung function GWAS from the ICFGMC at the *SLC9A3* modifier locus (min. GWAS p=4.62E-12; set-based SS p=7.12E-8) with eQTLs from nasal epithelia of 81 ICFGMC Canadian participants (min. eQTL p=9.6E-3; set-based SS p=0.47) shows no colocalization evidence (*SS-shrink* p=1.00).

*SS-shrink* is a flexible, unifying framework for data integration and improves over traditional methods in the presence of weak signals, LD or allelic heterogeneity.

---

Chronic Obstructive Pulmonary Disease (COPD) is a phenotypically heterogeneous disease. Identifying subtypes would be of high value from a clinical and public health perspective. Extensive prior work has attempted to identify subtypes by phenotype clustering, but these methods often do not account for differences in severity, disease course, or underlying biologic mechanisms. Here, we used genetic association results to infer potential COPD subtypes and assessed the biological relevance of these subtypes using individual level data from the COPDGene study. We used a set of COPD and related phenotype-associated SNPs derived from recent GWAS, and decomposed the Z-score associations at those SNPs across hundreds of traits from the UK Biobank. Decomposition was performed using a recently developed Bayesian approach, and results were used to build SNP clusters with similar cross-trait characteristics. Finally, we derived cluster-specific genetic risk scores (GRS) and assessed their association with clinical features available within COPDGene.

We selected variants from three GWAS studies of obstructive lung disease: 164 from COPD, 279 from lung function, and 45 from asthma. Our clustering revealed three clusters consistent across different settings; the top trait (signed) weights were (1) +eosinophils, +wheeze, +neutrophils; (2) +obesity, -height; (3) +height, -neutrophils. Only 25% SNPs contributed with normalized weights >0.5, highlighting a sparse decomposition. By building cluster-specific GRSs in the COPDGene study and associating them to clinical measures relevant to COPD, we found cluster-specific differences in BMI, lymphocyte counts, and chronic bronchitis. Further, we found no significant overlap between our genetic and phenotypic clusters in COPDGene, potentially suggesting a complementary role of genetic stratification. We also conducted a consensus version of clustering for SNP sets from three GWAS studies: trait weights are shared, but SNP weights are set-specific. Contrasting SNP sets by weights confirm that COPD and lung function SNPs mostly overlap, while asthma SNPs are separated (SVM classifier: 82% precision, 60% recall).

Phenotypic clustering of obstructive lung disease related risk SNPs can identify genetically driven phenotypic patterns in COPD. Selection of SNPs and traits for the clustering analysis as well as further exploration of the characteristics of subjects with differential on these GRSs are open questions for future research.

## PgmNr 2980: Association study of genetic variants in autophagy pathway genes and NSCL/P risk.

### Authors:

S. Lou<sup>1,2</sup>; L. Ma<sup>1</sup>; X. Yu<sup>1,2</sup>; D. Li<sup>1,2</sup>; Y. Pan<sup>1,2</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

---

### Objective:

Although genetic variants in autophagy genes were associated with the risk of oral cancers and early development, their associations with nonsyndromic cleft lip with or without cleft palate (NSCL/P) risk are not understood.

### Methods:

We systematically selected single-nucleotide polymorphisms (SNPs) in 23 autophagy genes and investigate this issue in a case-control study. The logistic regression model was used to calculate the effects of SNPs on NSCL/P susceptibility. In addition, we performed a gene-based analysis via sequence kernel association test (SKAT). Expression quantitative trait loci (eQTL) analysis was conducted using the Genotype-Tissue Expression (GTEx) dataset.

### Results:

Two SNPs in *KRAS* were significantly associated with NSCL/P susceptibility in the case-control study (rs12813551: OR=0.75, 95% CI=0.61-0.93,  $P=7.95E-03$ ; rs147020828: OR=0.67, 95% CI=0.50-0.90,  $P=7.67E-03$ ). Rs2301104 in *HIF1A* was also associated with NSCL/P susceptibility (OR=1.39, 95% CI=1.00-1.92,  $P=4.55E-02$ ). Furthermore, rs12813551 and rs147920828 exhibited eQTL hits, which showed a significant association with expressions of *KRAS* ( $P=4.49E-04$  in fibroblast cells, and  $P=2.4E-02$  in lymphocyte cells, respectively). Moreover, the expression level of *KRAS* is higher in dental pulp stem cells (DPSC) of NSCL/P cases than those in controls, while *HIF1A* exhibits the opposite.

### Conclusion:

Our results indicated that SNPs in autophagy pathway genes *KRAS* and *HIF1A* played important roles in NSCL/P susceptibility.

## PgmNr 2981: Identification of new susceptibility loci for nonsyndromic cleft lip with or without cleft palate.

### Authors:

L. Ma<sup>1</sup>; S. Lou<sup>1,2</sup>; X. Yu<sup>1,2</sup>; D. Li<sup>1,2</sup>; Y. Pan<sup>1,2</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Nanjing Medical University, Nanjing, China; 2) Jiangsu Key Laboratory of Oral Diseases, Nanjing Medical University, Nanjing, China

### Objective:

Although several genome-wide association studies (GWAS) of non-syndromic cleft lip with or without cleft palate (NSCL/P) have been reported, more novel association signals could be exploited by combining individual studies together, which will further elucidate the genetic susceptibility of NSCL/P.

### Methods:

We performed a meta-analysis of two published Chinese GWAS cohort studies (858 NSCL/P cases and 1,248 controls) and followed by replication in two stages. In addition, we calculated the weighted genetic risk score (wGRS) of the susceptibility loci based on odds ratio of each variant from the replication cohort.

### Results:

In the combined analysis of GWAS meta-analysis and replication stages, we identified five novel association signals: rs11119445 (OR=0.73, 95% CI: 0.67 to 0.79;  $P=6.44E-14$ ), rs227227 (OR=1.34, 95% CI: 1.24 to 1.45;  $P=5.02E-13$ ), rs12561877 (OR=0.72, 95% CI: 0.65 to 0.79;  $P=2.80E-11$ ), rs643118 (OR=1.25, 95% CI: 1.13 to 1.37;  $P=4.45E-06$ ), and rs2095293 (OR=1.22, 95% CI: 1.11 to 1.34;  $P=2.98E-05$ ), which were independent of the previously reported SNP at the same locus. The nucleotide polymorphism (SNP) marker rs11119445 maps 7.4kb 3' of *SERTAD4-AS1*, a non-coding RNA on 1p32.2. The SNP markers rs12561877 and rs227227 locate in the intron of *SYT14*. The SNP marker rs643118 lies in the intron of *TRAF3IP3*. The SNP marker rs2095293 resides in an intron of *NR6A1*. The mean (standard deviation) of the wGRS was 1.83 (0.64) for NSCL/P cases and 1.59 (0.68) for controls respectively, which showed a clear separation between them ( $P=2.67E-16$ ). Based on the ToppFun online tool, the most enriched pathway is *POU5F1 (OCT4)*, *SOX2*, *NANOG* activate genes related to proliferation ( $P=1.04E-03$ ).

### Conclusion:

Our studies have improved our understanding of the genetic susceptibility to NSCL/P and provided further clues to its etiology in the Chinese population.

## PgmNr 2982: Transcriptome-wide association studies (TWAS) for regional brain volumes and brain white matter microstructure in >20,000 individuals.

Brain imaging features are promising endophenotypes for psychiatric disorders, cognitive function, and psychosocial factors. Understanding how genetic variants impact variations in brain structure and function help us understand how the brain works. Recent studies have investigated the heritability of brain imaging features and performed corresponding genome-wide association studies (GWAS), in particular for regional brain volumes (quantified by regions of interest [ROIs]) and for brain white matter microstructure (quantified by diffusion tensor imaging [DTI] features). To further reveal genetics underlying brain imaging phenotypes, we performed transcriptome-wide analysis (TWAS) on 101 ROIs (sample size  $n=22,748$ ) and 110 DTIs ( $n=20,115$ ) features derived from brain MRI from UK Biobank (UKB), Alzheimer's Disease Neuroimaging Initiative (ADNI), Pediatric Imaging, Neurocognition, and Genetics (PING) Study, the Philadelphia Neurodevelopmental Cohort (PNC), and the Human Connectome Project (HCP). Specifically, we first trained gene expression prediction models from the CommonMind eQTL data containing 467 samples with both genotype and dorsolateral prefrontal cortex gene expression data, then we performed transcriptome-wide ( $\sim 12,000$  genes) and phenome-wide (101 ROI and 110 DTI features) association analysis adjusting for kinship coefficients in a linear mixed model framework. Our TWAS identified 83 signals (49 for ROI and 34 for DTI; adjusting for transcriptome-wide and phenome-wide multiple testing), among which 45 (32 for ROI and 13 for DTI) are novel when compared to the corresponding GWAS results. We additionally applied Unified Test for Molecular Signatures (UTMOST) to perform TWAS across multiple tissues using UKB GWAS summary statistics, which confirmed 9 ROI and 13 DTI signals out of the 83 individual-level discoveries. Our individual-level TWAS signals include several genes with supporting evidences from the literature. For example, *EEF1AKMT2* and *LEMD3* (also discovered by our GWAS) were reported to be associated with hippocampal volume; *KTN1-AS1* (not by our GWAS) was reported to be associated with putamen volume. Among the identified genes, many are annotated with cognitive functions or psychiatric disorders. Our analyses demonstrate the value of TWAS for uncovering genetic mechanisms underlying regional brain volumes and brain white matter microstructure, which will shed light on genetics behind many brain related traits and disorders.

## PgmNr 2983: Analysis of whole exome sequencing of the *ClinSeq*<sup>®</sup> data with four regression-based tests of association.

*ClinSeq*<sup>®</sup> is a medical sequencing study designed to investigate associations of sequence variants with traits related to Coronary Artery Disease (CAD). The study currently includes more than 1,000 participants between the ages of 45 and 65 with normal to severe coronary artery calcification scores. About 200 CAD-related traits were measured at the NIH Clinical Research Center in Bethesda, Maryland. Exome sequencing was performed with four distinct capture kits at the NIH Intramural Sequencing Center (NISC): Agilent SureSelect with 38 Mb and 50 Mb (Index and ICGC) capture kits for 396 and 320 individuals, respectively, TruSeq (V1 and V2 combined) for 285 individuals, and SeqCap EX Exom+UTR for 18 individuals respectively. Data cleaning was performed within data from each capture kit separately and then in the combined data after merging. Single nucleotide variants (SNVs) common to all capture kits were used yielding 589,727 SNVs in 886 unrelated European Americans for analysis. Tests of association were performed for each SNV and each of the 130 CAD-related untransformed and rank-inverse transformed traits pre-adjusted for age, sex, BMI, the use of cholesterol lowering medication and capture kit. Traits were selected if any SNV was significant at the indicated level for both the untransformed and rank-based inverse normal transformed trait. Tests included simple linear regression (SLR), ComPaSS-GWAS, ComPaSS-rare and tiled regression (TR). Fifteen traits were significant at a critical value of  $10^{-7}$  for SLR, 5 and 9 traits for a corroboration score of 0.6 for ComPaSS-GWAS and ComPaSS-rare, respectively, and 15 traits for TR with selection criteria of  $10^{-4}/10^{-5}/10^{-6}$  for tile, chromosome and genome levels. There were 5 traits with the same significant SNV found across all 4 tests of association. Compared to traditional SLR, ComPaSS-GWAS found fewer significant SNVs because the type I error rate was reduced through the use of repeated random splits. ComPaSS-rare using complementary random weights on each sample instead of binomial weights in splitting in half found more significant rare SNVs than ComPaSS-GWAS due to its increasing power to detect rare SNVs. TR found fewer significant SNVs than SLR by identifying independently and jointly significant SNVs across the genome. Tests of association performing ComPaSS-GWAS/ComPaSS-rare and TR in exome-sequencing data may help to reduce type I errors rates and prioritize SNVs for additional follow-up.

## PgmNr 2984: Design and prototype of the web implementation for the KING software package for relationship inference in genetic studies.

### Authors:

Chen; Z.N. Zhu; A.W. Manichaikul; W.M. Chen

[View Session](#) [Add to Schedule](#)

**Affiliation:** Center for Public Health Genomics, University of Virginia School of Medicine, Charlottesville, VA

---

**Introduction:** We have developed an integrated software toolset (KING, <http://people.virginia.edu/~wc9c/KING/>) for relatedness inference in large-scale genetic studies. KING has been widely used for quality control (QC) and genetic analysis in large-scale studies including all Biobank data, and many genomics and transcriptomics sequencing projects. While KING as a command line tool is sufficient for many genetic studies, some research team may not have the computational resources to utilize the full functionality offered by KING, for example, some visualization of relationship inference may require proper installation of several R packages.

**Objective:** To increase KING's usability and its feasibility of community free distribution to avoid downloading of the binary C++ KING software and its supportive compiling libraries for various computer platforms, we have developed a web-based KING system with graphical user interface to allow community researchers to apply our latest developed algorithms directly for analysis of their sequencing and other high-throughput array data.

**Methods:** The web frontend of our KING web system is implemented using HTML and JavaScript programming languages. The Common Gateway Interface (CGI) protocol is used to get frontend data and web user inputs for backend server processing via Perl CGI and Java Servlet technologies. Apache web server is utilized for web hosting, and the system is implemented in Linux operating system using a powerful backend server with 96 cores for parallel computing.

**Progress and Further Work:** We have prototyped the web interface of KING software and have implemented a CGI program to get the frontend user inputs for backend data processing. Users' data are encrypted and secured. The CGI program returns the results on the web or via email with downloading URLs if the data/results are too big for web quick display and response. We have established a development instance and also a test instance for project development, and are in the process of setting up a mature production instance for final public release. The web-based KING will implement the full functionality of our published and public downloadable KING software, including data visualization and IBD segment analysis, and among others. We will follow the standard software engineering practice to go through: design and prototype, development and test, and production phases to put out a mature KING software web system for the community to use.

## PgmNr 2985: HPrep: A model-based method to quantify reproducibility of HiChIP and PLAC-seq data.

---

High-throughput chromatin conformation capture (Hi-C) technology has been widely used to measure genome-wide chromatin spatial organization. Various statistical methods and computational tools have been developed for measuring the reproducibility of Hi-C data, a necessity for evaluating the validity of conclusions drawn from Hi-C data. Recently, HiChIP and PLAC-seq (HP) technologies have been developed for studying long-range chromatin interactions mediated by protein of interest, facilitating high resolution mapping of chromatin interactions at a much reduced cost. However, computational methods tailored for HP data are still lacking. In particular, existing methods for Hi-C reproducibility are not optimal for HP data, since none of them takes into consideration the ChIP enrichment level, a systematic biased unique to HP data.

To fill in this gap, we propose a novel model-based method, HPrep, to measure reproducibility in HP data. HPrep consists of four major steps: (1) preprocessing of the raw contact frequency matrix, (2) fitting positive Poisson regression model to normalize ChIP enrichment level and other systematic biases in HP data, (3) performing 1-D local smoothing on the normalized contact frequency, and (4) applying a stratified correlation algorithm to the smoothed contact frequency to quantify the reproducibility between two HP datasets.

We applied HPrep to H3K4me3 PLAC-seq data on both mouse embryonic stem cells (mESCs) and mouse anterior dorsal cerebellar vermis (ADCV), each consisting of two biological replicates. In addition, we created a set of pseudo-replicates by merging biological replicates followed by random sampling. We obtained measures of 0.94, 0.91, 0.84, and 0.52 for pseudo-replicates, mESC biological replicates, mouse ADCV replicates, and non-replicates, respectively. In addition, we applied HPrep to H3K4me3 PLAC-seq data on four human fetal brain cell types (radial glial cells, intermediate progenitor cells, neurons, and interneurons), each consists of two or three biological replicates, and found that biological replicates from the same cell type show higher reproducibility than biological replicates from different cell types. In comparison, results obtained by naively applying a standard Hi-C reproducibility methodology failed to show differentiation (for example, 0.09 for biological replicates and 0.05 for non-replicates). We believe that HPrep fills in an important gap to quantify reproducibility in HP data.

## PgmNr 2986: Regulatory-coding variant interactions shape genome structure and can be leveraged for gene mapping GWAS associations.

While GWAS have discovered variants associated with numerous traits, the molecular mechanisms through which these variants impact phenotypes remain poorly understood. Recent studies have shown that cis-regulatory variants modulate the effects of coding variants in their target genes such that pathogenic coding alleles on under-expressed haplotypes have reduced penetrance. Here we show how the long-term effect of these interactions shapes the patterns of variation across the genome and how ascertainment bias distorts these patterns in a way that can be used for gene mapping GWAS hits. We analyze eQTLs from the Genotype-Tissue Expression Project (GTEx) with genetic variation from 1000 Genomes and find that haplotypes with down-regulating eQTL alleles contain 14% (p-value  $6.7 \times 10^{-6}$ , paired t-test) more derived coding alleles on average than haplotypes with up-regulating alleles. This indicates that haplotypes with down-regulating eQTL alleles appear to be more tolerant of derived coding alleles over time and compliments previous work that shows missense variants that are predicted to be strongly deleterious tend to be under-expressed when allele-specific expression data is available. We hypothesize that the distribution in a gene of the number of derived alleles on up- and down-regulated haplotypes will deviate from what is observed across a population sample if haplotypes are ascertained based on the the presence or absence of a GWAS top hit risk allele that is impacting the gene in question. We propose a test that maps top GWAS risk loci to pertinent genes without needing in-sample data or summary statistics. Across six traits with a large number of intergenic GWAS hits, we find genes prioritized by our method are 7.4 times (p-value  $2.5 \times 10^{-7}$ , Fisher's exact) more likely to be reported in the original GWAS as pertinent for the traits than the genes not prioritized. This demonstrates that our test provides a novel source of information for gene prioritization.

## PgmNr 2987: Estimating correlations between genetic effects at interacting regions.

---

In the past few years, technological advances in chromosome conformation capture methods have identified numerous regions across the genome that physically interact. Interactions between regions such as enhancers and promoters are crucial to regulation of gene expression. For example, if a specific enhancer-promoter interaction regulates expression of a gene that is involved in some trait-influencing pathway, we would expect the effect sizes of variants in those regions to be correlated. However, the vast majority of methods for post-GWAS analysis assume that there is zero covariance between causal effect sizes. Thus, existing methods likely cannot reveal insights into how interacting regions influence complex traits.

Here, we propose an approach to model and estimate the correlation between effect sizes at two non-overlapping regions while explicitly modeling linkage disequilibrium (LD). We model the dependence between genetic effects in pairs of regions with a constant correlation coefficient between all contact pairs, and we estimate this correlation coefficient from GWAS data with a method-of-moments procedure. Through extensive simulations starting from real genotypes of the UK Biobank and 1000 Genomes Phase 3 reference panel, we show that given a known set of interactions and per-SNP variances, the correlation coefficient can be consistently estimated and the standard error decreases as the LD block size decreases.

## PgmNr 2988: Using information across tissues and genes to predict gene expression in transcriptome-wide association studies.

Recent years have seen the development of several methods that combine GWAS data with expression reference panels (e.g., GTEx) to discover genes associated with complex traits. One class of such methods is Transcriptome-wide Association Study (TWAS). These methods involve three steps. First, predictors of gene expression for each gene based on genotypes are constructed using reference panels such as GTEx. Second, the genetically regulated portion of gene expression is imputed in GWAS samples based on their genotypes and the predictors previously built. Finally, the imputed expression is correlated with the phenotype of interest.

While the TWAS methods initially developed build gene expression predictors for one tissue at a time, the increasing availability of measurements from multiple tissues opens to the possibility of exploiting patterns of expression Quantitative Trait Locus (eQTL) sharing across tissues to improve imputation accuracy. Recently, a couple of multivariate regression methods have been developed that use information from multiple tissues concurrently. Extensive analysis of both simulated and real data showed a greater prediction accuracy of multivariate methods compared to univariate methods. However, currently available multivariate prediction methods analyze only one gene at a time, therefore not exploiting the increased amount of information about eQTL sharing that multiple genes can provide. Motivated by this, we sought to evaluate the accuracy of gene expression prediction of a Bayesian multivariate sparse regression method – initially designed for fine-mapping – with a prior that captures patterns of eQTL sharing across tissues and borrows strength across genes. Preliminary results from simulations show that our method can predict as well as currently available multi-tissue methods, while enhancing interpretability due to concurrent fine-mapping of causal variants.

## PgmNr 2989: Linkage disequilibrium pruning improves gene expression prediction across diverse populations.

### Authors:

R. Schubert<sup>1,2,3</sup>; P. Okoro<sup>2</sup>; A. Luke<sup>4</sup>; L. Dugas<sup>4</sup>; H. Wheeler<sup>1,2,4,5</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Dept of Biology, Loyola University Chicago, Chicago, IL.; 2) Dept. of Mathematics and Statistics, Loyola University Chicago, Chicago, IL; 3) Program in Bioinformatics Loyola University Chicago, Chicago, IL; 4) Dept. of Public Health Sciences, Loyola University Chicago, Stritch School of Medicine, Maywood, IL; 5) Dept. of Computer Science, Loyola University Chicago, Chicago, IL

Transcriptome-wide association studies are widely used for identifying potential regulatory mechanisms underlying complex traits. However, the portability of gene expression prediction models varies between populations likely due to different linkage disequilibrium (LD) patterns and allele frequencies. We sought to determine whether LD pruning prior to elastic net model building improves or maintains cross-population predictive performance while lowering runtimes.

We used transcriptome data from two cohorts, MESA (Multiethnic Study of Atherosclerosis, monocytes) and METS (Modeling the Epidemiological Transition Study, whole blood), as our primary training and test datasets. We pruned linked SNPs with a window size of 50kb, variant SNP shift size of 5, and  $r^2$  threshold of 0.8 within each of the 3 self-identified populations that comprise MESA: African American (AFA=233), Hispanic (HIS=352), and European (CAU=578). Then, in each population, we built pruned and unpruned models using elastic net with nested cross-validation to assess the predictive performance ( $\rho$ ) of local SNPs (within 1Mb) surrounding each gene. Genes with average predicted vs observed  $\rho > 0.1$  were considered significant. More genes were significant in pruned (AFA=3449, HIS=4048, CAU=4534) than unpruned models (AFA=3096, HIS=3856, CAU=4419). We predicted gene expression in METS (n=77 Ghanaians and African Americans) using the pruned and unpruned models built in MESA and compared predicted to observed METS expression. Spearman correlations were not significantly different when comparing pruned (median=0.089) and unpruned AFA (median=0.093) in METS ( $p=0.44$ ). However, Spearman correlations were higher in the pruned models for both HIS (pruned median=0.070, unpruned median=0.058,  $p=3.6e-4$ ) and CAU (pruned median=0.048, unpruned median=0.042,  $p=0.016$ ). The average runtime for building pruned models was 55 s per gene (95% CI [45.8, 64.2]), compared to 205 s per gene for unpruned models (95% CI [192.8, 218.1]).

Our results indicate that by LD pruning we decrease runtime and predict more genes both within and between populations without sacrificing accuracy. While prediction is best between similar ancestry populations, LD pruning prior to elastic net modeling prefilters out highly correlated SNPs within a population and thus may reduce potential sources of noise in the elastic net selection, which leads to improved predictive performance across populations compared to unpruned models.

## PgmNr 2990: Accounting for covariates in tiled regression analysis of complex traits.

**Authors:**

A.J.M. Sorant; J.A. Sabourin; A.F. Wilson

**Affiliation:** Computational and Statistical Genomics Branch, NIH/NHGRI, Baltimore, Maryland.

---

Complex traits typically have both genetic and non-genetic components which should be considered in forming a model explaining trait variation. Tiled regression, which determines an additive model with stepwise regression applied in stages, can incorporate covariates with several methods. The traditional method is to adjust a trait for covariates of presumed importance by regressing the trait on the covariates and then to use the residuals from the fitted model as a new trait for the usual tiled regression considering genetic predictors. However, it is also possible to incorporate covariates directly into tiled regression either by forcing them into every considered model or by testing them along with genotypes as potential predictors. Forcing inclusion of all covariates produces a predictive model similar to that determined by pre-adjustment, except that the covariate coefficients are not fixed, but determined in combination with genetic components under consideration at each stage. When covariates are instead tested as potential predictors for inclusion in the model, they may or may not be retained. For this study, four ways of handling covariates were considered: (1) ignoring them, (2) pre-adjusting the trait for them, (3) forcing them to be included in every model considered, (4) testing them for inclusion in the final model. Tiled regression was performed with each method, using software TRQUANT v 1.0, for several previously studied metabolic phenotypes from the Trinity Student Study (TSS) with 670,081 imputed genotypes on 2,232 individuals and also for several simulated traits using the same genotypes. Analysis of TSS phenotypes methylmalonic acid, serum vitamin B12 and holo-transcobalamin concentrations (log-transformed), considering covariates age, sex, body mass index and vitamin B6 supplementary intake, produced similar predictive models with all analysis methods. With simulated phenotypes based on five independent SNPs and two covariates, preliminary results (with 200 replicates) show that all analysis methods have similar ability to detect causal SNPs, with pre-adjustment or keeping all considered covariates usually having slightly higher power and type I error rate.

---

For the vast majority of trait-associated loci from genome-wide association studies (GWAS), the identity of the causal gene(s) underlying the association is unknown. Although previous work has shown that genome-wide patterns of enrichment can be informative about disease biology, no method we know of takes advantage of the full set of genome-wide signals to prioritize disease genes. Moreover, we are not aware of any statistical framework for combining results from independent methods to identify high-confidence genes supported by multiple lines of evidence.

Here, we first propose a new method that leverages genome-wide enrichments of gene features to compute a polygenic priority score (PoPS) and a p-value for each gene based on its features. We applied our method to summary statistics for 40 complex traits and diseases using 18,920 gene features derived from 12 gene expression datasets, 5 pathway databases, and a protein-protein interaction network. We validated our method on 14 sets of gold standard genes, where we predicted significantly higher scores for all 14 sets of gold standard genes tested, compared to all protein-coding genes. To further validate, we used Benchmarker (Fine et al. 2019 *AJHG*) to show that our

prioritized genes are significantly enriched for heritability for 38 of 40 traits, and we found that they are significantly enriched for their overlap with GWAS loci for 19 of 40 traits. We also used Benchmarker to show that we outperform DEPICT (Pers et al. 2015 *Nat Comm*) across 100% (13 of 13) traits tested.

Second, we propose a new framework for combining information from multiple independent gene prioritization methods. Based on the estimate that 30-70% of causal genes in GWAS loci are the closest gene to the index SNP, we estimated the probability that our prioritized genes are causal. By combining the results of our method with results of independent methods, we nominated 461 genes across 29 traits with probability of being causal greater than 0.8. These genes included well-established disease genes such as ACE for cardiovascular disease and MYOCD for atrial fibrillation. They also included genes recently nominated in other work as causal, such as IRF1 for IBD, and novel disease genes, such as FCER1G for Asthma. Overall, we present a framework to harness local and polygenic signal to prioritize causal genes from GWAS data and provide a promising list of candidate genes for targeted and cost-efficient follow up experiments in ~30 traits.

## PgmNr 2992: Incorporating single-cell RNA-seq data to infer allele-specific expression.

### Authors:

Allele-specific expression (ASE) can be quantified by the relative expression of two alleles in a diploid individual, and such expression imbalance may explain phenotypic variation and disease pathophysiology. Traditional methods detect ASE using easily obtainable bulk RNA-seq data, a data type that averages out the possible heterogeneity in a mixture of different cell types. Since patterns of ASE may vary across cell types, it is desirable to infer ASE in a cell-type-specific manner. This can be achieved by analyzing single-cell RNA-seq (scRNA-seq) data across many individuals. However, such analysis requires full-length transcript sequencing in single cells, which are costly to generate. To circumvent this limitation, we propose to incorporate cell-type composition information inferred from a small set of scRNA-seq data, possibly obtained from a different set of individuals, to characterize cell-type-specific ASE in a larger set of bulk RNA-seq data. To do so, we first employ MuSiC, a deconvolution algorithm, to infer cell-type compositions in bulk RNA-seq data using an external scRNA-seq dataset as the reference. To infer cell-type-specific ASE, we regress the bulk level allele-specific read counts over the estimated cell-type proportions through a linear mixed-effects model, and test for the presence of cell-type-specific ASE effect. Extensive simulations shown that our method performed consistently well under a wide range of scenarios. The type I error rate was under control and it was powerful in detecting cell-type-specific ASE effect even for rare cell types. We further evaluated our method on a benchmark dataset generated from human pancreatic islets where the true cell-type-specific ASE effect is known. Among 11,290 genes analyzed, the traditional bulk ASE analysis method, only detected three genes showing ASE. However, our method not only detected these three genes, but also detected an additional 2,400 genes showing cell-type-specific ASE. We further applied our method to another pancreatic islet bulk RNA-seq dataset for 89 individuals. Controlling for cell-type composition differences across individuals, our preliminary analysis recovered genes showing cell-type-specific ASE that are related to T2D. As bulk tissue data are more easily accessible than scRNA-seq, our method allows the utilization of the vast amounts of disease relevant bulk tissue RNA-seq data for elucidating cell type contributions in disease.

## PgmNr 2993: Characterizing the block-jackknife based significance testing used in stratified LD-score regression.

### Authors:

Stratified LD-Score Regression (S-LDSC; Finucane et al. 2015 Nat Genet) is a widely used method to detect whether trait heritability is enriched in a functional annotation. S-LDSC has previously been used to report the heritability enrichment of an annotation, the regression coefficient corresponding to the annotation (i.e., the contribution of the annotation to per-SNP heritability in a joint-fit model), and their corresponding p-values for a wide range of functional annotations. However, there are limitations of the block jackknife-based significance testing used in S-LDSC to control type 1 error for small annotations.

Here, we investigated type 1 error control in S-LDSC for small annotations using simulations. We implemented a simulation framework using 50,000 white-British UK Biobank samples and 9.3 million imputed variants to produce three sets of 1,250 phenotypes with 200, 1,000, and 10,000 causal SNPs and no functional enrichments. We tested 94 random annotations that varied in size, the number of jackknife blocks they overlapped, and average segment length of the annotation, 100 gene sets sampled from MSigDB, as well as the baseline\_v1.1 SNP annotations by running S-LDSC with one annotation at a time plus baseline\_v1.1 for each of the 3,750 phenotypes to estimate the per-SNP heritability and enrichment, and perform significance testing.

We observed inflation for both the one-sided and two-sided tests of the per-SNP heritability at low numbers of independent SNPs and overlapping jackknife blocks. Null calibration could be recovered by restricting to annotations overlapping more than 100 jackknife blocks and with more than 7,500 independent SNPs for the one-sided test of the per-SNP heritability. The two-sided test required restricting to 12,000 and 15,000 independent SNPs to recover null calibration for the most and least polygenic phenotypes, respectively. The enrichment estimates required a weaker threshold of 4,500 independent SNPs. The baseline\_v1.1 annotations had enrichment p-values that were well calibrated across all levels of polygenicity except for conserved regions, which had very mild inflation for the most polygenic set of phenotypes. We have implemented a test in the S-LDSC software to warn the user when their annotation does not meet the criteria required to produce statistically valid p-values and plan to continue to investigate analytical solutions to estimate standard errors in the S-LDSC framework.

## PgmNr 2994: Imputation of variable number tandem repeat variants reveals VNTRs driving GWAS loci.

### Authors:

R.E. Mukamel<sup>1,2</sup>; R.E. Handsaker<sup>2,3,4</sup>; S.A. McCarroll<sup>2,3,4</sup>; P. Loh<sup>1,2</sup>

The role that variable number tandem repeat (VNTR) loci play in heritable traits remains largely unknown, primarily due to difficulties genotyping these genomic structural variants at population-scale. To investigate the phenotypic impact of VNTRs, we developed statistical methods to phase and impute VNTR lengths. We identified 257 genic VNTRs—ranging in size from 18-bp repeats within exons to megabase-scale gene family polymorphisms—by scanning the human reference genome for repetitive sequence. We estimated the repeat lengths of these VNTRs from whole-genome sequencing read depth in 519 quartet families in the Simons Simplex Collection. We inferred allelic contributions to these measurements by drawing upon surrounding SNPs to model haplotype sharing.

Using these haplotypes as a reference panel, we imputed VNTR lengths into a cohort of 337,488 unrelated British UK Biobank participants and tested for associations with 124 phenotypes including neurodevelopmental, cardiovascular, and metabolic disorders and other health-related traits. We found 22 VNTR-phenotype associations involving 11 distinct VNTRs that reached Bonferroni significance ( $p < 1.6 \times 10^{-6}$ ) and for which conditional association analyses showed that the VNTR, rather than nearby SNPs, was the likely causal variant.

The strongest association ( $p < 1 \times 10^{-13,800}$ ) in our data replicated a known association between Lipoprotein(a) concentration (Lp(a)) and repeat length of a VNTR that encodes *LPA* KIV2 domains, a VNTR implicated in cardiovascular diseases. Intriguingly, Mendelian randomization analyses of KIV2 VNTR length together with nearby variants indicated that the contribution of *LPA* variation to other molecular traits, including triglycerides, was not mediated solely by Lp(a).

Other strong associations ( $p < 2 \times 10^{-96}$ ) identified VNTRs as likely causal variants in previously reported GWAS loci. SNPs near *ACAN*, which encodes a component of the cartilage extracellular matrix, have previously been associated with height; SNPs near *MUC1*, which encodes a transmembrane protein expressed in secretory epithelial cells, have previously been associated with urea levels. In our analysis, imputed repeat lengths for VNTRs in exons of *ACAN* and *MUC1* explained these associations. In addition, multi-allelic copy number variation modifying dosage of genes in the *PGA* and *TP53TG3* gene families drove novel associations ( $p < 3 \times 10^{-10}$ ) with albumin levels and age at menopause respectively.

## PgmNr 2995: Comprehensive characterization of genetic and phenotypic heterogeneity of obstructive sleep apnea across multiple United States clinics.

---

Obstructive sleep apnea (OSA) is a common, complex sleep disorder defined by frequent episodes of reduced or complete cessation of airflow during sleep. OSA is linked to negative health outcomes, and understanding the shared genetic mechanisms contributing to expression of symptoms and comorbidities in OSA may improve precision medicine and lead to new treatment strategies for this condition. We hypothesized that electronic health record (EHR) datasets would provide power to validate robust previously reported genomic variation associated with OSA risk and detect novel genetic relationships between these OSA variants and other comorbidities. We leveraged EHRs and biorepositories from Geisinger, Vanderbilt University Medical Center, and the eMERGE Network to conduct a cross-sectional, retrospective OSA study, including evaluating associations between these genetic variants and OSA phenotypes as well as phenome-wide evaluations using EHR data. We used 51 candidate single nucleotide polymorphisms (SNPs) identified through systematic literature review, and evaluated associations between these SNPs and an EHR-derived phenotypic algorithm defined OSA diagnoses, polysomnography data, and ICD-9 defined diagnoses. In individuals with genetically informed European ancestry, nine candidate SNPs were associated ( $p < 0.05$ ) with EHR-derived OSA, controlling for age, sex and body mass index. In individuals with African ancestry, two different candidate SNPs were associated with EHR-derived OSA. Results from phenome-wide association studies indicated that the majority of OSA candidate SNPs were associated with other EHR-derived traits reflecting cardiovascular disease, diabetes, anemia, autoimmune thyroid diseases, obesity, genitourinary symptoms, mental health disorders, pulmonary diseases, eye diseases and headache syndromes. Notably, 74% of patients with OSA and the most prevalent associated comorbidity, essential hypertension ( $OR_{\text{Geisinger}} = 4.40$  [4.26, 4.55],  $p < 4.4 \times 10^{-301}$ ;  $OR_{\text{VUMC}} = 3.71$  [3.43, 4.02],  $p = 9.91 \times 10^{-253}$ ), had their first essential hypertension code at least 5 years before their first OSA code ( $\mu = 5.28 \pm 4.52$  years). Our results highlight robust OSA-associated genomic variants, and provide knowledge of convergent mechanisms influencing risk for multiple disorders in the same individual. This knowledge can lead to better biomarkers of OSA and more personalized treatments for preventing OSA and related comorbidities.

## PgmNr 2996: Accounting for cell type composition in GTEx data.

**Authors:**

F. Takeuchi

[View Session](#) [Add to Schedule](#)**Affiliation:** Research Institute, Nat Cntr for Global Health & Med (NCGM), Tokyo, Japan

---

The Genotype-Tissue Expression (GTEx) project investigated 449 human donors across 44 tissues, and catalogued the genetic effect on gene expression as eQTLs. Whereas some eQTLs were shared across most of the 44 tissues, some were specific to a small subset of tissues. Gene expression was measured in bulk tissues (such as, pancreas), which indeed are mixtures of cell types (such as, alpha cell, beta cell, etc.). Some eQTLs might vary by cell type, in which case the average is observed at tissue level. Here, I account for cell type composition in GTEx data and refine the eQTLs by cell types. Cell types and their gene expression profile were obtained by published single-cell RNA sequencing experiments of human and mouse. By using gene expression profile of cell types as reference, the cell type composition of each tissue sample in GTEx was inferred. For this deconvolution, I developed a novel fast algorithm of mixture modeling. Using the inferred cell type composition, eQTLs in the GTEx data were refined.

# PgmNr 2997: A novel method for genome-wide scale phenome-wide G×E analysis and its application to UK Biobank.

## Authors:

W. Bi <sup>1,2</sup>; Z. Zhao <sup>1,2</sup>; R. Dey <sup>1,2,3</sup>; L.G. Fritsche <sup>1,2</sup>; B. Mukherjee <sup>1</sup>; S. Lee <sup>1,2</sup>

1) Department of Biostatistics, University of Michigan, Ann Arbor, MI.; 2) Center for Statistical Genetics, University of Michigan, Ann Arbor, MI; 3) Department of Biostatistics, Harvard T. H. Chan School of Public Health, Boston, MA

The etiology of most complex diseases involves genetic variants, environmental factors, and gene-environment interaction (G×E) effects. Compared with marginal genetic association studies, G×E analysis requires more samples and detailed measure of environmental exposures, which limits the possible discoveries. Large-scale population-based biobanks with detailed phenotypic and environmental information, such as UK-Biobank, can be an ideal resource to identify G×E effects. However, due to the large computation cost and the presence of case-control imbalance, existing methods often fail. For example, to analyze G×E for one phenotype and one environmental factor, standard Wald test requires 2 CPU years for 20 million variants, 400,000 samples and 15 covariates. For 1,500 phenotypes, the computation cost increases to 3,000 CPU years.

Here we propose a scalable and accurate method, SPAGE (SaddlePoint Approximation implementation of G×E analysis), that is applicable for genome-wide scale phenome-wide G×E studies. SPAGE fits a genotype-independent logistic model only once across the whole-genome analysis to reduce computation cost and uses a saddlepoint approximation (SPA) to calibrate the test statistics for analysis of phenotypes with unbalanced case-control ratios. Simulation studies show that SPAGE is 33-79 times faster than the Wald-test and 72-439 times faster than the Firth's test and can control type I error rates at the genome-wide significance level even when case-control ratios are extremely unbalanced.

We applied SPAGE to UK Biobank dataset of 344,341 white British European-ancestry samples. We totally analyzed 79 environmental factor × phenotype combinations and identified 34 significant G×E signals at a genome-wide significance level 5E-8. For example, in the analysis of chronic airway obstruction, we identified a significant G×E effect of the smoking status and a variant in gene *CHRNA5* (rs55781567,  $p=2.87E-8$ ). Smoking is an important risk factor to the chronic airway obstruction and the gene *CHRNA5* is well-known to be associated with the smoking behavior and some smoking-related diseases such as chronic obstructive pulmonary disease. In the analysis of cardiac dysrhythmias, we identified a significant G×E effect of gender and variants near gene *PITX2* (rs1906609,  $p=1.42E-12$ ). In the analysis of Hyperlipidemia, we identified a significant G×E effect of the vigorous physical activity and variants in gene *DNAH11* (rs10950866,  $p=3.64E-9$ ).

## PgmNr 2998: Parent-of-origin effect analyses provide evidence for maternal genetic and maternal environmental effects on the genetic variability in type 1 diabetes and rheumatoid arthritis.

Numerous studies have indicated that the development of autoimmune disorders including type 1 diabetes (T1D) and rheumatoid arthritis (RA) is not only determined by genetic and environmental but also by epigenetic factors. Genomically imprinted genes, which contribute to parent-of-origin effects (POEs), as their alleles are epigenetically inactivated depending on their parental origin, have often been mentioned in this context. However, findings have been contradicting and other POEs including maternal genetic effects and maternal environmental effects may have biased earlier findings as they are known to mimic imprinting if not considered in the model. A special type of linear mixed model with two random parental gametic effects was used to investigate the existence of imprinting effects on the susceptibility to T1D and RA and to disentangle their variation from the variation of other POEs. The inclusion of fixed effects, such as gender, birth year, and social economic index allowed the investigation of environmental effects. Through linkage of the Swedish Hospital Discharge Register and the Multigeneration Register, a suitable population database was available. For T1D the dataset contained 27,255 patients with 208,114 ancestors; for RA 15,850 patients with 60,684 ancestors were available.

With regard to T1D the imprinting variance did not turn out to be significant, however, the significance of the maternal environmental variance indicated the importance of familial effects explaining 18.8% ( $\pm 1.81\%$ ) of the phenotypic variance. Similar results were observed for RA as imprinting effects were not significant but significant variances were found for maternal effects. However, they could not clearly be determined to be either genetic or environmental as although both variances were significant, a considerable ratio of the phenotypic variance was explained by maternal genetic effects (14%;  $\pm 4.14\%$ ) whereas only 5% ( $\pm 6.81\%$ ) was explained by the maternal environment. The results indicated that imprinting does not play a great role for the susceptibility to T1D and RA but that POEs due to maternal genetic effects as well as maternal environmental effects have a considerable impact. Fixed effects turned out to be significant, which further supports the importance of environmental factors. The results implicate that POEs other than imprinting effects may have biased earlier results and that they must be taken into account in future imprinting studies.

## PgmNr 2999: When can population based imputation be improved upon by complementary identity-by-descent sharing information?

---

In population based imputation, there is an intuitive preference for a reference panel that contains haplotypes specific to the study population; the benefits of choosing such a panel have now been widely demonstrated. In certain situations, such as in the study of isolated populations, it is even possible to include reference panel haplotypes from individuals who are closely related to the target group; resulting in exceptionally high imputation accuracy.

Results of this nature indicate the potential importance of long matches between target and reference haplotypes, in other words regions that are likely to be shared in a state of identity-by-descent (IBD), whose detection is typically the basis of family based imputation methods. However, in most circumstances, IBD-sharing information will not be sufficient to impute missing genotypes across the whole genome as identifiable shared regions will not cover entire chromosomes.

This has led to the idea of combining IBD and population based imputation methods. Whilst a complete integration of the two has yet to be successfully demonstrated, two recent software have been put forward that provide two-step approaches: Ped-Pop and Kinpute. These methods seek to significantly improve upon the exactitude of imputed genotypes from population based methods by overlaying inference from IBD-sharing information. Here, we report on the functionality of these two software and perform tests on simulation data based on the structure of the known genetic isolates of Cilento in Southern Italy. This allows us to determine and provide examples of specific scenarios where these methods may be most or least successful.

## Background

Hepatitis B virus (HBV) infection is highly prevalent in East and Southeastern Asia, which is well documented as a risk factor for hepatocellular carcinoma. The associations between genetic variants and HBV chronicity remains inconclusive.

## Methods

The study included 15,352 subjects previously acquired HBV, defined by seropositive for hepatitis B core antibody in Taiwan Biobank (TWB). Among them, 2,591 (16.9%) were seropositive for hepatitis B surface antigen (HBsAg) and were defined as chronic HBV infected cases. The study subjects were randomly divided into genome-wide association study (GWAS) and replication phase in a three-to-one ratio. All the participants were examined by Axiom Genome-wide TWB Array. Subjects with a call rate <97%, minor allele frequency <1%, and violation of Hardy-Weinberg equilibrium ( $P < 10^{-4}$ ) were excluded in the subsequent analyses. The associations between single nucleotide polymorphisms (SNPs) and HBV chronicity were examined under an additive model adjusted for age and sex. 2-field *HLA* imputation was carried out on *DRB1*, *DQA1*, *DQB1*, *DPA1*, *DPB1* using HIBAG R package. Haplotype analysis was done by Arlequin software. The frequencies of *HLA* alleles between cases and controls were compared by the Fisher's exact test with p-value corrected by the number of alleles tested. Multiple logistic regression models were used to obtain adjusted odds ratios ( $OR_{adj}$ ) with 95% confidence interval (CIs) for their associations with HBV chronicity.

## Results

A total of 583,383 SNPs were compared among 9,002 HBV resolved controls and 1,810 chronic HBV infection cases in GWAS phase. There were 450 SNPs within *HLA* gene loci significantly associated with HBV chronicity ( $P < 8.6 \times 10^{-8}$ ). All of these SNPs could be validated in the replication phase ( $P < 0.05$ ). In the imputation analysis, *DPA1\*02:02* and *DPB1\*05:01* were significantly associated with HBV chronicity, with the  $OR_{adj}$  (95% CI) of 1.41 (1.07-1.84) and 1.62 (1.30-2.01), respectively. On the other hand, *DQA1\*01:02*, *DQB1\*06:09*, and *DRB1\*13:02* showed inversely associations with HBV chronicity, with the  $OR_{adj}$  ranging from 0.32 (0.17-0.60) to 0.68 (0.55-0.85). Individuals who carried *DPA1\*02:02-DPB1\*05:01* haplotype had increased probability ( $OR_{adj}=1.59$  (1.28-1.97)) to HBV chronicity, whereas *DRB1\*13:02-DQB1\*06:09* showed a negative association ( $OR_{adj}=0.33$  (0.18-0.63)).

## Conclusion

*HLA* class II gene variants contributed to susceptibility for HBV chronicity after the acquisition of HBV

in an endemic area.

We present *KnockoffZoom*, a flexible method for the genetic mapping of complex traits at multiple resolutions. *KnockoffZoom* localizes causal variants precisely and provably controls the false discovery rate using artificial genotypes as negative controls. Our method is equally valid for quantitative and binary phenotypes, making no assumptions about their genetic architectures. Instead, we rely on well-established genetic models of linkage disequilibrium. We demonstrate that our method can detect more associations than mixed effects models and achieve fine-mapping precision, at comparable computational cost. Lastly, we apply *KnockoffZoom* to data from 350k subjects in the UK Biobank and report many new findings.

Genome-wide Association Studies (GWAS) are under-powered to detect all associated variants, largely due to a huge multiple-testing burden. There is recent interest for conducting prioritized GWAS primarily using SNP-level functional annotations and statistical methods have been developed to enable incorporation of SNP-level knowledge. Another, rich source of biological knowledge exists in the form of gene-level functional annotations (e.g. pathways). Gene expression regulation through cis or trans expression Quantitative trait loci (eQTLs) can also serve as biological knowledge to inform GWAS. It is imperative to use knowledge of pathways/networks and information from gene-expression/eQTLs a-priori to 'inform' the genome-wide search. Conventional pathway enrichment analysis can help in the interpretation of findings; but does not by itself improve the power of detecting additional novel loci. Here, we develop a statistical method to enable a prioritized GWAS using knowledge from a very large number of gene-level annotations. Our method being based on penalized logistic regression is computationally efficient and scalable for routine use with large number of annotations. We demonstrate using simulations and real GWAS data on various diseases that prioritized GWAS using gene-level annotations can indeed gain substantial power over unbiased GWAS. Unlike most prioritization tools using FDR, our method maintains global false-positive rates at the same stringency as in a usual GWAS (i.e.  $p < 5 \times 10^{-8}$ ). We have demonstrated correct type I error as well as increase in overall power using simulations. We have created an R package **'GKnowMTest' (Genomic Knowledge-guided Multiple Testing)** for flexible incorporation of gene-level knowledge into GWAS. Further, we incorporated knowledge from other sources such as Gene-Expression Omnibus (GEO) to get differential-expression information or GTEx to extract eQTL information in order to prioritize GWAS. Using a novel whole genome simulation strategy, we were able to show substantial improvement in power of detection by exploiting gene-level knowledge. Further the method was applied to several real GWAS datasets and gave encouraging results in terms of detecting genomic regions missed by standard unweighted GWAS.

## PgmNr 3003: Leveraging pleiotropy in genome-wide association studies across multiple traits with per trait interpretations.

Genome-wide association studies (GWAS) have been instrumental in identifying genetic variants associated with complex traits. As sample sizes in GWAS have increased, more and more variants have been discovered which suggests the presence of a large number of variants at low effect size. Additionally, many of these variants are shown to be associated with multiple traits. With this in mind, it is natural to assume there is more statistical power for identifying additional variants when traits are analyzed together.

We present PAT, a pleiotropic association test, for joint analysis of summary statistics across multiple traits. Our method assumes genetic effect sizes follow Fisher's polygenic model and are correlated according to genetic correlation estimates obtained from GWAS. We perform hypothesis testing to determine whether a variant is associated with at least one of the traits. Under the null model, summary statistics are derived from a variant with no genetic effect; therefore, any deviation in the summary statistic is fully attributed to environmental effects. Under the alternative model, however, there is at least one trait for which the variant has a non-zero genetic effect. This results in variation in the summary statistics to be the sum of genetic and environmental effects. For simulations that follow our assumed model, we find PAT has a substantial increase in power. We also find our method still has a moderate power increase in many scenarios where our model assumptions are violated.

While PAT is able to determine whether a variant is associated with the set of traits, it cannot state for which of the trait(s), the variant is associated. We extend the M-value framework to account for estimated genetic covariation to interpret PAT results. If we consider all possible models of genetic effect (ie. the variant affects no traits, all traits, or the variant affects only the first trait, etc.), we have  $2^m$  total models where  $m$  is the number of traits. We take the sum over all models as well as sum over the models that are compatible with the variant affecting a particular trait to compute the posterior probability of a variant affecting that trait. We analyze traits from the UK Biobank which shows that utilizing multiple traits increases power for detecting variants that affect more than one trait in real data.

## PgmNr 3004: Complex-Traits Genetics Virtual Lab: A community-driven web platform for post-GWAS analyses.

**Motivation:** For over a decade, genome-wide association studies (GWAS) have been an important method for mapping genetic variation underlying complex traits. With the ever-increasing volume of data generated however, new tools are needed to integrate the vast array of GWAS results and perform further analyses to maximize their utility for biological discovery.

**Results:** Here we present the Complex-Traits Genetics Virtual Lab (CTG-VL) — <https://genoma.io>. CTG-VL integrates these key components: **(i)** publicly available GWAS summary statistics; **(ii)** a suite of analysis and visualization tools; and **(iii)** several data sets for genomic annotations. This platform makes available results from post-GWAS analyses of >1,500 complex traits for assessing pleiotropy at the genetic variant through to gene-, pathway- and tissue-based levels. Further, CTG-VL integrates many analysis functions from other widely used web platforms (e.g., FUMA GWAS, LD-Hub). Here we demonstrate CTG-VL using summary statistics from a chronic pain GWAS (i.e., pain at any site >3 months) derived from UK Biobank (N=288K). Using Mendelian Randomization (MR) approaches implemented in the platform, we performed a phenome-wide MR analysis of chronic pain and found evidence for causal relationships with dozens of traits including inflammation biomarkers, type of diet and sleep.

**Conclusion:** CTG-VL is a freely available online web application to further harness GWAS data for research reproducibility, collaboration and translation.

## **PgmNr 3005: MF-TOWmuT: Testing an optimally weighted combination of common and rare variants with multiple traits using family data.**

---

With rapid advancements of sequencing technologies and accumulations of electronic health records, multiple disease phenotypes and a large number of genetic variants become available in many genetic association studies. Thus, it becomes necessary and important to develop new methods that can jointly analyze multiple traits and multiple genetic variants and help us to better understand genetic etiology of complex human diseases. Comparing with methods that only use a single trait or marker, the joint analysis of multiple genetic variants and multiple phenotypes is more powerful since such analysis can fully incorporate correlation structure of genetic variants and/or phenotypes and their mutual dependence pattern. However, most of existing methods are only applicable to unrelated samples. We propose a new method called MF-TOWmuT to detect association of multiple phenotypes and multiple genetic variants in a genomic region using an optimally weighted combination of variants with family samples. Our method can be applied to both qualitative and quantitative phenotypes and both rare and common variants. We evaluate and compare our method with MFQLS and mFARVAT-SKAT-O. Our simulation results show that (1) the type I error of our method is well preserved; (2) MF-TOWmuT is robust to the proportion of dichotomous or continuous traits and to the proportion of risk or protective variants; (3) MF-TOWmuT outperforms MFQLS and mFARVAT-SKAT-O in terms of power in extensive scenarios. We apply MF-TOWmuT to GoKind study - a study for searching susceptibility genes for diabetes and is able to find some novel susceptibility genes.

---

Family history of disease can provide valuable information about an individual's genetic liability for disease in case-control association studies, but it is currently unclear how to best combine case-control status and family history of disease. We developed a new association method based on posterior mean liabilities under a liability threshold model, conditional on both case-control status and family history (LT-FH); association statistics are computed via linear regression of genotypes and posterior mean liabilities, equivalent to a score test. LT-FH captures the fact that controls with family history have higher genetic liability than controls without family history (and likewise for disease cases). In contrast to GWAX (Liu et al. 2017 Nat Genet), which assigns the same binary phenotype to all cases and "proxy cases" (controls with family history of disease) to increase power for diseases of low prevalence, LT-FH accurately models a broad range of case-control status and family history configurations, greatly increasing power for diseases of both low and high prevalence.

We applied LT-FH to 12 diseases from the UK Biobank for which family history (parental and sibling history) was available for most target samples (average  $N=350K$ ). We compared LT-FH to genome-wide association without using family history (GWAS) and GWAX. LT-FH was +56% (block-jackknife s.e. 6%) more powerful than GWAS and +36% (s.e. 4%) more powerful than the trait-specific maximum of GWAS and GWAX (+37% for lower-prevalence diseases and +35% for higher-prevalence diseases), based on the number of independent genome-wide significant loci detected across all diseases (e.g. 693 independent loci for LT-FH vs. 445 for GWAS). The second best method was GWAX for lower-prevalence diseases and GWAS for higher-prevalence diseases, consistent with simulations. We also confirmed that LT-FH was well-calibrated (assessed via the stratified LD score regression attenuation ratio), consistent with simulations. When using BOLT-LMM (Loh et al. 2018 Nat Genet) instead of linear regression to compute association statistics for all three methods (increasing the power of each method), LT-FH was +59% (s.e. 6%) more powerful than GWAS and +38% (s.e. 4%) more powerful than the trait-specific maximum of GWAS and GWAX. In summary, LT-FH greatly increases association power in case-control association studies when family history of disease is available.

## PgmNr 3007: BLUP-based mixed-model approach for biobank-scale GWAS.

Linear mixed models (LMM) are a preferred approach to account for population structure and/or relatedness in genome-wide association studies (GWAS); however, scaling LMM approaches to biobank-scale sequence data is challenging. Software such as BOLT and SAIGE address the challenges of big sample size,  $N$ , and large numbers of sequence variants,  $M$ , by using a corrected linear regression to approximate the LMM score statistic to achieve time complexity linear in  $N$ . The approach is not without issues. Fitting the null model and computing the correction factor(s) are computationally intensive and the approximation may result in inaccurate test statistics and lose power. To address these problems, we develop a fast and accurate LMM approach based on best linear unbiased prediction (BLUP).

Our approach has three steps, 1) variance component estimation (VCE), 2) SNP-BLUP, and 3) association testing. The VCE step makes use of a recently proposed randomized Haseman-Elston (HE) regression estimator with sub-linear time complexity in  $N$ . The SNP-BLUP step fits a smaller set of  $M_p$  markers as random effects in LMM, based on HE estimates. We use a block-wise Gauss-Seidel (GS) method to compute BLUP (?) of  $M_p$  marker effects. To avoid inversion of the large  $M_p \times M_p$  matrix to compute  $\text{var}(?)$ , we set our GS block size ranging from 1K to 5K, which is less than a few percent of  $M_p$ . Our  $?^2/\text{var}(?)$  is equivalent to LMM score statistic. To perform association tests, we scan the variants block by block, and compute ? and  $\text{var}(?)$  for each of them based on the SNP-BLUP output. Association testing has time complexity that scales linearly in block size,  $N$  and  $M$ .

To test the accuracy of our approach, we simulated many data sets ranging from 5K to 20K subjects under different genetic models. Genotypes were simulated in unrelated, admixed, and related samples using HAPGEN2, bnpsd, and genosim, respectively. We then simulated major QTL effects, polygenic effects, and random errors, and summed them to construct quantitative phenotypes. Our approach produced nearly identical results ( $r^2 \approx 0.999$  for chi-square statistics) compared with exact results from EMMAX. We also compared our approach with SAIGE using dairy cattle data with 300K cows and  $M_p=60K$  SNPs. We identified all the QTLs that SAIGE found but also a few known QTLs that failed to pass Bonferroni threshold in SAIGE. More importantly our software took <2 hours on a typical PC while SAIGE used >200 hours.

---

Pleiotropy refers to a phenomenon that the same genes or variants affect more than one trait simultaneously. Pleiotropic loci can give us intuition about shared pathways and etiology of multiple traits. To detect pleiotropic loci, several methods have been proposed. These cross-trait analysis methods aggregate summary statistics of multiple traits together, of which an added benefit is the increased effective sample size. However, these methods have limited flexibility in that the traits have to be in the same category, either qualitative or quantitative. For example, no systematic methods have been suggested to aggregate odds ratios for dichotomous traits and regression coefficients for continuous traits together. Moreover, even in the same continuous category, traits may differ in their units. Some traits may be morphological indices, some may be lipoprotein densities, and some may be confidence scores for questionnaires in the survey. In these situations, a method assuming a shared underlying distribution of effect sizes can suffer from the inevitable violation of the assumption. Furthermore, the results will be dependent on the unit scales, such as kilogram versus gram. Here, we introduce DELPY (DEtecting Loci with PleiotropY), a novel unified framework for joint analysis of multiple traits to detect pleiotropic loci. Given summary statistics of multiple traits, our method projects the statistics into the space representing genetic liabilities for dichotomous traits and the space representing standardized phenotypes for continuous traits. This way, different categories are seamlessly put together and the outcomes are independent of the units and scales. A benefit of using this projection is that this space is the basis for heritability and coheritability calculations. Therefore, we can utilize the estimated genetic covariance as the prior information for effect sizes to increase statistical power. In addition to genetic covariance, our method estimates and accounts for the environmental covariance due to sample overlap or hidden relatedness. Given the genetic and environmental covariance matrices, our method tests the genetic contribution of a variant toward the overall heritability of multiple traits using likelihood ratio test. Since the asymptotic p-value is only accurate when the number of traits is large, which is rarely the case, we developed an efficient importance sampling procedure to rapidly assess the significance of test.

Circulating proteins play vital roles in human physiology but their characterisation at scale, including inter-individual differences due to DNA variation, regulatory pathways, and potential causal roles in disease is incomplete. We mapped protein quantitative trait loci (pQTL) for 90 circulating proteins, measured using the Olink proximity extension assay CVD-I panel, by meta-analysing 13 genome-wide association studies encompassing up to 21,758 participants. Primary signals were replicated in two independent cohorts encompassing 9,500 subjects. A total of 467 pQTLs for 85 proteins were identified and replicated, including 123 signals significant after conditioning for lead variants in the same loci. By integrating pQTLs with curated protein-protein interaction networks and text-mining, we show examples of molecular processes involved with the regulation of circulating proteins. Using Mendelian randomization and mining of drug databases, we highlight several protein-outcome associations with established development (e.g. IL1RA in rheumatoid arthritis), with predicted successful drug development (e.g. IL6RA in coronary heart disease), and ?drugs in early development that target proteins with a causal role in biology (e.g. DDK1 and osteoporosis).

## PgmNr 3010: Considerations for tests of disease risk and age at onset.

Genetic studies often look for genes that influence one's *risk* of developing disease, typically by comparing genotype (or allele) frequencies between affected and unaffected individuals. Instead of modeling disease risk, we may look for genes that control the timing of disease onset, or *age at onset* (AAO). We can test for AAO effects by looking for association between genotypes (or alleles) and AAO as a quantitative variable in a group of cases. These two categories are not disjoint; a gene that influences AAO might also appear to influence risk. For example, if an allele lowers AAO, then we would expect that allele to be enriched in a set of cases (relative to controls) taken at any cross-sectional timepoint. In this scenario, when an allele influences both AAO and risk, a reasonable question is whether we would have more power to detect association using a case-control design to test risk or a case-only design to test AAO, or some alternative.

To address this question, we propose a genetic model for AAO, and use this to analytically compute the required sample size for 80% power for the Cochran-Armitage trend case-control test for risk and a linear regression case-only test for AAO. We also use simulations to compare power of these tests with a 2-df joint test (which combines the risk and AAO statistics) and the Cox Proportional Hazards (CoxPH) model testing AAO with censored data in controls.

We find that neither risk nor AAO test is most powerful in all situations. In general, when there is little heterogeneity, the case-control risk test has more power than the case-only AAO test (with equivalent sample sizes), but when the model is complex (e.g., with heterogeneity or reduced penetrance), this pattern reverses and the case-only AAO test tends to have more power than the risk test. Our simulations show that in many scenarios, the 2-df joint test outperforms either test alone, particularly as heterogeneity increases. When there is reduced penetrance, case-only tests are to be preferred, and we find that the CoxPH test with cases only has more power than the linear-regression based case-only test.

The results have implications for choice of test statistic(s), study design and interpretation. If genotype data from both cases and control are available, then using all data in a joint test is generally most powerful. However, with substantial heterogeneity, putting resources into a case-only design might be prudent, and the CoxPH approach may be preferred.

## PgmNr 3011: Multi-allelic method for genome-wide association studies: The kernel trick.

---

Genome-wide association studies (GWAS) typically focus on associations between single-nucleotide polymorphisms (SNPs) and traits like major human diseases. In many cases of GWAS, the reference allele is defined as “0”, whereas the alternative allele as “1”. In datasets of large samples, many variant sites are observed to be multi-allelic. For example, 274,620 sites are multi-allelic among genomic sequences of 2,504 people determined by 1000G. The analysis of multi-allelic sites is currently often ignored in GWAS and sequence-based association studies. In this study, a method for conducting statistical tests on multi-allelic sites is proposed. This method treats sequence identity between two sequences as a kernel function. Kernel function defines inner product in the sequence space. It is proven that sequence identity kernel is equivalent to previous methods when all the sites are biallelic. Thus, the proposed method is a natural extension of previous methods. This kernel method can be used in support vector machine, analysis of principal components, and sequential kernel association test. The proposed method enables to study large samples with multi-allelic sites for GWAS.

## PgmNr 3012: Meta-PheWeb: Meta-analysis and cross-comparison between PheWAS datasets.

To allow intuitive browsing, comparison and interpretation of continuously growing publicly-available genetic association results across a wide range of complex traits we developed a free online tool, PheWeb. This web-based tool allows users to view summary statistics for thousands of phenotypes in datasets such as the UK Biobank and the Michigan Genomics Initiative. Users can also view associations to a gene or variant across all phenotypes in several datasets and can also compare and meta-analyze similar phenotypes across datasets. Meta-PheWeb is available at <http://pheweb.sph.umich.edu> and source code is at <https://github.com/statgen/pheweb> .

## PgmNr 3013: Gene-based analysis using gene expression data and polygenic risk score.

Conventional genome-wide association studies (GWASs) have been successfully applied to identify the association of genetic variants with phenotypes. In spite of many successes, there existing two major challenges: one is missing heritability of complex diseases, due to the polygenic effects and small effect sizes; the other one is the difficulty of interpretation because some identified genetic variants are not in protein-coding regions.

Recently, gene-based association studies show that integrating GWAS with expression quantitative trait locus (eQTL) data can boost statistical power and many studies also have shown the advantage of using polygenic risk scores (PRS) to evaluate the putative association to biologically informative features. Since many complex diseases are associated with gene expression which is influenced by genetic variants, and the genetic liability of phenotypes can be captured by PRSs, using both eQTL data and PRS may gain more statistical power to identify the underlying association. In this presentation, we propose a set-based statistical method that use integrated gene expression measurements and PRS to identify genes that are associated with a phenotype of interest. We use a generalized linear model to associate a phenotype with gene expression and PRS, use a score test statistic to test the association between the phenotype and the gene set.

Simulation studies, as well as a real data application, are used to compare the proposed method with some existing methods that use either gene expression data or PRS to test the association between a gene set and a phenotype. Our simulation studies show that the proposed method has correct type I error rates, the power is boosted by using both integrated gene expression measurements and PRS comparing to other methods. The real data analysis shows that the proposed method is applicable to GWAS and is more powerful than the methods we compare with.

Family-based imputation allows better imputation of rare variants compared to population-based imputation. With whole genome sequencing becoming inexpensive, there is an opportunity to investigate rare variation. In the search for disease-associated rare variation, family-based designs have again become common, because rare, highly-penetrant genotypes can segregate in pedigrees.

In pedigrees, for subjects without genotype data, phenotype data can be available. Family-based imputation has the strength of imputing genotypes on such subjects using the genotypes of the available relatives. This likely increases the sample size and therefore the statistical power if imputation is accurate. In association testing, when related subjects are included, a kinship matrix must be used to account for relatedness. Relationships may be known from pedigree structure, or can be inferred using observed genotypes. For subjects without genotype data, however, no approach is able to infer relatedness, which is crucial to control the type 1 error.

In this work, we assess the performance of family-based imputation (GIGI2) for imputing subjects with no genotype data. We also propose a solution for inferring relatedness between such subjects by incorporating posterior probabilities of missing genotypes in an Expectation-Maximization approach. Through simulation, we obtained an average correlation of 0.6 between imputed and observed subjects. Correlation reached one for some subjects. Imputation performance decreased with size of imputation reference panel. Our approach succeeded in inferring many relationship types. The average kinship estimates were 0.19, 0.1267, 0.0641, and 0.03068 for underlying kinships of 0.25, 0.125, 0.0625, and 0.03125, respectively, for pairs of subjects without genotype data.

## PgmNr 3015: Evaluation of polygenic risk scores and machine learning methods for the prediction of complex diseases.

Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL

---

Polygenic risk scores (PRSs) examine the cumulative effect of genetic variants on a disease or trait by aggregating many individual variants, typically weighted by their effect sizes, into a single measure. PRSs provide a convenient way to quantify the overall genetic risk estimation for a particular disease. Suppose  $m$  independent single nucleotide polymorphisms (SNPs) are obtained from genome-wide association studies, weighted PRS is defined as  $PRS = \sum_m (\beta_i * G_i)$ , where  $\beta_i$  and  $G_i$  are the effect size from a genetic association analysis and the allele dosage for each SNP  $i$ , respectively. Though the PRS calculation is straightforward, presently there is no consensus on how to select the best set of SNPs for optimal prediction accuracy. Many reports have used the genome-wide significance threshold,  $P < 5 \times 10^{-8}$ , to select SNPs for calculating PRSs. In other reports,  $P < 5 \times 10^{-5}$  was used for selecting SNPs. There are also a number of methods that use Bayesian methods, including LDpred, to derive the proportion of SNPs that have non-zero effect sizes. However, they also may not give the best prediction accuracy in certain situations. Furthermore, the majority of predictive models have been based on classic regression models. We conducted this study with 435,678 European participants from the UK Biobank dataset. We evaluated a number of PRS calculation approaches using a grid of  $p$ -values (0.01, 0.001,  $10^{-4}$ ,  $5 \times 10^{-5}$ , and  $5 \times 10^{-8}$ ) and LD-clumping cutoffs ( $r^2 = 0.2$  and 0.5) for selecting SNPs based on the results from our previous report on intraocular pressure (IOP) and glaucoma risk prediction (Gao *et al.* 2019). We also compared different predictive models, such as logistic regression and Xgboost (an efficient machine learning approach). The weighted IOP PRS constructed based on SNPs with  $P < 10^{-4}$  and LD-clumping  $r^2 = 0.2$  gave the best performance in predicting glaucoma among the  $p$ -value and LD-clumping cutoffs that we tested. Furthermore, Xgboost gave better prediction accuracy than logistic regression in our tests using cross-validation and independent testing samples (AUC increased by 1%,  $P < 0.001$ ). We are further evaluating these methods using the Alzheimer Disease Genetics Consortium (ADGC) dataset. Our results provide guidelines for constructing PRSs and apply extrapolative models for the prediction of complex diseases.

## **PgmNr 3016: A unifying framework for region-based association testing in family-based designs without the need for asymptotic assumptions or approximations, including higher criticism approaches, SKATs, multivariate and burden tests.**

For the region/set-based association analysis of rare variants in family-based studies, we propose a general methodological framework that integrates higher criticism approaches, SKATs, burden, and multivariate tests into the FBAT approach. Using the haplotype algorithm for FBATs to compute the conditional genotype distribution under the null hypothesis of Mendelian transmissions, virtually any association test statistics can be implemented straightforwardly in our approach, requiring no assumptions about the asymptotic distribution or approximations. Given the conditional joint distribution of the rare variants, simulation-based or exact p-values can be computed without the need to estimate the genetic correlation/linkage disequilibrium (LD) structure between variants empirically. Using simulations, we compare the features of the proposed test statistics in our framework with the existing region-based methodology for family-based studies under various scenarios. Under realistic assumptions, the tests of our framework outperform the existing methodology. We provide general guidelines for which scenarios, e.g., the sparseness of the signals or local LD structure, which test statistic will provide distinct power advantages over the others. We illustrate our approach in an application to a whole-genome sequencing dataset with 900 asthmatic trios.

## PgmNr 3017: Haplotype analysis of more than 450,000 US veterans in the VA's Million Veteran Program (MVP), and its impact to imputation and GWAS.

---

The Million Veteran Program (MVP) has recently released the raw and imputed genotypes of more than 450,000 ancestrally diverse individuals. Here, we conducted a haplotype analysis to understand its impact on phasing, imputation, and ultimately GWAS across 275,000 European Americans (EA), 80,000 African Americans (AA), and 34,000 Hispanic/Latinos (H/L). As expected, significantly different distribution of identical-by-descent (IBD) segments were observed, where H/L had the greatest enrichment of large IBD segments. The decay of phasing accuracy as a function of distance between two phased variants were slower for AA and H/L compared to EA, showing the positive effect of longer haplotype blocks from recent admixture to better phasing performance. Within-cohort phasing showed better consistency and accuracy for AA compared to EA when sample size was matched and larger than 25,000. A mean switch error rate (SER) of 15% was observed when using only EA to phase AA, whereas using only AA to phase EA showed a 1% increase in mean SER. For the large EA cohort, the effect of increasing the number of conditioning haplotypes (k-hap) plateaued with increasing number of samples, whereas phasing performance of AA increased consistently with increasing k-hap up to 80,000 individuals. However, the increase in phasing performance did not directly lead to a meaningful improvement in imputation performance. A significant difference was observed depending on the reference panel used for imputation. We compared the 1000 Genomes Project Phase 3 (G1K), the Haplotype Reference Consortium (HRC), and the African Genome Resource (AGR). Imputation quality was assessed using precision-recall on a subset of samples that were whole genome sequenced. Although HRC includes G1K, using HRC to impute AA samples showed worse performance than using G1K alone. The incorrectly imputed variants were enriched in local segments of non-European ancestry. On the other hand, using AGR was consistently better than G1K in all MVP ancestries, with the largest improvement on AA individuals. Although ancestry-matched reference panels have the best imputation performance, we show that AGR is a more generic panel that performs better than G1K across all ancestries considered in MVP. Finally, we tested the effect of the optimized imputation to the GWAS of height. The effect of improved imputation metrics correlated well with improved heritability estimates and inflation metrics across all ancestries.

## PgmNr 3018: MetaMinimac2: An efficient tool to combine genotype data imputed against multiple reference panels.

### Authors:

---

Genotype imputation has become an integral tool in genomewide association studies. Imputation uses a reference panel of densely sequenced samples to infer unobserved genotypes for study samples with genotype array data. With increasing availability of whole genome sequence datasets, investigators have access to a multitude of reference panel choices. It is desirable to construct a combined reference panel from all available sequencing studies to achieve optimal imputation accuracy, but challenging in practice due to data sharing and use limitations.

Here, we describe MetaMinimac2, a novel method which allows for imputation results generated using different reference panels to be combined into a consensus dataset without requiring the sharing of individual-level data for underlying panels. The meta-imputed results are a weighted average of the imputed allele counts from different panels. The weights are individual and region specific, reflecting the optimal choice of the reference panel which varies along the genome. Weights for each region and individual are estimated through a hidden Markov model, utilizing corresponding diagnostic metrics reported by our minimac4 imputation software.

We tested our method by meta-imputing 61 African-American genomes against two homogenous reference panels comprised of 600 African samples and 503 European samples. The results show that meta-imputation consistently outperforms imputation using a single reference panel and performs as well as imputation using a combined panel. For very rare variants (with minor allele frequency of ~0.1%), the imputation  $R^2$  was 42.6% using meta-imputation versus 42.4% using a combined panel, and 0.9% using only the European panel or 33.3% using only the African panel.

An additional benefit of meta-imputation is in reduced computation time with no decrease in variant quality when imputing against large panels. We randomly split the 60,039 genomes in the TOPMed Freeze 5 panel into three non-overlapping subsets, imputed against each subset, and then merged the imputation results. We saved 45.7% of the net computational time with negligible loss in imputation accuracy, compared with imputing directly against the full panel.

In summary, we have developed a flexible method that enables researchers to efficiently merge imputation results from multiple panels to improve the overall accuracy of imputed genotypes without the need to access individual genotype data for the underlying reference samples.

## PgmNr 3019: Defining and characterizing pleiotropy across 57 common diseases and complex traits.

Genetic variants implicated by GWAS often affect multiple traits, a phenomenon known as pleiotropy. Existing methods to quantify pleiotropy capture only a fraction of pleiotropic signal, either because they only measure signed relationships (Bulik-Sullivan et al. 2015b Nat Genet) or because they restrict to genome-wide significant SNPs (Pickrell et al. 2016 Nat Genet). Thus, new approaches are needed to define and estimate genome-wide pleiotropy.

We define the *excess squared effect size correlation* ( $Q_e$ ), quantifying the excess correlation in squared standardized effect sizes between two traits beyond what is expected based on their signed genetic correlation ( $r_g$ ). Intuitively;  $Q_e$  quantifies the similarity between Manhattan plots for each trait. We developed a method, cross-trait LD 4th moments regression (C-LD4M), to estimate  $Q_e$  by regressing products of  $\chi^2$  statistics for two traits on LD 4th moments (sums of  $r^4$ ). We confirmed via extensive simulations that C-LD4M produces unbiased estimates of  $Q_e$ .

We applied C-LD4M to 57 diseases and complex traits (max  $N=460K$ ), yielding three main observations. First, a majority (>60%) of all trait pairs have  $Q_e$  estimates that are significantly positive (FDR<5%) but very small ( $Q_e<0.05$ ). Thus, shared genetic risk variants do not imply meaningful shared biology. Second, complex traits with shared causal tissues consistently have high  $Q_e$ , even when  $r_g$  is low. In particular, we detected strong pleiotropy among 12 brain-related traits (avg  $Q_e=0.41$ ; e.g.  $Q_e=0.80$  vs.  $r_g=0.16$  for # children and # sexual partners), and among 12 immune-related traits (avg  $Q_e=0.19$ ; e.g.  $Q_e=0.37$  vs.  $r_g=-0.04$  for celiac disease and primary biliary cirrhosis). Although there was little pleiotropy between brain- and immune-related traits (avg  $Q_e=0.03$ ), an exception was ulcerative colitis, which had high  $Q_e$  with several brain-related traits, consistent with the hypothesized role of psychological stress. Third, highly polygenic traits are highly pleiotropic, with a correlation of 0.77 across traits between polygenicity and average  $Q_e$ . We recently showed that extreme polygenicity is explained by negative selection, which flattens the distribution of heritability across the genome (O'Connor et al. in press AJHG). We hypothesize that negative selection likewise amplifies pleiotropy between traits by flattening strong genetic signals in trait-specific genes and pathways, leaving behind weaker genetic signals that are often tissue specific and pleiotropic.

Biologically functional gene-set association (GSA) analysis can be complementary to single-variant or single-gene test and can provide insights into the genetic architecture of complex diseases. Existing GSA methods have low statistical power, especially when only a small fraction of the genes are associated with the phenotype. Additionally, since most of the existing methods cannot identify active genes within the gene-set, interpreting results is challenging. Here, we introduce Gene-Set association Using Sparse Signals (GAUSS), a method for GSA with summary statistics which additionally selects the subset of genes with maximum association signals as the active genes. The simulation-based p-value for GAUSS can be efficiently calculated by using pre-computed correlation structure of test statistics from a reference data. Numerical experiments show that GAUSS can increase power over several existing methods while controlling type-I error. We analyzed summary statistics from the UK-Biobank data for 1201 phenotypes with 10679 gene-sets to demonstrate that GAUSS can identify novel associations across a large number of phenotypes and gene-sets. For example, GAUSS detected two fatty-acid related gene-sets associated with E.Coli-infection (p-values  $< 10^{-06}$ ) which illuminate the antibacterial role of fatty-acids. Additionally, GAUSS allows us to investigate active genes for different phenotypes using phenome-wide analysis of a given gene-set, which has been unexplored till now. This highlights genetic and mechanistic similarities or differences between the phenotypes. For example, the association of ATP-binding-cassette transporter gene-set in KEGG database with digestive diseases like Cholelithiasis is driven by *ABCG5* while those with Celiac disease and other intestinal malabsorptions are driven by *TAP2*. The novel associations detected by GAUSS along with the information on active genes and its computational scalability make it an attractive choice to perform GSA.

## PgmNr 3021: Multi-phenotype transcriptome-wide association study using summary statistics identifies new genes associated with lipid phenotypes.

Tests that combine evidence for association between single SNPs and multiple phenotypes are well established. Here, we extend these methods to transcriptome-wide association (TWAS) to improve power of detecting genes associated with multiple phenotypes regulated through similar pathways. We show analytically that the multi-phenotype TWAS has a similar form as a standard multi-phenotype marginal SNP association statistic. Thus, established methods for combining marginal-SNP association tests across multiple traits (e.g., SUM, Wald, or ASSET) can be directly extended to TWAS. We evaluate the Type I error rate and power of multi-phenotype methods via simulation across different residual covariance structures. We show that multi-phenotype TWAS improves the power of traditional single-phenotype TWAS, with the Wald test being near-optimal in most of the scenarios. However, we observed no uniformly best multi-phenotype TWAS method, since the relative power of the methods varies across different alternatives. We showcase these methods in empirical data from the Global Lipids Genetics Consortium of 4 traits (LDL, HDL, TG, and total cholesterol) with cross-tissue weights built with sparse canonical correlation analysis on GTEx gene expression data. The joint analysis identified additional trait-associated genes (222%, 137%, 198% and 132% for the 4 traits respectively and 14% compared to Bonferroni correction). The set of genes identified by joint testing methods also provided new information into the gene regulation architecture for these traits.

## PgmNr 3022: Mendelian randomization accounting for horizontal and correlated pleiotropic effects using genome-wide summary statistics.

Mendelian randomization (MR) is a valuable tool for detecting evidence of causal relationships between pairs of traits. Opportunities to apply MR are increasing rapidly as the number of genome-wide association studies (GWAS) with publicly available summary statistics grows. Unfortunately, existing MR methods are prone to false positives caused by pleiotropic variants. *Horizontal pleiotropy* occurs when a single variant is associated with two traits through different biological pathways. Many methods have been proposed to account for horizontal pleiotropy, which has been shown to be a widespread phenomenon. *Correlated pleiotropy* occurs when a variant affects two traits through a shared pathway/factor. If multiple variants act through the same shared factor, a subset of variants will have correlated effects on both traits. This pattern can result in false positives using most existing approaches.

We propose a new approach, Causal Analysis Using Summary Effects (CAUSE) that accounts for both types of pleiotropy using variants genome-wide. The key idea of CAUSE is that, in the presence of a causal effect, all variants associated with the causative (up-stream) trait should have correlated effects on the outcome (down-stream) trait. This is a stronger criterion than most alternative methods use and allows CAUSE to avoid false positives.

We demonstrate in simulations that CAUSE is substantially better at controlling false positive rate in the presence of correlated pleiotropic effects than other methods. CAUSE is also able to achieve better power when GWAS are under-powered. This is a result of using all variants rather than only those that are genome-wide significant.

We apply CAUSE to study relationships between pairs of complex traits and between blood cell composition and autoimmune disorders. CAUSE makes fewer discoveries than alternative methods. However, many of the pairs that CAUSE determines to be consistent with a causal effect have strong literature support. These including effects of LDL cholesterol on heart disease and of blood pressure on stroke risk. CAUSE is also able to identify an effect of blood pressure on heart disease risk that is not found using other methods. We find that many of the discoveries made by less robust methods may be explained by unmeasured shared factors rather than causal effects, suggesting that correlated pleiotropy may be a major contributor to MR false discoveries.

# PgmNr 3023: Assessment of performance of methods for polygenic Mendelian randomization analysis under realistic genetic architecture of complex traits.

## Background

Mendelian randomization (MR) has provided major opportunities for understanding the causal relationship across phenotypes. Previous studies have often evaluated MR methods based on simulations that do not incorporate realistic models for genetic architecture of complex traits, and/or ignore the process through which instruments are selected based on genome-wide association analysis. These issues can lead to discrepant performance of MR methods in simulations and in real studies.

## Methods

We use a simulation framework that closely mirror what is empirically observed in genome-wide association studies. We simulate data on full GWAS for the exposure and outcome of interest under realistic model for effect-size distribution coherent with heritability, coheritability and polygenicity typically observed for complex traits. We select instruments based on SNPs which reach genome-wide significance in the underlying study of exposure. We then compare performance of 10 MR methods under different sample sizes of underlying GWAS, proportion of valid instruments and mechanism of pleiotropy.

## Results

Simulations show that when the InSIDE assumption holds, i.e. the instrument strength and pleiotropic effect are uncorrelated, IVW, MR-Robust, MR-RAPS, Egger regression, mode-based estimator (MBE) and MRMix have reasonably well controlled type I error rate. Among them, IVW, MR-Robust and MR-RAPS lead to the most accurate point estimates in terms of mean squared error (MSE). MRMix estimator has comparable MSE to the above three methods when the sample size is large (e.g.  $n_x > 200k$ ,  $n_y > 100k$ ), but large MSE when the sample size is smaller. The MBE and Egger regression lead to large MSE throughout the settings. Other methods, including median, MR-PRESSO, MR-Lasso and contamination mixture, have inflated type I error rate especially when  $>50\%$  of the instruments are invalid. When the InSIDE assumption is violated, we observe severe type I error inflation for most of the methods but that of MRMix and the MBE remain well controlled. MRMix leads to smaller MSE than MBE when the sample size is moderately large ( $n_x > 100k$ ,  $n_y > 50k$ ).

## Conclusions

Our simulation studies indicate different performance of MR methods in difference scenarios. Implementing multiple methods can be helpful to obtain robust conclusions.

---

Massive, unselected population-based biobanks offer new opportunities to explore the segregation, penetrance and expressivity of variants thought to be underlying Mendelian forms of diseases. Here we examine Mendelian disease variants segregating in the UK Biobank (UKBB). We hypothesize that patterns of settlement will result in fluctuations in variant frequencies, particularly in historically rural and recent diaspora populations.

Of 6184 one star or above variants asserted to be unconflicted, and pathogenic or likely pathogenic in ClinVar, 1578 segregate in the UKBB. Variants were linked to one or more diseases in OMIM, and the variant-disease pairs (VDP) were binned according to mode of inheritance; Autosomal Dominant (AD) or Autosomal Recessive (AR). We extracted Easting and Northing coordinates for region of birth for UK born participants and mapped these to 167 county-level regions across Britain (ranging in size from N=35 for the Shetland Isles to N=26733 for Manchester). Variant frequencies were calculated within geocoded regions, and to account for variation in population size we report the lower bound of the 95% confidence interval of the minor allele frequency (MAF). We observe 34 AR VDPs segregating at a MAF of >1% in at least one region of the UK, and 39 AD VDPs segregated at a MAF >0.01%. We observed a significant enrichment of these VDPs (3) in the Outer Hebrides ( $p < 6.3 \times 10^{-7}$ , Fisher's Exact), a region we have previously shown has elevated cryptic relatedness in the form of Identity-By-Descent sharing (median pairwise IBD in Outer Hebrides=22cM ; versus 4.03 cM in UK-born participants overall), indicative of a founder effect in this region. Specifically, we see AR VDP for PYGM (p.R50X), PPA2 (p.R127L) and PRKN (p.R275W) each segregating at MAF of >1% in this region, associated with glycogen storage disease, sudden cardiac failure and juvenile parkinsons respectively. We are currently extending this work to >100 recent diaspora populations to the UK, and 18 known or hidden founder populations we have previously detected in the UKBB. Where possible, we will link to relevant ICD10 codes and biomarkers to examine evidence for expressivity and penetrance.

This work shines a light on population health implications of Mendelian disease variants, and a framework for generating evidence of pathogenicity, potential links to local environmental effects, and understanding populations at risk.

Genome-wide association studies (GWAS) have been extensively used to estimate the signed effects of trait-associated alleles and compute polygenic risk scores. Recently, two independent studies failed to replicate the strong evidence for selection for height across Europe, implying that standard population structure correction approaches may not be enough, and that more rigorous and sophisticated methods are required. Here, we provide a correction technique for complex population structure while leveraging the linkage disequilibrium (LD) induced distances between individuals. We implement CluStrat, which performs agglomerative hierarchical clustering using the Mahalanobis distance based Genetic Relationship Matrix (GRM) representing the population-level covariance (LD) for the SNPs. With the growing size of data, computing and storing the genome wide covariance matrix is a non-trivial task. We get around this overhead by computing the GRM directly using a connection between statistical leverage scores and the Mahalanobis distance. For biobank-scale datasets, we also implement a fast algorithm to approximate all leverage scores, therefore approximating the GRM. We test CluStrat on a large simulation study of discrete and admixed, arbitrarily-structured subpopulations with allele frequencies simulated from the Balding-Nichols and Pritchard-Stephens-Donnelly models respectively for 100,000 SNPs and 5,000 individuals across 21 different scenarios. We simulated a quantitative (and its binary equivalent) trait with genetic effects at causal loci drawn from the normal distribution and varied the genetic, environmental and noise variances. CluStrat not only observed the lowest number of spurious associations for all the scenarios, but also identified two to three-fold more rare variants at causal loci as obtained by other Linear Mixed Model (LMM) or Principal Component (PC) based stratification methods. CluStrat returned similar results when applied to the Parkinson's Disease data set from WTCCC, identifying less spurious associations than LMM or PCA-based approaches. Harnessing the LD structure by fast approximation of the Mahalanobis distance is also useful in calculating the kinship matrix in LMM for heritability estimation in tera-scale datasets as well as large GWAS summary statistics. Here, we provide a comprehensive guide to stratification and subsequent disorder trait prediction or estimation utilizing the underlying LD structure of the genotypes.

---

Identifying the genetic and environmental factors underlying phenotypic differences between populations is fundamental to multiple research communities. To date, studies have focused on the relationship between population and phenotypic mean. Here we consider the relationship between population and phenotypic variance, i.e., “population variance structure.” In addition to gene-gene and gene-environment interaction, we show that population variance structure is a direct consequence of natural selection. We develop the ancestry double generalized linear model (ADGLM), a statistical framework to jointly model population mean and variance effects. We apply ADGLM to several deeply phenotyped datasets and observe ancestry-variance associations with 12 of 44 tested traits in ~337K UK Biobank British individuals, 19 of 21 tested traits in a multi-ethnic sample of ~464 UK Biobank individuals, and 3 of 14 tested traits in ~3K recently admixed Mexican, Puerto Rican, and African-American individuals. We show through extensive simulations that population variance structure can both bias and reduce the power of genetic association studies, even when principal components or linear mixed models are used. ADGLM corrects this bias and improves power relative to previous methods in simulated datasets. Additionally, ADGLM identifies 4 novel genotype-variance associations across 4 phenotypes in admixed datasets and numerous such associations across 8 phenotypes in the UK Biobank British dataset. By focusing primarily on the effect of genetic variation on phenotypic mean and ignoring its effect on phenotypic variance, we have been missing an important axis contributing to phenotypic variation and disease emergence. Modeling phenotypic variance with ADGLM will enable discoveries along this axis, particularly as human studies continue to increase in their size and diversity.

## PgmNr 3027: Rare variants are disproportionately impacted by population structure in large genome-wide association studies.

---

Population structure leads to spurious associations in genome-wide association studies (GWAS). While many methods have been developed to detect and correct for population structure in GWAS, there are still lingering questions regarding the efficacy of these methods, especially as we move into the Biobank era, with such large sample sizes that even subtle substructure can create false positive associations. Here, we investigated the impact of population structure in the UK Biobank (UKB) study by simulating a large GWAS in a population with spatial structure that closely mimics geographic structure in the UKB.

The population structure in the UK is relatively recent, following almost complete population replacement in the last 5,000 years. We therefore assumed that demes become panmictic 100 generations ago, which is roughly the time to the last population replacement in the UK, and chose the migration rate among demes to match the  $F_{st}$  ( $\approx 0.001$ ) and genomic inflation ( $\lambda \approx 10$ ) observed in the UKB. We model phenotypes as a function of the environment—either smoothly distributed across demes (clinal effects e.g. latitude)—or affecting only a single deme (i.e. local effects). We show that when environmental effects are sharply distributed, rare variants exhibit more inflation compared to common variants, consistent with previous results in simpler models. This is because rare variants, which are more geographically structured, are more likely to be correlated with localized environmental variables.

We further show that because of the fact that demes become panmictic in the relatively recent past, the population structure is driven primarily by rare variants. Thus, principal component correction does not fully account for environmental confounding, even in common variants, and even when the environment is smoothly distributed across demes. This explains empirical observations that residual population structure continues to confound estimated effect sizes even after correcting for hundreds of PCs. We show that this effect also applies to rare variant burden tests. These results emphasize the difficulty in performing variant association tests under complex population structure, particularly for rare variants, highlighting the need for alternative methods of correction.

## PgmNr 3028: Negative selection on complex traits limits genetic risk prediction accuracy between populations.

**Authors:**

A. Durvasula; K. Lohmueller

[View Session](#) [Add to Schedule](#)

**Affiliation:** Human Genetics, UCLA, Los Angeles, California.

---

Genetic risk prediction is a key goal for medical genetics. Along these lines, great progress has been made towards identifying individuals with extreme risks across several traits and diseases using polygenic risk scores (PRS). However, many of these studies have been done in predominantly European populations, and the portability of PRS between populations is poor. The reasons for this poor portability of PRS across populations remain elusive. Here, we use population genetic simulations to show that negative selection maintains private variants at low frequency, creating population-specific genetic architectures. We find that variants present in Europe but not Africa are predicted to explain ~30% of the heritability when traits are not tied to fitness. When there is negative selection, these population-specific variants can explain 50-70% of the heritability. We show that the heritability accounted for by population-specific variants directly leads to inferior performance in risk prediction between populations, especially in the tails of the risk distribution where individuals have the most extreme phenotypes. To evaluate the impact of population-specific variants for real traits, we built a Bayesian model to stratify heritability between private and shared variants and applied it to 43 traits and diseases in the UK Biobank. Across these phenotypes, we find ~60% of the heritability is attributable to private variants, setting an upper bound on the accuracy of genetic risk predictions between populations. We conclude that the interplay between recent population growth and purifying selection contributes to the decreased accuracy of PRS in non-European populations. Consequently, genetic association studies need to include more diverse populations to enable the utility of genetic risk prediction in all populations.

## PgmNr 3029: A catalog of likely-causal, coding variant associations from imputed UK Biobank exome data.

---

Determining the causal effects of coding variants on complex traits is challenging because most coding variants are rare. Imputation of rare, coding variants is generally limited by the size of sequenced reference panels and by imperfect matching to GWAS cohorts, while direct exome sequencing is typically only feasible in smaller cohorts. To overcome this challenge, we leveraged recently-released whole-exome sequence data for 49,960 UK Biobank participants to serve as a reference panel for imputation into the remaining ~90% of the remaining UK Biobank cohort. This approach successfully imputed variants with minor allele frequencies as low as 0.005-.01% at an accuracy of  $R^2 > 0.5$ .

To assess which of these variants might causally affect phenotypes, we performed association analyses using linear regression with principal component covariates on 34 heritable traits measured in  $N \approx 337K$  unrelated UK Biobank participants of British ancestry. Among coding variant associations that reached genome-wide significance ( $p < 5e-8$ ), we identified a subset of potentially-causal associations not explained by linkage disequilibrium with nearby SNPs. Most coding variant associations that reached significance were unlikely to be causal: our approach filtered ~90% of associated variants that were annotated as having a functional impact on a gene (missense, frameshift, etc.). Upon restricting to variants with CADD score  $\geq 20$ , most high-CADD, coding variant associations (~69%) were still filtered.

We identified 1,036 remaining associations involving coding variants with CADD  $\geq 20$  as putatively causal (across the 34 traits). To assess the extent to which our imputation approach improved our ability to detect these associations, we compared our association results to analogous results using imputation data provided by UK Biobank on the same set of samples but imputed using the Haplotype Reference Consortium (HRC) panel. We found that ~24% of variants we identified as putatively causal did not reach genome-wide significance in the UK Biobank HRC-imputed data release; most such variants were rare. Furthermore, approximately half of all the genes implicated by these variants were not previously reported in the NHGRI-EBI GWAS Catalog for the corresponding trait.

Our results demonstrate the utility of within-cohort imputation in population-scale GWAS cohorts and provide a resource of likely-causal, coding variant associations for follow-up analysis and fine-mapping method development.

---

Complex human diseases are affected by both genetic and environmental risk factors. Gene-environment interaction (GEI) tests for aggregate genetic variant sets have been developed in recent years. With the advance of sequencing technology, whole exome and genome sequencing data are now being collected at an unprecedented scale in biobanks. However, existing statistical tests become computationally intensive in such large-scale sequencing studies with correlated samples. We propose efficient Mixed-model Association tests for GEne-Environment interactions (MAGEE), for testing the GEI between an aggregate genetic variant set and environmental exposures on quantitative and binary traits in large-scale sequencing studies. Joint tests for genetic main effects and GEI are also developed. A null generalized linear mixed model adjusting for covariates but without any genetic effects is fitted only once in a whole genome GEI analysis, thereby vastly reducing the overall computational burden. Score tests for variant sets are performed as a combination of genetic burden and variance component tests by accounting for the genetic main effects using matrix projections. The computational complexity is dramatically reduced in a whole genome GEI analysis, which makes MAGEE scalable to hundreds of thousands of individuals. Furthermore, MAGEE allows flexible weighting schemes to incorporate functional genomic information. We applied MAGEE to the exome sequencing data of 49,959 related individuals from the UK Biobank, and the analysis of 19,442 protein coding genes finished within a few hours on a single computing node.

## PgmNr 3031: Carriers-only tests of association of rare genetic variants with a binary outcome.

---

**Background:** Rare variants association analyses with binary outcomes that use likelihood-based tests such as the Score and Wald tests, suffer from inflated type 1 error. The problem is exacerbated when pooling together individual-level data from diverse parent studies, with potentially different proportions of affected individuals and different frequencies of genetic variants. For example, the analysis of short sleep (< 6 hours/night) considers ~22,000 individuals from TOPMed of European, African, Hispanic, and Asian descent, and the proportion of short sleepers is highest among African Americans. Here, the Score test detected many spurious associations

**Methods:** We propose a class of semi-parametric tests for association of rare variants with binary traits. Given a vector of probabilities of affection status among a set of (possibly correlated) carriers of a rare variants, we test whether the number of affected individuals among these carriers is consistent with their probability vector. Our carriers-only tests use the Poisson-Binomial (BinomiRare test) or Conway-Maxwell-Poisson (CMP test) distributions.

**Results:** We performed genetic analysis of short sleep in TOPMed. The Score test did not control the type 1 error. The SAIGE test improved upon the Score test, but had also high inflation when there were less than 30 carriers of the rare variant, and was slower than the carriers-only approach. When there are at least 30 carriers, the SAIGE and carriers-only tests had similar performance (correlation between p-value = 0.96), with SAIGE being often slightly more powerful. Still, in the single region that passed the genome-wide significance threshold, the most significant associations were detected by BinomiRare. A variant chr2:33765596:A:G (chr2 p22.3; 65 carriers; CADD score=15.3) had BinomiRare p-value  $7.4 \times 10^{-9}$ , SAIGE p-value =  $2.6 \times 10^{-8}$ .

**Conclusions:** carriers-only tests offer a computationally efficient alternative to other tests of rare variant associations in the mixed model settings, in terms of both time and memory. They protect the type 1 error for arbitrary number of carriers of the rare variant and for arbitrary case-control proportion. These tests can be applied on single variant and on a burden of multiple variants.

## PgmNr 3032: Polygenic risk modeling with latent trait-related genetic components.

---

Polygenic risk models have led to significant advances in understanding complex diseases and their clinical presentation. While simple linear models of genetic risk like polygenic risk scores (PRS) can be quite accurate, they do not generally account for disease subtypes or pathways which underlie within-trait diversity. Meanwhile, etiology- and pleiotropy-aware models of genetic effects offer the opportunity to more deeply analyze the underpinnings of complex traits within individuals and across populations. Here, we introduce a latent factor model of genetic risk based on components from matrix DEcomposition of Genetic ASSociations (DEGAS), and compute DEGAS risk scores for high body mass index, diabetes, and renal failure in a cohort of array-genotyped individuals from UK Biobank. We assess the predictive performance of DEGAS relative to traditional PRS, and validate its characterization of genetic risk profiles for each trait.

## PgmNr 3033: Methodology for differential gene expression analysis in large samples: Application to cystic fibrosis lung disease.

---

Read counts from RNA-seq experiments are a measure of gene expression. After quality control and normalization procedures, the analysis goal is to identify truly differentially expressed genes in the presence of additional biological or technical variation that remains in the count data. While overdispersion is most common, some genes have read counts that are under dispersed. Existing statistical methods model the mean-variance relationship by either assuming a negative binomial distribution or by transforming the counts to a continuous scale, but the tools to estimate dispersion as well as outliers can bias the results. As sequencing technology decreases in price, RNA-seq experiments using larger sample sizes is becoming more accessible, and thus so are more robust tools that rely on large sample statistical properties. We propose a novel method for differential gene expression analysis using robust profile likelihoods, RPLR. Poisson log-linear regression is used as the working model, and after a data-driven robust adjustment, the profile likelihood ratio displays accurate inference on the fold change of gene expression under binary or quantitative conditions of interest. We simulated count data genome-wide from a negative binomial, generalized poisson and rounded gamma distribution and showed the RPLR performs at least as well as edgeR (Robinson et al. 2010), DESeq2 (Love et al. 2014) and limma-voom (Law et al. 2014) for a binary condition of 2 fold change at sample sizes as low as 25 per group, resulting in a sensitivity of 0.8 controlled at a 10% nominal FDR. By sample sizes of 40 per experimental group, RPLR had the highest AUC, and performed uniformly better under under-dispersion, presence of outliers and for different mean-variance relationships. In RNA-Seq of nasal epithelia from 80 individuals with Cystic Fibrosis (CF) the RPLR method identified differentially expressed genes associated with CF lung disease. These genes included those identified by existing methods (eg *MFHAS1*, *CYP2T3P* and *THG1L*) and novel findings such as *UBE2G1* (FDR of 0.03) whose 6th exon has complete sequence homology with a lncRNA at the known *SLC26A9* CF modifier locus. RPLR provides a flexible approach to differential gene expression analysis that is designed for larger sized studies. It can accommodate any unknown mean-variance relationship, is robust to outliers, and is applicable to categorical or quantitative variables of interest and complex experimental designs.

## PgmNr 3034: TWO-SIGMA-geneset: TWO-component SInGle cell model-based association method for gene set testing.

---

Gene set testing (GST) methods allow omnibus testing for a pre-specified set of genes, often by assigning an overall  $p$ -value to the set of genes. By considering such sets of genes, GST methods can improve statistical power and help to understand how genes in a common pathway jointly regulate biological processes. There are many GST methods for bulk RNA-seq data, however no such methods are specifically designed for use with single-cell RNA-seq data, which often exhibits excess zeros and overdispersed counts compared to traditional bulk RNA-seq data. Here, we propose TWO-SIGMA-geneset to conduct gene set testing using single-cell RNA-seq data. We utilize our previously developed TWO-SIGMA, a flexible TWO-component SInGle cell Model-based Association method. The first component of TWO-SIGMA models the “drop-out” probability with a mixed effects logistic regression, and the second component models the (conditional) mean read count with a log-linear negative binomial mixed-effects regression. TWO-SIGMA accommodates excess zeros and overdispersed counts, and can, using random effects, explicitly account for the possible dependency introduced by measuring multiple single cells from the same sample. TWO-SIGMA-geneset focuses on conducting competitive gene set testing, in which the genes in a given set are compared to the remaining collection of genes. Each gene in the set is assigned an individual statistic, such as a likelihood ratio statistic from the joint test of both components, produced from TWO-SIGMA. These gene-level statistics are then combined into one set-level statistic, with options including the average, median, or sum of the ranks. Finally, the set-level statistic is compared to the complement set of genes using, for example, the t-test, Wilcoxon rank-sum test, or a Monte Carlo  $p$ -value. Simulation studies show that type-I error is well controlled in a variety of representative scenarios. Power is improved over state-of-the-art methods, including CAMERA, for a variety of scenarios consistent with real single-cell RNA-seq data, including when varying: gene set sizes, the scales of the differential expression, the proportion of drop-out events, or the presence of individual-level random effects. Extensions to allow for inter-gene correlation are explored. We demonstrate our method with an application to a real dataset consisting of 36,849 single cells from 10 mice and gene sets from the Molecular Signatures Database.

# PgmNr 3035: Robust filtering of cell-free droplets from single-cell RNA sequencing.

## Authors:

---

The advances of single-cell RNA sequencing (scRNA-seq) technologies and analytic methods enable massively parallel profiling of single cell transcriptomes of thousands of cells using droplet-barcoding microfluidic devices. Due to the stochastic nature of the technology, it is expected that a large fraction of droplets does not contain cells. Ideally, the barcodes of these cell-free droplets should not present in the sequenced scRNA-seq library. However, in actual scRNA-seq data, the microparticles in cell-free droplets occasionally react with transcripts after the droplets are broken for library preparation. This results in the sequencing of cell-free droplets with typically low UMI read counts. As a result, the number of barcoded droplets is orders of magnitudes larger than the droplets representing individual cells. A very first step to analyze droplet-based scRNA-seq data is to filter out cell-free droplets to focus on droplets representing actual cells. However, typical procedures to determine cell-free droplets is very naive, for example, relying only on the total number of UMIs per droplet. Such a heuristic procedure may result in serious bias and systematic underrepresentation of cell types with lower UMI counts. We propose a robust method to distinguish cell-free droplets from cell-containing ones in scRNA-seq datasets by integrating transcriptomic profiles, genetic information, and the UMI distribution together. We use Dirichlet multinomial distribution to model the likelihood of cell-free droplet and combine them with genetic variants (if multiplexed) to determine whether the droplet is likely cell-free or not. We apply our method to various scRNA-seq datasets generated by DropSeq and 10x Chromium technologies and show that our method rescues more droplets that are likely to represent individual cells compared to existing methods. For example, among 247,027 droplet barcodes obtained from a DropSeq experiment across a mixture of 3 cancer lines, we observed that Cell Ranger's UMI-count method and EmptyDrops software filtered 938 and 2,407 as valid barcodes, while our proposed method filtered 3~7-fold more (7,179) barcodes. False negative rates based on carefully chosen high-quality droplets were 54% for Cell Ranger, 24% for EmptyDrops, and 2.4% for our method. Fraction of apparent doublets among filtered droplets (which is enriched for cell-free droplets) was estimated to be 8.4% for Cell Ranger, 18.8% for EmptyDrops, and 11.2% for our method.

## PgmNr 3036: Japanese specific imputation reference panel using 7,000 whole genome sequences.

---

The inclusion of population-specific whole genome sequences (WGS) into established reference panels has been demonstrated to improve imputation quality at minor allele frequency (MAF) thresholds of <5%. While population-specific WGS at deep depth is expected to improve imputation both quantitatively and qualitatively, the impact of combining WGS at different depth (deep and low depth vs deep depth) remains unexplored.

We created three Japanese population specific reference panels using combinations of WGS from the BioBank Japan Project to augment the 1000 Genomes Project (1KG): 1000 Genomes Project augmented with 1000 Japanese WGS (1KG+1K) at 30x depth; 1000 Genomes Project augmented with 3000 Japanese WGS (1KG+3K) at 30x depth; and 1000 Genomes Project augmented with 7000 Japanese WGS (1KG+7K) of mixed depth (3000 at 30x and 4000 at 3x depth).

A cohort of 30,042 Japanese individuals genotyped on the Illumina OmniExpress and HumanExome chips was prephased with EAGLE2 and imputed up to each of the reference panels using minimac3. Comparisons of imputation quality (based on estimated  $R^2$  provided by minimac3) were conducted on a subset of imputed variants shared across the three reference panels and 1KG alone.

Analyses of autosomes demonstrated that the addition of WGS data substantially improved imputation quality, particularly for SNPs with MAF <5%. A total of 42,380,426 SNPs were shared across reference panels. Of these, after imputing up to the 1KG panel alone, 10,850,678 (25.6%) SNPs were 'well imputed' ( $R^2 > 0.3$ ), including 3,172,237 (9.3%) SNPs with MAF <0.5%. After imputing up to the 1KG+3K panel, the number of well imputed SNPs increased to 16,452,081 (38.8%). We also

observed a dramatic increase in the number of well imputed SNPs with MAF <0.5% to 8,499,108 (24.8%). The highest quality imputation was derived from imputing up to the 1KG+7K panel: 18,065,768 (42.6%) of SNPs were well imputed, including 10,114,995 (29.5%) with MAF <0.5%. The mean  $R^2$  of SNPs with MAF <0.5% increased from 0.094 after imputation up to the 1KG panel alone to 0.203 after imputation up to the 1KG+7K panel. The addition of 7000 Japanese WGS of mixed depth to the 1KG panel resulted in a much-improved imputation into Japanese individuals in terms of both the number of variants and their imputation quality, and would be expected to increase power for discovery of rare variant associations with complex human disease.

## PgmNr 3037: Equal Local Levels (ELL): A test statistic for trans eQTL detection.

In trans eQTL mapping it is common to have to test the association between a gene expression level and a genetic variant simultaneously for 1000s of genes and 100,000s of genetic variants. Properly maintaining type 1 error without sacrificing power becomes challenging. One strategy is, for a single SNP, to aggregate all tests of that SNP against each gene and test whether it is associated with - and thus an eQTL for - at least one gene, repeated over all SNPs in the genome. Global Type 1 error correction then adjusts for only the number of genetic variants not the product of that and the number of genes. Once SNPs that are eQTLs for at least one gene are found, further detailed analysis of those specific SNPs can be performed

We propose the Equal Local Levels (ELL) test statistic which aggregates test statistics -- Z-scores -- from the tests of association between a SNP and a set of genes to test if at least one is not null. ELL maintains high power and correct Type 1 error in the realistic setting of correlated gene expressions. In simulations, when a SNP is a trans eQTL for 10 to 80 of 10,000 tested genes, ELL has high power and outperforms other strategies (Generalized Higher Criticism, Generalized Berk-Jones, Score test, minimum p-value, FDR, CPMA) with, in many cases, relative power increases of 15 - 30% over the next best strategy while maintaining correct Type 1 error. We consider several scenarios of correlation between Z-scores for different genes. ELL is also computationally feasible such that evaluation against 100,000s of genetic variants can be done quite quickly.

We did trans eQTL mapping in the LG/J x SM/J advanced intercross line of mice (LG x SM AIL), which is a multi-generational outbred population dataset consisting of 523,028 SNPs and expression levels of 16,661 genes recorded for the hippocampus, pre-frontal cortex and striatum for 208 mice. We show that when applied to this data, ELL is fast -- it can be calculated for all 523,028 genetic variants in under an hour -- and powerful -- we are able to discover numerous trans eQTLs.

Our ELL statistic is a novel method that has the potential to significantly improve the efficacy of trans eQTL mapping studies.

## PgmNr 3038: Modeling imputation uncertainty in fine-mapping improves accuracy.

---

Identifying causal variants is a fundamental problem in analysis of genome-wide association study data. Existing computational methods for fine-mapping have led to important insights, but there are no scalable methods that explicitly model uncertainty due to genotype imputation.

Here, we first introduce a new simulation framework that allows us to assess the effects of ignoring imputation uncertainty and to evaluate potential solutions to this problem. To do this, we simulate human sequence data at large sample sizes using a coalescent model, and we use these sequences to simulate heritable phenotypes. We then mask variants to simulate the process of genotyping, and we re-impute the masked variants. Finally, we use our imputed genotypes and simulated phenotypes to perform fine-mapping. Our results show that ignoring imputation uncertainty can lead to high-confidence false positives.

Second, we introduce a new method for fine-mapping with imputed genotypes. Our method expands on the state-of-the-art 'Sum of Single Effects' model (Wang et al 2018). It uses the imputation as a prior for genotype values, which are treated as latent variables, to incorporate imputation uncertainty into the posterior inference. We use mean-field variational inference to approximate the joint posterior of genotypes and genetic effects. We demonstrate through simulations that explicitly modeling imputation uncertainty improves the accuracy of fine-mapping.

## PgmNr 3039: Revealing the complex genetic architecture of type 1 diabetes complications: Joint modeling of multivariate longitudinal and time-to-event traits.

### Authors:

---

Motivated by the complex genetic architecture of Type 1 diabetes complications (T1DC), where multiple SNPs are associated directly &/or indirectly with time to complications via intermediate longitudinal risk factors, we develop a joint model (JM) of multiple longitudinal & time-to-event traits. JM links (a) a multivariate linear mixed model for the observed longitudinal measures of each trait, accounting for measurement error, including a time trajectory, fixed SNP & random subject effects; and (b) a frailty survival model for time-to-event traits depending on the fitted longitudinal trajectories from (a), fixed SNP & random subject effects. The *overall* SNP association with a time-to-event trait can be decomposed into *direct* ( $\gamma$ ) & *indirect* ( $\beta$ ) effects on each longitudinal process. We classify a SNP association with a time-to-event trait as: *direct* if  $\gamma \neq 0$  &  $\beta = 0$ ; *indirect* if  $\gamma = 0$  &  $\beta \neq 0$ ; *direct & indirect* if  $\gamma \neq 0$  &  $\beta \neq 0$  and propose a multi-trait SNP test for global SNP association with at least one trait. Under a system model we formulate for the complex architecture of a T1DC study, we simulate datasets with phenotypes that involve 5 causal SNPs with various direct effects on two time-to-event traits (retinopathy, nephropathy) &/or indirect effects via two observed (glucose, blood pressure) and one simulated longitudinal traits. For each SNP, we fit (a) & (b) sequentially and estimate the covariance matrix via bootstrap. Compared to standard approaches (marginal (MM) and frailty survival models (FM) adjusted for observed longitudinal values instead of trajectories in (b)), SNP effect estimates from JM are more efficient, especially for SNPs associated with time-to-event outcomes with lower event rates, and JM detects direct or indirect SNP associations with highest power, even when the model is not fully specified. For direct & indirect SNP associations, MM & FM overestimate the direct SNP effect, due to their inability to separate correctly the direct & indirect effects from the overall effect when longitudinal traits are ignored from the model (for MM) or have measurement error (for FM). The proposed multi-trait SNP test can be more powerful for discovery of SNPs associated with multiple traits and has slightly inferior power than single parameter tests for other types of SNP associations. Application of JM methods provides improved SNP effect estimates & hypothesis tests that can reveal complex architecture of related traits.

## PgmNr 3040: Sparse empirical kinship matrices enable computationally efficient and accurate association tests in large samples.

Mixed models for genetic association testing have traditionally accounted for structure among samples by using an empirical genetic relationship matrix (GRM) that measures genetic covariance, genome-wide, from both ancestry and relatedness. However, fitting mixed models in samples with tens or hundreds of thousands of individuals can be a prohibitive computational burden. Here, we address this problem by using a sparse empirical kinship matrix (KM) and ancestry principal components in place of a GRM.

Standard forms of empirical GRMs and KMs estimated from genotype data are dense; i.e. have no entries equal to zero. To exploit the computational speedups that sparse matrices enable, we make an empirical KM sparse by clustering samples based on their pairwise kinship estimates, setting all inter-cluster estimates to zero; this can also be thought of as approximating low levels of relatedness as 'unrelated'. In today's large-scale population studies, where those in pedigrees are a small proportion of the overall sample, this approximation can be expected to be highly accurate, and the computational speedup substantial.

To illustrate the computational advantage and statistical impact of using sparse empirical KMs, we performed genetic association analyses using seven red blood cell traits and WGS data from TOPMed freeze 6. Between 17,469 and 48,858 samples were available for these traits. Using a 4th degree relatedness threshold (i.e. kinship > 0.022) and our proposed algorithm, 98.3% to 99.5% of entries in the sparse KM were set to zero, and the largest cluster ranged from 1667 to 2459 samples. Compared to using a GRM, using a sparse KM significantly improved computational performance; e.g. fitting the null models for these traits took just 0.5-6.2% of the CPU time and required 1.4-6.7% of the memory. Furthermore, differences in association p-values between the two approaches were small. For these traits, over 99.99% of tests differed in  $-\log_{10}(p)$  by less than 0.5; i.e. by an amount very unlikely to change the practical interpretation of results. With the level of sparsity attainable in population studies such as TOPMed, we also find that our approach performs favorably compared to SAIGE, another mixed model method designed for analysis of large samples. The use of sparse KMs is a promising and flexible approach to improve the computational efficiency of association testing in large population studies, without sacrificing accuracy.

## PgmNr 3041: Prediction-based functionally informed priors for fine-mapping.

### Authors:

R. Cui<sup>1</sup>; O. Weissbrod<sup>2</sup>; M. Kanai<sup>1,3,4</sup>; J. Ulirsch<sup>1,5</sup>; H. Finucane<sup>1</sup>

---

Using functional annotations to inform prior causal probabilities for fine-mapping can increase power to identify causal variants. However, taking advantage of a large number of functional annotations with existing methods requires very strong modeling assumptions. Here we introduce a new procedure for constructing Bayesian priors for fine-mapping from hundreds to thousands of functional annotations that is more flexible and potentially more robust to model misspecification than previous methods. Our procedure has two steps: first, we learn a function of the annotations that allows us to rank SNPs; second, we partition the SNPs to equally sized bins based on this ranking, and we compute one value per bin that we use as the prior probability of causality for SNPs in that bin.

To rank the SNPs, we use a prediction framework. First, we compute posterior inclusion probabilities (PIPs) by running a state-of-the-art fine-mapping algorithm such as SuSiE<sup>[1]</sup> with a uniform prior. Second, we select annotations to include in our procedure by marginally evaluating each one using stratified LD score regression<sup>[2]</sup> which leverages polygenic signal, and keeping those that are significantly associated with the trait in question. We then train a predictor of the PIPs using the selected annotations.

In a preliminary analysis of UK Biobank Height data, using baselineLDv2.2 annotations, we compared five methods for prediction in a leave-one-chromosome out framework: Ordinary Least Squares (OLS), Decision Tree (DT), Gradient Boosted Tree (GBT), Random Forest (RF), Logistic Regression (LR). To assess prediction accuracy, we first computed the mean target PIPs in each quintile of predicted PIP, and we then took a ratio of mean target PIP in the top and bottom quintile. For OLS, GBT, and LR we see ratios of 22.05, 22.48, and 17.68 respectively; DT and RF had ratios of 1.78 and 3.31 respectively. Using only top loci to run the model fitting step decreased this ratio slightly (OLS: 18.26).

To compute priors for fine-mapping that are robust to model misspecification, we rank the SNPs using a trained predictor, we partition the SNPs into equally sized bins, and we use the average target PIP within the bin as the prior for the SNPs on the fine-mapping chromosome. We use separate chromosomes for training the predictor, binning, and fine-mapping.

Polygenic risk scores (PRS), which summarize the effects of genome-wide genetic markers to measure the genetic liability to a trait or a disorder, have shown promise in predicting human complex traits and diseases, and may facilitate early detection, risk stratification, and prevention of common complex diseases in healthcare settings. Conventional methods for PRS construction, which rely on LD-pruning and P-value thresholding (P+T), discard information and limit prediction accuracy. More sophisticated Bayesian polygenic prediction methods (such as LDpred) often model SNP effect sizes as a discrete mixture of normal distributions, which imposes daunting computational challenges and may result in inaccurate adjustment for LD structure. We have developed PRS-CS, a polygenic prediction method that utilizes a high-dimensional Bayesian regression framework and places a conceptually novel class of priors --- continuous shrinkage (CS) priors --- on SNP effect sizes, which can accommodate varying genetic architectures, enable accurate and multivariate modeling of local LD patterns, and provide substantial computational advantages over discrete mixture priors. In addition, with our pre-calculated, population-specific LD references, PRS-CS infers posterior SNP effect sizes from GWAS summary statistics and does not require individual-level genotype data. We conducted extensive simulations across a wide range of genetic architectures, GWAS sample sizes and SNP heritability, using data from the UK Biobank. PRS-CS robustly improved the predictive performance of PRS over existing methods. We applied PRS-CS to predict six common complex diseases (breast cancer, coronary artery disease, depression, inflammatory bowel disease, rheumatoid arthritis, and type 2 diabetes mellitus) and six quantitative traits (height, body mass index, high-density lipoproteins, low-density lipoproteins, cholesterol, and triglycerides) in the Partners HealthCare Biobank. PRS-CS consistently outperformed all alternative methods examined, with an average improvement of 14% in prediction accuracy relative to LDpred and an average improvement of 55% relative to P+T. We envision that PRS-CS will demonstrate bigger advantages as the GWAS sample sizes continue to grow. We will further present new results on trans-ethnic polygenic modeling and prediction using GWAS summary statistics and LD reference panels from multiple populations, based on an extension of the modeling framework of PRS-CS.

## PgmNr 3043: Causal inference for highly pleiotropic biomarkers using Mendelian randomisation and Bayesian networks.

**Authors:**

R. Howey; H.J. Cordell

[View Session](#) [Add to Schedule](#)

**Affiliation:** Institute of Genetic Medicine, Newcastle University, Newcastle upon Tyne, United Kingdom

---

Mendelian randomization (MR) is a popular tool for performing causal inference in genetic epidemiology, but it can have limitations for evaluating simultaneous causal relationships in complex data sets. We consider a scenario that may arise when analysing biomarker data as generated from modern “omics” technologies, whereby multiple genetic variants are associated with multiple potential intermediate variables (biomarkers) that mediate an outcome of interest. This highly pleiotropic scenario violates one of the required assumptions of MR. However, Bayesian network analysis (BN) offers an alternative approach. In BN, the conditional dependencies and independencies of variables are described by a graphical model (a directed acyclic graph) and its accompanying joint probability, which may be estimated using individual-level data.

We perform computer simulations to investigate the utility of BN in this situation. We simulate data using previously estimated real effect sizes of 150 genetic variants on 12 biomarkers which are assigned to have either an effect on the outcome, no effect or a reverse effect from the outcome to the biomarker. As well as BN and MR we evaluate several other recently-proposed causal inference methods: multivariable MR based on Bayesian model averaging (MR-BMA), a multi-SNP mediation intersection-union test (SMUT) and a latent causal variable (LCV) test. Our results showed that BN outperformed all other methods in terms of high power to detect an effect in the correct direction, while maintaining low type I error. As expected, MR had high power but also very high type I error due to pleiotropy. MR-BMA performed well at identifying which biomarkers were causal and had excellent type I error, but it is not designed to detect reverse effects.

We conclude that BN is a useful complementary approach to existing methods for performing causal inference in complex data sets such as those generated from modern “omics” technologies.

## PgmNr 3044: A resource-efficient tool for mixed model association analysis of large-scale data.

---

The genome-wide association study (GWAS) has been widely used as an experimental design to detect associations between genetic variants and a phenotype. Two major confounding factors, population stratification and relatedness, could potentially lead to inflated GWAS test-statistics and thereby spurious associations. Mixed linear model (MLM)-based approaches can be used to account for sample structure. However, genome-wide association (GWA) analyses in biobank samples such as the UK Biobank (UKB) often exceed the capability of most existing MLM-based tools especially if the number of traits is large. Here, we developed an MLM-based tool (called fastGWA) that controls for population stratification by principal components and relatedness by a sparse genetic relationship matrix for GWA analyses of biobank-scale data. We demonstrated by extensive simulations that fastGWA is reliable, robust and highly resource-efficient. We then applied fastGWA to 3,613 traits on 456,422 array-genotyped and imputed individuals and 2,090 traits on 46,191 whole-exome-sequenced (WES) individuals in the UKB.

## PgmNr 3045: Fine-scale estimates of regional polygenicity provide insights into the genetic architecture of complex traits.

Investigating how many genetic variants contribute to phenotypes and how they are distributed throughout the genome is a fundamental question in quantitative genetics. While previous studies have used partitioned heritability within regions of the genome to gain insights into genetic architecture, estimates of heritability alone do not provide information about the number of SNPs with nonzero effect sizes (causal SNPs).

We propose an approach to infer the proportion of causal SNPs and the expected per-causal SNP effect size at each region. Our approach, BEAVR (Bayesian EstimAtion of Variants in Regions), estimates the proportion of causal SNPs in a region from GWAS data while accounting for linkage disequilibrium. We introduce a new inference algorithm that leverages the intuition that most SNPs are not causal to perform efficient inference that scales linearly with the number of SNPs.

We divide the genome into 470 non-overlapping 6MB regions (~1K SNP per region) and apply our method to estimate the regional proportion of causal SNPs across each region for 22 complex traits from the UK Biobank. We find that each 6MB region contains an average of 19 (SD: 16.8) causal SNPs aggregated across all traits. First, we show that heritability is proportional to the number of causal SNPs both at the genome-wide scale and within most regions. On average across all regions and traits, each causal SNP contributes 3.9E-05 of heritability. Second, we identify 42 regions that deviate from this pattern, where the increased heritability is attributed to increased effect sizes as opposed to a higher number of causal SNPs. To understand the factors that affect the distribution of causal SNPs, we regressed the number of causal SNPs against the number of genes per region. We observe a linear relationship between the number of causal SNPs and the number of genes for most traits ( $r^2 = 0.02$  across 13 traits,  $P = 1.0E-15$ ). After controlling for heritability and the total number of SNPs in a region, this relationship remains significant for height, BMI, and asthma ( $P = 1.6E-03$ ;  $4.2E-02$ ;  $1.8E-02$ ). Finally, we model the genome-wide effect size distribution by aggregating our estimates of regional heritability and polygenicity to define a distribution parameterized by a mixture of variance components. Compared to effect size distributions described only by genome-wide parameters, this

distribution described by regional parameters contains 3.6x more SNPs within the tails of the distribution.

## PgmNr 3046: Partitioning genetic correlation by annotation using LD score regression.

LD score regression (LDSC) is a method for detecting confounding and estimating genetic correlation and components of heritability from GWAS summary statistics. Here we extend LDSC to estimate genetic correlation within annotations and analyze the properties of this method.

Using genotype data from the UK Biobank, we simulate phenotypes and summary statistics for genetically correlated traits with annotation-specific enrichment of genetic covariances. By simulating under a range of parameter values for overall trait heritability and enrichment of heritability and genetic covariance within annotations (minor allele frequency bin, coding, conserved, and DHS), we describe the conditions under which LDSC produces reliable and numerically stable estimates of annotation-level genetic correlation. For traits with low annotation-specific heritability, it is often impossible to estimate genetic correlation within an annotation due to numerical instability of heritability estimates within some LD blocks, even for traits for which genome-wide genetic correlation can be estimated. For example, we simulated pairs of correlated traits with and without enrichment of correlation in a MAF 1%-5% annotation, with genome-wide genetic correlation 0.6, heritability 0.5, and no enrichment of heritability in the annotation, at a sample size of 50K. We were able to estimate the genome-wide genetic correlation using LDSC in 98% of these simulations, but could not estimate the presence or absence of enrichment of genetic correlation within the annotation in 19.1% of null simulations (no enrichment) and 25.0% of non-null simulations (annotation-specific correlation 0.9).

For certain pairs of traits which permit estimates, we also present preliminary results from real data.

## PgmNr 3047: Is the first-order variance approximation in Mendelian randomization OK?

Mendelian randomization (MR) is a method of using genetic variants as instrumental variables (IV) to estimate causal effect between exposure and outcome. Recently, summary statistics released from genome-wide association studies with large sample size facilitated MR by providing exposure effect sizes of multiple genetic variants. This type of MR analysis utilizing external dataset for exposure effect sizes is called two-sample MR design. The causal effect between exposure and outcome is commonly obtained by combining the per-variant ratio estimates via inverse-variance weighted method. In this procedure, conventionally, the standard error of the ratio estimate is approximated by the first-order term from the delta method. However, as indicated in [Thomas et al., 2007], this approximation can lead to underestimation of variance. Here, using simulations, we show how much an impact this approximation has on the false positive rate and power of MR. Our simulations showed that when the IVs were selected with stringent p-value threshold ( $5 \times 10^{-8}$ ), the errors in variance due to the first-order approximation was about 3%. Interestingly, this value appeared to be independent of the effect size ratio between the exposure effect and causal effect, and of the sample size ratio between the two datasets in the two-sample design. However, when the IVs were selected by less stringent threshold, the error in variance increased. In contrast, an analytical approximation including up to the second order term in variance was nearly as accurate as the empirical estimation. In sum, these results showed that there is no reason not to use the more accurate analytical approximation for the variance estimation of ratio estimates.

## PgmNr 3048: Identifying causal variants by fine mapping across multiple studies.

Genome-Wide Association Studies (GWAS) have identified numerous loci associated with a variety of common traits. However, within each of these loci, many SNPs are associated with the trait of interest, and most are likely to be non-causal variants that are in LD with a limited number of causal SNPs. Identifying these causal variants is crucial for elucidating the genetic architecture of complex traits, but it is too costly to test all significantly-associated variants with biological assays.

The problem of statistical “fine mapping” addresses this challenge by identifying a small set of variants that, with strong statistical evidence, contains all of the causal variants. Various methods have emerged in recent years to perform fine mapping, and have successfully been used to help identify causal variants. However, there is great interest in multiple study settings, such as trans-ethnic fine mapping, because they maximize sample size and therefore statistical power. The existing methods do not generalize well to this setting, because they do not take into account the fact that effect sizes of causal variants in different studies are expected to be correlated. Additionally, computational efficiency is critical due to the necessity of inverting large matrices that contain many SNPs from multiple studies.

In this work, we present a method that performs statistical fine mapping efficiently in the multiple-study setting. We generalize a model introduced by CAVIAR and extended by CAVIAR-BF and FINEMAP, in which association statistics are modeled from a multivariate normal distribution and a Bayesian framework is applied to find minimum-sized putative sets of causal SNPs with high posterior probability. The covariance matrix for causal SNPs in all studies models the correlation between the causal SNP effect sizes in different studies according to the random effects model. This matrix must be inverted and its determinant must be taken to compute the multivariate normal likelihood function. However, we show that its structure forms a repetitive “block” structure that can be leveraged to compute the inversion and determinant efficiently.

Our method provides an efficient, statistically sound framework for performing fine mapping while leveraging information from multiple studies, and therefore shows promise for improved discovery of causal variants across populations.

## PgmNr 3049: Fine-tuning polygenic risk score models using GWAS summary statistics.

Polygenic risk scores (PRSs) have wide applications in human genetics research. It is straightforward to construct a PRS using variant effect estimates from genome-wide association studies (GWAS). More sophisticated methods, including Bayesian frameworks (e.g. LDpred) and penalized regression models (e.g. LASSOSUM), have also been developed. These methods use GWAS association statistics as input to re-estimate variant effects and improve PRS performance. Notably, from the simplest approach to highly sophisticated methods, nearly all PRS models include tuning parameters. These parameters, such as the p-value cutoff in simple PRS and the causal variant proportion in LDpred, add flexibility to PRS models and improve the predictive performance when properly selected. Although fine-tuning methods are well established in the statistical learning literature, most methods (e.g. cross-validation) require individual-level data and do not apply to PRS methods. Consequently, tuning parameters in PRS need to be selected by maximizing the predictive performance on a validation dataset that is independent from both the input GWAS and the testing dataset in downstream application. However, such data rarely exist in practice, creating a significant gap between PRS methodology and application. Here, we introduce PUMAS (Parameter-tuning Using Marginal Association Statistics), a novel method to fine-tune PRS models. PUMAS has two key steps. First, we sample marginal association statistics for a subset of individuals based on the complete GWAS summary data. Using this, we can generate summary statistics for a training set (e.g. 75% of the samples) and a testing set (e.g. 25% of the samples) without actually partitioning the samples. Second, we propose an approach to evaluate the predictive performance of PRS using summary statistics from the validation set. Both steps in PUMAS are statistically rigorous, computationally efficient, and highly novel. Combining these two steps, PUMAS can conduct a variety of model tuning procedures including cross-validation for PRS models that use GWAS summary data as input. Through extensive simulations, we demonstrate that the performance of PUMAS is nearly as good as cross-validation based on individual-level data. Further, we apply our method to publicly available GWAS summary statistics and provide an atlas of optimized PRSs for thousands of diseases and traits. We believe our method will greatly benefit risk prediction applications.

---

The vast majority of genome-wide association studies (GWAS) are performed in individuals of European descent, limiting their applicability to other populations. However, increasingly large genetic datasets of diverse individuals are beginning to emerge. These data present key methodological challenges regarding how best to estimate effect sizes for each population. We have developed the multi-ancestry meta-analysis (MAMA) method, which produces unbiased and precise effect size estimates for each population. This method models summary statistics together with LD patterns within and across all available population pairs by extending two related methods, LD score regression and multi-trait analysis of GWAS (MTAG). In this approach, more information is shared across populations for genomics regions where LD patterns are similar and when estimation error is low, and less information is shared otherwise; we leverage these relationships to boost signal where local genomic effects are consistent across populations. We have computed LD scores from 15,708 whole genomes in gnomAD to use with MAMA or for other purposes. Our approach is unique among existing trans-ethnic meta-analysis approaches in its direct modeling of LD, production of easily interpretable summary statistics, ability to consider two or more cohorts or populations, and

generation of summary statistics for each population. We apply this method to summary statistics for quantitative and disease traits from large-scale biobanks, including the UK Biobank, FinnGen, BioBank Japan, and China Kadoorie Biobank. Unlike several existing methods, MAMA is unbiased and has correct statistical coverage; among methods that meet these criteria, MAMA is the most precise, has the highest power, and is computationally efficient. Thus, MAMA is an effective method for jointly analyzing multi-ethnic GWAS data, providing an approach towards the goal of ensuring that genetics does not exacerbate disparities for those already most underserved.

## PgmNr 3051: Polygenic phenotype analysis by estimating risk scores and associated pathways.

### Authors:

R. Ota; S. Morishita

[View Session](#) [Add to Schedule](#)

**Affiliation:** Department of Computational Biology and Medical Sciences, Graduate School of Frontier Sciences, The University of Tokyo

---

A number of causal genomic mutations associated with diseases have been reported. These mutations on genes can alter the functions of the genes and may also affect the subsequent pathways. For studying polygenic diseases, genome-wide association study (GWAS) has been largely contributing to identifying single nucleotide polymorphisms (SNPs); however, SNPs for polygenic diseases often have low odds ratio (1.1-1.3) and only explain a small proportion of heritability, which is called 'missing heritability.'

Recently, Khera *et al.* has reported that one can identify SNP sets with large odds ratio ( $>3.0$ ) by using LDpred (Vilhjalmsson *et al.*, 2015), which calculates polygenic risk scores via estimation of effect size of each SNP under a linear additive model. However, it remains largely unexplored how to interpret an enormous number of relevant SNPs output by LDpred (e.g. 6.6 million associated SNPs are claimed to be associated to coronary artery disease, CAD, Khera *et al.*, 2018). With numerous candidate SNPs, it is difficult to understand mechanisms (e.g. relevant pathways) of polygenic diseases.

Although a number of pathways associated with many diseases have been reported by GWAS, most of previous pathway analyses assume that only a small number of genes have larger effects than the others in contrast to numerous SNPs with small effect sizes in polygenic diseases. To settle this problem, we propose an extension of the theory of polygenic risk score, aiming to identify polygenic-disease-related pathways and functions of mutations by associating a set of mutations with genes which have a large effect size on the relevant pathway.

We introduce the notion of effect sizes of SNVs in each pathway whose sums are assumed to be effect sizes of the SNVs, thereby enabling us to evaluate the contribution of each pathway to the focal phenotype while considering the situation where a SNV is involved in several pathways. We evaluated the effect sizes of SNVs in each pathway from summary statistics of GWAS using Bayesian statistics. We then introduce indicators showing how large each pathway contributes to the phenotype. One can identify with the indicators which pathway is potentially causal.

This proposed new method allowed us to interpret the result of polygenic risk score even in the presence of a large number of associated SNPs and is therefore useful in an era that thousands or millions of exome sequencing data or whole genome sequencing data are available.

## PgmNr 3052: Case-case GWAS of two different disorders using case-control summary statistics.

**Authors:**

W.J. Peyrot; A.L. Price

[View Session](#) [Add to Schedule](#)**Affiliation:** Harvard T.H. Chan School of Public Health, Boston, USA

---

Comparing cases of different disorders can help elucidate biological differences between disorders (PGC 2018 Cell), but currently requires individual-level data from cases of both disorders. We developed a new method (CC-GWAS) to test for differences in allele frequency among cases of two different disorders using summary statistics from the respective case-control GWAS. CC-GWAS (i) maximizes power by employing sample-size dependent weights for each case-control GWAS that minimize the expected genome-wide squared difference between estimated and true effect sizes, accounting for sample overlap, and (ii) controls type I error by incorporating theoretical weights based on infinite sample size. CC-GWAS can be extended to incorporate case-case summary statistics when available. We confirmed via simulations and analytical computations that CC-GWAS attains accurate control of type I error and higher power than other approaches.

We applied CC-GWAS to summary statistics from case-control GWAS of Crohn's disease (CD;  $N=6k$  cases, 15k controls, 55 independent GWAS loci) and ulcerative colitis (UC; 7k cases, 20k controls, 38 independent GWAS loci) with an estimated genetic correlation of 0.58. CC-GWAS identified 20 independent genome-wide significant loci with different allele frequencies in CD cases vs. UC cases, including 7 novel loci that were independent from the 55 CD and 38 UC loci. For replication, we applied CC-GWAS to independent CD and UC case-control ImmunoChip summary statistics. Summary statistics were available for 13 of the 20 loci, including 2 of 7 novel loci. All 13 loci were significantly replicated ( $P<0.05/13$ ) with the same direction of effect.

We also applied CC-GWAS to summary statistics from case-control GWAS of schizophrenia (SCZ; 41k cases, 65k controls, 97 independent GWAS loci) and major depressive disorder (MDD; 171k cases, 329k controls, 45 independent GWAS loci) with an estimated genetic correlation of 0.29. CC-GWAS identified 72 independent genome-wide significant loci with different allele frequencies in SCZ cases vs. MDD cases, including 6 novel loci independent from the 97 SCZ and 45 MDD loci.

In conclusion, CC-GWAS robustly identifies novel loci with different allele frequencies among cases of different disorders using case-control summary statistics. Thus, CC-GWAS can help elucidate biological differences between disorders, which may facilitate improved clinical diagnoses and treatment.

## PgmNr 3053: Testing epistasis between eQTLs using whole-genome sequencing and RNA-seq data in COPDGene.

Chan School of Public Health, Boston, Massachusetts

**Introduction:** Epistasis has long been hypothesized to be present in complex human traits, but identifying these effects has been challenging. Major limitations to date include lack of comprehensive sequence data, insufficient power, and control of false positives in statistical testing. With the availability of large-scale whole-genome sequencing (WGS) data and RNA-Seq data in COPDGene, we are interested in identifying SNP-SNP interactions that are associated with gene expression levels. Gene-expression is an ideal phenotype to study epistasis since there are known molecular interactions and large effect sizes have been shown for marginal expression quantitative trait locus (eQTL) studies.

**Methods:** To explore the properties of interaction tests, we used simulated WGS data and RNA-Seq data, and real data from the COPDGene study to perform simulations under several scenarios: 1) Two SNPs with or without linkage disequilibrium (LD), where 0, 1, or 2 of them is causal; 2) One of the two SNPs is interacting with a third SNP (heteroscedasticity); 3) both SNPs are in LD with the same causal SNP (confounding); and 4) both SNPs are in LD with a different causal SNP. We used the Wald test for interactions, the Wald test with heteroscedasticity-consistent sandwich estimator, the 4-df test from Cordell's model, and the 4-df test with sandwich estimator, with different transformations of the RNA-Seq count data. We also looked at the type I error rates while conditioning on one causal SNP under scenarios 3 and 4.

**Results:** In a simulation study of 1,000 subjects, we found that tests using sandwich estimators require parametric bootstrapping to maintain the type I error rate. Tests using log transformation maintain the type I error rate, with little reduction in power. Methods without sandwich estimators do not guard against heteroscedasticity or confounding. Tests using sandwich estimator guard against heteroscedasticity, and could control the type I error rate after conditioning on one causal SNP. The Wald test has similar power to the 4-df test in most scenarios.

**Conclusions:** We recommend a general strategy to identify epistasis on gene expression, including 1) log transformation; 2) screening using the Wald test; 3) additional screening using the Wald test with sandwich estimators with parametric bootstrapping; and 4) conditional analysis to remove false positives due to confounding. We are currently testing this method using COPDGene data to identify epistasis eQTLs.

## PgmNr 3054: Estimating the autocorrelation of causal minor allele effect sizes as a function of genomic distance.

Most models of complex trait genetic architecture implicitly assume that signed causal trait effect sizes of nearby SNPs (defined with respect to the minor allele) are uncorrelated, i.e. the fact that a causal SNP lies close to a trait increasing SNP does not change its probability of being itself trait increasing rather than trait decreasing. Here we investigate this assumption, and evaluate implications for defining and estimating SNP-heritability. We developed a method to estimate the genome-wide autocorrelation of causal minor allele effect sizes as a function of genomic distance. The idea behind the inference method is that GWAS summary statistics of nearby SNPs can be correlated both due to correlated causal effects as well as LD tagging. Our method regresses products of GWAS summary statistics on distance dependent LD scores, accounting for LD tagging and yielding estimates of causal effect correlations. We determined that the method produces unbiased estimates in simulations, when model assumptions hold.

We applied the method to 18 UK Biobank traits, analyzing 114K UK-ancestry individuals and 18 million imputed SNPs (MAF>0.1%) and meta-analyzing results across traits. Our estimate of the correlation of causal minor allele effect sizes of SNP pairs <1000bp apart was  $-0.14 \pm 0.04$ , with negative estimates for 15 of 18 traits; we are currently incorporating explicit modeling of LD-dependent causal architectures into these estimates. Our result is supported by findings of Brown et al. (2016 Genetics), who observed many examples of pairs of adjacent linked SNPs with strong opposite signed effects, a phenomenon the authors term linkage masking. Our initial analysis implies that linkage masking is widespread and broadly impacts the architecture of complex traits. A plausible explanation for this widespread effect is natural selection: large-effect loci are often under strong selection, quickly removing isolated variants from these sites. In contrast, linked variant pairs with opposite signed effects neutralize each other and can therefore remain polymorphic. Our results suggest that GWAS analyses may commonly underestimate true causal effects, since linked SNPs with opposing effects cancel each other out. Furthermore, we show that the assumptions underlying commonly used definitions of SNP-heritability do not hold when causal SNP effects are correlated, and propose an alternative definition.

## PgmNr 3055: Perturbation-based clustering linear combination approach for analyzing multiple phenotypes.

### Authors:

Q. Sha; S. Yan; S. Zhang

[View Session](#) [Add to Schedule](#)

**Affiliation:** Mathematical Sciences, Michigan Technological University, Houghton, Michigan

Although the conventional genome-wide association studies (GWASs) focus on a single phenotype, there is an increasing interest in joint analysis of multiple phenotypes because cohort studies usually contain multiple phenotypes and jointly analyzing multiple phenotypes may increase statistical power. In addition, pleiotropy, the phenomenon of one genetic locus influencing several traits, has become a widely researched field in human genetics. Association studies based on multiple phenotypes can also provide great opportunities to systematically assess the genetic overlap between multiple phenotypes and diseases.

Recently, many statistical methods have been developed for joint analysis of multiple phenotypes, including the clustering linear combination (CLC) method [Bioinformatics, 2018]. In the CLC method, one first clusters individual statistics from the association tests for each phenotype into positively correlated clusters, then combine the individual statistics linearly within each cluster and combine the between-cluster terms in a quadratic form. It was theoretically proved that if the individual statistics can be clustered correctly, CLC is the most powerful test among all tests with certain quadratic forms. Due to the unknown number of clusters for a given data, the test statistic of CLC is the minimum p-value among all p-values of the test statistics obtained from each possible number of clusters. Therefore, a simulation procedure must be used to evaluate the p-value of the final test statistic. This makes CLC computationally demanding. In this presentation, we used a recently developed perturbation clustering approach to determine the number of clusters in the CLC method. It was shown that perturbation clustering approach is able to find the correct clusters when the data consists of distinct classes. Using the unique clusters identified by perturbation, the test statistic of CLC has an asymptotic distribution, which is very computationally efficient and makes perturbation-based CLC (PCLC) applicable for GWASs.

We used simulation studies as well as an application to a real data set to evaluate the performance of PCLC. Simulation results showed that PCLC is either the most powerful test or has similar power to the most powerful test among the tests we compared. By using perturbation, PCLC increases power comparing with CLC. In the real data analysis of COPDGene, PCLC identified more significant SNPs related to COPD than other tests.

---

A key limitation in the translation of genome-wide association studies into the identification of the next generation of therapeutic targets is the difficulty in identifying potentially causal genes underlying genetic associations. This is made more difficult by the fact that the majority of GWAS associations are driven by non-coding variants. Incorporation of expression quantitative trait loci (eQTLs) is a promising approach to prioritize potentially causal genes where there is evidence that the same variant(s) affect both gene expression level and the disease phenotype. Many studies have focused on reciprocal single-variant lookups between gene expression and disease results, which are prone to spurious association findings making Bayesian colocalization approaches a particularly attractive alternative.

Here, we demonstrate scalability and test utility in target identification by systematically applying colocalization of all GTEx and Blueprint eQTLs with 34,200 genome-wide significant associations from GWAS of 2,120 phenotypes from UK Biobank (~2.6 billion tests in total). By evaluating success of historic drug development pipelines, we find that colocalization of an eQTL-phenotype pair is associated with a higher rate of successful drug development and conclude that this supports the ability of colocalization approaches to identify causal associations at scale. By taking a comprehensive approach to colocalization, we are now able to implement colocalization in a PheWAS-like manner and have the capacity to instrument up to 18,720 protein coding genes in at least 51 tissues, offering an exciting opportunity for therapeutic target discovery and validation.

## PgmNr 3057: Fast multivariate estimation for heterogeneous traits.

As has been commonly observed, decreasing sequencing costs and increasing computational power in recent years have provided an increasing availability of genomic data. Such increased availability of data naturally invites greater demand for methodological sophistication in modeling, testing, and inference. However, at the same time, striving for such methodological improvements can face material headwind in the form of computational challenges and/or lack of clear statistical frameworks.

Thus, we look to meet this demand by presenting some novel methods for genomics and precision medicine, but can also be applied in other settings. High priority concerns include computation time and statistical efficiency.

We introduce a Two-Stage Composite Likelihood approach for multivariate probit estimation for responses with binary components. This approach is designed to be fast, lending itself well to settings such as Genome Wide Association Studies (GWAS) for detecting Single Nucleotide Polymorphism (SNP) associations with mean changes in phenotype.

For the multivariate probit, we are chiefly concerned with settings where the correlation parameters are unconstrained (aside from variances constrained at 1)–and among these in particular, where the coefficient parameters are unconstrained, as well. Historically, multivariate probit estimation has been slow and/or computationally intensive. As the number of components and predictors increases, the number of coefficient and correlation parameters tends to grow quickly, adding to the difficulty of numerical optimization in finding estimates. This can be especially challenging in the genomics space, due to the number of predictors involved.

Next, we extend this approach to incorporate heterogeneous multivariate responses, i.e. where the response can include both binary and continuous components. For example, in genomics and/or precision medicine settings, these could be phenotypic traits and/or disease statuses. Now instead of having only bivariate probits as associated likelihoods, there can also be bivariate normal densities for continuous-continuous pairs, as well as associated likelihoods for binary-continuous pairs.

Further considerations could include heteroskedasticity in the GWAS setting, i.e. nonconstant variance across allele counts. There could be possible tie-ins here with gene-gene and/or gene-environment interactions. SNPs associated with variance may be indicative of the presence of interactive effects.

## PgmNr 3058: Approximately LD independent regions for biobank scale genetic analyses.

### Authors:

J.C. Ulirsch<sup>1,2</sup>; M. Kanai<sup>1,3,4</sup>; L. Abbott<sup>1</sup>; C. Seed<sup>1</sup>; J. Bloom<sup>1</sup>; H.K. Finucane<sup>1</sup>

### Affiliations:

1) Broad Institute, Cambridge, MA.; 2) Program in Biological and Biomedical Sciences, Harvard Medical School, Boston, MA.; 3) Program in Bioinformatics and Integrative Genomics, Harvard Medical School, Boston, MA.; 4) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA.

A number of statistical methods have been developed to improve on the biological return of genome-wide association studies (GWASs) that have identified thousands of genomic loci linked to complex traits and diseases. Many of these methods, including genetic fine-mapping (e.g. fgwas, FINEMAP, and SuSiE), estimators of local heritability and genetic correlation (HESS and p-HESS), and signed estimators of polygenic TF binding disruption (SLDP) are performed at or have key procedures that are performed at a per-locus level. For these methods to produce valid estimates and/ or inference, loci are assumed to be independent (*i.e.* there is negligible linkage disequilibrium (LD) between SNPs in different loci). Typically, to identify approximately LD independent (ALDI) regions, **(A)** a small window (0.5 - 3 Mb or cM) is taken around a SNP of interest or **(B)** the “anti-diagonal” LD vector is minimized at the boundaries, often using a 1000G reference panel (Berisa and Pickrell 2016).

Here, we compute in-sample dosage LD from 361,144 densely genotyped, unrelated individuals in the UK Biobank, and find considerable LD among regions identified as approximately independent using the Berisa and Pickrell method in 1000G. We then introduce a new method for identifying ALDI regions that minimizes different functions of the full “off-diagonal” LD band at region boundaries and apply it to our UK Biobank LD matrix. We show that our method **(1)** allows for application-specific parameter tuning to balance approximate independence with region length, **(2)** produces boundaries correlated with relevant features such as recombination hotspots, **(3)** validates previously reported (Price et al. 2008) regions of long range (3 Mb - 10Mb) LD, and **(4)** highlights the impact of newly arisen, low allele frequency (0.1 - 1%) variants on boundary identification.

In simulations, we show that methods aimed at gaining insight into genetic architecture and underlying trait biology, particularly genetic fine-mapping, can be less biased when using our definitions of ALDI regions compared to other widely used definitions. In up to 361,144 individuals from the UK Biobank, we performed genetic fine-mapping on over 30 complex traits and diseases using FINEMAP and SuSiE. We identify thousands of likely causal genetic variants with high posterior probability (> 0.90) and assess the impact of ALDI region choice. Our method will have wide application to a number of commonly used statistical genetics methods.

## PgmNr 3059: Evaluation of modern approaches for the complex trait prediction using genetic data.

Genome-wide association studies (GWAS) have been widely used to discover the genetic basis of complex phenotypes. As such, GWAS provide starting points and potential opportunities for researchers to develop methods to predict complex traits. As a natural extension to GWAS, the polygenic risk score (PRS) is one of most popular methods for complex traits prediction in the genetics community. The main motivations behind PRS are 1) only GWAS summary statistics are needed in the PRS calculation; 2) multiple SNPs works together to predict a given trait. At the same time, other PRS extensions and

alternatives have also been developed in the context of greater precision in prediction. To explore the advantages and disadvantages among various prediction methods under different genetic architectures, we leverage genotype data and phenotype data collected from surveys from a subset of over one million AncestryDNA customers who have consented to research. First, we perform genome-wide association analyses on various traits with different architectures, and select promising markers for prediction from these GWAS using various forms of linkage disequilibrium (LD) pruning and significance thresholding. Then, we assess the prediction ability of standard PRS and other models. Our study shows that no specific method dominates across all traits, as each method has its merits in terms of model complexity and prediction accuracy under certain genetic architectures. While more in-depth research is still required, this work provides a sound foundation in the comparison of various statistical techniques for prediction, as well as in our attempts to understand and effectively interpret variation in the human genome.

# PgmNr 3060: UK Biobank whole exome sequence binary phenome analysis with robust region-based rare variant test.

In biobank data, most binary phenotypes have unbalanced case-control ratios, which can cause inflation of the type I error rates. Recently, saddlepoint approximation (SPA) based single variant test has been developed to provide an accurate and scalable method to test associations of such phenotypes. However, for region-based rare variant tests, the existing methods are either less accurate when case-control ratios are unbalanced or not scalable for large data analyses.

To address these problems, we propose robust SKAT/SKAT-O type region-based tests that adjust single variant score statistics using SPA and efficient resampling (ER), and aggregate the adjusted statistics. The accuracy of region-based tests largely depends on the accuracy of estimated variances of single variants. The SPA and ER help to precisely calculate the reference distribution of the single variant score statistics, thereby properly controlling for the type I error rates.

Through simulation studies, we show that the proposed method provides well-calibrated p-values. In contrast, the unadjusted approach has greatly inflated type I error rates ( $2.25 \times 10^{-4}$  when exome-wide  $\approx 2.5 \times 10^{-6}$ ) when the case-control ratio is 1:99. Additionally, the empirical power of the robust methods is almost the same as or larger than unadjusted methods across all case-control ratios. Furthermore, the computation cost of the robust methods is comparable to unadjusted tests, and hence can be applied to large biobank data.

We applied the robust region-based tests to UK Biobank whole exome sequence (WES) data analysis with 45,596 unrelated European samples and analyzed 791 binary phenotypes. We tested rare variants ( $MAF < 0.01$ ) of the nonsynonymous and splicing variants in the exon and neighboring regions of 18,360 genes. The analysis identified 117 gene $\times$ phenotype associations with p-values  $< 2.5 \times 10^{-6}$ , where 10 associations had p-values  $< 10^{-7}$ , including the associations between *JAK2* and myeloproliferative disease (p-value:  $8.92 \times 10^{-30}$ ; previously reported), *TNC* and large cell lymphoma ( $6.10 \times 10^{-9}$ ), and *HOXB13* and prostate cancer ( $3.00 \times 10^{-8}$ ; previously reported). Among the 10 gene $\times$ phenotype pairs, only 2 had a single rare-variant p-value  $< 5 \times 10^{-8}$ , suggesting that region-based approaches can be more powerful than single variant analyses. All ten associations remained significant after the conditional analysis, which indicates that these rare variant association signals are not driven by the nearby common variants.

## PgmNr 3061: Testing and controlling for horizontal pleiotropy with the probabilistic Mendelian randomization in transcriptome-wide association studies.

Integrating association results from both genome-wide association studies (GWASs) and expression quantitative trait locus (eQTL) mapping studies has the potential to shed light on the molecular mechanism underlying disease etiology. Several statistical methods have been recently developed to integrate GWASs with eQTL studies in the form of transcriptome-wide association studies (TWASs). These existing methods can all be viewed as two sample Mendelian randomization (MR) methods, which are also widely used in various GWASs for inferring the causal relationship among complex traits. Unfortunately, most existing TWAS and MR methods make an unrealistic modeling assumption that the instrumental variables do not exhibit horizontal pleiotropic effects. However, horizontal pleiotropic effects have been recently discovered to be wide spread across complex traits, and as we will show here, are also wide spread across gene expression traits. Therefore, allowing for no horizontal pleiotropic effects can be overall restrictive, and, as we will be show here, can lead to a substantial inflation of test statistics and subsequently false discoveries in TWAS applications. Here, we present a probabilistic MR method, which we refer to as PMR-Egger, for testing and controlling of horizontal pleiotropic effects in TWAS applications. PMR-Egger relies on a new MR likelihood framework that unifies many existing TWAS and MR methods, accommodates multiple correlated instruments, tests the causal effect of gene on trait in the presence of horizontal pleiotropy, and, with a newly developed parameter expansion version of the expectation maximization algorithm, is scalable to hundreds of thousands of individuals. With extensive simulations, we show that PMR-Egger provides calibrated type I error control for causal effect testing in the presence of horizontal pleiotropic effects, is reasonably robust for various types of horizontal pleiotropic effect misspecifications, is more powerful than existing MR approaches, and, as a by-product, can directly test for horizontal pleiotropy. We illustrate the benefits of our method in applications to 39 diseases and complex traits obtained from three GWASs including the UK Biobank and show how PMR-Egger can lead to new biological discoveries through integrative analysis.

---

Over the past two decades, telomere length (TL) has emerged as a marker of biological aging. TL is highly heritable, reflects gender dysmorphism and is also influenced by race/ethnicity. Some studies report that people of African ancestry harbor longer TL than those of European ancestry, while other studies observe the opposite trend or no differences. However, to our knowledge, the association between admixture components and TL has not been explored. We examined the association between estimated ancestry proportions and TL by leveraging existing whole genome sequence (WGS) data from the NHLBI-supported multi-centered, case-control Consortium on Asthma among African-ancestry Populations in the Americas (CAAPA).

Global estimates of ancestry were obtained using ADMIXTURE on 677 CAAPA participants including African-admixed individuals from North, Central, and South America, the Caribbean Islands and Yoruba-speaking individuals from Ibadan, Nigeria. TL on each individual was estimated using a bioinformatic approach (TelSeq). After exclusions based on QC, linear regression models were implemented on the analytic samples (N=673) to assess the relationship between TL, African

ancestry (%YRI) and Native American ancestry (%NAT) across the African diaspora. After adjusting for age and sex, each percent increase in YRI and NAT was associated with a 14bp ( $p_{\text{YRI}} = 2.64\text{e-}05$ ) and 30bp ( $p_{\text{NAT}} = 6.66\text{e-}05$ ) increase in TL, respectively. Additional adjustments for asthma case status did not change this association.

Our results suggest that YRI and NAT admixture components are significantly associated with TL. As CAAPA genomes were collected across 21 different sites, we are also examining the possibility of technical sources of variation that may have been inevitably introduced in our TL data and could confound our associations. Prior GWAS predominantly used European ancestry populations to identify 16 loci associated with TL resulting in poorly understood ancestry-specific genetic architecture behind these loci. We propose to replicate these implicated loci using a candidate gene study design while concurrently probing for novel variants affecting TL in individuals of African descent in the CAAPA study.

## **PgmNr 3063: Phasing aware modelling of allele-specific expression for X chromosome inactivation prediction elucidates the important contribution of XCI escape genes to gender-biased diseases.**

### **Authors:**

R. Sauteraud <sup>1</sup>; L. Carrel <sup>2</sup>; D. Liu <sup>1</sup>

[View Session](#) [Add to Schedule](#)

### **Affiliations:**

1) Department of Public Health Sciences, Penn State College of Medicine, Hershey, PA, 17033, USA; 2) Department of Biochemistry and Molecular Biology, Penn State College of Medicine, Hershey, PA, 17033, USA

X chromosome inactivation (XCI) mechanism randomly silences one female X and only expresses the alleles on the active X. Yet, it is estimated that ~30% of the X-linked genes may escape at least partially in a subset of individuals. Escape genes result in unequal expression levels between sexes, which may be disease causative. It is thus of great interest to identify XCI escape genes.

We seek to develop methods to infer XCI escape genes from bulk RNA-seq due to its broad availability. We first estimate the sample skewing using the allelic specific expression (ASE) from a set of commonly inactivated genes, which reflects the fraction of cells where a particular X is active. Then, we will identify escape genes as the ones with statistically significantly more balanced ASE than sample skewing. Current methods to obtain ASE either use the most expressed SNP or sum up read counts on phased haplotypes. Summing reads across haplotypes can be more powerful as it aggregates information across different SNPs. Yet, it may result in biased estimates of sample skewing when the haplotype phase is incorrect. To solve this problem, we propose a new mixture model based approach that incorporates the likelihoods with and without phasing errors as different components. The new approach allows us to obtain consistent estimates of the sample skewing and hence reliable inference of the escape genes even in the presence of phasing errors.

In simulations, we show that our model accurately corrects phasing errors to provide optimal read counts for each gene, and increase the power of identifying escape genes by 30%. We apply the proposed method to 217 females of the GEUVADIS project and obtained updated annotations for XCI escape status. Based on these annotations, we examined the contribution of X-linked genes to the disease heritability in the UK Biobank dataset. We show that escape and variable escape genes explain the largest proportion of X heritability, which is in large part attributable to X genes with Y homology. We also investigated the role of each XCI state in gender-biased diseases and found that while XY homologous gene pairs have a larger overall effect size, enrichment for variable escape genes is significantly increased in female-biased diseases. Our results, for the first time, quantitate the importance of variable escape genes for the etiology of gender-biased disease and our pipeline allows analysis of larger datasets for a broad range of phenotypes.

---

We have previously revealed a genetic association between Takayasu arteritis and a non-coding genetic variant in an enhancer region within *IL6* (rs2069837 A/G). The risk allele in this variant (allele A) has a protective effect against chronic viral infection and cancer. Using a combination of experimental and bioinformatics tools, we identified the monocyte/macrophage anti-inflammatory gene *GPNMB*, ~520kb away, as a target gene regulated by rs2069837. We revealed preferential recruitment of myocyte enhancer factor 2-histone deacetylase (MEF2-HDAC) repressive complex to the Takayasu arteritis risk allele. Further, we demonstrated suppression of *GPNMB* expression in monocyte-derived macrophages from healthy individuals with the AA compared to AG genotype, which was reversed by histone deacetylase inhibition. Our data show that the A allele in rs2069837 represses the expression of *GPNMB* by recruiting MEF2-HDAC complex, enabled through a long-range intra-chromatin looping. Suppression of this anti-inflammatory gene might mediate increased susceptibility to Takayasu arteritis and enhance protective immune responses in chronic infection and cancer. Our data highlight long-range chromatin interactions in functional genomic studies.

## PgmNr 3065: Preconception TGM1 carrier screening for autosomal recessive congenital ichthyosis: A new variant.

Preconception care is the provision of biomedical, behavioural and social health interventions to women and couples before conception occurs. In this context, a first degree consanguineous couple has been seen at our genetic counselling following the birth of a Collodion male baby and asking for preconception testing before any other pregnancy project. The newborn was the second child of a 31 and 27 years old male and female, who have already a first healthy son. He was delivered by cesarean section at 38 WG. At birth he had dry and thick skin with deep fissures as well as generalized erythematous desquamation. He survived for 5 days at the neonatal intensive care unit with clinical diagnosis of Harlequin ichthyosis baby. Unfortunately, no DNA banking was made. Molecular investigation of TGM1 gene was done as a first step using direct sequencing of the entire coding parts and splice sites of the gene. While no pathogenic mutations were detected in the father's TGM1 gene, a heterozygous unclassified variant was detected in the mother: c.281G-A (p.Gly94Asp). The pathogenicity of this variant is very unclear, because it is a non-conservative change of a weakly conserved amino acid. The inheritance of congenital ichthyosis is autosomal recessive, and affected babies are usually homozygous for the mutation. So, molecular results of TGM1 gene screening don't allow explanation of the ARCI condition in the diseased child of the counselees. Mutation screening must be extended to the other genes related to ARCI to look for a composite status of mutations.

# PgmNr 3066: MHC risk haplotype sequencing and allele-specific genome editing by CRISPR/CAS9 system reveal *CCHCR1* as a susceptibility gene for alopecia areata.

## Introduction & Objectives:

Previous genome-wide association study about Alopecia areata (AA) results have implicated a number of immune and non-immune loci in the aetiology of AA. However, no variants among those have provided experimental evidence for biological functions between alleles and AA pathogenesis. Therefore, we attempted to pinpoint a susceptibility variant within the major histocompatibility complex (MHC) and to confirm the susceptibility variant.

## Materials & Methods:

We performed association and haplotype analysis for the MHC region to identify risk haplotypes using AA patients and controls. Next, we sequenced the risk and control haplotypes to identify AA-susceptibility variants. Next, we engineered mice carrying the human risk allele using allele-specific genome editing with the CRISPR/Cas9 system to reproduce AA phenotype.

## Results:

We sequenced risk and non-risk MHC chromosomal segments. Among the large number of variants there was only one nonsynonymous variant identical in the AA risk haplotype. The variant is located in the coiled-coil alpha-helical rod protein 1 (*CCHCR1*) gene. Next, mice were generated with the risk allele concordant with the variant of *CCHCR1* in humans, then we established mouse strains with risk alleles (AA mice). Half of AA mice displayed patched hair loss until 10 months after birth, thus successfully phenocopying the hair loss phenotype. Over time, the initial area of hair loss expanded in the majority of the AA mice, though constant and recovered hair loss was observed in some of those mice. Their surface displayed black spots, while the hairs appeared to be broken and tapering, similar to the conditions seen in humans with AA and specific for AA-associated hair loss.

## Conclusions:

First, the discovered susceptibility variant is a rare example of a non-mendelian common disease variant that can be phenocopied in a mouse model. Second, our alopecia model mouse model provides a novel mechanism for the observed hair loss and potential avenue for developing a drug for AA patients.

## PgmNr 3067: Regulation of impaired hepatic glucose homeostasis in a single extra copy of Down syndrome at critical region 1-4.

---

### OBJECTIVES:

During fasting, hepatic gluconeogenesis is induced to maintain energy homeostasis. Moreover, abnormal dysregulation of hepatic glucose production is commonly observed in type 2 diabetes. However, the signaling components controlling hepatic glucose production to maintain normal glucose levels are not fully understood. Here, we examined the physiological role of Down syndrome critical region 1-4 (DSCR1-4), an endogenous calcineurin signaling inhibitor in the liver that mediates metabolic adaptation to fasting.

### METHODS:

We assessed the effect of cyclosporine A, an inhibitor of calcineurin signaling on gluconeogenic gene expression in primary hepatocytes. DSCR1-4 expression was examined in diet- and genetically-induced mouse models of obesity. We also investigated the metabolic phenotype of a single extra copy of DSCR1-4 in transgenic mice and how DSCR1-4 regulates glucose homeostasis in the liver.

### RESULTS:

Treatment with cyclosporin A increased hepatic glucose production and gluconeogenic gene expression. The expression of DSCR1-4 was induced by refeeding and overexpressed in obese mouse livers. Moreover, transgenic mice with a single extra copy of DSCR1-4 exhibited pyruvate intolerance and impaired glucose homeostasis. Mechanistically, DSCR1-4 overexpression increased phosphorylation of the cAMP response element-binding protein, which led to elevated expression levels of gluconeogenic genes and, thus, enhanced hepatic glucose production during fasting.

### CONCLUSION:

A single extra copy of DSCR1-4 results in dysregulated hepatic glucose homeostasis and pyruvate intolerance. Our findings suggest that nutrient-sensitive DSCR1-4 is a novel target for controlling hepatic gluconeogenesis in diabetes.

## PgmNr 3068: Common noncoding variant at PPP1R3B/LOC157273 promotes liver glycogen storage and metabolic syndrome, but protects against myocardial infarction.

---

Human glycogen storage diseases are rare. Using multiple population-based cohorts we show that carriers of SNP rs4841132-A (frequency 2-19%) have increased liver attenuation, liver damage, serum lactate and triglyceride levels similar to what is seen in individuals with liver glycogen storage diseases. Rs4841132 is in the second exon of a liver-specific long noncoding RNA (*LOC157273*) and 190kb upstream of *PPP1R3B* which has been shown to regulate glycogen synthesis. Using allelic imbalance analysis, we demonstrate that rs4841132-A increases *PPP1R3B* expression through a cis genetic effect (allele on the same chromosome as the variant). We used the CRISPR/Cas9 system to produce a 105bp deletion of exon 2 of *LOC157273*, including the rs4841132 SNP. This deletion leads to increased levels of PPP1R3B protein and increased levels of glycogen. We also show that PPP1R3B overexpression increased glycogen in HuH-7 cells. Based on EHR data, rs4841132-A associates with all components of the metabolic syndrome: increased waist-to-hip ratio, hypertension, insulin resistance, serum triglycerides and decreased total serum high-density lipoprotein cholesterol. However, rs4841132-A decreases total cholesterol and myocardial infarction risk. A metabolic pattern for rs4841132-A includes increased serum glycine, lactate, triglycerides, and decreased serum acetoacetate, and beta hydroxybutyrate. These results show that rs4841132-A promotes hepatic glycogen storage disease by disrupting *LOC157273* allowing constitutive increase in PPP1R3B protein levels that promotes liver glycogen accumulation and promotes development of metabolic syndrome but lowers serum low-density lipoprotein cholesterol and myocardial infarction risk. These results suggest that elevated hepatic glycogen is one cause of metabolic syndrome that does not invariably promote myocardial infarction.

## PgmNr 3069: Enhancer-based immune dysregulation revealed by integrated analysis of T1D-associated genetic variants.

Type 1 diabetes (T1D) is a polygenic autoimmune disease that results in the loss of functional pancreatic  $\beta$ -cells. Although chromosome 6 human leukocyte antigen (HLA) locus is a well-established T1D risk region, the mechanisms of the non-HLA genetic factors to the risk of T1D are still unclear. GWAS have identified over 200 T1D genetic variants, most of which lie in the non-coding regions of the genome, suggesting that gene regulatory changes substantially contribute to inter-individual differences in susceptibility to T1D. However, finding regulatory variants and their target genes are still challenging. To identify regulatory variants with a functional role in T1D risk, here we performed an integrated functional annotation analysis using various public databases. We first defined 1,817 candidate T1D SNPs, utilizing the GWAS catalog and 1000 Genomes Project European population data and then performed comprehensive annotation analyses using; 1) RoadMAP, ENCODE, and RegulomeDB for epigenome data; 2) GTEx for tissue-specific gene expression and eQTL data; 3) lncRNASNP2 for long non-coding RNA data. Integrating our results, we found 159 genes associated with the candidate T1D SNPs, and gene ontology analysis revealed an enrichment of the processes related to immune response and antigen presentation. We identified 26 high-probability causal SNPs, all of which were residing in enhancer regions. Furthermore, we found complex regulatory circuits at HLA (6p21) and non-HLA (16p11.2) loci. The HLA locus includes *rs886424* and *rs3129716* as well as 25 associated genes, including 6 HLA genes. The non-HLA locus contains *rs4788084*, *rs743590*, *rs762633*, and *rs62031562* as well as 19 downstream genes, including 3 immune-related genes (*IL27*, *SH2B1*, and *NUPR1*). Besides, among the 53 normal human tissues of GTEx, the HLA genes were highly expressed in Epstein-Barr virus (EBV)-transformed lymphocytes, lung, and spleen. From an independent cell type-specific enrichment analysis SNPsea using the candidate T1D SNPs, we found that the highly expressed genes were significantly enriched in CD4<sup>+</sup> T cells and CD8<sup>+</sup> T cells. These results indicate that enhancer-based immune dysregulation is likely to contribute to T1D pathogenesis. And these results suggest that our prioritized causal variants may help to diagnose T1D and can be therapeutic targets for patients.

Type I diabetes is characterized by the autoimmune destruction of insulin-secreting  $\beta$ -cell in the pancreas. Current therapies for treating Type I diabetes are inadequate. We are developing protocols to derive insulin-producing cells directly from adipose stem cells without de-differentiation into embryonic-like cells. Preclinical studies are underway in companion animals to demonstrate these bioengineered insulin-producing cells can compensate for inadequate  $\beta$ -cell function prior to human application. Here, we analyze the differentiation process using biomarkers that represent key milestones as mesenchymal stem cells (MSC) differentiate into islet cells. MSCs are harvested from adipose tissue surrounding the reproductive organs. The MSCs are exposed to a 3-stage protocol incorporating growth factors that encourage differentiation into insulin-secreting cells. Using qRT-PCR, biomarkers including Sox17, Gata-6, PDX-1, and insulin, were used to assess the differentiation cycle. The cycle was divided into 3 stages based on the time point of added differentiation factors that initiate the differentiation of the MSCs into insulin-producing cells. Preliminary results indicate presence of Gata-6 and Sox17 in all stages of the differentiation. PDX1 was detected in the final stage of the differentiation, suggesting that the cells were progressing toward insulin-producing cells. These studies open the door to using engineered stem cells to produce an alternative therapy for restoration of appropriate glucose metabolism.

## PgmNr 3071: Chromatin accessibility and gene expression changes during adipocyte differentiation identifies regulatory elements at cardiometabolic trait GWAS loci.

GWAS have identified thousands of cardiometabolic trait loci, but most lie in noncoding regions with mechanisms that remain poorly understood. At these loci, chromatin accessibility (CA) and gene expression in relevant cells and contexts can guide identification of regulatory elements and mechanisms. To identify elements that influence adipocyte differentiation, we performed ATAC-seq and RNA-seq in SGBS human adipocytes at days 0, 4, and 14 of differentiation (D0, D4, D14). We evaluated differential CA between timepoints (DESeq2, log2 fold change (LFC)>1, FDR<5%) and identified elements more accessible in adipocytes compared to preadipocytes (D4>D0=30,038 elements, D14>D0=20,158 elements). 90.6% of CA elements more accessible at D14 compared to D0 were also more accessible at D4 compared to D0, suggesting that CA changes occurred early and the majority remained stable. Of 17,250 expressed genes, we evaluated differential gene expression between timepoints (DESeq2, LFC>1, FDR<5%) and identified genes more expressed in adipocytes compared to preadipocytes (D4>D0=1,012 genes, D14>D0=1015 genes). 51.2% of genes more expressed at D14 compared to D0 were also more expressed at D4 compared to D0, suggesting that gene expression continues to change between timepoints. We evaluated differentially expressed genes in proximity (10,000 bases) to differential CA elements and identified 512 (50.4%) of genes more expressed at D14 compared to D0 near CA elements more accessible at D14 compared to D0. To identify differential regulatory elements at cardiometabolic GWAS loci, we examined loci with differential CA and a colocalized adipose eQTL. Of 14,938 candidate variants ( $r^2>0.8$ ), 370 variants at 130 loci were located in an element of differential CA. For example, at a GWAS locus for phospholipids colocalized with an adipose eQTL for *SCD* ( $P=8.4E-23$ ), we observed an adipocyte CA element (D4>D0 LFC=4.2, D14>D0 LFC=2.7) containing rs603424. *SCD* was also more expressed in adipocytes (D4>D0 LFC=5.4, D14>D0 LFC=7.5). This variant exhibited stronger allelic differences in transcriptional reporter activity in adipocytes (FC=3.1,  $P=0.003$ ) than in preadipocytes (FC=1.4,  $P=0.09$ ). These results demonstrate that epigenomic annotation in different cell contexts can guide discovery of regulatory variants at GWAS loci. Identification of CA elements and gene expression changes in other disease-relevant contexts could aid identification of additional regulatory mechanisms.

## PgmNr 3072: Adipose eQTL meta-analysis of 1,426 individuals identifies eQTLs for 512 genes colocalized with GWAS signals for cardiometabolic traits.

---

Genome-wide association studies (GWAS) have discovered hundreds of loci associated with complex cardiometabolic traits; however, identifying causative genes at these loci has proven more difficult. Expression quantitative trait loci (eQTL) in relevant tissues, such as adipose, may help identify candidate genes for GWAS loci, if a GWAS signal and eQTL signal are colocalized. We conducted an eQTL meta-analysis with adipose tissue RNA-sequencing-based eQTL data from 3 studies: METSIM (n = 426 males), FUSION (n = 151 males; 131 females), and TwinsUK (n = 718 females). All studies retained genes with >5 counts in >25% of samples, analyzed normalized counts per million, adjusted for BMI and PEER factors, and tested variants with a MAF>0.01 in cis-eQTL (within  $\pm 1$  Mb from TSS) analyses. In a preliminary sample-size weighted meta-analysis using METAL, we identified 21,545 genes with at least 1 significant eQTL variant (FDR< 1%, equivalent  $p$ -value<4.9e-04). We tested the adipose eQTLs for colocalization with 3,038 GWAS signals from 70 cardiometabolic traits (clumped by linkage disequilibrium [LD]  $r^2 \geq 0.8$ ). GWAS and eQTL signals were considered colocalized if the lead variants were identical or in strong LD ( $r^2 \geq 0.8$ ) with each other. We found eQTLs for 512 genes that were colocalized with GWAS signals for one or more of 35 traits. Among these, we identified 48 eQTL signals colocalized with type 2 diabetes (T2D) GWAS loci (16.9% of T2D loci tested), including colocalization of recently-identified T2D loci with expression level of *CAMK2G*, *AOC1*, *DCAF16*, *CALR*, *PHBP9*, *MRPS30*, *NUAK2*, *FAM154A*, and *CITED2*. For example, *NUAK2* ( $r^2 \geq 0.91$ ; eQTL  $p$ -value 1.36e-11), also known as *SNARK*, is a kinase that exhibits decreased adipose tissue expression in obesity and influences inflammation and lipid deposition in liver and muscle. Further analysis of additional eQTL signals for each gene will likely identify additional colocalized eQTL signals. These preliminary results demonstrate that a larger eQTL sample size from meta-analysis improves our ability to detect adipose eQTLs and GWAS candidate genes.

## PgmNr 3073: Exploring the utility of activity QTLs in identifying genes mediating complex traits.

Genome-wide association studies (GWAS) have uncovered a wealth of genetic signals affecting complex traits. Most GWAS variants are non-coding, suggesting effects on gene expression without indicating which gene(s) are affected. Expression quantitative trait loci (eQTL) analysis is the gold standard for identifying the gene(s) mediating the effects of GWAS variants. However, multiple studies comparing GWAS and eQTL signals have found co-localization of typically ~50% of GWAS signals with any-tissue eQTLs and a much smaller proportion among single-tissue eQTLs. As a proof-of-concept we have explored the use of activity QTLs (aQTLs) in identifying genes mediating BMI GWAS signals using the Eurobats adipose eQTL dataset. Activities of expression regulators were inferred from the expression of downstream target genes using VIPER. Analyses of 2,920 regulator genes within 1Mb of 41,103 BMI GWAS variants identified 565 eGenes with 1,405 *cis*-eQTLs and 72 aGenes with 335 *cis*-aQTLs at FDR<0.05. The *cis*-eQTL associations were typically stronger than the corresponding aQTLs, but there were some interesting exceptions. For example, the BMI GWAS signal at 1p36.12 had *EPHB2* *cis*-aQTL *P*-values up to three orders of magnitude better than the corresponding *cis*-eQTLs. We speculated that aQTLs may hold more advantage in *trans* analyses, particularly when looking at master regulators (MRs) that integrate upstream genetic and environmental information into a gene regulatory program instantiating a cell state of interest. MRs of the BMI-associated adipose cell state were inferred by cross-validated Random Forest feature selection based on the adipose samples' regulator activities. This yielded 100 BMI MRs that were validated in GTEx subcutaneous adipose. *Trans* analyses between BMI GWAS variants and these BMI MRs identified 6,287 and 8,996 significant *trans*-eQTLs and *trans*-aQTLs, respectively, and showed all 100 MRs were *trans*-eGenes and aGenes at FDR<0.05. Among these *trans*-QTLs, 60% showed stronger aQTL versus eQTL association. Strikingly, the 1p36.12 BMI signal had significant *trans*-aQTLs with 67/100 BMI MRs while only 8 had significant *trans*-eQTLs. Furthermore, the *EPHB2* *cis*-aQTL signal co-localized with the MR *trans*-aQTLs, suggesting this BMI GWAS signal may be mediated through effects on *EPHB2* activity that subsequently affect BMI MR activities. In conclusion, aQTL analysis may provide a useful method to supplement eQTLs in linking GWAS signals to their mediating genes.

## PgmNr 3074: Functional characterization of *NFIA-AS2* in human obesity.

---

Obesity which is estimated by body mass index (BMI), primes several chronic diseases and is a global health concern. Its common forms are highly polygenic and environmentally influenced; so, studies in populations with high prevalence of obesity, and minimal genetic admixture and environmental variability may aid in the identification of genetic markers. Pima Indians have these features, and many Pimas from a community in Arizona participated in longitudinal exams providing height and weight measures to calculate BMI. In this study, we used genome-wide imputed data (whole genome sequence data from Pimas as reference and genotypes in 7,701 Pimas from a custom array as scaffold) to identify all common SNPs that nominally associate ( $p < 10^{-4}$ ) with maximum BMI recorded after 18 years of age in 6,800 Pimas. Such 6,983 SNPs were meta-analyzed with reported BMI associations in GIANT ( $N = 253,288$ ) and GIANT-UKBB ( $N = 795,640$ ) datasets. On top of the known BMI genes- *FTO*, *TMEM18*, *AKAP6*, *NLRC3*, *KCNQ1* and *GRP*, we identified strong association with variants residing in an uncharacterized long non-coding RNA gene- *NFIA-AS2* ( $p = 10^{-??}$ ). This locus has never been implicated in obesity and its variants had fourfold higher frequency in Pima Indians as compared to Caucasians ( $MAF = 0.16$  and  $0.04$ , resp.) with a large effect in Pimas e.g., each copy of minor allele for exonic variant rs1777538 resulted in a decrease of  $0.8 \text{ kg/m}^2$  in BMI. This SNP was observed *in silico* to be associated with *NFIA-AS2* expression in human subcutaneous adipose tissue ( $p = 0.01$ ). Thus, we studied expression of 12 genes flanking *NFIA-AS2* in adipose tissue biopsies of 210 non-diabetic Pimas and found a strong inverse correlation of mRNA levels of *NFIA* with BMI ( $p = 0.004$ ). *NFIA* (Nuclear Factor IA) is required for differentiation of brown adipocytes. Analysis of *NFIA-AS2*, *NFIA* and neighboring genes in human brown pre-adipocyte cell-line PAZ6 revealed significant changes in *NFIA* as well as *NFIA-AS2* expression upon differentiation ( $p_{(\text{adipocyte stage})} = 0.0021$ ;  $0.00022$  resp.). Through cellular fractionation of PAZ6 cells, we learnt that *NFIA-AS2* localizes to the nucleus which implies that it regulates gene expression via epigenetic processes. We are now studying how perturbation of lncRNA expression affects brown adipocyte differentiation and *NFIA* levels. Alleles of variant rs1777538 were predicted to produce a local change in secondary structure of *NFIA-AS2* lncRNA; experiments to validate this change are ongoing.

## PgmNr 3075: In vivo models for Qatari-specific classical homocystinuria as platforms for development of novel treatment.

**Authors:**

G. Nasrallah

[View Session](#) [Add to Schedule](#)**Affiliation:** Biomedical Science, College of Health Sciences, Qatar University, Doha, Qatar

---

Homocystinuria is a rare inborn error of methionine metabolism caused by cystathionine  $\beta$ -synthase (CBS) deficiency. The prevalence of homocystinuria in Qatar is 1:1,800 births, mainly due to a founder Qatari missense mutation, c.1006C>T; p.R336C (p.Arg336Cys). We characterized the structure-function relationship of the p.R336C-mutant protein and investigated the effect of different chemical chaperones to restore p.R336C-CBS activity using three models: in silico,  $\Delta$ CBS yeast, and CRISPR/Cas9 p.R336C knock-in HEK293T and HepG2 cell lines. Protein modeling suggested that the p.R336C induces severe conformational and structural changes, perhaps influencing CBS activity. Wild-type CBS, but not the p.R336C mutant, was able to restore the yeast growth in  $\Delta$ CBS-deficient yeast in a complementation assay. The p.R336C knock-in HEK293T and HepG2 cells decreased the level of CBS expression and reduced its structural stability; however, treatment of the p.R336C knock-in HEK293T cells with betaine, a chemical chaperone, restored the stability and tetrameric conformation of CBS, but not its activity. Collectively, these results indicate that the p.R336C mutation has a deleterious effect on CBS structure, stability, and activity, and using the chemical chaperones approach for treatment could be ineffective in restoring p.R336C CBS activity.

## PgmNr 3076: Multi-omics evaluation of a patient-derived HNF-1A MODY iPSC disease model.

Maturity Onset Diabetes of the Young (MODY) due to *HNF1A* mutations is the most common cause of monogenic diabetes. It results from heterozygous, loss-of-function mutations in the transcription factor HNF-1A, which plays a critical role in pancreatic development. Mice with heterozygous *Hnf1a* mutations do not recapitulate the diabetic phenotype, therefore human iPSC-derived cells are more suitable for disease modelling.

We established a patient-derived *HNF1A* Pro291fsinsC/+ iPSC model, and using CRISPR-Cas9 genome-editing corrected the mutation to establish isogenic controls. We differentiated multiple (n=6) iPSC clones towards endocrine lineage in triplicates, and performed RNA-seq (bulk and single-cell), ATAC-seq and methylation assays at definitive endoderm (DE), pancreatic endoderm (PE) and beta-like cells (BLC) stages.

No expression of the MODY allele in the RNA-seq data confirmed *HNF1A* haploinsufficiency in the patient lines. We found that *HNF1A* expression was restored at both transcript and protein level in the corrected lines. Genes differentially expressed at BLC stage were significantly enriched in targets of HNF-1A identified in an independent *HNF1A* knock-down experiment in EndoC-βH1 cell line (p=4.4e-132). Consistent with reported effects of HNF-1A on insulin secretion, we observed downregulation of *INS* (p=7.2e-03) and other insulin secretion genes in the MODY clones. At the PE stage, corrected clones showed higher expression of *SOX9* (p=7.1e-04) and *PTF1A* (p=1.5e-03), known regulators of pancreatic progenitors, suggesting that HNF-1A is involved in establishment of this cell population. These findings were replicated in the single-cell RNA-seq data, which additionally highlighted differences in cell populations between the MODY and corrected clones. We also identified 7811 sites at PE and 1710 sites at BLC with significant changes in open chromatin, with >90% of the sites being more accessible in the corrected clones. These sites were enriched for HNF-1A binding motifs, suggesting its direct role in establishing open chromatin.

In summary, the patient-derived HNF1A-MODY iPSC model provides a valuable resource for studying of the transcriptional and epigenetic rewiring during pancreatic development caused by the Pro291fsinsC/+ mutation, and yields insights into the cellular and molecular phenotypes caused by HNF-1A deficiency.

This work has received support from the EU/EFPIA Innovative Medicines Initiative Joint Undertaking

(StemBANCC grant°115439).

## PgmNr 3077: Subcutaneous adipose tissue eQTLs identify hundreds of candidate genes at cardiometabolic GWAS loci.

Genome-wide association studies (GWAS) have identified thousands of genetic signals associated with cardiometabolic traits including type 2 diabetes (T2D), circulating lipid levels, and body fat distribution. However, the underlying genes remain unknown. To identify variants that may influence the expression of nearby genes, we used genotypes and RNA-sequencing of subcutaneous adipose tissue from 434 Finns from the METabolic Syndrome in Men (METSIM) study. We tested for association of 7.8M variants with expression levels of 21,735 genes using FastQTL and identified 9,687 genes associated with  $\geq 1$  variant within  $\pm 1$  Mb of the TSS (eQTLs, FDR<1%). To identify additional signals, we conditioned on the variant most strongly associated with each gene (eSNP) and identified 2,785 genes with secondary eQTLs. Compared to primary eQTL signals, secondary signals were located further from transcription start sites, had smaller effect sizes, and were less enriched in adipose tissue regulatory elements. We used linkage disequilibrium (LD) between the GWAS and eQTL variants and conditional analysis to assess colocalization. Among 2,843 cardiometabolic GWAS signals, 262 colocalize with primary or secondary eQTLs for 318 transcripts. Of cardiometabolic traits examined, waist-hip ratio adjusted for BMI (WHRadjBMI) and circulating lipid traits showed the highest percentage of colocalized eQTLs (12% and 11%, respectively). Among alleles associated with increased cardiometabolic GWAS risk, approximately half (47%) were associated with increased gene expression level. For 21 (66.7%) GWAS signals colocalized as secondary eQTLs, no primary eQTL was colocalized with the GWAS variant, thus no colocalization would have been identified without the secondary eQTL analysis. For example, the primary eQTL signal for *DGKQ* does not colocalize with the WHRadjBMI GWAS variant, rs11724804 (LD  $r^2=0.26$ ), but the secondary eQTL variant, rs13101828 ( $P_{\text{initial}}=2.9 \times 10^{-8}$ ), does colocalize ( $r^2=1.0$ ;  $P_{\text{conditional}}=0.67$ ). Silencing *DGKQ* in hepatic cells has been shown to alter mTOR signaling, and misregulation of the mTOR pathway has been shown to promote

adipogenesis and lipogenesis in adipose tissue. Taken together, these results demonstrate that GWAS-adipose eQTL colocalization can identify candidate genes for cardiometabolic trait loci.

## PgmNr 3078: Analysis of alterations in gene expression related to chronic obstructive pulmonary disease.

We identified COPD-related differentially expressed genes (DEGs) using 189 samples accompanying either adenocarcinoma (AC) or squamous cell carcinoma (SC), comprising 91 normal and 98 COPD samples. DEGs were obtained from the intersection of two DEG sets separately identified for AC and SC to exclude the influence of different cancer backgrounds co-occurring with COPD. We also measured patient samples named group 'I', which were unable to be determined as normal or COPD based on alterations in gene expression. The Gene Ontology (GO) analysis revealed significant alterations in the expression of genes categorized with the 'cell adhesion', 'inflammatory response', and 'mitochondrial functions', i.e., well-known functions related to COPD, in samples from patients with COPD. Multi-omics data were subsequently integrated to decipher the upstream regulatory changes linked to the gene expression alterations in COPD. COPD-associated expression quantitative trait loci (eQTLs) were located at the upstream regulatory regions of 96 DEGs. Additionally, 45 previously identified COPD-related miRNAs were predicted to target 66 of the DEGs. The eQTLs and miRNAs might affect the expression of 'respiratory electron transport chain' genes and 'cell proliferation' genes, respectively, while both eQTLs and miRNAs might affect the expression of 'apoptosis' genes. We think that our present study will contribute to our understanding of the molecular etiology of COPD accompanying lung cancer.

## PgmNr 3079: Aberrant biogenesis and trafficking of secretory proteins is a common pathogenetic mechanism of autosomal dominant tubulointerstitial kidney disease (ADTKD).

---

Autosomal dominant tubulo-interstitial kidney disease (ADTKD) encompasses a group of genetic disorders characterized by renal tubular and interstitial abnormalities, leading to slow progressive loss of kidney function requiring dialysis and kidney transplantation. This condition has been identified in almost 1000 families world-wide. Genetic studies revealed causal mutations in *UMOD*, *REN*, *MUC1* and *SEC61A1* encoding uromodulin, renin, mucin-1 and translocon subunit SEC61A, respectively.

Uromodulin, renin and mucin-1 are glycoproteins that are prominently expressed in kidney.

Uromodulin and mucin-1 are targeted to tubular cell membrane and released into urine, whereas renin is actively secreted into circulation. Biosynthesis of these three proteins is dependent on proper function of the translocon.

Disease-causing mutation of uromodulin, renin, mucin-1 and *SEC61A1* affect biogenesis and trafficking of the corresponding proteins. This leads to intracellular accumulation of mutated proteins along the secretory pathway and to various forms of cellular responses such as organelle stress or unfolded protein response in affected nephron structures. In the long term the sustained cellular responses initiate processes that lead to deterioration of kidney function and development of ADTKD.

## PgmNr 3080: Blood metabolome diversity in heterozygous adult carriers of pathogenic variants of newborn screening diseases.

Although heterozygous carriers of causative variants for recessive disorders are not expected to develop the diseases, molecular phenotypes of the variant carriers have not been clarified well. Here we examine blood metabolite levels as a molecular phenotype in variant carriers in adults in general Japanese residents for 16 congenital metabolic disorders for primary targets of newborn screening in Japan. Utilizing whole genome reference panel of 3552 general Japanese individuals (3.5KJPNv2), we identified pathogenic variants for the 16 diseases through variant annotation and interpretation. The number of individuals having at least one of the selected pathogenic variants were 211 (5.9%) based on ACMG-AMP guideline (2015), 319 (9.0%) with additional ClinVar variants, and 605 (17.0%) with additional HGMD disease-causing variants. Then we analyzed metabolite levels of the variant carriers in the cohort participants. One example is phenylalanine hydroxylase (PAH), which is involved in the conversion of phenylalanine to tyrosine and functional defects cause hyperphenylalaninemia (HPA) and phenylketonuria (PKU). A missense variant, p.Arg413Pro existed at the allele frequency of 0.00099, which was reported as frequently found among PKU/HPA patients in Japan. Our analysis with blood metabolite showed that this missense variant, p.Arg413Pro increased the levels of phenylalanine in heterozygous individuals. Another example is methylenetetrahydrofolate reductase (MTHFR), which is involved in folate-mediated one-carbon metabolism. Deficiency of MTHFR increases homocysteine levels and causes hyperhomocystinemia with homocystinuria, mild hyperhomocystinemia, and is also involved in other diseases, such as vascular disease, neural tube defects, cancer, and developmental delay. In 3.5KJPNv2, a missense variant p.Ala222Val (rs1801133, c.665C>T) was found in 1674 individuals as heterozygous and 522 individuals as homozygous (allele frequency = 0.383) as well as low-frequency reported pathogenic variants. Our analysis with blood metabolite showed that this variant is associated with concentration of plasma formate. Our results suggest that common and rare variants in causative genes Mendelian diseases affect molecular phenotypes in a human body in heterozygous and these metabolome individualities with possible effects on disease susceptibilities can be monitored by metabolome analysis.

## PgmNr 3081: Functional assessment of 38 intronic and 19 exonic putative splice variants in *CFTR* to interpret pathogenicity and inform treatment.

Genetic variants that cause missplicing are often thought to result in no protein production. In fact, some of these variants preserve a fraction of normal splicing thus producing reduced levels of functional protein. On the other hand, exonic variants that alter amino acids are thought to cause disease by reducing protein function, but may instead alter splicing. To identify *CFTR* variants in these two categories, we evaluated 57 variants that occurred in extended consensus splice signals or were predicted to introduce cryptic splicing by *in silico* algorithms (CryptSplice, NNSplice). Using expression mini-genes (EMGs) containing *CFTR* full-length or abridged introns, we evaluated the functional consequences of each variant (intronic=38, exonic=19).

Of the 38 intronic variants, 35 resulted in missplicing while 3 spliced normally. Importantly, 8 variants generated reduced levels of normally spliced transcript indicating that they should allow synthesis of full-length *CFTR*. Of the 19 exonic variants, 9 misspliced completely, 2 generated reduced levels and 8 generated wild-type levels of normally spliced transcript. We assessed protein by immunoblotting for 41 variants (intronic=34, exonic=7) and found 7 variants that produced no protein, 25 with shortened protein, and 9 that produced full-length protein.

We hypothesized that variants producing shortened or full-length protein would respond to FDA-approved *CFTR* modulators. We created cell lines expressing EMGs for 11 variants and found that 6 variants that allowed synthesis of reduced levels of full-length protein responded to modulators, while 5 variants that produced shortened protein did not. While improvement of modulators leaves the possibility of protein-level treatment of these variants, splice variants that produced no protein will require alternative treatments.

For two exonic variants, we evaluated the effect of the missense change using cells expressing *CFTR* cDNA. In both cases, we found that the amino acid substitution had little detriment to *CFTR* function and responded to modulators. This result indicates that treatments focused on correction of missplicing could allow for production of functional protein, but also reveals the potential for false categorization of exonic variants as modulator responsive. This study demonstrates the importance of characterizing the functional consequences of both intronic and exonic variants at the RNA level in order to select appropriate molecular treatments.

## PgmNr 3082: Functional characterization of tumor-associated, germline *TMEM127* variants reveals novel insights into membrane topology and protein trafficking.

TMEM127, identified as a tumor suppressor in highly hereditary neuroendocrine tumors known as pheochromocytomas (PHEOs), is a poorly characterized transmembrane (TM) protein with no substantial identity to any other protein and no identifiable functional domains other than its three putative TM domains. The function and regulation of TMEM127 remain poorly defined which limits prediction of pathogenicity of germline *TMEM127* variants. Characterizing structure-function features of TMEM127 is relevant for understanding how dysfunction of this tumor suppressor can lead to inherited tumors. Moreover, a better understanding of TMEM127 functional domains and critical residues will increase our ability to identify pathogenic variants which will improve interpretation of genetic screening results and help guide clinical decisions for patients and their families. In this study, we used tagged TMEM127 plasmid constructs based on patient-derived, tumor-associated, germline *TMEM127* variants (n=21; 16 missense and 5 truncating/frameshift/indel variants) and investigated their subcellular localization using confocal microscopy and steady-state levels using immunoblot analysis. Wild-type (WT) TMEM127 localized predominantly to endo-lysosomal vesicles (punctate appearance) with some plasma membrane localization. The localization of variant TMEM127 proteins separated into three distinct categories: punctate (similar to WT), diffuse (cytoplasmic), and plasma membrane. All diffuse proteins, and a few punctate proteins, decreased at a faster rate than the WT suggesting instability. Variants resulting in diffuse proteins occurred within TM domains and indicated that membrane binding ability was lost. This observation, supported by *in silico* analysis and additional *in vitro* assays, led us to conclude that TMEM127 is a four-TM protein, not a three-TM protein, as previously predicted, with a novel TM domain in the N-terminus. The variant that predominantly localized to the plasma membrane indicated that membrane binding ability was maintained but internalization capability was lost. By mutagenesis scanning, we identified an atypical, extended acidic dileucine motif in the C-terminus which is responsible for TMEM127 internalization through clathrin-mediated endocytosis. Our findings provide novel insights into structure-function features of TMEM127 which will allow for better understanding of its physiological role and improved prediction of pathogenic *TMEM127* variants.

## PgmNr 3083: Single-cell RNA sequencing identifies a novel profibrotic epithelial cell population in primary human lungs from patients with pulmonary fibrosis.

---

Pulmonary fibrosis (PF) is a chronic interstitial lung disease (ILD) in which lung epithelium is progressively replaced by fibrotic scarring tissue leading to respiratory failure. The most common and aggressive form of PF is idiopathic pulmonary fibrosis (IPF), yet IPF accounts for only 20% of all PF cases. Available therapeutic approaches to this irreversible disease only slow down the fibrotic progression and lung transplantation is often required for late stage patients. To date, the precise mechanisms that drive fibrosis remain incompletely understood. To better understand pulmonary remodeling during the fibrotic progression, we performed single-cell RNA sequencing (scRNA-seq) on lung tissues collected from 18 healthy lungs (declined donors) and 29 lung explants from patients with a diverse set of PF diagnosis to obtain a comprehensive census of cell identities. Jointly analyzing cells from both healthy and diseased samples reveals at least 32 diverse pulmonary cells covering heterogeneity of epithelial cells, mesenchymal cells, endothelial cells, and immune cells. For examples, *TP63*<sup>+</sup>, *KRT17*<sup>+</sup>, *KRT5*<sup>+</sup> basal cells, *FOXJ1*<sup>+</sup> ciliated cells, and *ABCA3*<sup>+</sup> alveolar type 2 cells were shown and consistent with previously addressed cell characteristics. Interestingly, we identified a novel epithelial cell population which co-expresses *TP63* and *KRT17*, but not *KRT5* (*KRT17*<sup>+</sup>*KRT5*<sup>-</sup>). Moreover, a large number of genes associated with profibrotic processes (e.g. *COL1A1*, *VIM*, and *FN1*) were detected. The *KRT17*<sup>+</sup>*KRT5*<sup>-</sup> cells were almost exclusively found in PF lungs. Finally, this population appears to be the unique population in the lung expressing integrin  $\alpha\text{v}\beta_6$ , a heterodimer that is being actively investigated as a target for antifibrotic therapies. Using RNA scope, we validated the expression and localized the *KRT17*<sup>+</sup>*KRT5*<sup>-</sup> cells to be next to collagen-enriched fibroblasts, generally apart from *SFTPC*<sup>+</sup> epithelial cells. We are currently carrying out in vitro studies to functionally assess the impact of *KRT17*<sup>+</sup>*KRT5*<sup>-</sup> cells, their interactions with fibroblasts, and their biological significance in lung disease.

## **PgmNr 3084: Single-cell RNA-sequencing of primary human lung reveals disease-specific cell types and cell type-specific molecular mechanisms associated with disease progression.**

---

Pulmonary fibrosis (PF) is a heterogeneous clinical syndrome that represents the end-stage of chronic interstitial lung diseases (ILD). The most common (20%) and severe form of ILD is idiopathic pulmonary fibrosis (IPF), which typically leads to respiratory failure within 5 years of diagnosis. While current therapies for IPF can slow disease progression, they have not been shown to improve survival or quality of life, and they are not effective for the 80% of ILD patients with other PF diagnoses. To better understand the cell types and molecular mechanisms involved in the initiation of ILD and its progression to PF, we performed single-cell RNA-sequencing (scRNA-seq) of 67 samples from explant lungs of patients with IPF (n=17) or from healthy controls (n=21), as well as from patients diagnosed with other forms of ILD (n=12) including sarcoidosis, nonspecific interstitial pneumonia (NSIP), and chronic hypersensitivity pneumonitis (cHP). To further harness the natural pathology of the disease, we sampled two sites from a majority of the diseased lungs: 1) more fibrotic (n=28) and 2) less fibrotic (n=18). Using graph-based clustering, we identified over 30 distinct clusters representing the major known subtypes in the lung and found an enrichment of fibroblasts, macrophages, and T-cells in diseased lungs compared to controls. Interestingly, we observed cell states specific to diseased lungs including a previously undescribed population of profibrotic epithelial cells and a distinct fibroblast population specific to IPF. Furthermore, we identified hundreds of differentially expressed genes in most cell types when comparing diseased to control lungs, or within diseased state (less fibrotic samples vs more fibrotic samples or controls), some of which exhibited previously uncharacterized cell type specificity. By combining these results with trajectory inference, we were able to identify genes that are potentially driving disease initiation and progression. Finally, we identified cell type-specific expression quantitative trait loci (eQTLs) in diseased and healthy samples. To our knowledge, this is the largest single cell transcriptomic analysis of primary human lung tissue from patients with multiple forms of ILD and the first scRNA-seq eQTL analysis of diseased samples from primary human tissue.

## **PgmNr 3085: *WNT1*, causing autosomal recessive osteogenesis imperfecta, is required to sustain functional skeletal stem cells.**

### **Authors:**

N. Haelterman; K. Lei; D. Park; B. Lee

[View Session](#) [Add to Schedule](#)

**Affiliation:** Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

---

Mutations in *WNT1* cause an autosomal dominant form of early onset osteoporosis as well as an autosomal recessive form of the brittle bone disorder Osteogenesis Imperfecta (OI), identifying the molecule as an important regulator of human bone homeostasis. Similarly, loss of *WNT1* leads to severe bone loss in mice, whereas increasing *WNT1*-expression in osteoblasts strongly increases bone density in mice. The identity of the cell types that are responding to *WNT1*, and the mechanism by which alterations in *WNT1* levels induce such significant changes in bone density remains unclear. Here, we tested the hypothesis that *WNT1* regulates the maintenance and/or function of the skeletal stem cells that build and sustain bone throughout life. To this end, we first compared the prevalence of Paired-related homeobox gene-1 (PRX1)-expressing progenitor cells between *WNT1* mutants and their wildtype littermates. PRX1 is expressed in a population of postnatal skeletal stem cells that resides in the sutures of the calvaria and is necessary for calvarial bone regeneration upon injury. Surprisingly, we found a significant increase in the population of PRX1<sup>+</sup> progenitor cells, residing in *WNT1* mutant calvarial sutures. In addition, this pool of progenitor cells persists in 4-month-old mutant mice, whereas they have largely disappeared in wildtype animals by this age. We next tested the ability of *WNT1* mutant PRX1<sup>+</sup> progenitor cells to regenerate calvarial injuries and found that although mutant cells are able to migrate to the defect, bone regeneration is significantly delayed upon loss of *WNT1*. We are currently assessing the expression profile as well as the differentiation potential of *WNT1* mutant PRX1<sup>+</sup> stem cells in order to clarify how *WNT1* regulates this pool of progenitor cells. In summary, we find that loss of *WNT1* increases the pool of PRX1<sup>+</sup> skeletal progenitor cells in the skull, but that these cells are unable to perform their function in bone repair.

## PgmNr 3086: Integrating genomic fine-mapping and Hi-C to dissect causal variants and regulatory target genes underlying osteoporosis GWAS association.

### Authors:

Chen; F. Jiang; R.H. Hao; S.S. Dong; M.R. Guo; T.L. Yang

[View Session](#) [Add to Schedule](#)

**Affiliation:** School of Life Science and Technology, Xi'an Jiaotong University, Xi'an, China

---

Genome-wide association studies (GWASs) have successfully identified thousands of independent genetic variants conferring osteoporosis risk, while the underlying regulatory mechanisms are largely unknown. To fulfil this gap, we firstly performed genomic fine-mapping analysis implemented by FINEMAP using GWAS summary data on bone mineral density at 6 different sites (forearm, femoral neck, lumbar spine, heel, total body and total-body less head) and fracture from the GEFOS portal. We prioritized 21,188 high-confident causal variants at 1,523 conditionally independent signals ( $\log_{10}BF \geq 3$ ), of which only 1.5% ones are coding or splicing, indicating the prevalent regulatory roles for osteoporosis risk variants. We therefore leveraged paired high-throughput chromosome interaction data (Hi-C, capture Hi-C, HiChIP, ChIA-PET) and cis-eQTL data across three bone-related cell types (osteoblast, monocyte and lymphocytes) to identify the potential regulatory target genes. We performed Hi-C analysis in primary osteoblasts induced from human mesenchymal stem cells at 2-KB resolution. We identified 72 distal regulated gene targets with both cis-QTL and chromatin interaction evidence in the same cell type as well as 49 local cis-regulated genes (SNPs within target gene promoter). Notably, 75.8% of target genes could be regulated by distal causal SNPs, indicating the critical regulatory roles of chromatin looping in osteoporosis. We further employed the Coloc and PICCOLO method to assess whether GWAS signal and eQTL association shared the same causal variant, and detected strong colocalization evidence ( $PP4 > 0.7$ ) for 58 gene targets. These genes included some well-characterized bone-related genes (*TNFSF11*, *NFATC1*, *MAFB*) and several other genes whose KO in mouse model could lead to abnormal bone phenotypes (*ATPAF2*, *GPATCH1*), as well as 17 genes with nominal significant ( $P < 0.05$ ) expression difference between low and high BMD samples in either osteocytes (E-MEXP-1618), monocytes (GSE2208) or B lymphocyte (GSE7429). Moreover, the summary data-based Mendelian randomization (SMR) analysis suggested that 25/33 measurable genes had causal regulatory roles for osteoporosis in either osteoblast or lymphocytes ( $P_{SMR} < 0.05$ ,  $P_{HEIDI} > 0.05$ ). In summary, we systematically explored the regulatory effects linking osteoporosis risk casual variants to distal target genes and further evaluated their functions. Our analysis results might facilitate the future experimental follow-up.

## PgmNr 3087: Validation and classification of atypical splicing variants associate with osteogenesis imperfecta.

Osteogenesis Imperfecta (OI) is a rare inherited bone dysplasia, which is mainly caused by mutations in genes encoding type I collagen including *COL1A1* and *COL1A2*. Typical mutational spectrum of OI includes missense, nonsense, frameshift and splice site mutations. However, functional examination of whether the atypical splicing variants that locate beyond splice sites affect splicing in OI patients is limited. Here we collected blood samples from 34 patients carrying the variants that located close to splice donor/acceptor sites in either *COL1A1* or *COL1A2* from a cohort of 867 OI patients. Whole exome sequencing combined with Sanger sequencing were performed to detect and verify the variants, followed by minigene splicing assay to investigate the splicing effect. The results of minigene assay showed that 19 of 34 variants led to aberrant splicing effects, while 15 without any remarkable aberrant splicing effect. There were 21 variants located in introns and 17 of them led to aberrant splicing and 4 with no aberrant splicing. Three splicing effects can be categorized: (i) variants that led to exon skipping (n=9); (ii) truncated exon (n=2); and (iii) intron retention (n=4). The rest of 13 variants located in exons and most of them showed no effect on alternative splicing (n=11), which were confirmed to be missense mutation. While variant *COL1A2*: c.792G>A, which expected to be a synonymous mutation, was proved to cause exon skipping. Interestingly, there were some complicated cases (n=3) in which more than one mutant transcript were found caused by recognition of different splice sites, and this can be found in variants located in either introns (n=2) or exons (n=1). We further analysed the correlation between genotypes of aberrant splicing and their phenotypes, and found that most of the patients who have the aberrant splicing presented mild OI phenotype, especially in the patients with multiple mutant transcripts and those with intron retentions. While for the most prevalent effect, the exon skipping, phenotypes of those patients varied from mild to severe: 30% mild OI, 30% moderate OI and 40% severe OI. The mechanism on the development of aberrant splicing from these atypical splicing variants was proposed and summarized. This study expands our knowledge of atypical splicing variants, and emphasizes the importance to classify the splicing effect for variants near exon/intron boundaries.

## PgmNr 3088: Genetic and genomic variants in *EPHA4*-mediated dendritic spine morphogenesis pathway contribute to idiopathic scoliosis.

**Background:** Idiopathic scoliosis (IS) is one of the most common pediatric skeletal disease. Complex genetic factors have been implicated in its etiology. Recently, advances in exome sequencing (ES) and whole genome sequencing (WGS) have made it efficient to investigate disease-associated variants in complex traits.

**Methods:** A total of 15 trios and 242 singleton patients with IS recruited in DISCO (Deciphering Disorders Involving Scoliosis & Comorbidities) project were included. ES was performed on the 15 trios and 124 singletons, while WGS was performed on 103 singletons, totaling 257 cases (287 subjects). A previously reported case affected with Waardenburg syndrome was also recruited and followed up for scoliotic phenotype. Western blot was performed to investigate the function alterations of likely-pathogenic *EPHA4* mutation.

**Results:** Using a de novo strategy for the 15 trios after ES, a splicing variant c.1443+1G>C in *EPHA4* was prioritized as a candidate variant for IS. Minigene assay showed that this variant induced a new splicing site, which lead to a 34del frameshift change. Another *EPHA4* heterozygous missense variant (c.2546G>A, p.Cys849Tyr) was identified in a sporadic IS patient. Western blot showed that this variant could disrupt the phosphorylation function of the *EPHA4* protein. In addition, we followed up a previously reported patient affected with Waardenburg syndrome caused by a 4.46 Mb de novo deletion which encompasses *EPHA4*, and found that he newly developed a mild IS (Cobb angle 15°, located at lumbar vertebrae). Under the hypothesis that *EPHA4* could lead to IS through dendritic spine morphogenesis pathway, we analyzed five genes involved in this process. Three potential pathogenic genetic variants were identified, including a novel missense variant c.896G>A, p.Gly299Asp in *EFNB3*, a de novo start-loss variant c.1A>G, p.Met1\* in *NGEF*, and a novel missense variant c.596G>A, p.Ser199Asn in *NGEF*.

**Conclusion:** In this study, we identified five (5/257, 1.9%) potential pathogenic variants in the *EPHA4*-mediated dendritic spine morphogenesis pathway in our IS cohort and one deletion encompassing *EPHA4* in an isolated IS patient, demonstrating the important role of this pathway in the etiology of IS.

Cardiospondylocarpofacial syndrome (CSCF, OMIM#157800) is characterized by growth retardation, dysmorphic facial features, brachydactyly, vertebral synostosis, cardiac septal defects, and deafness. We encountered a patient with growth retardation, dysmorphic facial appearance, vertebral abnormalities and congenital heart defect, who was clinically diagnosed with CSCF. Here we reveal that the patient is caused by a loss-of-function type of variant in *MAP3K7* by whole exome sequencing (WES). Effect of the variant was analyzed using model animals.

The patient was a 4-year-old boy. The boy was born at 39 weeks of gestation with Apgar index of 3 (1 min) and 6 (5 min). After birth, the boy was soon administrated our hospital due to severe cyanosis. At 4 year-of-age, the patient showed severe growth retardation (short stature (-5 S.D.)), developmental delay, dysmorphic facial features with macrocephalus, long face, frontal bossing, epicanthal fold and mid-face hypoplasia, congenital heart defects with coarctation of aorta and atrial septal defect, scoliosis due to vertebral synostosis and joint laxity. He was clinically suspected to CSCF.

Written informed consent was obtained from his parents. WES analysis was performed and a novel heterozygous missense variant in the *MAP3K7* gene (NM\_145331.3(MAP3K7\_v001):c.574A>G, p.(Ser192Gly)) was identified in the patient. The variant was confirmed using Sanger sequencing. It was de novo.

We investigated the effect of the *MAP3K7* variant in Zebrafish and Drosophila. Inhibition of *MAP3K7* function using zeaenol or morpholino affected head and heart development in zebrafish. The *MAP3K7* gene variant was introduced into transgenic Drosophila overexpressed eiger (TNFalpha), which phenotype was reduced the eye-size. It is known that *MAP3K7* acts at downstream of a signaling pathway of TNFalpha. Then, the eiger effect was suppressed by introduction of the variant *MAP3K7*, suggesting that the variant showed dominant negative effect.

We concluded that CSCF was caused by loss-of-function of *MAP3K7* and the patient was caused by dominant negative effect of the variant in *MAP3K7*.

## PgmNr 3090: Functional effects of 13 rare *WNT10A* variants identified in individuals with isolated tooth agenesis.

---

Tooth agenesis (TA) is a common craniofacial anomaly affecting ~200 million humans worldwide that results from failure or disturbances during initial stages of tooth development. Both syndromic and isolated forms have been described, the latter which may occur sporadically or segregating in families. Numerous gene variants have been identified as potentially pathogenic for TA and their relevance in tooth development has been supported by studies using cells or animal model systems. *WNT10A* has been suggested as a major gene for TA, and yet the biological effects of associated variants remain unknown. Further, phenotypes in animal models showing *Wnt10a* knockdown/out are contradictory. In this study, we evaluated the effects of 13 rare *WNT10A* missense variants previously associated with TA using computational modeling (using VIPUR) and functional validation using a patient-based *in-dish* model system. Plasmid constructs for wild-type and each mutant *WNT10A* were transfected into SHED (stem cells of exfoliated deciduous teeth) cells for evaluation of *WNT10A* gene and protein expression, activation of WNT pathway, and their effects on expression of additional tooth development genes. Experiments were performed in triplicate and repeated twice. Data analysis was performed using one-way ANOVA followed by post-hoc tests as applicable; P-values<0.05 were considered statistically significant. Results showed that *WNT10A* variants located in exons 3 and 4 appear to contribute to a decrease in gene transcriptional activity and in WNT pathway activity. Specifically, T357I-, R360C-, and R379C-mutant cells presented significantly decreased *WNT10A* protein expression, likely through a reduced ability to bind to FZD. *WNT10A*-mutant cells also showed perturbed expression of *PAX9*, *MSX1*, *AXIN2*, and *RUNX2*. RNA-seq of T357I-mutant cells in comparison to WT cells identified 38 differentially expressed genes (10 upregulated, 38 downregulated), belonging to pathways related to cell pattern specification/regionalization, and adaptive immune response. Our results suggest that distinct *WNT10A* variants may present different biological effects contributing to impaired gene/function leading to milder or more severe TA phenotypes. Further studies investigating the potential additive effects of more than one *WNT10A* variant are currently under way.

# PgmNr 3091: The functional variant of *NTN1* contributed to the risk of non-syndromic cleft lip with or without cleft palate.

## Authors:

D. Li; L. Ma; S. Lou; X. Yu; Y. Pan

[View Session](#) [Add to Schedule](#)

**Affiliation:** Jiangsu Key Laboratory of Oral Diseases, Nanjing Medical University, Nanjing, Jiangsu, China

**Objective:** Our previous genome-wide association study of non-syndromic cleft lip with or without cleft palate (NSCL/P) identified a susceptible variant (rs4791774) in the intronic region of *NTN1*. We hypothesized that the functional single nucleotide polymorphism (SNP) may be in linkage disequilibrium with the lead SNP rs4791774 and contribute to the susceptibility to NSCL/P through a specific biological mechanism.

**Methods:** Bioinformatic analysis was conducted and the potential functional SNP (rs4791331) was identified. A case-control study with 891 cases and 830 healthy controls was designed. Odds ratios (ORs) and 95% confidence intervals (CIs) were calculated using logistic regression analyses. The allele-specific DNA-protein binding preference was predicted by the JASPAR database. Cell proliferation, apoptosis, the cell cycle, luciferase activity and *NTN1* mRNA expression were examined after transfection with the rs4791331 C/T vector in HEK-293 and HEPM cell lines. Forty-six lip tissues of NSCL/P patients were collected to detect *NTN1* expression. The relative expression of *Ntn1* in 10.5–14.5 day mouse embryos was downloaded from the Gene Expression Omnibus database. *ntn1a* knockout zebrafish models were generated by CRISPR/Cas9 and observed with micro-CT.

**Results:** rs4791331 was identified as a functional variant highly linked to rs4791774. In the case-control study, the T allele was associated with an increased risk of NSCL/P (OR=1.41, 95% CI=1.19–1.68), as well as the subgroups: cleft lip only (OR=1.46, 95% CI=1.14–1.87) and cleft lip and palate (OR=1.58, 95% CI=1.27–1.96). The T allele of rs4791331 exhibited anti-apoptotic effects (HEK-293:  $P=0.011$ , HEPM:  $P=0.007$ ) and promoted cell cycle progression at the G1/S transition in HEK-293 ( $P=0.001$ ) and HEPM ( $P=0.011$ ) cells. Dramatically decreased enhancer activity and reduced expression of *NTN1* ( $P<0.001$  in HEK-293 and HEPM cells) following transfection of plasmids containing the T allele were observed. Carriers of the CT/TT genotypes showed significantly lower expression of *NTN1* than CC carriers ( $P=0.004$ ). *Ntn1* was detected in the distal and proximal maxillary process, with an increased trend of expression in the 10.5–14.5 day mouse embryos. The *ntn1a*<sup>-/-</sup> zebrafish showed relatively wider intermaxillary fissures than the control zebrafish.

**Conclusion:** rs4791331 (C>T) resulted in disrupted motif binding and led to abnormal expression of *NTN1*, which may be involved in the development of NSCL/P.

## PgmNr 3092: Somatic mutations in clonally expanded memory T-lymphocytes in type 1 diabetes and celiac disease.

---

Autoimmunity is known to depend on both inherited susceptibility and environmental factors. However, these alone may not explain all variation in disease risk, for example the discordance of early-onset autoimmunity in monozygotic twins living in a shared environment, or the discordance in inbred-strain animal models kept in a controlled environment. These could be explained by stochastic events and one plausible, never explored, such event is post-zygotic mutations (PZMs) in the expanding antigen-specific autoreactive T-cell lineages, by analogy to their implication in the expanding tumor lineages of cancer cells.

In this study, we tested the hypothesis that somatic mutations in autoreactive T-cells involved in type 1 diabetes (T1D) and celiac disease (CD) contribute to the autoimmune process. Lymphocytes obtained from newly diagnosed T1D patients, proliferating after *ex vivo* activation by pro-insulin, were tested for somatic copy-number aberrations (CNA) not present in the germline (non-proliferating cells) by CGH array.

We found that 66.6% (12/17) of our study subjects harbor somatic copy-number mutations in insulin-reactive CD4+ T-cell clones. Many of these CNAs recurrently affected the same gene(s) in different patients, a strong evidence for pathogenicity in the cancer paradigm. Some of these genes have known T-cell proliferation and differentiation regulatory functions such as *CASZ1* and *E2f1*. As negative controls, we used lymphocytes proliferating in normal host defense by reacting to tetanus toxoid. They also harbored somatic mutations but these were significantly smaller in size ( $p = 0.0018$ ). Next, we tested the hypothesis in CD, another autoimmune disease. T-cells of CD patients, sampled after a 3-day gluten challenge and expanded *ex vivo* with gluten-peptides, were also examined for somatic CNAs. We found that 70% (7/10) of tested patients harbored somatic mutations in their gluten-reactive T-cells with three recurrent genes *CHD7*, *C8orf33*, and *LOC339685*.

Our data provide evidence for a potential causal role for PZMs in autoreactive T-cells in the pathogenesis of autoimmunity and suggested a putative mechanistic overlap between autoimmunity and cancer. These findings offer novel avenues for decrypting autoimmunity and its future individualized treatment through targeting disease causing cells.

## PgmNr 3093: Autoimmune disease-associated MHC polymorphisms influence T cell receptor repertoire.

T cell reactivity to pathogenic autoantigens is a fundamental feature of autoimmunity, and is driven by T cell receptors (TCRs). Complementary determining region 3 (CDR3) is located at the antigen contact region of TCRs, and CDR3 determines antigen specificity. During the developmental process in thymus, TCRs are selected based on its affinity to autoantigens presented on major histocompatibility complex (MHC). Autoimmune disease-promoting MHC polymorphisms are primarily located in the antigen-binding pockets, and such polymorphisms affect spectrum of peptides presented to T cells. In this study, we hypothesized that these MHC polymorphisms would affect thymic selection of T cells and modify TCR repertoire.

To test our hypothesis, we performed CDR3 quantitative trait loci (cdr3-QTL) analysis where we treated the ratio of each amino acid (AA) at each position of CDR3 (position 104-118) as a quantitative trait, and tested its association with the AA dosages at each position of MHC genes. We first analyzed a deep-sequenced TCR dataset of peripheral blood presented in Emerson R. et. al. *Nature Genetics* (n=666). Among 181 CDR3 AAs and 835 HLA AA pairs we tested, 70 CAD3 AA had significant associations with at least one MHC AAs ( $P < 3.3e-07 = 0.05/151135$  hypothesis tested). We next validated these cdr3-QTL associations using the RNA-seq data of CD4<sup>+</sup> T cells from the BLUEPRINT consortium (n=169). The associations among class II MHC regions in the first dataset, which reflect the biology of CD4<sup>+</sup> T cells, were successfully replicated in the same effect directions (binomial test  $P$  value=1.7e-15). Finally, we examined the colocalization between MHC AA positions with significant cdr3-QTL effects and those associated with the risk of two autoimmune diseases (rheumatoid arthritis (RA) and type I diabetes (T1D)). In total, we identified 48 CDR3 AA modifications were possibly influenced by disease-promoting MHC polymorphisms. For example, the presence of valine or leucine at *HLA-DRB1* position 11, which is strongly associated with RA risk (OR~3.7), also alters glutamate usage at position 112 of CDR3.

Our previous understandings of the biological consequences of autoimmune disease-promoting MHC polymorphisms were limited to their high binding affinity to the pathogenic autoantigens (e.g. citrullinated peptides in RA). Here, we presented novel evidences that such MHC polymorphisms modify TCR repertoire, which might lead to aberrant T cell reactivity to pathogenic autoantigens.

# PgmNr 3094: Strong discordance between expression-level and secreted protein-level QTLs in induced monocyte cytokines.

## Introduction

Research into genetic determinants of human immunity is focused on either proximal cellular traits (e.g. gene expression) or systemic traits (e.g. blood cell counts). This approach neglects the role of effector cell function and context-modulated intracellular communication crucial to immune system function. Cytokines are signaling molecules that are sentinel to innate and adaptive immune responses, thus identification of genetic determinants of release is of high relevance to disease susceptibility. Here, we explore the impact of genetic variation on cytokine secretion during monocyte response to stimulation.

## Methods

Data were generated from monocytes exposed to LPS (20 ng/ml, 2 or 24 hours), or IFN $\gamma$  (20ng/mg for 24 hours) across 513 individuals. Gene expression and genotyping for this cohort has been previously described. 50 cytokines, chemokines and other inflammatory mediators (hereafter called cytokines) were quantified in collected supernatant using Luminex-based technology. After batch quantile normalization, and covariate regression, 23 high consistency cytokines were analysed. Genetic association analysis was performed using a MANOVA of genotype versus all 23 phenotypes.

## Results

Four genetic variants were associated with cytokine secretion profiles ( $p < 5e-8$ ). Two were *cis* (PDGF-BB and IL-1RA), and formed eQTLs to the relevant RNA. Two were in *trans* (*CCR1*, associated with multiple cytokines including MIP-1 $\beta$ ; *IFNB1*, impacting IP-10). Both PDGF-BB and *CCR1* are associated with inflammatory bowel disease. The PDGF-BB variant is only resolvable post-stimulation, suggesting cell-state specificity. The *CCR1* variant is associated with circulating MIP-1 $\beta$  but interestingly impacts multiple induced cytokines, indicating the strong systemic QTL may not be causal.

13/31 peak cytokine eQTLs across the three conditions have a nominal effect ( $p < 0.05$ ) on protein secretion. In many cases however, the RNA level post-stimulation is not correlated with protein levels. For example, a post-IFN $\gamma$ -stimulation eQTL explaining 8.8% of *TNF* RNA ( $p = 9.3^{-19}$ ) has no effect on measured TNF $\alpha$  ( $p = 0.78$ ).

## Discussion

This study demonstrates the importance of studying the correct “layer” of biological activity and the frequent mismatch between intermediate phenotypes, illustrative of biological buffering. Here we show that studying cytokine secretion from a single cell type can reveal phenotypes of disease-associated variants not noted in either eQTL or systemic QTLs.

## PgmNr 3095: Identification of novel cryptic pathogenic variants in two independent patients with deficiency of adenosine deaminase 2.

Deficiency of adenosine deaminase 2 (DADA2) is an autosomal recessive disorder that manifests with fever, rash, hypocellular bone marrow, early-onset vasculitis, and propensity to ischemic and hemorrhagic stroke. This study aimed to identify novel pathogenic variants in *ADA2* through the application of a variety of molecular and biochemical methods.

The first index patient is a 5-year-old female who was born to a consanguineous Pakistani family and presents with features consistent with Diamond-Blackfan anemia (DBA). Sequencing analysis did not identify pathogenic variants in DBA associated genes and a CMA did not detect duplications or deletions. Several regions of homozygosity were identified in the proband, one of which comprises *ADA2*. Sanger sequencing of *ADA2* did not identify a pathogenic variant. MLPA analysis identified a homozygous duplication comprising exon 7 of *ADA2* in the proband, her affected sister, her affected father, and a heterozygous duplication in the mother. QRT-PCR experiments confirmed a loss of RNA-expression in the homozygous individuals. In agreement with mother's carrier status, she showed 50% reduction in *ADA2* RNA. Reduced *ADA2* enzyme activity corroborated the qRT-PCR findings. Long range PCR and long read sequencing were performed to localize the breakpoints of the duplication.

The second index patient is a 17-year-old female with a history of ischemic strokes, livedo and vasculitis. She was found to be heterozygous for a known pathogenic variant in *ADA2* (c.1358A>G, p.Y453C). It was inherited from the father and is present in her three unaffected siblings. *ADA2* enzyme activity assay revealed that the proband and two of her siblings have absent *ADA2* activity. Her parents, and a third sibling, exhibit *ADA2* carrier activity. Haplotype analyses found that the three children with low *ADA2* activity inherited the same maternal allele while the fourth sibling received the other maternal allele. WGS of mother and three affected children identified a novel canonical splice site variant (*ADA2*: c.-47+2T>C) present in all four individuals. Sanger sequencing confirmed segregation with disease. RNA analysis showed that the affected individuals express 50% of normal *ADA2* mRNA and cDNA sequencing confirmed that only the allele carrying the p.Y453C variant is expressed.

The identification of novel cryptic mutations in *ADA2* not detected by Sanger sequencing, suggests the incorporation of additional methods in the diagnosis of DADA2.

## PgmNr 3096: Using in vivo eQTL interactions to resolve the regulatory drivers of sepsis endotypes.

Sepsis is defined as organ dysfunction caused by a dysregulated host response to infection. Extensive variation in response across individuals has limited attempts to develop targeted treatments. We have previously identified two disease endotypes (Sepsis Response Signatures [SRS]) from transcriptomic data, which are associated with differential early mortality and response to hydrocortisone treatment in a clinical trial setting, but the regulatory drivers of these endotypes are unclear.

Expression quantitative trait locus (eQTL) mapping can identify genetic variants contributing to heterogeneity in gene expression. Specific eQTL may also be modulated by external factors, resulting in a genotype-by-environment interaction. We hypothesised that identification of a set of eQTL modulated by an environmental variable (e.g. causative infection type or SRS group) in the context of sepsis would reveal key regulatory factors and pathways through which the variable impacts the host response.

We recruited 550 adult patients with sepsis due to community acquired pneumonia or fecal peritonitis. We profiled gene expression (microarray, Illumina HT12-v4) in 730 peripheral blood leukocyte samples collected within five days of ICU admission and generated genome-wide genotyping data (Illumina OmniExpress, CoreExome, Global Screening Array).

We used a linear mixed model to identify *cis* eQTL genome-wide, and subsequently tested significant loci for interactions with SRS endotype and source of sepsis. Preliminary analysis identified eQTL for >2000 genes (Bonferroni corrected  $p < 5.2e^{-9}$ ), which were enriched for genes differentially expressed in the sepsis response and SNPs previously implicated in autoimmune and inflammatory disease. We observed 279 interactions (FDR < 0.05) with SRS, and 30 with infection site (lung/abdominal). These interaction eQTL involve a number of disease-relevant genes, including the transcription factor *IRF5* (SRS) and the viral response gene *OAS1* (site of infection). SRS interaction eSNPs were also enriched for GWAS risk variants for autoimmune disease; however, the majority of interaction eGenes were not differentially expressed between SRS groups, suggesting that this approach provides additional information to further resolve disease endotypes.

Identification of these eQTL interactions will help elucidate the mechanisms driving inter-individual

variation in the response to infection, and contribute to the development of personalised medicine in sepsis.

**Background:** Expression quantitative trait loci (eQTL) data have emerged as a source to characterize the function of disease associated genetic variants (DAGVs). Cell type specific data have recently allowed refined mapping of several disease associated loci, that were previously unattainable with tissue level results. Additionally, activation of cells and data derived from patients, instead of healthy controls, could allow further refinement of genetic functional mapping. An important question in the quest to functionally characterize DAGVs is whether data derived from subjects with the same disease and/or relevant activated cell types necessary.

**Methods:** We generated genetic and transcriptomic data for three immune cells - naïve CD4+ T cells (nT), memory CD4+ T cells (mT), and classical monocytes (Mo)- from multiple sclerosis (MS) subjects, untreated (UNT; n=55) or treated with glatiramer acetate (GA; n=84), and healthy controls (HC; n=38). We generated data at baseline (unstimulated) and after cell-specific activation (stimulated). We performed *cis* (*cis*-eQTL) and *trans* (*trans*-eQTL) analyses. We quantified the similarity of the genetic transcript expression regulation per cell type and condition within each group. Finally, we developed an algorithm to quantify the probability that the observed eQTL can be explained by the MS samples only.

**Results and Discussion:** We identified 600, 450, and 704 transcripts whose expression was controlled by nearby genetic variants (eGenes) in nT, mT, and Mo in the UNT MS group, respectively. The genetic control of transcript expression was more similar between the nT and mT ( $\rho=0.73$ ;  $p\text{-value}<10^{-50}$ ) compared to Mo ( $\rho<0.51$ ;  $p\text{-value}<10^{-50}$  in both). Activation resulted in decrease of the observed eGenes in all cell types with most prominent changes in Mo (1.5-fold in nT and mT, and 6-fold in Mo). A similar pattern was observed in the GA group, although more eGenes were identified, due to the larger sample size. Post-activation, the eGenes of the UNT and GA group were consistently similar across all three cell types ( $\rho\sim 0.85$ ;  $p\text{-value}<10^{-50}$  in all), implying that GA modulated the genetic control of subset of transcripts in different way compared to the UNT group. A similar pattern was observed with the identified *trans*-eQTL results. A small percent of identified eQTLs, either *cis*- or *trans*-, were only present in MS subjects suggesting genetic regulation of gene expression in the presence of disease-related context.

## PgmNr 3098: Post GWAS functional evaluation of SLC15A4 single nucleotide variants for Systemic Lupus Erythematosus (SLE) susceptibility.

### Authors:

G.P. Maiti; J.E. Molineros; B. Singh; J. Kaplan; S.K. Nath

[View Session](#) [Add to Schedule](#)

**Affiliation:** Oklahoma Medical Research Foundation, Oklahoma City, OKLAHOMA, 825 NE 13th St, OK 73104

**Background:** Systemic Lupus erythematosus (SLE) is a complex autoimmune disease with strong genetic basis. Recent studies have identified SLC15A4 gene as an important contributing factor for SLE pathogenesis. Several GWASs identified multiple disease associated SNPs within SLC15A4. However, the actual causal SNP(s) and contributing allele of SLC15A4 associated with SLE pathogenesis were largely unknown.

**Objective:** To characterize the candidate functional SNPs to define how they associate with disease susceptibility.

**Method:** Our meta-analysis with 6 independent cohort identified the significant SNPs in SLC15A4 gene region. Our *in-silico* bioinformatics and epigenetic analyses predicted the potential regulatory effects of SNPs on gene expression. Allele specific enhancer activity was measured in HEK, Jurkat and THP1 cell lines using luciferase reporter assay (LRA). Allele specific binding of different nuclear proteins were identified using DNA pull down assay followed by Electrophoretic Mobility Shift Assay (EMSA), Mass Spectrometry and western blot.

**Result:** Meta-analysis of SLC15A4 identified 653 informative SNPs among which 102 SNPs were qualified genome wide significance level associated with SLE. Further bioinformatics and epigenetic analysis prioritized 6 intronic SNPs which might have potential regulatory effects on gene expression. LRA identified significant allele specific different enhancer activities of 3 SNPs in HEK cell, 2 SNPs each in Jurkat and THP1. Interestingly the rs35907548 was showing highly significant difference ( $p < 0.005$ ) of allele specific enhancer activity across 3 cell lines. DNA pull down assay followed by EMSA and Mass Spectrometry identified cleaved PARP1 as an allele specific differential binding partner in rs35907548 region. We observed significant allele-specific bindings with several histones (H3K27Ac, H3K4Me3, and H3K4Me1). Our eQTL analysis demonstrated rs35907548 allele specific expression correlated with SLC15A4, GLT1D1 and TMEM132C.

**Conclusion:** The SNP rs35907548 of SLC15A4 is a potential functional variant predicted to alter the expression of SLC15A4, GLT1D1 and TMEM132C through its allele specific differential enhancer activity. Allele specific histone modification and differential binding of regulatory proteins may influence the expression of SLC15A4, GLT1D1 and TMEM132C, which might be leading to lupus.

## PgmNr 3099: Investigating the synaptic organisation of costimulatory IBD risk variants.

### Authors:

J. Hamp; P. Cespedes; S. Valvo; M. Dustin; L. Jostins-Dean

[View Session](#) [Add to Schedule](#)

### Introduction

Inflammatory bowel disease (IBD) remains a highly prevalent disorder with a poorly understood aetiology and no cure. Genome-wide association studies (GWAS) have successfully identified 241 risk loci. These show a significant enrichment for eQTLs in CD4+ T cells, and contain numerous costimulatory molecules. These immunomodulators help form the immune synapse (IS), the interface between T cells and antigen presenting cells that helps regulate T cell activation. The organisation of immune synapses in IBD has not yet been explored. Here we investigate costimulatory molecule IBD risk genes within the IS of IBD patients as a first step in characterising a possible disease-related phenotype.

### Methods

Blood samples were obtained from consenting IBD patients attending the John Radcliffe Hospital (Oxford, UK). CD4+ Memory and Naïve T cells were isolated and stimulated using either anti-CD3 + anti-CD28 or isotype controls immobilised on 96-well plates. After 48hrs, cells were transferred onto glass-supported lipid bilayers (SLB) holding fluorescently tagged Anti-CD3, CD80, ICAM-1 and the costimulatory ligand of interest. After 20mins, SLBs were imaged on an Olympus IX83 inverted microscope and analysed using the Fiji software. Cells were also analysed by flow cytometry to confirm the expression of the costimulatory molecules.

### Results

Initial experiments on CD4+ T cells from healthy donors showed all GWAS-implicated costimulatory molecules could be detected upon activation. 24hrs and 48hrs post-activation were identified as shared time points for high expression of the costimulatory molecules compared to unstimulated controls.

Post-identification of key timepoints, we analysed the localisation of synaptic ICOS. ICOS signalling is a potential IBD risk factor as both ICOS and ICOSLG lie within IBD risk loci. CD4+ T cells were activated for 24hrs and introduced to a SLB containing ICOSLG, from which statistically different features of the IS could be discerned. The median fluorescent intensity (MFI) of Anti-CD3 was lower in stimulated samples; in contrast ICOSLG MFI was significantly higher. Additionally, the synaptic area for both Anti-CD3 and ICOSLG showed significant differences between stimulated and unstimulated groups.

This data shows our approach has the ability to quantify costimulatory molecule localisation within the IS. Our next steps are to implement this approach to all costimulatory molecules of interest for our IBD patient cohort.

## PgmNr 3100: RNA expression of *HLA-DRB* and *HLA-DQ* genes in healthy individuals differs between MHC class II haplotypes.

---

**Background:** *HLA-DRB1* alleles have been associated with several autoimmune diseases. In anti-citrullinated protein antibody positive rheumatoid arthritis (ACPA-positive RA), *HLA-DRB1* shared epitope (SE) alleles are the major genetic risk factor. In contrast, the *HLA-DRB1*\*13:01 allele provides protection against ACPA-positive RA while the *HLA-DRB1*\*15:01 allele is not associated with RA. We investigated transcriptomic profiles of peripheral blood mononuclear cells (PBMCs) and isolated CD4+ T cells, CD8+ T cells, and CD14+ monocytes from healthy individuals carrying *HLA-DRB1* SE-positive and SE-negative alleles. **Methods:** Total RNA was extracted from PBMCs of genetically pre-selected healthy female individuals ( $n = 29$ ) and from CD4+ T cells ( $n = 26$ ), CD8+ T cells ( $n = 21$ ), and CD14+ monocytes ( $n = 10$ ) that were isolated from PBMCs via positive selection using microbeads. Sequencing libraries were generated using the Illumina TruSeq Stranded Total RNA kit and sequenced on an Illumina HiSeq 2500 platform, yielding about 40 million paired-end reads per sample. Reads were aligned to the standard reference using STAR. For the major histocompatibility complex (MHC) region, reads were mapped to available MHC reference haplotypes and *AltHapAlignR* was used to estimate gene expression. Differential gene expression (*HLA-DRB1* SE-positive versus SE-negative alleles (*HLA-DRB1*\*13:01 and *HLA-DRB1*\*15:01)) analyses were conducted using DESeq2. **Results:** We found no genes outside the MHC region that were differentially expressed between healthy individuals carrying *HLA-DRB1* SE-positive and SE-negative alleles in blood cells. In opposite, we found that *HLA-DRB* and *HLA-DQ* are differentially expressed between healthy individuals carrying *HLA-DRB1* SE-positive and SE-negative alleles. Interestingly, we found that *HLA-DRB1* is higher expressed in all studied cell types from individuals with *HLA-DRB1*\*04:01 alleles compared to individuals with *HLA-DRB1*\*15:01 alleles. **Conclusion:** Our data demonstrate that *HLA-DRB* and *HLA-DQ* genes are differentially expressed in healthy individuals carrying *HLA-DRB1* SE-positive and SE-negative alleles. This provides new insights into the molecular mechanisms of the development of autoimmunity.

## PgmNr 3101: *DLGAP4*: A novel candidate gene for autism spectrum disorders.

---

Autism spectrum disorders are a group of neurodevelopmental disorders characterized by impaired verbal/nonverbal communication, stereotyped behavior and abnormal social skills. Several chromosomal imbalances and mutations have been demonstrated to contribute in the etiology of autism. However, for most cases the cause remains elusive. We studied monozygotic twin sisters with autism spectrum disorder carrying a balanced translocation 46,XX,t(9;20)(q22;q13.3),9qh+,9qh+. Chromosome microarray analysis did not disclose any imbalances. In order to precisely map the translocation breakpoints, we performed mate-pair sequencing. The breakpoint on chromosome 9 maps to 9q21.12 with no genes mapped nearby. The breakpoint on chromosome 20 disrupts *DLGAP4* between exons 4 and 5. *DLGAP4* belongs to *DLGAP* gene family that includes 5 genes. DLGAPs are highly expressed in the postsynaptic density and are involved in neuronal signaling through glutamate receptors. Mutations in *DLGAP1-4* have been described in several neurodevelopmental disorders such as obsessive compulsive disorder, parkinson's disease and schizophrenia. *DLGAP2* has been proposed as a candidate for autism spectrum disorder. *DLGAP4* has been previously linked with early-onset cerebellar ataxia but not autism, though Sapap4 (Dlga4) deficient mice present autistic-like behavior. Therefore, there is strong evidence that dysregulation of *DLGAP4* might cause neurodevelopmental disorders. Hence we propose that *DLGAP4* is a strong candidate for autism spectrum disorders.

## PgmNr 3102: New cases with “CNV-mutator” phenotype characterized by concurrent *de novo* NAHR-mediated deletion events.

---

**Background:** The CNV-mutator phenotype is described by multiple *de novo* copy number variants (MdnCNV) arising independently at multiple loci throughout the human genome. The MdnCNV genomic phenotype is ultra-rare, and reported cases are predominantly copy number gains resulting from tandem duplications or complex genomic rearrangement (CGR) restricted to the perizygotic period of early embryogenesis. A Replication-based repair mechanism (RBM) involving template switching (TS), such as FoSTeS/MMBIR, is proposed to cause MdnCNVs, as suggested by mutational signatures at the breakpoint junctions. It is hypothesized that deficient protein contributing to faithful DNA replication and repair machinery is expressed in maternal germ cells, carried over to the fertilized zygote, and functioning at the early cleavage stage before post-maternal clearance. However, an inheritable genetic defect causing this phenomenon is not-yet identified.

**Methods:** New samples with CNV profiles consistent with the MdnCNV phenomenon were ascertained from individuals subjected to chromosome microarray analysis (CMA) at Baylor Genetics (BG). DNA sequencing further characterized the MdnCNVs.

**Results:** We identified one new MdnCNV sample. Eight *de novo* duplications, ranging from 901 Kb to 1.032 Mb, dispersed on eight chromosomes including 4, 5, 6, 10, 12, 13, 14 and 21, along with an 8 Mb copy number neutral region with absence of heterozygosity (AOH) on 15q14q21.1. Interestingly, among 65,000 CMA samples at BG, we identified two cases with two concurrent NAHR-mediated recurrent deletion CNVs ranging from 227 Kb to 3.062 Mb (15q13.3 and 17q21.31 in one sample, and 15q24 and 16p11.2 in the other sample). These two cases with recurrent deletion CNVs are reminiscent of the MdnCNV phenomenon yet the “genomic character” is distinct from the previous predominant observation of gains.

**Conclusion:** We provide additional evidence for the MdnCNV genomic phenomenon. The MdnCNV duplications coupling AOH are consistent with CGRs due to potential RBM malfunctioning during replicative repair of single-ended, double-stranded DNA (seDNA). The two MdnCNV cases with multi-locus *de novo* NAHR-mediated deletions suggest contribution of a different mutational mechanism. Could these be caused by defects in repair of double strand breaks initiated during chromosome pairing and meiotic homologous recombination?

## PgmNr 3103: Disruptive *KMT5B* variation alters growth and adhesion properties in an *in vitro* model.

**Affiliation:** Pharmacology & Neuroscience, Creighton University School of Medicine, Omaha, NE.

---

Advances in sequencing technology have revealed extensive overlap in risk genes among complex, yet seemingly unrelated, human disorders. Recently, publications have highlighted *de novo* disruptive mutations in *KMT5B* as potentially-pathogenic in neurodevelopmental disorders (NDDs); variants in *KMT5B* have also been implicated in metastatic human breast cancer. As a chromatin-modifying enzyme, lysine methyl transferase 5B (*KMT5B*) is responsible for dimethylating the N-terminal lysine 20 residue of histone protein 4 (i.e., H4K20me2). Published data suggest that H4K20me2 is crucial in chromatin compaction, regulation of gene expression, cell cycle progression, maintenance of stem cell quiescence and in DNA double-stranded break repair. However, what role disruptive mutations in *KMT5B* have in NDD and/or cancer etiology is currently unknown. This study is aimed at understanding the biology underlying *KMT5B* mutations with the hypothesis that early-truncating, disruptive *KMT5B* mutations in human cell line models will result in reduced H4K20me2 and cell growth defects that may be initially characterized in this model system. CRISPR/Cas9 engineering was used to induce *KMT5B* mutations into the human myeloid cell line, K562. Multiple isogenic clones were derived, and three lines (SCC1, SCC2, and SCC3) containing unique heterozygous frameshifting mutations in *KMT5B* were chosen for further characterization. Although all three lines contained similar *KMT5B* variation (p.Ser69Profs\*11, p.Met72Thrfs\*3, and p.Ala74Glufs\*5, respectively), only SCC1 and 2 showed significant decreases in proliferation ( $p < 0.001$ , Student's t-test). Further, SCC2 showed reduced levels of H4K20me2, defects in G1-S phase transition, and an accumulation of double-stranded breaks in G1 and G2/M ( $p < 0.05$ , Student's t-test). RNA-sequencing of all three lines highlighted a conserved upregulation of *p21* (*CDKN1A*;  $p < 0.01$ , Student's t-test) and significant pathway changes in cell adhesion, cell lineage, proteoglycans, and Rap1 signaling compared to the sham control line ( $p < 0.05$ , FDR-corrected Fisher's exact test). Ongoing ChIP-sequencing experiments aim to better define putative *KMT5B* targets associated with the gene expression changes observed. Preliminary data indicate that disruptive mutations in *KMT5B* affect pathways common to tumorigenesis and neurogenesis—proliferation, cell cycle dysregulation, migration, and adhesion—suggesting that this gene may be important for the etiology of multiple disorders.

## PgmNr 3104: Loss-of-function mutation in inositol monophosphatase 1 (IMPA1) in intellectual disability patients impairs neurogenesis but not gliogenesis.

### Authors:

---

The IMPA1 enzyme is responsible for the generation of free inositol, and is therefore a modulator of signal transduction via the production of the second messengers, inositol triphosphate and diacylglycerol in brain as well as in numerous other tissues. In 2016, we described a novel homozygous 5-bp duplication leading to a frameshift and a premature stop codon in the inositol monophosphatase 1 (*IMPA1*) in nine individuals with severe intellectual disability and disruptive behavior. Currently, this mutation co-segregated in 59 genotyped family members from Northeastern Brazil. In this study, we derived iPSC lines from 3 patients with *IMPA1* mutation and 2 controls to expand the studies to understand the mechanisms by which impairment of *IMPA1* lead to development of severe ID and disruptive behavior. The iPSCs from our cohort were differentiated into hippocampal dentate gyrus-like neurons (hDG neurons), pan-neuronal cells and astrocytes and we investigated the effect of the mutation on signaling pathway networks, cellular processes, morphology and electrophysiological properties. The transcriptome analysis of hippocampal dentate gyrus-like neuronal precursors cells (hDG NPCs) and hDG neurons revealed significant alterations in genes involved in multiple developmental processes including embryonic development and morphogenesis, brain development, neurogenesis, neuron differentiation and gliogenesis. Moreover, we observed that neural progenitor cells have defects in proliferation and survival. These defects were associated with cell cycle arrest and increased apoptosis specifically in NPCs and not in iPSCs or GPCs (glial progenitor cells). Importantly, we showed that *IMPA1* mutation affects the ability of progenitor stem cells to differentiate into neurons but not into astrocytes and that inhibition of Rho-associated kinases (ROCK) rescued neurogenesis. Adaptor protein (AP) complexes mediate clathrin-coated vesicle assembly, intracellular sorting, and vesicular trafficking of membrane proteins in the cell. Various subunits of AP complexes are involved in severe human inherited disorders like MEDNIK syndrome, developmental and epileptic encephalopathy, and intellectual disability (ID). Of the five adaptor protein complexes (AP-1 to -5), AP-1 mediates cargo sorting between endosomes, lysosomes and trans-Golgi network, as well as in synaptic recycling in neurons. Here, we report two novel predicted homozygous pathogenic variants, including a missense variant c.1096 A>G (p.Met366Val) in *AP1G1* and a c.3211\_12delAA (p.Lys1071Glufs\*7) frameshift variant in its interacting partner *AP1GBP1* (*SYNRG*) segregating with mild to moderate ID, developmental delay, pectus excavatum, B/L toe micronychia, hypotonia, and epilepsy in two large consanguineous Pakistani families. *AP1G1* is part of the adaptor related complex 1, crucial for vesicular transportation and formation. However, the function of *SYNRG* is yet to be defined. By co-immunoprecipitation (co-IP) and immunofluorescent studies, we confirmed localization of both *AP1G1* and *SYNRG* proteins in specific vesicle bodies, and interactions with each other as well as with other AP-1 adaptors. Although the protein targeting or stability was not impacted by the disease-causing variants, however, co-IP studies revealed significant impact on the protein-protein interactions. Furthermore, *AP1G1* harboring p.Met366Val variant significantly delayed transferrin recycling through recycling endosomes, while the *SYNRG* with p.Lys1071Glufs\*7 frameshift mutation delayed both static early and late endosomes recycling. In zebrafish, knocking-out *Ap1g1* leads to severe morphological defect and lethality by 6 days post fertilization (dpf). Using CRISPR/Cas9 technology, we introduced truncation in *Synrg* similar to human variant. In contrast to the depletion of *Ap1g1*, truncation of *Synrg* does not affect survival of fish but decreased size of corpus callosum was observed as early as 3dpf. Taken together, these results confirm the function of both *AP1G1* and *SYNRG* in endocytic recycling and their role in normal brain development, as well as expand the repertoire of genes associated with ID and developmental delay in humans.

## PgmNr 3106: A novel homozygous variant in *TRAPPC2L*, a core subunit of the human TRAPP tethering factor complexes involved in membrane trafficking, results in a neurodevelopmental disorder.

Membrane trafficking shuttles proteins to the various intracellular compartments using membrane bound vesicles and requires numerous proteins including tethering factors. TRAPP (TRANsport Protein Particle) tethering factors are highly conserved protein complexes in eukaryotes which regulate fusion of vesicles to membranes. In humans, two TRAPP complexes, II and III, have been described. Each has a core of common subunits (*TRAPP-C1*, *C2*, ***C2L***, *C3*, *C4*, *C5* & *C6*) as well as complex-specific proteins.

Recently, 2 unrelated individuals with a homozygous p.Asp37Tyr variant in the ***TRAPPC2L*** core subunit were described with neurodevelopmental delay, fever associated encephalopathy & rhabdomyolysis, followed by developmental arrest, epilepsy and tetraplegia (J Med Genet. 2018 Nov;55(11):753-764). Using genome sequencing, we identified a novel *TRAPPC2L* homozygous missense variant (**p.Ala2Gly**) which segregated in 3 affected individuals in a sibship of 5, from a single Ashkenazi Jewish (AJ) family. This rare variant is only seen in the AJ cohort (AF-0.0002243) in GnomAD and is predicted to be deleterious (CADD 28.3, REVEL 0.68, MPC 0.46, MetaSVM damaging 0.58, GERP 3.78). The affected siblings have a history of global developmental delay, intellectual disability, severe speech delay and acquired microcephaly. Developmental regression after illness, rhabdomyolysis and seizures were not consistently noted.

To assess the effect of the *TRAPPC2L* p.Ala2Gly variant we performed functional studies, using yeast and human cells. Yeast two hybrid analysis showed that this variant blocks the interaction with *TRAPPC6a* and the TRAPP III-specific *TRAPPC12* subunit whereas the p.Asp37Tyr variant disrupts the interaction with TRAPP II-specific *TRAPPC10* subunit. In a yeast system with growth dependent on a functional form of *TRAPPC2L*, the p.Ala2Gly variant was unable to rescue the growth defect at 37°C. Analysis of membrane trafficking between the endoplasmic reticulum and the Golgi in live cells derived from the affected individual showed a delay, which was rescued by expression of wild type *TRAPPC2L*. *TRAPPC2L* is postulated to bind the complex close to the *TRAPPC3-TRAPPC6* interface. We found that the p.Ala2Gly, but not the p.Asp37Tyr variant, reduced the interaction of *TRAPPC2L* with the *TRAPPC3-TRAPPC6a* heterodimer *in vitro*. Collectively, these data support the pathogenicity of the *TRAPPC2L* p.Ala2Gly variant that may be due to a reduced association of *TRAPPC2L* with *TRAPPC6a* and or *TRAPPC12*.

## PgmNr 3107: JAK/STAT inhibitor therapy rescues the lipodystrophic and autoimmune phenotype in *Clec16a* KO mice.

*CLEC16A* is implicated in multiple autoimmune diseases. We generated *Clec16a* inducible knockout mice to address the role of *CLEC16A* loss of function in autoimmunity. *Clec16a* KO mice exhibited increased food consumption and without evidence of hyperglycemia, loss of adipose tissue, severe weight loss, elevated Immunoglobulins and significantly reduced circulating insulin levels. Metabolic analysis revealed disturbances in lipid profile measures. White adipose tissue decreased concomitantly with enhanced inflammatory response and energy wasting. The loss of *CLEC16A* leads to a vicious cycle of autophagic impairment and endoplasmic reticulum (ER) stress, which contributes to excessive lipolysis and lipotoxicity resulting in activation of JAK/STAT, mTOR, P38 and JNK and release of multiple proinflammatory mediators under compromised mitophagy environment. Treatment with a JAK/STAT inhibitor (tofacitinib) partially rescued the lipodystrophic phenotype of KO mice and improved survival by alleviating ER stress and JAK-STAT mediated cytokine signaling. These results establish a link between *CLEC16A*, ER stress, lipid metabolism and the immune system. *CLEC16A* is regulator of autophagy and mitophagy. ER stress is known to activate lipolytic cascade. Aberrant or excess cytokine production plays a key role in driving autoimmune and autoinflammatory disorders. Collectively, our data indicate that loss of *CLEC16A* induces ER stress, dysregulated autophagy and mitophagy, which in turn activates lipolytic cascade resulting in excessive adipocyte lipolysis which generates lipid mediators and triggers inflammation via activation of JNK/NF- $\kappa$ B signaling pathway. Thus, *CLEC16A* exerts its effect on a wide variety of immune cells through modulation of ER stress, SOCS expression and regulation of cytokine signaling, suggesting that perturbations in the molecular link between *CLEC16A*, ER stress, mitophagy, lipophagy, and SOCS1 may underlie inflammatory and autoimmune disorders. In patients with autoimmune disease, harboring variants that result in *CLEC16A* hypofunction, drugs with modulatory effects on ER stress/mitophagy/autophagy/SOCS1-JAK-STAT signaling could compensate for the attenuated *CLEC16A* activity and be developed for targeted interventions. Our *Clec16a* KO highlights multifaceted roles of *Clec16a* in normal physiology, including a novel target for weight regulation, as well as mutation-mediated pathophysiology.

## PgmNr 3108: Identification of novel genetic mechanisms involved in development and progression of non-alcoholic fatty liver disease.

---

Non-alcoholic fatty liver disease (NAFLD) is the most prevalent form of chronic liver disease, characterized by excess fat accumulation in the liver without a history of excessive alcohol consumption. Patients with NAFLD often progress to an advanced stage of non-alcoholic steatohepatitis (NASH) and ultimately irreversible end-stage liver disease. To date, there are no available pharmacological treatments against NAFLD and NASH.

The overall aim of this study was to investigate genetic mechanisms regulating lipid accumulation and lipotoxicity in hepatocytes, which will help us understand the cause of NAFLD and NASH. We treated human hepatocytes (HepG2) with the two most abundant dietary plasma fatty acids; a saturated fatty acid, palmitic acid (PA), and a monounsaturated fatty acid, oleic acid (OA); as well as TNF to study their impact on steatosis, apoptosis and inflammation, as well as gene expression, with the goal of developing an *in vitro* model for NAFLD development and progression.

First, we showed that OA markedly induced lipid accumulation, as well as mRNA expression of the lipid droplet binding protein, *Plin2*. In contrast, PA had little effect on lipid accumulation, but significantly activated the Caspase 3/7 apoptotic and NF- $\kappa$ B p65 inflammatory pathways. Second, using RNA-seq analysis, we studied differential expression (DE) by our perturbations. In addition to genes from lipid metabolism pathways, OA reduced expression of several fibrosis-related genes (*COL3A1* and *COL1A2* being the top DE genes;  $\log_2$ FC, -5.8 and -4.9;  $P_{adj}$ , 4.9E-14 and 1.4E-9, respectively); while the top DE gene after PA treatment was carnitine palmitoyltransferase 1A (*CPT1A*), a key enzyme in fatty acid oxidation ( $\log_2$ FC, 1.2;  $P_{adj}$ , 1.1E-15). As expected, top DE genes after TNF treatment were leucine-rich alpha-2-glycoprotein 1 (*LRG1*) and interleukin 32 (*IL32*) ( $\log_2$ FC, 1.1 and 1.6;  $P_{adj}$ , 1.27E-13 and 1.46E-08, respectively), which are involved in immune response.

Our preliminary results indicate that perturbations with PA, OA and TNF induce different effects on the hepatocyte lipid accumulation and inflammation that closely resembles development and progression of NAFLD and NASH. Next, we plan to perform further molecular profiling in our system and integrate findings from human genetics to advance knowledge about NAFLD and NASH.

## PgmNr 3109: Variants associated with liver chromatin accessibility suggest mechanisms for loci associated with lipid levels and gene expression.

Genetic variants that alter chromatin accessibility in disease-relevant tissues are candidate functional regulatory variants and provide mechanistic insight at GWAS loci. We mapped chromatin accessibility in frozen liver tissue from 20 individuals from the St Jude liver bank and used MACS2 to identify 287,589 consensus accessible chromatin regions (peaks, FDR<5%, median width=538 bp) that were present in at least 2 individuals. We mapped chromatin accessibility quantitative trait loci (cQTL) with RASQUAL using variants (imputation  $r^2 > 0.3$  and MAF>.10) within 25 kb of consensus peak centers, correcting for library size and 4 ATAC-seq principal components. We identified cQTL for 1,011 peaks (genome-wide FDR<5% after correcting for local peak variant density), corresponding to 1,001 unique variants. Consistent with previous cQTL studies, we found that cQTL lead variants are often located close to the associated peaks; 429 (43%) cQTL variants are within the associated peak, and the median distance from lead variants to peak centers is 1,628 bp. To identify variants that alter gene expression by modulating chromatin accessibility, we identified cQTL variants in high linkage disequilibrium (LD) with lead variants from a new liver eQTL meta-analysis (n=1183). 120 (12%) cQTL lead variants were in high LD ( $r^2 > 0.8$ ) with a lead liver eQTL variant. 5 of these cQTL were in high LD ( $r^2 > 0.8$ ) with liver eQTL that colocalized with GWAS loci for blood lipid levels (*PRMT6*, *SORT1/CELSR2/PSRC1*, *ANGPTL1/C1orf220/RALGPS2*, *LITAF*, and *DNAH11*). At the well-characterized *SORT1* GWAS locus for LDL and total cholesterol, the lead cQTL variant (rs12740374,  $p < 8.5 \times 10^{-11}$ ) is also the lead eQTL variant for *SORT1*, *PSRC1*, and *CELSR2*. Allele rs12740374-T, which has been shown to generate a CEBP binding site and increase *SORT1* expression in liver cells (Musunuru *et al.*, 2010), is associated with increased chromatin accessibility of a peak overlapping the 3' end of *CELSR2* and increased expression level of all three genes, suggesting that this variant increases gene expression by increasing chromatin accessibility and binding of a CEBP transcription factor. Despite modest sample size, we identified genetic variants that may alter gene expression and metabolic

traits by modulating chromatin accessibility. These results suggest that mapping liver cQTL in larger sample sizes will be a powerful method to identify candidate functional variants and molecular mechanisms at metabolic trait GWAS loci.

## PgmNr 3110: Colocalizing gene-lifestyle interaction associations with molecular signatures of smoking and alcohol consumption.

---

Cigarette smoking and alcohol consumption modify genetic effects on lipid and blood pressure levels, yet the underlying mechanisms remain largely unexplained. We leveraged trans-ancestry GWAS summary statistics from the Gene-Lifestyle Interactions working group (GLIWG) within the Cohorts for Heart and Aging Research in Genomic Epidemiology consortium with data from external publications to colocalize genetic associations with molecular signatures of lifestyle exposures.

GWAS summary statistics, generated within the GLIWG, for three lipid (total triglycerides, HDL and LDL cholesterol) and four blood pressure traits (systolic [SBP], diastolic [DBP], pulse [PP], and mean arterial [MAP] pressure) with two lifestyle factors (cigarette smoking and alcohol consumption) as interaction terms in over 600,000 individuals of diverse ancestry were used. Associations were selected by interaction  $P$ -value  $< 5E-8$  per trait-exposure pair.

Molecular signatures of traits and exposures were taken from the literature focusing on epigenome-wide association studies (EWAS), methylation quantitative trait loci (mQTL), expression quantitative trait methylation (eQTM), and expression quantitative trait loci (eQTL) in adipose, liver, whole blood, and pancreatic tissue. Tissues were chosen based on differential heritability enrichment between exposed and unexposed individuals.

Colocalization was established by intersecting associations with molecular signatures relevant to each trait-exposure pair. Two criteria defined colocalization: at least one association (1) within 500kb of an EWAS/eQTM site and an eQTL of the eQTM target or (2) is an mQTL of an EWAS/eQTM site.

Two loci showed colocalization in analyses of HDL and alcohol: C1QTNF4 and SIRT2. rs10769254 ( $P=1.4E-8$ ) was an eQTL for C1QTNF4 ( $P=3.2E-7$ ) and 250Kb upstream of cg27051260, an EWAS site for alcohol consumption ( $P=1E-4$ ) and an eQTM of C1QTNF4. rs7121347 ( $P=2.4E-12$ ) was an eQTL for SIRT2 ( $P=2.3E-10$ ) and 185Kb upstream of cg24064506, an EWAS site for alcohol consumption ( $P=1.7E-5$ ) and an eQTM of SIRT2. 51 variants with  $P<5E-8$  were within the SIRT2 locus. These

variants show low LD with multiple known independent signals for HDL within the region. Further, SIDT2 has been implicated in lipid storage in mouse knockouts.

EWAS/eQTM in alcohol consumption provided context for observed genetic interaction. Our colocalization analysis suggests a genetic role in the epigenetic mechanism of alcohol consumption's effect on lipid levels.

## PgmNr 3111: Capture C-based variant to gene mapping for GWAS-implicated total cholesterol loci points to a degree of common genomic etiology between adipocytes and hepatocytes.

---

Genome-wide association studies (GWAS) of total cholesterol levels have identified hundreds of associated loci; however, localization of causal variants at these loci, plus the corresponding effector genes, remain to be fully determined. It has been shown that liver and adipose exchange very low density lipoproteins and free fatty acids, via the vascular system, to form a common fatty acid pool for both storing and distributing energy to other tissues and organs. This suggests that adipocytes and hepatocytes represent key cell types in which to conduct variant to gene mapping for GWAS-implicated total cholesterol loci. We elected to leverage human mesenchymal stem cell (hMSC) derived adipocytes and induced pluripotent stem cells (iPSC) derived hepatocytes to physically implicate effector genes at these loci. We extracted proxy SNPs in LD with each sentinel variant and cross-referenced them with the ATAC-seq-determined open chromatin landscape in both cell types. We determined that 1,044 (2.7%) proxy SNPs in hMSC-derived adipocytes and 835 (2.2%) in iPSC-derived hepatocytes were in open chromatin out of a total of 38,117 proxies. Then leveraging our high-resolution, genome-wide, promoter-focused Capture C approach, we sought to characterize consistent contacts between open-proxy SNPs and candidate effector genes across the two cell types. We identified 33 contacts between open chromatin proxy SNPs and 22 shared gene promoters. Shared effector genes across the two cell types included *GPR146* (with two identical SNP promoter interactions plus other interactions to different proxy SNPs), *SORT1* and *PCBP1* (with interactions to different open proxy SNPs). These results suggest a degree of common genomic etiology influencing total cholesterol levels in both adipocytes and hepatocytes.

## PgmNr 3112: Disrupting early biogenesis peroxins restores growth to mutants of late-acting biogenesis peroxins.

Peroxisomes are organelles that house essential oxidative reactions in almost all multicellular eukaryotes. Peroxisome biogenesis disorders (PBDs) are a suite of autosomal recessive congenital disorders that are often lethal within the first year of life, including Zellweger syndrome, Neonatal Adrenoleukodystrophy, and Infantile Refsum Disease. These disorders are caused by mutations in peroxin (*PEX*) genes, which encode the proteins that generate and maintain peroxisomes. Over-accumulation of very-long-chain fatty acids and reduced synthesis of plasmalogen due to defective peroxisomes are hallmarks of PBDs and were often used to diagnosis the disease prior to the development of genomic sequencing tests. As in mammalian cells, plant cells rely on peroxisomes for breakdown of fatty acids stored in lipid droplets, and mutations in peroxin genes confer a range of developmental defects that are easily assayed to monitor peroxisome function in various *Arabidopsis* mutants. We screened for mutant suppressors that restored post-germinative growth to *pex12-1* and *pex6-1*, mutants that display severe growth defects and over-accumulation of lipid droplets stemming from disrupted import of peroxisome luminal proteins. Our independent *pex12-1* and *pex6-1* suppression screens recovered nearly identical early nonsense mutations in *PEX3B* that result in complete loss of protein. The loss of PEX3B protein likely results in reduced but not abolished PEX3 function because a *PEX3A* paralog remains intact. Paradoxically, both *pex3b* mutants markedly improved *pex12-1* or *pex6-1* growth without restoring luminal-protein import, suggesting that previously unrecognized *pex12-1* and *pex6-1* defects contribute to their stunted growth. Elucidating these suppression mechanisms may reveal novel roles for PEX3B in lipid droplet or peroxisome dynamics beyond well-established roles in pre-peroxisome budding from the ER and peroxisomal membrane protein insertion. Moreover, this study highlights PEX3 as a potential drug target for the development of PBD therapy.

## PgmNr 3113: Novel rare variants in *APOC3* and their association with serum triglycerides, diabetes and coronary heart disease.

### Authors:

C. Bejar <sup>1</sup>; S. Ralhan <sup>2</sup>; G.S. Wander <sup>2</sup>; J.R. Singh <sup>3</sup>; N.K. Mehra <sup>4</sup>; D.K. Sanghera <sup>1</sup>

Elevated serum triglyceride (TG) concentration is heritable and a strong independent risk factor for coronary heart disease (CHD). Apolipoprotein CIII (ApoC3) is an important regulator of lipid metabolism and plays a key role in regulating plasma triglycerides. Elevated plasma levels of ApoC3 are correlated with the increased risk of CHD. Recent exome sequencing studies on populations of European and African ancestry have identified rare loss of function (LOF) variants associated with reduced triglycerides and decreased risk of CHD. However, no such information is available in any population of South Asian (SA) ancestry despite the fact that SAs constitute ~1/4<sup>th</sup> of the global population and contribute the highest proportion of CHD burden compared to any other region in the world.

Here we performed targeted resequencing of 13 candidate genes of dyslipidemia (including *APOC3*) to identify functional variants underlying their biological functions. We sequenced 820 Sikhs from India with extreme hypertriglyceridemia (HTG) levels and used 2,239 samples for replication; all 3,059 participants were part of the Asian Indians Diabetic Heart Study. Many rare and loss of function variants identified earlier in Europeans and Africans including R19X were not present in our sample. However, our data revealed 23 novel rare variants (MAF <0.001) including 5 variants in 5'UTR, 3'UTR, insertion or deletions that were not present in any public database. Mean plasma TG levels were lower 57.8% among carriers of any of these variants compared to non-carriers ( $p=3.8 \times 10^{-5}$ ). Similarly, HDL levels were elevated 19.8% and LDL was reduced 12.8% among carriers compared to non-carriers. Collectively, these results highlight the importance of genetic evaluation of diverse ancestries for identifying clinically important therapeutic targets.

**Funding Acknowledgements:** The Sikh Diabetes Study/ Asian Indian Diabetic Heart Study was supported by NIH grants-R01DK082766 (NIDDK) and NOT-HG-11-009 (NHGRI) and grants from Presbyterian Health Foundation. Sequencing services were provided through the RS&G Service by the Northwest Genomics Center at the University of Washington, Department of Genome Sciences, under U.S. Federal Government contract number HHSN268201100037C from the National Heart, Lung, and Blood Institute of the NIH.

## PgmNr 3114: Longitudinal multi-omic analyses of whole blood gene expression and metabolite levels in the MultiMuTHER study reveal differences in longitudinal variation patterns between 'omics.

The body is a dynamic system of interacting subunits whose combined influences define its phenotypic trajectories. Multi-omic datasets represent a snapshot of the system's physiological state, integrative analysis of which may enable a precision medicine approach to health monitoring and earlier identification of disease risk. Critically, to identify deviation on an individual-level indicative of adverse outcomes, we must first understand the extent of normal variation over time in individuals and on a population level. We therefore sought to investigate how gene expression and metabolite levels in blood change over time, and what genetic or environmental factors drive these changes.

To address this, we have generated gene expression (RNASeq) and metabolomics (1,197 metabolites) data in whole blood at three or more timepoints per individual from 335 TwinsUK subjects [age range 32-80; median=61yrs]. TwinsUK is a deeply-phenotyped cohort of twins with extensive 'omics data and repeat phenotypic measures. Time between first and last visit ranges from 3 to 8 years (median 6yrs).

We observed moderate correlation in metabolite and gene expression profiles within individuals across timepoints (median rho-metabolites=0.44; median rho-gene expression=0.28). Intriguingly, correlation of metabolomic profiles decreased with increased time between sampling (median rho Timepoint1-3=0.33;  $P < 2.2 \times 10^{-16}$ ), whereas correlations in gene expression profiles showed stability over time, with no significant reduction in correlation comparing two timepoints longest apart versus those closer together ( $P > 0.05$ ).

Expression levels of ~30% of genes showed significant longitudinal associations (FDR 5%), including genes previously associated cross-sectionally with age such as *ACAA2* and *CD248*, as well as *CASP2*, previously associated with premature ageing in Caspase-2 deficient mice. ~12% of metabolites

showed significant longitudinal associations ( $P < 5 \times 10^{-5}$ ), including classes indicative of both environmental and physiological changes over time. Significant metabolites included environmental toxins, as well as androgenic steroids including dehydroisoandrosterone sulfate (DHEA-S). Metabolite associations were replicated in a sample of 2,000 twins with three timepoints per subject.

Integrative multivariate analyses of gene expression and metabolomic data, together with whole genome sequencing, longitudinal phenotypic data and disease outcomes in TwinsUK are also currently underway.

## PgmNr 3115: Revisiting the start codons for mitochondrial *MT-ATP6*, *MT-ND1* and *MT-ND5* genes.

### Authors:

H. Cui; K. Haude; G. Richard; R.K. Bai

**Affiliation:** Gene Dx, Gaithersburg, Maryland.

The human mitochondrial genome encodes 13 structural subunits of the mitochondrial respiratory chain, 22 tRNAs, and 2 rRNAs. All respiratory chain complexes with the exception of complex II contain components encoded by mitochondrial DNA. Approximately 8000 variants have been reported as sequence variants in the 13 coding genes; among these, 10 unique variants alter non-wobble positions within the start codons of three genes: *MT-ATP6*, *MT-ND1*, and *MT-ND5*. In total, these variants were reported in 746 individuals (PMID: 25489354; <http://www.mitomap.org>). In conjunction with our data from diagnostic mitochondrial genome sequencing, these findings raise doubt on the validity of the assigned start codons of *MT-ATP6*, *MT-ND1* and *MT-ND5* in the Revised Cambridge Reference Sequence (rCRS, GenBank #NC\_012920.1).

A homoplasmic m.8527 A>G variant in *MT-ATP6* has been reported in a patient with suspected mitochondrial disorder (PMID: 14697245). This variant changes the start codon from AUG to GUG (normally coding for valine). However, it was also observed in the healthy mother of the reported patient. This change is seen in two non-anthropoid species and has a global minor allele frequency of 0.45% (208/46,092) (PMID: 25489354, 28510580). We have observed m.8527 A>G in 162 homoplasmic individuals, most of whom are either asymptomatic or have phenotypes that are atypical of mitochondrial disorders. However, variant m.8528 T>C affecting the second nucleotide of the start codon has been published in multiple patients (PMID: 19188198, 26803244) and seen at our lab in a patient with suspected mitochondrial disorder. The next downstream methionine (Met) is distant at p.57, with the second nucleotide of this codon being polymorphic. This cumulative evidence suggests the resulting GUG codon at p.1 is a functional start codon.

In contrast, the start codons of *MT-ND1* and *MT-ND5* are close to the second Met located at p.3. Our lab observed 6 distinct nucleotide changes in these start codons in 629 homoplasmic individuals, including healthy adults. No changes at the non-wobble position of the p.Met3 codon have ever been reported or detected at high heteroplasmy/homoplasmy in our lab. Based on this observation, we suspect that the p.Met3 is more likely to represent the real start codon for the *MT-ND1* and *MT-ND5* genes. Further functional studies and clinical correlation are warranted to fully elucidate the start codon of these two genes.

## PgmNr 3116: The molecular mechanisms by which the *MTTL1* variant mt.3250T>C causes mitochondriopathy.

---

Mitochondrial diseases can be caused by pathogenic mutations in the mitochondrial or the nuclear genome. The *MTTL1* gene is located in the mitochondrial genome (mtDNA) and encodes the mitochondrial tRNA-leucine. The variant mt.3250T>C in the *MTTL1* gene has been previously associated with mitochondrial dysfunction and mitochondriopathy in three families. Males and females were reported to be affected equally, with complete penetrance. Despite efforts to document the phenotypic presentation associated with this variant, the molecular mechanism resulting in disease is yet to be established. Here, we have identified a large, multigenerational family with the mt.3250T>C variant. Next generation sequencing (NGS) was performed on mtDNA from ten individuals (both affected and unaffected) to quantify mt.3250T>C heteroplasmy load. Fibroblast samples were collected from the affected individuals for mitochondrial function studies. In parallel, additional families with the mt.3250T>C variant have been collected and detailed phenotypes were analyzed. In the large, multigenerational family, we identified nine individuals with a medical history of exercise intolerance, chronic fatigue, muscle weakness and elevated lactate levels. Two members of this family passed from sudden cardiomyopathy in early adulthood. Surprisingly, all affected individuals in this family are males, with all female carriers being asymptomatic despite several of them demonstrating homoplasmic or near homoplasmic levels of the mt.3250T>C variant. Additional studies are currently in progress to investigate the molecular mechanisms underlying this sex-based difference in phenotypic penetrance as well as the mechanisms by which the mt.3250T>C variant causes mitochondriopathy.

---

Chronic pain (CP) is defined by the International Association for the Study of Pain as pain without apparent biological value that has persisted beyond normal tissue healing time. CP is estimated to affect 20% of U.S. adults; it affects quality of life, productivity, rates of workplace absenteeism, and has a greater economic impact than other health conditions. It is thus important to understand the progression of pain, and identify those at risk of developing CP. Previous research has unveiled that mitochondria play a role in the acute to chronic pain transition. We sought to further investigate the relationship between mitochondria genome and CP in a cohort of human subjects with at least one of five Complex Persistent Pain Conditions (CPPC): episodic migraines, irritable bowel syndrome, vulvar vestibulitis, temporomandibular disorders, and fibromyalgia. This cohort comprises representative US racial groups, ages 18-64, 85% females, n=752. High-coverage (>100x) mitochondria DNA sequencing from whole blood fractions was performed to determine allele content at each genomic position. We conducted a mitochondria-wide association study on CPPC using PLINK with sex, age, and self-declared race as co-variables. SNP rs28358579 was found significantly associated with fibromyalgia in women after Bonferroni correction ( $P=4.0 \times 10^{-3}$ , OR=2.9, C allele, MAF=6%). This result was replicated in the OPPERA cohort ( $P=2.8 \times 10^{-2}$ , OR=4.2, C allele, MAF=7%). The SNP is located in mitochondrial 16S rRNA and is not listed yet in the OMIM and ClinVar catalogs. In African-Americans the minor C allele for SNP rs28358579 appears at about 20%, when in Caucasians is almost non-existent. We explored the effect of this SNP in immortalized B lymphoblast cell lines made available from the 1,000 genomes project of African-American ancestry subjects. To test the ability of mitochondria to utilize oxidative phosphorylation we measured their inner mitochondrial membrane potential. A total of 20 samples from unique individuals, where half of them had the risk allele, were screened using JC-10 staining followed by 2D flow cytometry. We found that a distinct population of live cells with lower potential was significantly more abundant in samples that carried the C allele. This indicated that mitochondrial function was impaired in cells with the risk allele. Further investigation on the link between CPPC and mitochondrial membrane potential is under way.

## PgmNr 3118: High throughput identification of MCCRP2 genetic modifiers using *Caenorhabditis elegans*.

---

Microcephaly and chorioretinopathy 2 (MCCRP2) is a rare genetic disorder (RGD) due to biallelic loss of function variants in the *PLK4*, a gene that encodes a key regulator of centriole biogenesis. Centrioles are conserved, microtubule-derived organelles, involved in a number of essential processes, such as cell division (centrosomes) and sensation/signaling/motility (cilia). The first five centriole components were identified in *C. elegans*, and their orthologs were later shown to be conserved in other systems, including the *C. elegans* *PLK4* ortholog, ZYG-1 (ZYGote defective/embryonic lethal), a serine/threonine kinase. To establish our high throughput genomics approach to identification of genetic modifiers of MCCRP2, we used the *C. elegans* *zyg-1* mutant strain that results in complete embryonic lethality at restrictive temperature (24.5°C). We performed unbiased forward genetic mutagenesis screens using two different mutagens (e.g. ethyl methanesulfonate and N-ethyl-N-nitrosourea) leading to randomly located predominantly single nucleotide variants. Thus far, we have isolated more than 100 genetic modifiers that suppress the embryonic lethality of the *zyg-1/PLK4* mutant. To expedite the molecular identification of suppressors, we utilized Whole Genome Sequencing (WGS) followed by in-house bioinformatics approaches to call and prioritize the variants according to their effect on genes and biological functions. We show that our approach allowed us to identify candidate suppressor variants in the majority of WGS-tested suppressor genomes shortly after sequencing (~2-4 hours), greatly increasing efficiency over standard approaches. The candidate suppressors are further being validated by Sanger sequencing, segregation analyses and in some instances, CRISPR/Cas9. The majority of the suppressor genomes have a single genetic modifier; however, a subset of genomes were isolated with more complex genetic interactions, where more than one modifier gene was altered by mutagenesis. Notably, the vast majority of the identified modifier genes are conserved in humans, supporting the potential for translatability of our findings to patients with MCCRP2. Importantly, our high-throughput approach to understanding genetic modifiers shows a potential to accelerate the identification of genes and genetic networks not previously implicated in centriole function and thus RGDs like microcephaly, which in turn may enhance diagnosis, prognosis or provide new drug-able targets.

---

Noonan syndrome (NS) is characterized by distinctive craniofacial appearance, short stature, and congenital heart disease. Approximately 80% of individuals with NS harbor mutations in genes whose products are involved in the RAS/mitogen-activating protein kinase (MAPK) pathway. However, the underlying genetic causes in nearly 20% of individuals with NS phenotype remain unexplained. We identified four de novo *RRAS2* variants in three individuals with NS. *RRAS2* is a member of the RAS subfamily, and is ubiquitously expressed. Three variants, c.70\_78dup; p. Gly24\_Gly26dup, c.216A>T; p. Gln72His, and c.215A>T; p. Gln72Leu have been found in cancers; our functional analyses showed that these three changes induced elevated association of RAF1 and that they activated ERK1/2 and ELK1. Notably, prominent activation of ERK1/2 and ELK1 by p. Gln72Leu associates with the severe phenotype of the individual harboring this change. To examine variant pathogenicity *in vivo*, we generated zebrafish models. Larvae overexpressing c.70\_78dup; p. Gly24\_Gly26dup or c.216A>T; p. Gln72His variants, but not wild-type *RRAS2* RNAs, showed craniofacial defects and macrocephaly. The same dose injection of mRNA encoding c.215A>T; p. Gln72Leu caused severe developmental impairments and low dose overexpression of this variant induced craniofacial defects. In contrast, the *RRAS2* c.224T>G; p. Phe75Cys change, located on the same allele with p. Gln72His in an individual with NS, resulted in no aberrant *in vitro* or *in vivo* phenotypes by itself. Together, our findings suggest that activating *RRAS2* mutations can cause NS and expand the involvement of *RRAS2* proto-oncogene to rare germline disorders. The discussion will be made including recent findings from other groups.

## PgmNr 3120: A possible crosstalk disorder between BMP15 and TGF- $\beta$ family ligands and receptors in Mayer-Rokitansky-Küster-Hauser syndrome.

Mayer-Rokitansky-Küster-Hauser syndrome (MRKH) is a rare congenital disease (1/4500 female births) characterized by aplasia of the uterus and upper vagina, in young women with normal secondary sex characteristics and a normal female chromosome formula. Primary amenorrhoea is often indicative of the syndrome. MRKH syndrome can be isolated (type I). However it is most often associated with renal, vertebral, and, less frequently, auditory and cardiac abnormalities (MRKH type II or MURCS association).

Here, we report three clinical observations of girls with primary amenorrhea and for whom ultrasound revealed the absence or very rudimentary appearance of the uterus while the hormonal ovarian function was almost normal. The dysmorphological consultation revealed skeletal anomalies for all patients. The cytogenetic study revealed normal female chromosome formula (46, XX) whereas molecular study by direct sequencing of the two exons of the BMP15 gene, involved in early ovarian insufficiency, revealed the presence of a c.788insTCT / c.852C-T polymorphism of exon 2 of the BMP15 gene in the heterozygous state.

MRKH syndrome has often been reported as sporadic but familial forms have been reported in 20 percent of cases. The pathogenic mechanism of MRKHS may involve gene abnormalities, and there are various case reports associating MRKHS with the Wnt4 gene mutations. Analysis of genes mapped to regions in which deletion and duplication are frequently detected in patients with MRKHS has shown involvement of LHX1, HNF1B and TBX6 genes. We can suggest through our results a possible association between development of female reproductive tract, MRKHS and BMP15 polymorphisms. This association may involve a pathway crosstalk disorder between BMP15 and TGF- $\beta$  family ligands and receptors having many roles in primordial germ-cell development, sexual differentiation, and gonadal cell development.

## PgmNr 3121: VNTRs mediate the expression of genes involved in neurological disorders and familial cancers.

### Authors:

M. Bakhtiari; V. Bafna

**Background.** Variable Number Tandem Repeats have been implicated in multiple Mendelian and Complex disorders (Alzheimer's, Bipolar, familial cancer), usually due to repeating VNTR units regulating gene expression. While similar to short tandem repeats (STRs), VNTRs are harder to genotype due to larger and highly variant repeating units that confound traditional pipelines. Generative methods such as adVNTR (Bakhtiari, Genome Research 2018) now estimate genotypes accurately, but are computationally intensive, and cannot scale to computing genome-wide association with gene-expression and other quantitative traits.

**Method.** We developed a number of algorithmic and statistical strategies to identify VNTR genotypes at scale. Importantly, we designed neural networks that encoded each read based on its k-mer composition, and either assigned the read to a VNTR from a targeted list or discarded it. The filtered reads for each VNTR were then genotyped using adVNTR. Next, we assessed the effect of VNTR genotypes on expression of proximal genes in 27 tissues (GTEx data) after correction for technical co-variates, population structure, and sex of individuals. We used analysis of variance (ANOVA) to show that VNTR genotypes explain more variations in gene expression than nearby SNVs, as well as fine-mapping tool CAVIAR to confirm the causality of each variant, and determine if the VNTR directly mediates expression of the proximal gene in a specific tissue.

**Result.** We chose 13645 VNTRs from promoters, UTRs, and exons that could be genotyped using short-reads. Neural network filtering prior to genotyping using HMMs allowed us to genotype 100 individuals from the GTEx project in 10833 cpu-hours. We identified 435 VNTRs (VNTR eQTL) in 27 tissues with significant association between number of repeats and gene expression ( $p$ -value $<0.05$ ). These candidates were further validated by selecting for the lowest  $p$ -value among all SNPs within 100kb (320 VNTRs), explaining more variation than the top 20 eQTLs (301 variants), and being top-ranked in a statistical fine-mapping analysis of all variants using CAVIAR (298 VNTRs). To our knowledge, only four of the top 30 had previously been identified as causal variants using experimental methods, including *AS3MT* (Li, Nature Medicine, 2016), *HMGA2*, *KCNQ1OT1*, and *TERT*. The identified VNTR eQTLs mediate the expression of many genes with known associations to neurological disorders and familial cancers, illustrating the power of our approach.

## PgmNr 3122: A novel *SHH* variant associated with holoprosencephaly-3 modeled in *Xenopus*.

Holoprosencephaly-3 (HPE-3) is caused by loss-of-function variants in *SHH* and has wide clinical features. Even within families, abnormalities range from normal brain structure to presence of a single ventricle with no interhemispheric fissure and other midline birth defects. However, incomplete penetrance and the inaccessibility of variant-specific functional assays often result in inconclusive genetic diagnoses, especially in the case of inherited missense variants. We used whole exome sequencing to identify a novel variant, R310P, in a fetus with alobar HPE and the unaffected mother, whose mother was determined also to have the variant via Sanger sequencing. To assess the functional effects of R310P of SHH protein, we performed *in vivo* overexpression of WT SHH in *Xenopus tropicalis* and compared this to overexpression of SHH harboring the R310P variant. We analyzed *pax2* and *pax6* expression, as these are regulated by SHH, and found no change in *pax2* or *pax6* expression upon overexpression of the R310P variant, indicating a loss of normal SHH function. Additionally, we overexpressed other previously reported variants to test the accuracy and consistency of this assay. We aim to provide evidence that a *SHH* variant identified in a single family is causative for HPE-spectrum findings over three generations. We also test our hypothesis that *Xenopus* is an effective model for functional characterization of *SHH* variants.

## PgmNr 3123: Mining GWAS hits for therapeutic targets: *In vitro* validation of grip strength modulating genes using cell painting assays for phenotypic screening.

---

Frailty is a significant component of morbidity in old age and a predictor of mortality, although etiology remains unclear. To gain insight into the genetic influences on frailty, we previously performed a GWAS of grip strength (n=448,861) in UK Biobank identifying 208 significant loci and then used a variety of variant-to-gene (V2G) mapping methods (COLOC, IDEASpredict and functional coding variants) to identify putative effector genes at those loci. We identified 230 genes with varying degrees of mapping confidence and set out to use *in vitro* assays in relevant cell types to further resolve effector genes and validate those with potential to augment muscle size and function. Ideally, a good target for muscle frailty of aging would be a gene that generates more mitochondria, enhances growth, supports moderate autophagy and diminishes reactive oxidative stress (ROS) in muscle. To identify targetable genes from our GWAS list, we employed two strategies: first, we generated a 360-compound small molecule library through network analysis to identify interacting proteins, and secondly, we developed a lentiviral shRNA library to knockdown all 230 potential effector genes. We then utilized cell painting assays in both human muscle myotubes and U2OS cells to elucidate the impact of compound and genetic manipulations on mitochondrial morphology, cell growth and size, autophagy and oxidative stress.

Using multiparametric image analysis and Sammon projection mapping to cluster cellular manipulations by phenotypic similarity, we can build upon the GWAS identified target genes to assign biological context and develop integrated pathway maps. For example, an mTOR inhibitor from our compound library resulted in changes to cell morphology (spindly vs round shape), mitochondrial network distribution (punctate), and an increase in the golgi and endosomal network. Following analysis, we identified a second mTOR inhibitor as well as an inhibitor for another gene in the same pathway (S6Kα) that had similar phenotypic changes. This assay and analysis paradigm allow us to define a beneficial cell profile and mine the assay results for genetic manipulations with phenotypic similarity, delineate targets or compounds on the same pathways, and ultimately identify the best targets for therapeutic intervention.

## PgmNr 3124: Transcriptome analysis of single cell RNA-seq from Alzheimer disease admixture block brains: Differences in *APOE* e4 carriers risk conferred to local ancestry.

**Background:** Alzheimer Disease (AD) is the most common neurodegenerative cause of dementia. The apolipoprotein E epsilon 4 (*APOE4*) allele is the strongest genetic risk factor for late-onset Alzheimer Disease (LOAD). However, this risk for AD from *APOE4* is not homogenous between racial backgrounds: Asians > Non-Hispanic Whites (NHW) > African-American (AA). We have previously shown (Rajabli et al 2018) this difference is due to local ancestry surrounding the *APOE* gene. As gene expression can be difficult to interpret due to the cellular heterogeneity of the brain, single nucleus RNA-seq (snRNA-seq) allows us to evaluate cell-specific transcriptional changes that may accompany these risk variation from *APOE4* carriers.

**Methods:** We compared SnRNA-seq of frontal cortex (Brodmann area 9) from brains of homozygote African or NHW local ancestry *APOE4* carriers. Isolation of the nuclei was performed using a sucrose gradient protocol, followed by SnRNA-seq (10X Chromium platform) with analysis using Seurat for potential differences in expression between the samples. For cell-type identification, we used computational pipelines to align the raw sequencing data to a reference human transcriptome including intronic sequences and derive a gene expression matrix of ~22,000 genes across the cells.

**Results:** We obtained data from 5000-8000 nuclei sequenced at a median depth of ~120,000 reads per cell. We detected on average ~800 genes/cell. Transcriptome based resolution of nuclei resulted in similar clusters for African and NHW samples, classified based on previously established cell type specific gene sets as neurons (excitatory and inhibitory), oligodendrocytes, astrocytes, microglia, oligodendrocyte progenitors, and smaller subsets of endothelial and pericyte nuclei. We observed cluster-specific differential expression of *APOE* and differential proportion of a microglia sub-cluster, when comparing African vs NHW samples.

**Conclusions:** SnRNA-seq allows isolation of specific cell types expressing *APOE*, facilitating differential analysis between the *APOE4* local ancestry. This study is unique in its transcriptomic ancestral-specific focus in the identification of molecular pathways playing a role in AD pathogenesis.

## PgmNr 3125: Functional analysis of an Alzheimer disease-associated rare variant in SORL1.

---

Alzheimer's disease (AD) is the most common neurodegenerative disease. In 2015, of the ~47 million individuals with dementia worldwide, AD accounted for 50-70% of these cases. The fundamental mechanisms underlying AD are not fully understood but result from both genetic and environmental components. Over 20 genetic loci have been consistently associated with AD with accumulating evidence points to alterations of the endolysosomal pathway as playing key roles in AD. The sortilin-related receptor 1 (SORL1) gene has been associated with AD through multiple genetic studies and has been suggested to function by guiding APP to the endocytic pathway. We have recently identified a family with multiple AD affected individuals that bear a single base pair deletion (g.4292delG) that is predicted to result in a frameshift alteration and early termination of the protein (p.Cys143Ser\*1). Induced pluripotent stem cells (iPSC) lines were developed to examine the cellular and molecular consequences in neuronal and glial cell (astrocytes and microglia) populations, which can otherwise only be collected postmortem. Each iPSC line generated was validated for pluripotency through immunocytochemical staining and shown to be negative for any large-scale chromosomal abnormalities via karyotyping. In addition, we have generated control iPSC lines that have a single copy of the SORL1 gene knocked out. The patient iPSC lines, the SORL1 knockout iPSC lines, and control lines were differentiated into cortical neurons and glia cells. No difference in the cellular differentiation and growth were observed for the SORL1 cells compared to the control lines. The SORL1 variant bearing and SORL1 genome edited glia cells showed deficits in fibrillary Amyloid beta uptake, while the SORL1 neurons showed elevated production of Ab42 levels. These results support the hypothesis that SORL1 plays a role in endolysosomal trafficking and APP processing.

## PgmNr 3126: Genetic variants control RNA editing rates in Alzheimer disease in diverse populations.

RNA editing, the post-transcriptional modification of RNA bases, is a regulatory feature modulating a variety of physiological processes. We have shown significant differences in the RNA editing rates between Alzheimer disease (AD) cases and cognitively intact controls across diverse ancestral backgrounds, at several specific genomic sites, including some in AD candidate genes (Gardner 2019). Editing QTLs (edQTLs) are genetic variants that influence the rate of RNA editing at a specific site. Whether underlying edQTLs are responsible for a portion of the observed differences in editing AD is unknown. Thus, we examined the correlation of DNA variants with RNA editing levels at sites that are differentially edited between AD and controls. Since genetic effects can differ across ancestries, we tested for edQTLs in both African-American (AA) and non-Hispanic White (NHW) populations.

We performed genome-wide edQTL analysis using whole transcriptome RNA sequencing from peripheral blood of 216 AD cases (105 AA, 111 NHW) and 212 cognitively intact controls (105 AA, 107 NHW), all over age 65. REDIttools software was used to identify editing events and a logistic regression model to identify differentially edited sites. DNA for the same subjects was genotyped on the Infinium Global Screening Array. edQTL mapping was performed using FastQTL adjusting for appropriate covariates. Associations with false discovery rate (FDR) less than 1% were considered significant.

We identified 34,770 and 24,918 edQTLs in AA and NHW, respectively. Interestingly, only 1,810 variants were edQTLs in both ethnicities. A subset of these edQTLs was associated with at least one RNA editing site differentially edited between AD cases and controls. These include edQTLs for sites located in known GWAS implicated AD candidate genes, including *SORL1* and members of the HLA and SLC gene families. In addition to known genetic candidates, we find evidence for genetic regulation of sites in functional AD candidates (e.g. *GAS6*). edQTLs for these candidates appeared at significantly different allele frequencies in cases and controls (Fisher's Exact Test,  $p < 0.05$ ).

Sites in genetic and functional candidate genes have edQTLs that differ in frequency in cases and controls. Furthermore, we found significant differences between edQTLs in AA and NHW, suggesting

ancestry specific background effects of edQTLs. These results imply that edQTLs may modulate functional outcomes of some genetic risk factors for AD.

## PgmNr 3127: Cerebrospinal fluid high-throughput proteomics and Mendelian randomization analyses infer a causal role of CD33 on Alzheimer's disease.

Alzheimer's disease (AD) is a neurodegenerative disease, affecting around 5.8 million people in the United States as of 2019. It has been widely studied and characterized, but there is still no effective treatment. Using large-scale Genome-wide association studies and whole genome/exome sequencing, researchers have identified common and rare variants associated disease risk that can be used to build prediction models. For instance, GWAS have uncovered 25 AD risk loci, including one mapped to the gene *CD33*. Our previous work has shown the importance of employing protein levels in cerebrospinal fluid (CSF) as endophenotypes for genetic studies. These can help the elucidation of the molecular mechanisms for bridging the genomic variation to the disease.

Here, we have profiled 1305 proteins in CSF samples from AD cases and controls. Several known proteins associated with AD risk are included, such as CD33 and 14-3-3 protein. After quality control (QC) for both proteomic and genotype data, we kept 713 proteins and 510 samples. We aim to identify the genetic architecture that governs protein levels and how these proteins modulate AD risk. To do so, we first identified protein quantitative trait loci (pQTLs) from CSF samples passing QC. We employed linear regression models after adjusting for age, gender, two genetic principle components. We identified 82 proteins with cis-pQTLs study-wide significant ( $P < 7.01 \times 10^{-11}$  after Bonferroni correction), replicating 28 previously reported cis-pQTLs from CSF (e.g. rs2673908 associated with the protein Siglec-9,  $P=6.1 \times 10^{-160}$ ) reported by Sasayama et al 2017. We also discovered 54 CSF proteins with novel cis-pQTLs. Furthermore, we performed genome-wide association analyses and discovered 20 proteins with novel trans-pQTLs ( $P < 7.01 \times 10^{-11}$ ). Next, we studied the causal effect of protein levels in AD, by employing Mendelian randomization approaches and employing study-wide significant pQTL as instrumental variables. For example, increased protein level of CD33 elevated AD risk (Wald-ratio test, Beta=0.73,  $P=4.997 \times 10^{-8}$ ), using cis-pQTL (rs3865444,  $P=5.11 \times 10^{-49}$ ) in the two-sample MR analysis. Our results will be useful for both research into the basic mechanisms of protein functions in pathways causing AD and applicable to discovery of novel biomarkers for AD risk.

## PgmNr 3128: Hypomyelinating leukodystrophy: Do heterozygous variants in *HSPD1* deserve a closer look?

---

Heterozygous variants in *HSPD1* (heat-shock 60kDA protein [HSP60]) are associated with adult-onset spastic paraplegia-13. Whereas, biallelic variants cause pediatric-onset hypomyelinating leukodystrophy, also known as mitochondrial HSP60 chaperonopathy. HSP60 participates in the folding and trafficking of proteins into mitochondria and is expressed abundantly in myelin-forming glial cells.

Exome sequencing identified a de novo heterozygous *HSPD1* variant (p.Leu47Val) in a 23-year-old male with consanguineous parents. At 2 years, he presented with progressive ataxia, developmental delay and dysmyelination showing a symmetric tigroid pattern in the centrum semiovale and periventricular white matter on his MRI. He also had ethylmalonic aciduria, with the presence of homozygous variants in *ACADS*, considered to be a benign trait. In silico analyses, immunoblotting and immunofluorescence (IF) were used to determine the predicted impact of the variant, HSP60 protein expression, and subcellular localization. MitoTracker Red CMXRos was used to study mitochondrial morphology and membrane potential. Multiple prediction score across different in silico tools (e.g. CADD, DynaMut, SIFT, Polyphen2) all categorized the variant as pathogenic.

We propose that certain heterozygous variants in *HSPD1* may lead to more severe features resembling the biallelic phenotype, due to a dominant-negative effect or multigenic interactions. IF imaging of HSP60 demonstrated co-localization with mitochondrion as expected. Preliminary findings suggest decreased HSP60 expression and mitochondrial membrane potential in the proband fibroblasts compared to unaffected, age-matched control cell lines. Alterations in membrane potential are highly suggestive of mitochondrial dysfunction. Even as we actively investigate changes in mitochondrial mechanisms and HSP60 protein complex organization in more disease-representative in vitro models such as patient-derived neural precursor cells, these findings highlight the potential mitochondrial contribution to the progressive loss of neural cells and consequent hypomyelination patterns observed in our patient.

## PgmNr 3129: A rescue based screen to functionally assess *de novo* missense variants lined to autism spectrum disorders using *Drosophila*.

---

Autism spectrum disorders (ASDs) are complex neurodevelopmental disorders primarily characterized by varying degrees of impaired social communication, repetitive and restricted behavior patterns and atypical responses to sensory stimuli. While the disease mechanism(s) underlying ASD remain unclear, there is strong support for a substantial genetic component. Large-scale sequencing efforts indicate an overlap in candidate genes and pathways between ASD and a number of Mendelian syndromes with ASD as a feature. However, both disease heterogeneity and an expanding list of candidate genes have made assessing their functional significance a challenge. In attempts to functionally annotate potential disease-causing variants we are conducting a functional screen in flies to analyze ASD candidate genes from the Simon's Simplex collection (SSC). The SSC contains whole-exome sequencing data from 2,500 families with a proband with non-syndromic ASD. The majority of probands possess *de novo* missense variants and approximately 80% of these genes are conserved in *Drosophila*. We have prioritized examination of these variants based upon independent genomic data from non-Autism cohorts, potential gene expression in the CNS, and the availability of *Drosophila* reagents. Accordingly, we have selected 126 *Drosophila* Mi[MIC] lines with insertions in between coding exons for conversion to loss-of-function T2A-GAL4 lines. We successfully converted 111 Mi[MIC] lines to T2A-GAL4 insertions. 62/111 of these T2A-GAL4 lines are homozygous lethal, and rescue experiments using reference and variant UAS human cDNA are currently underway. The remaining 49/111 T2A-GAL4 lines are currently being evaluated for alterations in stereotyped patterns of behavior. Together with the parallel over-expression based screen (see poster by Deal et al.), our rescue based screen provides an assay system to assess the function of human variants linked to ASD and other diseases.

---

Reciprocal genomic disorders (RGDs) involve copy number variation (CNV), including both deletion (DEL) and duplication (DUP), of large genomic segments mediated by flanking duplicated sequence. Though individually rare, RGDs collectively account for 10-15% of broadly defined neurodevelopmental disorders and congenital anomalies. We previously demonstrated widespread, yet diverse and tissue-specific transcriptional changes associated with 16p11.2 RGD across 6 mouse tissues and CRISPR-engineered human neural stem cells (NSCs) and NGN2-induced neurons (iNs). That CNV alters a 740 kb gene-dense region (29 protein coding genes). Here, we compared these results to the transcriptional signatures associated with a larger 1.5 Mb CNV of 15q13.3 that spans only 7 genes (6 with measurable expression in brain) and is associated with variable phenotypes and lower penetrance than 16p11.2. For 15q13.3 analyses, we generated 119 RNASeq libraries across cerebellum, prefrontal cortex, and striatum from mice harboring CNV of the syntenic 7qc region, as well as from isogenic NSCs and iNs. Expression changed linearly with CNV for all 6 genes in the RGD. The only significant pathway changes in the mouse after multiple testing correction were observed in striatum, where differentially expressed genes (DEGs; FDR<0.1) were downregulated across several neuronal pathways, while the most significant pathways observed in the human neuronal models were associated with Wnt signaling in DEL NSCs. Co-expression analyses of brain tissues and cell lines isolated a single recurrent module that included all 15q13.3 genes and was highly enriched for DEGs across all tissues and neuronal models (maximum > 50% of DEGs in cerebellum), as well as modules enriched for constrained genes and genes associated with NDD and autism. Thus, the alterations due to 15q13.3 perturbation were far more modest than 16p11.2, yet more consistent across tissues. We next sought shared molecular pathways across these RGDs using a weighted z-score based meta-analysis in 279 RNAseq samples across the same three mouse tissues and CRISPR models. Significant commonalities between these RGDs converged on genes enriched for myelin sheath and dendritic function, as well as genes involved in mitochondrial respiratory chain function (FDR<0.1). These results suggest the pathogenic mechanisms associated with recurrent RGDs may converge on common molecular signatures, including changes in neuronal function and cellular respiration.

## PgmNr 3131: Quantifying genetic variability within intrinsically disordered regions of proteins.

Characterizing the impact of genetic variants is not only important for defining the etiology of complex traits and diseases, but identifying new drug targets as well. Due to their clear potential for impacting a phenotype, coding regions are often targeted first when searching for disease causing variants or potential pharmacogenetic interactions. However, even after applying methods that characterize single nucleotide variants (SNVs) based on evolutionary constraint, population frequency, gene regulatory properties, and potential pathogenicity, many variants of unknown significance remain. One reason this problem may exist is due to SNV annotation methods over emphasizing the utility of structured protein regions that maintain a stable three-dimensional shape, when there has been growing awareness to the vital functions of intrinsically disordered regions (IDRs). Moreover, pathogenic SNV predictions often underperform in IDRs, suggesting that refining our understanding of these regions could improve our ability to identifying pathogenic variants. IDRs do not conform to a defined three-dimensional shape and are critical for cell signaling and gene regulatory processes. Furthermore, IDRs represent a keystone of an emergent property of the cell to generate membraneless organelles (e.g. liquid-liquid phase separation) for compartmentalizing biochemical processes. While IDRs tend to evolve more rapidly than more structured regions of proteins, there is evidence of purifying selection associated with functional regions within the IDRs. We hypothesize, that the identification of these functional regions with purifying selection can inform the interpretation of the impact genetic variants have on phenotypes. We designed a workflow to identify regions in the genome that code for IDRs and functional regions that reside within them. Next, we used BioBin, a program for rare variant binning, to count low-frequency and rare variants in disordered regions using 1000 genomes data. By comparing the ratio of non-synonymous to synonymous SNVs at a global level in the entire IDR compared to functional regions within the IDR we can capture the substitution rate that occurs across the genome. This approach was applied across individuals of diverse backgrounds as a proof of concept study for later testing in Alzheimer's disease cohorts. This study presents a new strategy for studying the genetic etiology of disease by investigating disordered regions of proteins.

## PgmNr 3132: Is juvenile absence epilepsy with photosensitivity related to de novo LoF variant in *CIC* gene and folate deficiency?

### Authors:

---

Low concentration of 5-methyltetrahydrofolate (5-MTHF) in cerebrospinal fluid is associated with cerebral folate deficiency (CFD) syndrome, while folate levels in plasma are within the normal range. Mutations in several folate pathway genes (*FOLR1*, *DHFR* and *PCFT*) have been previously identified in CFD patients. Recently, some CFD cases with milder phenotype have been related to de novo mutation in human capicua (*CIC*) gene. Developmental delay and intellectual disabilities are the common characteristics with or without epilepsy.

Here we report a 14 year old girl, who manifested juvenile absence epilepsy and EEG photosensitivity two years ago. Since then she is on Valproic Acid treatment (1000 mg per day) with excellent response and no absences any more. She has no mental retardation, no behavioral problems, no developmental delay. In order to clarify the genetic cause of the juvenile absence epilepsy we performed array-CGH and whole exome sequencing (WES). The array-CGH showed normal results, while WES discovered a de novo frameshift mutation c.2414delC, p.Pro805GlnfsTer119 in the human Capicua gene (*CIC*). The mutation was confirmed by Sanger sequencing. The biochemical parameters in blood are: folic acid 12.0 to 22.0 nmol/l, ref. value 10.4 - 42.4. At the same time B12 was measured above the upper limit of the range: 684 pmol/l - ref. values 145-569. Moreover, MCH and MCV showed increased values in several blood tests (MCH 34 pg, ref. values 26.0-32.0; MCV 104 fl, ref. values 80.0-97.0), which corresponds to vitamin B12 and/or folic acid deficiency.

Could we consider the above mentioned results in blood as a marker for folic acid deficiency in cerebrospinal fluid and how it refers to the brain? Is it possible the higher B12 concentration to result from folic acid deficiency? Is the *CIC* gene loss-of-function (LoF) variant a disease causing in our case and why the clinical manifestation does not fit to the already published cases?

## PgmNr 3133: Exploiting *Drosophila* to examine RNA exosome-linked disease.

---

The RNA exosome is an evolutionary-conserved 3'-5' ribonuclease complex critically important for both precise processing and complete degradation of a variety of cellular RNAs. Given, the crucial role of the RNA exosome in post-transcriptional regulation of RNA, it is not surprising that the complex is essential in systems examined thus far. The recent discovery that mutations in genes encoding structural exosome subunits cause tissue-specific diseases makes defining the role of the RNA exosome within specific tissues critically important to understand the basis of these diseases. The *Drosophila* system provides ideal tools to examine tissue-specific gene function. Mutations in the RNA exosome subunit 3 gene (*EXOSC3*) cause Pontocerebellar Hypoplasia Type 1b, an autosomal recessive neurodegenerative disease. The disease-causing mutations identified are missense mutations in evolutionarily-conserved amino acids. The tissue-specific defects these changes cause are challenging to understand based on current models of RNA exosome function with only limited analysis of the complex in any multicellular model *in vivo*. The goal of this study is to provide insight into how mutations in *EXOSC3* impact the function of the RNA exosome leading to disease. *EXOSC3* is an evolutionarily conserved subunit, termed Rrp40 in *Drosophila*. To begin to determine the functional consequences of the specific amino acid substitutions that cause disease in humans, we developed a model of RNA exosome-linked disease in *Drosophila* utilizing CRISPR/Cas9 gene editing to introduce disease-linked mutations in *Rrp40* (*EXOSC3*). Preliminary data examining disease-linked amino acid substitutions in Rrp40 of differing severity reveal behavioral and morphological phenotypes that align with disease severity found in patients. Next, we performed RNA-Seq analysis to define the spectrum of RNA targets affected. Principal component analysis revealed that PCH1b-linked alleles in flies segregated into distinct molecular groups based on their gene expression profiles. Gene expression patterns among the PCH1b mutants highlight large-scale differences in lncRNAs and mRNAs in each PCH1b-mutant providing a molecular basis for the phenotypes observed. These data provide evidence that the *Drosophila* model can be used to provide insight into tissue-specific function of the RNA exosome *in vivo* and explore the functional consequences of amino acid substitutions linked to disease phenotypes.

---

The transport protein particle (TRAPP) complexes regulate key trafficking events and are required for autophagy. TRAPPC4 is a core component of the TRAPP complexes and one of the essential subunits in GEF activity. Pathogenic variants in specific TRAPP subunits are associated with neurological disorders. In an effort to determine the genetic etiology, we undertook exome sequencing (ES) in three unrelated families of different ethnicities with seven affected children with features of early onset seizures, developmental delay, microcephaly, sensorineural deafness, spastic quadriplegia and progressive cortical and cerebellar atrophy. In all seven affected individuals we identified a rare homozygous variant in a non-canonical well-conserved splice site within *TRAPPC4* (hg19:chr11:g.118890966A>G; *TRAPPC4*: NM\_016146; c.454+3A>G). Haplotype analysis is in progress. *In silico* analysis predicted the variant to cause aberrant splicing. Consistent with this, experimentally we showed both a reduction in full-length transcript and a shorter transcript missing exon 3, suggestive of an incompletely penetrant splicing defect. TRAPPC4 protein levels were

significantly reduced whilst levels of other TRAPP complex subunits were unaffected. Native PAGE and size exclusion chromatography demonstrated a defect in TRAPP complex assembly and/or stability. Intracellular trafficking through the Golgi using the marker protein VSVG-GFP-ts045 demonstrated significantly delayed entry and exit from the Golgi in patient fibroblasts. Lentiviral expression of wildtype *TRAPPC4* in patient fibroblasts restored trafficking, suggesting that the trafficking defect was due to reduced *TRAPPC4* levels. Consistent with the recent association of the TRAPP complex in autophagy, we found that patient fibroblasts had a basal autophagy defect and a delay in autophagic flux, likely due to unsealed autophagosomes. These results were validated using a yeast *trs23* temperature sensitive mutation that exhibits constitutive and stress-induced autophagic defects at permissive temperature and a secretory defect at restrictive temperature. We provide evidence for a disease-association mutation in a member of the core TRAPP subunit, *TRAPPC4* that is associated with an autophagy defect. Our findings add to the growing number of TRAPP-associated neurological disorders.

## PgmNr 3135: A holoprosencephaly-associated transmembrane domain mutation of human SMOOTHENED (SMO) leads to hypomorphic activity for forebrain and craniofacial development in a zebrafish model.

### Authors:

**Background and purpose:** Holoprosencephaly (HPE) is the most common congenital anomaly of the forebrain and face in humans. Sonic hedgehog (SHH) is one of the best characterized HPE genes, and its signaling pathway plays crucial roles in numerous developmental processes including craniofacial development and neurogenesis. However, the disease-related roles of *SMO* genetic variation are largely unknown. We now report functional testing of seven non-synonymous variants of *SMO* derived from HPE molecular and clinical data. Here we characterize human *SMO* variants function by a novel zebrafish rescue assay and systems biology analysis.

**Materials and methods:** For our rescue assay, *SMO* synthetic mRNA (WT\_*SMO*) or each variant's site-directed metagenesis *SMO* mRNA (SDM\_*SMO*) was injected separately into fertilized one cell stage of CRISPR/Cas9 *smo* K/O zebrafish embryos. The phenotype and genotype were analyzed after injection. In our systems biological assay, co-injection of wild-type zebrafish with small doses of SHH was effective in modulating the ability of endogenous zebrafish *Ptch* to inhibit injected human WT\_*SMO*. Therefore, this approach was adopted for each variants SDM\_*SMO*.

**Results:** We determined that WT\_*SMO* and many of its variants could rescue the abnormal phenotype of *smo* K/O fish. Interestingly, the overall rescue pattern was different for each variant. There were three types of phenotypic rescue: 1) complete, 2) mainly eye, or 3) mainly body. Three variants partially rescued ( $P < 0.01$ ), and only one variant, with a mutation point in the transmembrane domain, was a strong hypomorph ( $P < 0.01$ ). Co-injection of SHH with each SDM\_*SMO* independently replicated these findings based on our analysis of the over-expression phenotypic severity and modulation of eye development-related gene expression by *in situ* hybridization; however, these effects were only modestly different between each variant compared to WT\_*SMO*.

**Conclusion:** Our results reveal that variants in human *SMO* may be modifiers of brain and craniofacial development and implicate in the transmembrane domain. We conclude that the disease genes should not always be studied in isolation; rather the molecular pathway interactions should be incorporated into biological assay development and interpretation. In summary, we have characterized the role of the *SMO* locus in forebrain and craniofacial development and infer that the trans-membrane domain is crucial for normal function.

## PgmNr 3136: Humanized *STXBP1* animal models as a precision medicine approach to detecting pathogenicity in clinical variants.

Functional data on clinical variants addresses a growing problem in genomic data. Approx. 75% the variant entries in public databases are either unknown or VUS for their pathogenic consequence. Functional data is a significant contributor to pathogenicity assessment (PS3). Yet, even in cases where pathogenicity is known, clinicians and patients are often unsure of which therapeutics offer the best treatment for the specific variant. In response to these needs, our group has created a series of humanized animal models as Clinical Avatars for functional assessment and therapeutic best-fit discovery. CRISPR-based methods are used to insert human coding sequence as a gene replacement in *C. elegans*. When the human gene restores normal function in *C. elegans*, the system is ready for variant installation. In a demonstration with an epilepsy-associated gene, the human *STXBP1* coding sequence was inserted as gene replacement of *unc-18*. Next, a series of clinically-observed variants were installed in the hSTXBP1 humanized loci. Finally, change-of-function activity was quantified using a series of functional assays. CRISPR-based knock-out of *unc-18* results in loss of function characterized by uncoordinated movement. CRISPR-based knock-in of hSTXBP1 led to a rescue of function. Rescue of activity was observed to be complete (100%) by electrophysiology (up 4x from *unc-18* KO), 100% in liquid 'thrashing' assays for movement (up 3x), and 50% in a chemotaxis behavioral assay (up from 0%). Variants installed into hSTXBP1 locus showed a range of functional defects. For instance, selected variants of p.R292H (rs796053361 P), p.R406H (rs886041246 P) and p.R388X (rs121918321 P) are established pathogenic variants in *STXBP1* known to be autosomal dominant. Heterozygotes were examined in a modified chemotaxis assay for deficiencies in motivated behavior. The p.R388X variant creates a two-thirds truncation of STXBP1 protein and a dominant negative activity was observed in the heterozygote - approximately 3 fold more severe than a heterozygote with full gene KO. Variant activity profiling is revealing that gene function defects can be quantitatively measured in the nematode animal model. Larger sets of *STXBP1* variants (including VUS alleles) are in preparation. Drug testing is being implemented for pathogenic variants to find out which antiepileptic drugs (AED) are the therapeutic best fit for the variant-specific condition of *STXBP1* patients.

## PgmNr 3137: Clinical exome sequencing reveals KLHL40 mutation associated with cleft palate, severe nemaline myopathy, and fetal akinesia.

### Introduction

Congenital myopathies are heterogeneous group of neuromuscular disorders and characterised by hypotonia early onset muscular weakness, developmental delay. Congenital myopathies are classified into centranuclear myopathies, nemaline myopathies, core myopathies and congenital fiber-type disproportion based on major pathological features found in muscle biopsies.

### Material and Methods

The present study was conducted on 25 syndromic orofacial cleft patients present with different clinical features. After clinical evaluation, genomic DNA was extracted by standard protocol (Qiagen kit). Clinical exome sequencing (illumina platform) was performed in patient DNA sample and sequencing data was analysed for sequence variant and identified variant validation was done by Sanger sequencing method.

### Results

A homozygous nonsense variant in exon 1 of the KLHL40 gene (chr3:42727712G>A: Depth 53x) that results in a stop codon and premature truncation of the protein at codon 201 (p.Trp201Ter; ENST00000329777) was detected.

### Conclusion

This study suggest the involvement of KLHL40 mutation with fetal akinesia and severe nemaline myopathies, also associated with cleft palate. At present scenario there is no evidence which recognize that cleft palate associated with severe nemaline myopathies and fetal akinesia.

## PgmNr 3138: Genetic recapitulation and functional annotation of frequently mutated genes in myopathy.

---

In clinical exome-based variant identification for molecular diagnosis, researchers have encountered frequently mutated genes (FLAGS) with genetic variants of uncertain significance or as exome negatives. It has recurrently emerged as one of the contentious issues. However, regulatory functional implications of the FLAGS have still not been fully considered in rare genetic diseases. To evaluate the relevance of the FLAGS in myopathy, we conducted genetic recapitulation and comprehensive functional annotation. In seventeen trio-based whole exome analyses, we found that twenty putative genes intersected with the FLAGS. Using an integrative genetic-epigenetic approach, we demonstrated that epivariations were associated with regulatory changes underlying gene expression, DNA methylation, histone modification and open chromatin accessibility. Taken together, the twenty FLAGS genes may serve as a potential target in myopathy. Our findings might provide additional insight into understanding variable expressivity in rare diseases.

## PgmNr 3139: eQTL analysis in brain cortex samples of 3,833 individuals and 31,684 blood samples reveals distinct regulatory effects of disease-associated genetic variants.

Many studies have shown how genetic variation affects gene expression (expression quantitative trait loci; eQTL), with the aim to identify the molecular downstream consequences of genetic risk factors for disease. However, since eQTL effect sizes are usually small, large sample-sizes are required to uncover both *cis*- and *trans*-eQTLs. We therefore performed a very large-scale eQTL meta-analysis in brain, encompassing 8,654 RNA-seq samples obtained from AMP-AD, Braineac, TargetALS, CMC, GTEx, PsychEncode and public ENA resources, using the same eQTL analysis procedure as eQTLgen. To study both *cis*- and *trans*-eQTL, we rigorously harmonized the brain RNA-seq and genotype data permitting us to study 3,833 unique individuals of European descent. Out of 19,844 tested protein-coding genes, 11,942 were *cis*-eQTL genes (*cis*-eGenes) and 713 were *trans*-eQTLs genes (FDR<0.05).

We contrasted these brain eQTLs to eQTLgen, a large-scale eQTL analysis in blood samples from 31,684 individuals. We observed that *cis*-eQTLs are often unique to either brain or blood: of the 16,989 *cis*-eGenes in blood and 11,942 *cis*-eGenes in brain, 9,017 showed a significant effect in both tissues, yet 17% showed an opposite allelic direction for the SNP with the largest eQTL effect in eQTLgen (lead eSNP). While the majority of these opposite effects are potentially explained by imperfect linkage, the eQTLgen lead eSNP was also the lead eSNP in brain for 26 of these genes, suggesting tissue dependent regulation. Finally, we observed that highly expressed genes in brain are proportionally less likely to be regulated in *cis* than medium expressed genes in blood.

We subsequently compared the overlap of *cis* and *trans*-eQTL that we found in blood and brain with GWAS associated SNPs. We observed that *trans*-eQTL analysis in brain is informative for SNPs, associated to neurological disorders: we observed a significant enrichment of *trans*-eQTL signals in brain ( $P=7.6 \times 10^{-3}$ ), whereas we did not find any *trans*-eQTL enrichment in blood ( $P = 1$ ).

Our eQTL results provide a context-specific resource that can assist in fine-mapping and SNP prioritization for neurological disorders. We show the importance of large scale eQTL meta-analysis in brain by identifying genetic regulators that either cannot be found in blood or have a different direction of effect.

## PgmNr 3140: RNA binding of FMRP that is related to Fragile X syndrome may play an important role in neurite formation.

### Authors:

H. Shimizu; E. Suzuki; H. Hohjoh

[View Session](#) [Add to Schedule](#)

**Affiliation:** Department of Molecular Pharmacology, National Institute of Neuroscience, National Center of Neurology and Psychiatry, Tokyo, Japan

---

Fragile X syndrome (FXS) is an inherited disorder caused by mutant Fragile X mental retardation gene 1 (*FMR1*) carrying aberrantly expanded CGG triplet repeats: aberrant CGG repeats inhibit the expression of *FMR1*. *FMR1* encodes fragile X mental retardation protein (FMRP) that is a RNA binding protein, and involved in the stabilization and translation of its bound mRNAs. FMRP is present in dendrites and dendritic spines of neurons and plays an important role in the local translation of mRNAs, which contributes to neuronal development and synaptic function. Some FXS patients show similar characteristics of autism spectrum disorder (ASD), a developmental disorder: they exhibit changes in neurite outgrowth and dendritic spine formation. Immature dendritic spines were detected in FXS model mice, and the decrease in dendritic spines and the reduction of basal dendrite length and branching were observed in visual cortex pyramidal neurons of *Fmr1* knockout mice. Thus, FXS appears to be somehow associated with neurite formation, but is not yet well understood. In this study, to see the effects of *Fmr1* (FMRP) on process formation, we generated two lines of mouse neuroblastoma Neuro2a (N2a) cells in which *Fmr1* were knocked out by gene editing using CRISPR-Cas9. The two N2a cell lines showed little or no expression of FMRP by western blotting; and interestingly, they exhibited severe impairment of process formation under differentiation conditions. When the expression plasmid encoding full-length FMRP was introduced into *Fmr1*-deficient N2a cells, the cells restored their ability of process formation. In contrast, when mutant FMRP lacking RNA binding was introduced to *Fmr1*-deficient N2a cells, the resulting cells showed little improvement in process formation. Therefore, the findings suggest that FMRP, which is encoded by *Fmr1* related to FXS, is involved in process (neurite) formation, and that RNA binding of FMRP may play an important role in process formation. We are trying to isolate candidate RNAs associated with FMRP and involved in process formation.

---

With the large number of genes implicated in neurodevelopmental disorders (NDDs), it is unlikely that each has a unique molecular pathogenesis. Variation in gene families likely results in shared clinical spectrums due to shared molecular pathology that may allow for targeted therapies. To identify gene families that fit this model, we assessed 10927 published exomes of patients with NDDs, highlighting the heterogeneous ribonucleoproteins (hnRNPs), a large family involved in RNA processing, as a family with significantly more *de novo* likely gene-disruptive (LGD) variants than expected. With further investigation of our targeted sequencing data from an additional 20990 probands, combined with clinical sequencing data generated from Baylor Genetics Laboratories and GeneDx, collaborations through GeneMatcher and Geno2MP, as well as the literature (in total, 64393 individuals), we have identified 140 patients carrying hnRNP variations. Nine hnRNPs (hnRNPU, K, H2, R, Q, UL1, D, F, A2B1) were identified in our initial dataset, three of which met genome-wide significance ( $p < 4.2 \times 10^{-7}$ ) for LGD variants using the union of two statistical models, four having

nominal significance for LGD variants ( $p < 0.05$ ), and one reaching significance for missense variants. Our NDD cohort has significantly higher burden of hnRNP variants compared to gnomAD, supporting their pathogenicity. Clinically, we have found a shared spectrum of intellectual disability/developmental delay, autism spectrum disorder, and MRI abnormalities, with hnRNPs of higher similarity having more shared phenotypes.

Functionally, human fetal single-cell transcriptomic data shows high levels of expression of these NDD-related hnRNPs among excitatory neurons, radial glia, ventral progenitor cells, and intermediate progenitor cells, with decreased expression among inhibitory and newborn neurons. This shared expression is notable, as hnRNPs are implicated in many processes, including neuronal development, and often work cooperatively. Using Cas9 gene-edited induced pluripotent stem cells and differentiated neuronal and glial cells, we are investigating functional consequences of patient informed variants, identifying changes in cell viability/proliferation, neuronal morphology and activity, as well as hnRNP-specific functionality, including effects on splicing and binding targets (via CLIP-seq) and expression (via RNA-seq and ribosome profiling), as well as RNA/protein trafficking.

## PgmNr 3142: Neonatal lethality and genetic modifiers in a new mouse model of Niemann-Pick disease type C.

Niemann-Pick Disease, Type C (NPC) is a rare, fatal neurodegenerative disorder characterized by lysosomal accumulation of unesterified cholesterol and sphingolipids. These subcellular pathologies eventually cause phenotypes of hepatosplenomegaly and neurological degeneration leading to premature death. NPC is extremely heterogeneous in the timing of clinical presentation (prenatal to adulthood) and is associated with a wide spectrum of causative *NPC1* mutations. Miglustat (Zavesca) is the only approved therapy for NPC, and while it has been shown to improve clinical outcomes it is not a cure. To study the genetic architecture of NPC, including the clinical and genetic heterogeneity seen in this patient population, we have generated a new mouse model (*Npc1*<sup>em1Pav</sup>). Using this model, we identified strain-specific quantitative trait loci (QTL) affecting lifespan and characterized a novel lung phenotype causing neonatal lethality. Interestingly, *Npc1*<sup>em1Pav</sup> mutants on a C57BL/6J (B6J) genetic background had a more severe visceral pathology of foam cell accumulation than *Npc1*<sup>em1Pav</sup> mutants on a BALB/cJ background. These underlying pathological changes translated into B6J mutants having a significantly shorter lifespan ( $70 \pm 4.30$  days) than mutants on a BALB/cJ background ( $84 \pm 7.25$ ;  $p < 0.0001$ ), suggesting strain-specific modifiers contribute to disease severity. QTL analysis of backcross N2 mutants detected significant linkage to markers on chromosomes 1 (LOD=5.57) and 7 (LOD=8.91). Analysis of predicted deleterious sequence variants between B6J and BALB/cJ strains at these two loci resulted in a short list of candidate genes that can now be evaluated as potential modifiers of NPC severity and progression.

A significant reduction of viable *Npc1*<sup>em1Pav</sup> mice was also observed on the B6J background at Postnatal day 10 (P10) (10.5% vs. 25%,  $p < 0.0001$ ). Interestingly, the expected genotype frequency was observed at E18.5-E19.5 (26.5% vs. 25%,  $p = 0.034$ ) suggesting *Npc1*<sup>em1Pav</sup> mutants exhibit a previously uncharacterized lethal phenotype postnatally. C-sections accompanied by maternal fostering confirmed that the majority of *Npc1*<sup>em1Pav</sup> mutants died shortly after birth showing signs of respiratory insufficiency and abnormal surfactant pathology. A similar phenomenon reported in NPC patients with pre/perinatal onset indicates *Npc1*<sup>em1Pav</sup> may be the first valid animal model of this severely affected group.

---

Rett Syndrome (RTT) is a severe neurodevelopmental disorder that is mainly caused by mutations in the methyl-CpG-binding (*MECP2*) gene; however, between 5 – 40% of classical and atypical RTT patients do not have a genetic diagnosis. Classical RTT patients exhibit normal development until 6 -18 months of age after which developmental regression occurs. Moreover, patients develop characteristic abnormal hand movements, a hallmark of classical RTT. Atypical RTT patients have many features of classical RTT but do not meet all of the specific diagnostic criteria. There is an unmet need to provide a precise genetic diagnosis for these patients. To this end we have performed singleton genomic analysis on 40 of a cohort of 80 genetically undiagnosed RTT/RTT-like patients. To date, we have obtained a likely genetic diagnosis for 12 cases and identified 5 genes, including 2 novel candidate genes, potentially associated with RTT. We have identified a *de novo* heterozygous missense variant (c.744C>A; p.Asp248Glu) in the motor domain of kinesin-3 family member 1A

(*KIF1A*), which encodes a neuron-specific kinesin motor protein essential for ATP-dependent anterograde axonal transport of synaptic cargos. Through international collaborations, we have now identified 18 different heterozygous *KIF1A* variants in 25 patients with many clinical features seen in RTT including ataxia, spasticity, hypertonia, seizures and gait disturbances. All of these variants are within the highly conserved motor domain, and 11 variants are novel. *In-silico* tools predict all these variants to be pathogenic, and 3D molecular modelling predicts disrupted ATP hydrolysis and/or cycling rate. For 4 of the novel variants, we determined that the ability of mCitrine-tagged KIF1A-motor domain proteins to accumulate in neurite tips of differentiated SH-SY5Y cells is reduced by > 90-95% ( $p < 0.0001$ ) compared to the wild type protein. This suggests the variants prevent the movement of KIF1A along microtubules. Complementary studies using live-cell single-molecule KIF1A tracking, *in vitro* microtubule gliding assays and kinetic ATPase assays to determine variants' effect on KIF1A motor activity are under way. We are generating iPSC from patient's fibroblasts along with CRISPR/Cas-9 gene corrected controls to examine KIF1A-specific cargo trafficking defects in neurons. This work has identified a potentially novel disease-causing gene in RTT/ RTT-like patients which may be tractable to future targeted therapies.

## **PgmNr 3144: Constitutive activation of mTORC1 signaling induced by biallelic loss-of-function mutations in *SZT2* underlies a discernible neurodevelopmental disease.**

---

There have been increasing number of reports of *SZT2*-related neurological diseases, the main symptoms of which are epilepsy, developmental delay, macrocephaly and a dysmorphic corpus callosum. *SZT2* functions as a regulator of mechanistic target of rapamycin complex 1 (mTORC1) signaling in cultured human cell lines and mouse tissues. However, it remains to be determined whether mutations in *SZT2* in human patients alter mTORC1 signaling. In this study, we aimed to investigate the functional consequence of biallelic *SZT2* variants in Epstein-Barr virus-induced lymphoblastoid cell lines (LCLs) established from two patients with a typical *SZT2*-related neurodevelopmental disease. Increased phosphorylation of S6 kinase and S6 was identified in patient-derived cell lines under amino acid-starved condition, suggestive of constitutive hyperactivation of mTORC1 signaling. This result was validated by constitutive lysosomal localization of mTOR in patients' LCLs. Furthermore, patients' LCLs display an excessive response to slight amino acid stimulation. Our data suggest the loss-of-function nature of *SZT2* mutations in the patients, and consequent hyperactivation of mTORC1 signaling in response to both amino acid starvation and stimulation in their LCLs. By these functional analyses, the pathogenicity of newly identified *SZT2* variants can be determined, allowing for more detailed characterization of genotype-phenotype correlations.

## PgmNr 3145: Somatic L1 retrotransposition in cortical neurons and non-brain tissues of Rett patients and healthy individuals.

---

Somatic mosaicism results from genetic variations that occur in the somatic cells during the development and aging process of the human body. Retrotransposon is a major source of genetic variation, jumping in the human genome in a copy-and-paste manner via TPRT-mediated retrotransposition. Mounting evidence supports that human-specific LINE-1 (L1s) can retrotranspose postzygotically in human tissues and contribute to intra-individual genetic diversity. However, the genomic distribution, rate, accumulation, and selective pressure of somatic L1s insertions and their potential impact on carrier cells remain largely unclear.

Here, we developed HAT-seq (human active transposon sequencing), the first PCR-based bulk sequencing method capable of identifying rare somatic insertions in a small fraction of cells—even unique cells—from non-tumor human tissues. We profiled 9,181 somatic L1s insertions from 20 postmortem tissues obtained from five Rett patients and five matched healthy controls. Low-level clonal somatic insertions from both cortical neurons and non-brain tissues were thoroughly characterized using the 3' and 5' L1-genome junctions resolved by nested PCR and Sanger sequencing. To our knowledge, for the first time we reported somatic insertions in non-brain tissues of healthy individuals. In Rett patients, somatic insertions were significantly depleted in exons—mainly contributed by long genes—than healthy controls, implying that cells carrying *MECP2* mutations might be defenseless against a second exonic L1s insertion. We observed a significant increase of somatic L1s insertions in the brain compared with non-brain tissues from the same individual. Compared to germline insertions, somatic insertions were less sense-depleted to transcripts, indicating that they underwent weaker selective pressure on the orientation of insertion. When comparing Rett patients with matched healthy controls, we only observed a slight but not significant increase of somatic L1s insertion rate in the Rett group.

In conclusion, our results demonstrate that, in addition to neuronal cells, endogenous L1Hs could retrotranspose in a variety of non-brain tissues and contributes to the inter-cellular genomic diversity. We estimated the rate of somatic L1Hs insertions to be 0.38–1 per PFC neuron and 0.21–0.43 per non-brain cell in healthy individuals. Under pathological condition, MeCP2 dysfunction alters the genomic distribution of L1Hs retrotransposition in Rett patients.

## PgmNr 3146: A novel mutation in *MYBPC1* is associated with mild myopathy and tremor.

*MYBPC1* encodes the slow skeletal Myosin Binding Protein-C protein (sMyBP-C), which belongs to a family of sarcomeric accessory proteins with a major role in the regulation of cross-bridge cycling. sMyBP-C is expressed in both slow and fast twitch skeletal muscles, is highly modular, and plays both structural and regulatory roles.

Here we describe a three-generation family with a skeletal myopathy characterized by muscle weakness, hypotonia, skeletal deformities and spinal rigidity, accompanied by tremor. Exome sequencing analysis of four family member samples revealed the presence of a novel dominant missense mutation in the *MYBPC1* gene, c.742G>A p.E248K. The E248K mutation is located in a highly conserved linker region within the NH<sub>2</sub>-terminus of the molecule. Several *in silico* prognostic tools classify this mutation as deleterious. *In vitro* binding assays using wild type and mutant NH<sub>2</sub>-terminal sMyBP-C proteins revealed that the presence of the E248K mutation results in markedly increased binding to heavy meromyosin (HMM; ~3.5-fold) compared to wild type protein.

Our findings expand the phenotypic spectrum caused by alterations in the *MYBPC1* gene, which were previously associated exclusively with severe and lethal forms of distal arthrogryposis. Based on the familial segregation, absence from the general population, *in-silico* assessment, and altered binding properties of the E248K mutant protein, we can classify it as pathogenic by ACMG guidelines.

To evaluate the impact of the E248K mutation, we used CRISPR technology to generate the respective knock-in mouse model. Our studies show that the E248K mouse model faithfully recapitulates the myopathic phenotype and disease progression observed in patients. While homozygous mice exhibit neonatal lethality, heterozygous mice are significantly smaller, develop tremor, and exhibit behavioral, morphological and contractile deficits compared to their wild-type littermates.

## PgmNr 3147: *Clec16a* knockout compromises autophagy and mitophagy and facilitates ER stress-induced inflammation and neurodegeneration.

### Authors:

Recent studies revealed that CLEC16A is an important regulator of autophagy/mitophagy. Given its association with several autoimmune disorders, we generated an inducible global knockout (KO), *Clec16a*<sup>AUBC</sup> mice to investigate its role in autoimmunity. KO mice exhibited immune dysfunction, severe weight loss through lipolysis, and a neuronal phenotype with an increase in severity over time leading to morbidity. As observed previously, attenuation of CLEC16A disrupted autophagy, mitophagy and caused neurodegeneration. Accelerated mitophagy in cerebellum, cortex, trigeminal ganglia, dorsal root ganglia, and spinal cord was observed in KO mice as compared to control mice. ER stress and mitochondrial dysfunction results in increased oxidative stress and production of multiple proinflammatory mediators. Dysregulated OXPHOS signaling was observed in DRG's and splenic lysates of the *Clec16a*<sup>AUBC</sup> KO mice. KO mice also exhibited an inflammatory cytokine/chemokine profile. KO displayed elevated antibody levels, including IgM, IgA, Ig2b, IgG3 and autoantibodies in sera.

While treatment with a JAK/STAT inhibitor (tofacitinib) partially rescued the lipodystrophic phenotype and improved survival, it only rescued the autophagy in neuronal tissues and did not alter the neuronal phenotype. STAT proteins in neuronal tissues showed no significant change with tofacitinib-treatment as compared to untreated *Clec16a*<sup>AUBC</sup> KO mice. This may be due to the negative feedback loop associated with JAK/STAT/SOC1 signaling.

Our data indicate loss of function variants in *CLEC16A* that are associated with decreased CLEC16A levels may contribute to autoimmunity through elevated ER Stress resulting in dysregulated mitophagy and autophagy, which contributes to adipose lipolysis and production of inflammatory mediators. Drugs modulating ER stress, mitophagy/ autophagy or the JAK/STAT pathway partially reverse the process and may be effective in treating and preventing symptoms of autoimmune disorders in individuals with risk associated *CLEC16A* variants. A combination of such drugs may be optimal for this.

## PgmNr 3148: Unravelling the mechanism underlying *IRF2BPL* in a neurodevelopmental disorder with regression, abnormal movements, loss of speech, and seizures.

---

We recently identified 7 individuals who carry *de novo* variants in *IRF2BPL* and are affected with neurological symptoms. Five individuals who carry *IRF2BPL* nonsense variants exhibit a severe neurodevelopmental disorder with regression, abnormal movements, loss of speech, and seizures (NEDAMSS, OMIM-618088). Two individuals with missense variants display milder phenotypes of seizures with global developmental delay or autism spectrum disorder. We showed that the fruit fly *IRF2BPL* ortholog, called *pits*, is broadly expressed, including in the nervous system. Complete loss of *pits* is embryonic lethal, whereas knockdown with RNAi in neurons leads to neurodegeneration, revealing a requirement for this gene in proper neuronal function and maintenance. The *IRF2BPL* nonsense variants behave as severe loss-of-function alleles in flies, while the missense variants lead to milder phenotypes. Our results show that *IRF2BPL/pits* are required in the nervous system in humans and flies, and that their loss leads to a variety of neurological phenotypes.

To better understand the biological function of *IRF2BPL*, the impact of novel variants, and to identify potential targets for therapeutic intervention we embarked on detailed fly studies. Based on cancer studies *IRF2BPL* has been shown to be an E3 ligase that ubiquitinates  $\beta$ -catenin, the transcriptional co-activator responsible for transcribing Wnt target genes. We find that Wnt protein levels are reduced when *IRF2BPL/pits* is elevated, and that Wnt levels are elevated when *IRF2BPL/pits* is reduced. Hence we hypothesize that excess Wnt signaling in patients with NEDAMSS may contribute to the disease. We have generated new models of neurodegeneration caused by loss of *pits*. Firstly, we generated *pits* loss of function clones in the fly retina which causes rapid phototransduction and synaptic transmission defects as measured by electroretinograms. Secondly, we spatially and temporally reduced *Pits::GFP* in neurons with the deGradFP system in flies which results in a decreased lifespan. Using these phenotypes we have generated a platform for drug testing using approved, blood-brain barrier penetrable drugs that inhibit Wnt signaling. Together, our data indicate that *IRF2BPL* regulates WNT protein levels directly which may be important for human disease.

## PgmNr 3149: Single-cell RNA-seq in a mouse model of Parkinson disease reveals potential disease mechanisms affecting subpopulations of dopaminergic neurons.

### Authors:

S. McClymont; A. McCallion

[View Session](#) [Add to Schedule](#)

**Affiliation:** McKusick Nathans Institute of Genetic Medicine, Johns Hopkins School of Medicine, Baltimore, Maryland.

---

Degeneration of dopaminergic (DA) neurons is the hallmark feature of Parkinson disease (PD). However, not all DA neurons perform the same functions nor are they equally sensitive to degeneration by PD-causing mutations. To help illuminate the subpopulations of DA neurons preferentially degenerated in PD and begin to understand the mechanisms of degeneration, we are examining the transcriptomes of DA neurons from a mouse model of PD.

We are using single-cell RNA-seq (scRNA-seq) to interrogate the consequences of the *SNCA* A53T familial PD mutation on developing (P7) DA neurons of the ventral midbrain. We have collected transcriptomes from >2,400 DA neurons from wildtype, hemizygous, and homozygous mutants bearing the A53T mutation (B6;C3-Tg(*Prnp*-*SNCA*\*A53T)83Vle/J).

Our initial goals were three-fold: 1) Identify subpopulations of DA neurons and their marker genes; 2) Establish which subpopulations are preferentially susceptible to the PD mutation and; 3) Identify differentially expressed genes between genotypes within affected populations to explore disturbed genes and pathways to assess potential mechanisms of action.

We are able to resolve distinct subpopulations of midbrain DA neurons within our scRNA-seq data: the ventral tegmental area (VTA), substantia nigra (SN), periaqueductal grey area (PAG), and a neuroblast population of developing neurons. We are able to further identify five novel subpopulations and associated markers within the SN (three) and PAG (two).

In comparing the distribution of the three genotypes across these subpopulations of DA neurons, we observe an under-representation of mutation-bearing neurons in the neuroblast, VTA, and one of the SN subpopulations, with commensurate increases of mutant cells in the remaining two SN clusters.

We have examined these affected subpopulations for differential gene expression and are investigating the mechanisms by which the mutation might affect neuron differentiation or degeneration. Of note, the A53T mutation appears to decrease the number of DA neurons present in the VTA and within this cluster, the *Aldh1a1* gene is differentially regulated by genotype (adjusted p-value = 0.014), with 100% of wildtype cells and only 55% of homozygous cells expressing *Aldh1a1*. Functional validation via RNAscope of the anatomical location of these subpopulations, their novel marker genes, and the effect of the A53T mutation on select genes and subpopulations is ongoing.

## PgmNr 3150: Spastic paraparesis and dopa-responsive dystonia associated to pathogenic variant in GCH1 gene.

### Authors:

---

Dopa-responsive dystonia includes a group of inherited disorders characterized for an alteration in the dopamine metabolism, that usually has onset in childhood or adolescence and which main symptom is dystonia that has an overwhelming and sustained response to low doses of L-dopa. It also can be associated with mild parkinsonism, marked diurnal fluctuations and other symptoms although, those are not specific and can be associated to other neurological diseases. It is usually caused by monogenic mutations and has autosomal recessive or dominant inheritance mechanisms. Pathogenic variants have been identified in these genes: GCH-1 (Guanosine triphosphate cyclohydrolase 1), SPR (sepiapterin reductase) and TH (tyrosine hydroxylase). The most common pathophysiological mechanism is a deficiency in bipterin which is a cofactor for tyrosine hydroxylase implicated in dopamine synthesis and is caused by a pathogenic variant in the GCH-1 gene.

In this case report we present a 30-year-old female patient, with a rare clinical presentation that started with gait difficulty, spasticity in lower limbs and hyperreflexia at 6 years old. Initially spastic paraparesis diagnosis was made. Then symptoms remained stable and at 22 years old she presented neck dystonia, so L-dopa treatment was started having well response with complete disappearing of dystonic movements, for that reason dopa-responsive dystonia diagnosis was made. To confirm this diagnosis a sequencing panel testing for dystonia including GCH1, TH and SPR genes was made, showing a pathogenic heterozygote variant in GCH1: c.602G>A (p.Gly201Glu) already correlated with Dopa-responsive dystonia in data bases, nevertheless, this variant in the cases described in the literature, has never been related with spastic paraparesis.

---

Somatic mutations arising during the course of development are increasingly recognized as important causes of human diseases, now extending beyond just cancer into the realm of developmental disorders. Proper interpretation of somatic mutations requires consideration of a number of factors not necessarily accounted for in the current 2015 ACMG/AMP Sequence Variant Interpretation Guidelines, which focuses predominately on germline variation. These include: (1) logical rules for assessing mosaic variants that may be detected only at low allele fraction or that (2) may be variably present in different tissues within the same individual, (3) the use of reference databases of somatic variants, and (4) guidelines for predicting gain-of-function activity (since many disease-associated somatic mutations are biochemically activating as opposed to loss-of-function). New and generalizable frameworks are necessary to address these issues.

The ClinGen Brain Malformation Expert Panel was recently formed to curate genes and variants associated with developmental brain malformations, a significant fraction of which have been linked to somatic mutations. In particular, somatic mutations in the MTOR pathway (e.g. *MTOR*, *AKT3*, *PIK3CA* and *PIK3R2*) are known to cause a spectrum of brain overgrowth syndromes ranging from focal cortical dysplasia to dysplastic megalencephaly. Targeted genetic testing for low-level mosaicism has recently become available for many of these malformations.

To curate these genes and variants, we have drafted a framework for the curation of somatic mosaic (post-zygotic) variants that addresses many of the issues unique to somatic variants. We will describe the finalized *MTOR*, *AKT3*, *PIK3CA*, and *PIK3R2* specific variant classification criteria, and present the results of pilot testing of 31 published variants, including 14 likely pathogenic/pathogenic variants, 7 variants of uncertain significance, 9 benign/likely benign, and one with conflicting evidence. Our work should provide a useful framework, not only for standardizing the curation of MTOR pathway mutations, but also for the interpretation of somatic mutations in other settings as well.

## **PgmNr 3152: Family-based genome-wide association study identifies 13q12 associated with major depressive disorder and Alzheimer's disease.**

### **Authors:**

**Introduction:** Major depressive disorder (MDD) and Alzheimer's disease (AD) are comorbidity; while MDD may be associated with the development of AD. However, limited study was observed on shared genetic basis between two disorders.

**Material and methods:** we conducted genome-wide association study (GWAS) of MDD and AD to search for novel- and shared - genetic variants for these disorders using a family-based design and to examine whether MDD associated genes are associated with AD (pleiotropic effects) based on 1266 AD cases and 1279 healthy relatives as well as 422 MDD patients and 1688 non-MDD individuals using PLINK and haplotype analysis using generalized estimating equations (FBAT- GEE) statistics in PBAT software.

**Results:** Family-based GWAS identified 12 single nucleotide polymorphisms (SNPs) associated with MDD with  $p < 10^{-5}$ . The most significantly associated SNP was rs930436 ( $p = 1.28 \times 10^{-6}$ ) within PAXIP1 gene, followed by rs1376088 ( $p = 1.97 \times 10^{-6}$ ) within LOC152594. Interestingly, among the 12 SNPs, rs12875434 within LOC646164/DDX39AP1 gene at 13q12 was associated with both MDD ( $p = 3.54 \times 10^{-6}$ ) and AD ( $p = 0.03216$ ). At 13q12, 12 SNPs were associated with MDD; four SNPs were associated with MDD and AD located in one haplotype block. Haplotype analyses further supported the associations of LOC646164/DDX39AP1 gene at 13q12 with MDD and AD.

**In conclusion,** this is the first report of that the variants located 13q12 region were associated with MDD and AD based on GWAS. Future replication and functional studies are required to validate our findings.

## PgmNr 3153: Integrating multi-omics data for gene-level association test identifies schizophrenia risk genes.

### Authors:

Transcriptome-wide association study has been successfully used to explain GWAS signals for psychiatric disorders. Those studies used RNA-Seq data to impute gene expression and performed gene-level association analyses. However, the malfunction of risk genes that affect disorders may occur not only at transcription level, but also at translation level. Different levels of gene expression should have their unique signals that may help identify risk genes. Integrating multi-omics data in gene expression prediction can increase the statistical power.

The PsychENCODE BrainGVEX project generated multi-omics data for over 400 samples in human brain prefrontal cortex region. The omics types include genotypes, RNA-Seq, Ribo-Seq, etc. Ribo-Seq measures gene expression during translation by capturing ribosome-wrapped RNA, which is closer to traits and should be more straightforward to decipher disease risks. However, Ribo-Seq sequences reads of only 27 bps, which may be not so accurate as RNA-Seq. Therefore, gene expression predicted by RNA-Seq and Ribo-Seq data should be complementary at some extent and integrating both models should provide more information.

We performed gene-level association tests to identify schizophrenia risk genes based on GWAS summary data from the Psychiatric Genomics Consortium. To build expression models for RNA-Seq and Ribo-Seq data, we trained the correlation between in-cis SNPs and gene expression. For each gene, we used elastic net with 10-fold cross-validation to select SNPs within gene body and 1Mb flanking region. We used a generalized Berk-Jones test to identify risk genes from the joint two models.

As proof of concept, we first evaluated unique signals in RNA-Seq and Ribo-Seq data. When conditioning on Ribo-Seq data, the correlation between actual and predicted expression for RNA-Seq data dropped from 0.61 to 0.54. When conditioning on RNA-Seq data, the correlation for Ribo-Seq dropped from 0.67 to 0.56. Using the RNA-Seq model only, we identified 342 schizophrenia risk genes. Using the Ribo-Seq model only, we identified 119 risk genes. Integrating the two models, we identified 370 risk genes, which outperforms any single model. Comparing with single models, 307/342 and 113/119 genes were preserved in the joint model. 119 of the 370 genes were located within 500Kb flanking region of 50 known GWAS loci. In a word, integrating multi-omics data can increase the power of identifying risk genes.

---

**Background:** To identify non-coding genetic variation relevant to schizophrenia (SCZ) risk, we previously characterized chromatin accessibility in the dorsolateral prefrontal cortex (DLPFC) and identified eight colocalizations of SCZ-associated variants and DLPFC cQTLs, providing a functional context for those genome-wide association (GWA) loci (Bryois et al. 2018). We now extend that work to the anterior cingulate cortex (ACC), which is also implicated in SCZ pathology. **Methods:** We performed ATAC-seq on postmortem ACC samples from 48 SCZ cases and 48 controls. We performed differential chromatin analysis to identify regions associated with SCZ risk and association analysis to identify cQTLs in ACC, DLPFC, or both tissues. **Results:** We identified 89,057 ATAC-seq peaks in the ACC samples, which largely overlapped ones previously identified in the DLPFC. There were no significant differences in ACC chromatin accessibility between SCZ cases and controls. After merging ATAC-seq peaks from ACC and DLPFC for each subject, we identified 32,055 cQTLs significant in both ACC and DLPFC: 21 cQTLs were in a SCZ GWA locus. Five cQTLs were unique to the ACC, 405 cQTLs were unique to the DLPFC, and no tissue-specific cQTLs overlapped SCZ GWA loci. A common haplotype (77% frequent) on chromosome 2 associated with open chromatin drives the most significant DLPFC cQTL. For all ACC-specific cQTLs, the associated SNP was >1kb from the ATAC-seq peak. In contrast, 25% of DLPFC-specific cQTL SNPs were <1kb from the peak and 5% were <100bp. The distance from the SNP to the peak in cQTLs common to both tissues were more similar to DLPFC-specific cQTLs. No gene ontology enrichment was observed among ACC-specific cQTLs. However, DLPFC-specific peaks were enriched for targets of MIR-355 and the interferon gene family (FDR  $q < 0.05$ ). Among cQTLs shared by both tissues, several terms related to the major histocompatibility complex were enriched (FDR  $q < 0.0001$ ). **Conclusions:** Regions of chromatin accessibility and cQTLs are generally shared between ACC and DLPFC in SCZ cases and controls, consistent with Sieberts et al. (2019) demonstrating most eQTLs are shared across brain regions. Nonetheless, some unique characteristics exist. DLPFC cQTL SNPs reside closer to the chromatin peak compared with ACC cQTL SNPs. DLPFC-specific and shared cQTLs are enriched in pathways believed to be important for SCZ risk, underscoring the utility of our approach to dissect SCZ risk mechanisms.

---

Chromatin state plays an important role in regulating gene expression and cellular differentiation. Open chromatin landscape during human cortical neurogenesis has been well demonstrated for its ability in influencing gene expression during neurodevelopment; however, the effect of genetic variation on chromatin openness pertaining to neurodevelopmental disorders remain poorly understood. Using human induced pluripotent stem cell (iPSC)-derived neurons as a neurodevelopmental model, we identified abundant open-chromatin regions absent in brains and thousands of genetic variants exhibiting allele-specific open-chromatin (ASoC). We found that ASoC variants are prevalent within the human genome, and neuronal cell type-specific ASoC variants were over-represented in brain enhancers and more likely to affect brain gene expression (eQTL), histone acetylation (hacQTL), and DNA methylation (meQTL). More importantly, neuronal ASoC variants were highly enriched for genetic risk of schizophrenia (SZ), intelligence, educational attainment, bipolar, major depression and Alzheimer's disease. For SZ, we identified 20 ASoC variants showing genome-wide significant associations at 17 risk loci, followed by a systematic functional confirmation using multiplex CRISPRi epigenomic perturbation combined with single-cell RNA-seq (scRNA-seq) in NPCs. In addition, precise nucleotide editing of the top ASoC variant associated with SZ at the *VPS45* locus verified the regulatory effect of the ASoC variant and its regulated genes. Moreover, in combination with computational fine-mapping, we further confirmed the regulatory activities and *cis*-targeted genes. Our results provide the first snapshot of the ASoC landscape in major neuronal cell types relevant to neurodevelopmental disorders, depicted a framework for prioritising functional disease variants, and support ASoC as an effective functional readout of regulatory noncoding disease risk regions.

## PgmNr 3156: Metabolic dysfunction as a contributor to 3q29 deletion syndrome phenotypes.

---

3q29 deletion syndrome (3q29Del) is caused by a rare (~1:30,000) 1.6 Mb heterozygous deletion on chromosome 3 and is associated with a wide range of phenotypes, including mild to moderate intellectual disability; increased risk for autism, ADHD, and schizophrenia; and reduced birth weight and growth deficits. Individuals with 3q29Del have significantly reduced birth weight compared to matched controls (15.04oz difference,  $p=1.5E-6$ ); this phenotype is recapitulated in the mouse model of 3q29Del created at Emory University (1.81g difference, 8% of body weight,  $p=8.8E-12$ ). Based on the consistency of this phenotype and the presence of four mitochondria- or metabolism-associated genes within the 3q29 interval (*Pcyt1a*, *Tfrc*, *Bdh1*, and *Senp5*), we hypothesize that there may be a previously unidentified metabolic dysfunction in individuals with 3q29Del. Using untargeted metabolomics in liver tissue from our mouse model, we found that palmitoylcarnitine was significantly increased in 3q29 animals after adjusting for sex ( $p<0.05$ ,  $FC=0.314$ ). In stratified analyses, phosphatidate was significantly increased in female mutants versus wild-type (WT) littermates ( $p=0.02$ ,  $FC=1.997$ ), with males showing a similar trend ( $p>0.05$ ). Metabolome-wide association studies identified the carnitine shuttle and fatty acid metabolism pathways as significantly associated with these target metabolites ( $p<0.05$ ), suggesting that mitochondrial function and fat metabolism may be impacted by the 3q29 deletion. We used metabolic chambers to measure gross features of metabolism in our mouse model, including food and water consumption, activity, and energy expenditure. On standard chow, the 3q29Del mice were not significantly different from their WT littermates for any of the parameters measured. These data confirm that the 3q29Del-associated weight deficit and metabolic features are not due to decreased feeding or increased energy expenditure, and instead likely result from altered metabolism. Studies are underway to assess specific deficits in mitochondrial function and fatty acid metabolism in the mouse model of 3q29Del; preliminary results suggest that the 3q29Del-associated weight deficit is ameliorated when mice are fed a high-fat diet. Together with our metabolomics results, these data may highlight metabolic pathways relevant to intellectual disability, autism, and other neurodevelopmental and neuropsychiatric phenotypes.

## PgmNr 3157: Weighted gene co-expression network analysis of the human frontal cortex reveals novel insights into the schizophrenia-associated 3q29 deletion syndrome.

---

**Background:** The 3q29 deletion is a recurrent copy number variant resulting in hemizygous deletion of 21 protein coding genes; the syndrome is characterized by developmental delay (DD) and increased risk for autism spectrum disorders (ASD) and schizophrenia (SZ). The functional role of 3q29 genes and the mechanism underlying the neurodevelopmental sequelae of their hemizygosity remain largely unknown. **Objectives:** To interrogate functional consequences of the 3q29 deletion, we built an undirected gene co-expression network of the human frontal cortex and leveraged the principle of guilt-by-association to generate predictions about pathways and candidate genes contributing to syndrome phenotypes. **Methods:** We applied weighted gene co-expression network analysis (WGCNA) to publicly available RNA-Seq data (Genotype-Tissue Expression Project) and grouped genes into clusters that are likely functionally related. We established preservation in another dataset (BrainSpan Developmental Transcriptome Project), indicating high reliability of the network. We then identified clusters that harbor 3q29 genes and defined their top neighbors. We tested whether known risk genes for SZ, ASD and DD are overrepresented among these neighbors. Consequently, we generated a list of candidate drivers that are highly co-expressed with 3q29 genes and are associated with risk for SZ, ASD and/or DD. We tested the enrichment of this list for biological pathways and tissue expression. **Results:** The resulting data suggest that 3q29 interval genes are organized into seven highly correlated groups with overlapping effects on the same biological pathways. We identified *UBXN7* as a hub-gene, suggesting central influence on a large network of neighbors. We also revealed that ten 3q29 genes have top neighbors that are enriched for SZ, ASD and/or DD-risk, resulting in a prioritized list of 163 candidate drivers. This list maps onto key biological processes such as chromatin organization, protein-protein interactions at synapses and NMDA receptor activity. Intriguingly, this list is enriched for expression in the granular layer of the cerebellum, a brain region with abnormal volume in 3q29 deletion carriers. **Conclusion:** The molecular pathways and prioritized gene list identified in this study will inform new directions of neurobiological inquiry. Emerging transcriptional profiling data from the Emory 3q29 Project (both human cellular models and mouse models) will be used to validate our predictions.

## PgmNr 3158: Differentially expressed genes and eQTLs implicate oxidative stress and mitochondrial function in risk for PTSD.

---

PTSD is a complex psychiatric disorder that can develop following traumatic events. The Psychiatric Genomics Consortium PTSD group (PGC-PTSD) has collected over 20,000 multi-ethnic PTSD cases and controls and has identified both genetic and epigenetic factors associated with PTSD risk (Duncan et al., 2018; Wolf et al., 2018). To further investigate biological mechanisms underlying PTSD risk, we examined three PGC-PTSD cohorts comprising 977 subjects to identify differentially expressed genes among PTSD cases and controls. Whole blood gene expression was quantified with the HumanHT-12 v4 Expression BeadChip for 726 OEF/OIF veterans from the VA MIRECC (Ashley-Koch et al., 2015), 155 samples from the INTRuST Clinical Consortium (Bomyea et al., 2019), and 96 Australian Vietnam War veterans (Mehta et al., 2017). Probe and sample quality control, background adjustment, and normalization were performed using limma and batch effects were corrected using ComBat. The proportion of monocytes and lymphocytes for each sample was estimated using an approach described in Logue et al. (2015). Differential gene expression analysis was performed in each cohort separately controlling for age, ethnicity, sex (if applicable), and cell proportions using limma, followed by meta-analysis using METAL. Inflation and bias were controlled using the empirical null distribution. Finally, we performed expression QTL (eQTL) analysis in the MIRECC cohort followed by pathway analysis. While no gene survived false discovery, the most differentially expressed genes were *EXOC6* ( $p=9 \times 10^{-6}$ ) and *IL1B* ( $p=3 \times 10^{-5}$ ). *EXOC6* has been nominally associated with major depressive disorder (MDD) risk, a condition commonly comorbid with PTSD (Wray et al., 2012). *IL1B*, a pro-inflammatory cytokine, is associated with PTSD in humans (Hovhannisyan et al., 2017) and involved in stress-enhanced fear learning in rodents (Jones et al., 2015). We also identified 2,710 FDR significant eQTLs in the MIRECC cohort. eQTL target genes were enriched for mitochondrion and oxidoreductase GO terms. Mitochondrial function is associated with PTSD (Mellon et al., 2019), as well as with innate immune response in MDD (Culmsee et al., 2019). In conclusion, we observed differential gene expression between PTSD cases and controls in genes and pathways involved in oxidative stress, innate immune response and associated with psychiatric disorders often comorbid with PTSD. These data provide further insight into PTSD pathomechanisms.

## PgmNr 3159: Transcriptomic network signature of synaptic pruning in prefrontal cortex with increased copy number of complement component 4.

---

**Introduction:** Genome-wide association studies (GWAS) have successfully identified hundreds of genomic regions associated with schizophrenia. Subsequent fine-mapping of the strongest association signal, which lies in the major histocompatibility complex (MHC) locus, found that risk for schizophrenia was partially mediated by increased expression of complement component 4A (*C4A*) arising from complex structural variation of *C4* genes. Although *C4A* is believed to partake in synaptic pruning, its precise function in human brain—and its relation to other schizophrenia risk variants—remains difficult to examine due to lack of an appropriate experimental system and lack of evolutionary conservation in model organisms.

**Methods:** Here, we integrated genotype array and RNA-seq data of frontal cortex samples from 344 individuals with schizophrenia and 422 controls as part of the PsychENCODE project. To provide human brain-specific functional annotations, we imputed *C4* structural alleles and generated *C4A*-seeded co-expression networks stratified by *C4A* copy number. We then assessed whether resulting networks show enrichment for known pathways, cell-types, and GWAS SNP-heritability.

**Results:** *C4A*-seeded networks expanded in size with increasing *C4A* copy number and exhibited greater connectivity in frontal cortex compared to other brain regions. Positive co-expression partners were enriched for astrocytic and microglial markers as well as NFkB signaling pathway genes, whereas negative co-expression partners were enriched for synaptic/neuronal markers. We find that negative—but not positive—co-expression partners of *C4A* exhibited substantial enrichment for SNP-heritability in schizophrenia, providing strong evidence for additive polygenic effects in schizophrenia. Consistent with this result, negative co-expression partners were expressed in a limited set of neuronal cell-types that have previously been shown to be enriched for schizophrenia GWAS signals.

**Conclusion:** Functional genomic analyses of a large-scale human brain dataset could provide novel insights into *C4A*-mediated biological process and implicate that frontal cortex might be particularly susceptible to this process. We identify a gene expression network signature likely representing synaptic pruning that integrates multiple genetic risk factors for schizophrenia and thereby highlights some level of convergence in schizophrenia pathophysiology.

## PgmNr 3160: An iPSC-derived neuronal model of the schizophrenia-associated 3q29 deletion.

---

A major goal in psychiatric genetics is to determine the biological mechanisms of schizophrenia risk genes. A fundamental challenge is that common variants confer very low risk individually and therefore must act in concert with many other factors. By contrast, rare, high-risk copy number variants (CNVs) offer a more direct path from genotype to understanding risk gene mechanisms. The 3q29 deletion is a highly-penetrant, recurrent CNV that is associated with neurodevelopmental disorders and confers a striking 40-fold increased risk for schizophrenia, and therefore represents a high-value target for mechanistic study.

The Emory 3q29 Project (<http://genome.emory.edu/3q29/>) was formed to advance study of the 3q29 deletion, and unites a team of investigators toward understanding the phenotypic spectrum, natural history, and molecular mechanism of the deletion. One specific goal of The Emory 3q29 Project is to investigate the effects of this CNV on neuronal development. In this ongoing study we have now obtained peripheral blood mononuclear cells from six individuals with the 3q29 deletion enrolled in The Emory 3q29 Project and created induced pluripotent stem (iPS) cell lines. Neurotypical controls were recruited for comparison and matched by age, sex, and race. Following in-depth characterization of iPSC lines, we used dual-SMAD inhibition to differentiate all lines to PAX6, Nestin, and SOX2 positive neural progenitor cells (NPCs). Transcriptional profiling of NPC lines is underway and will be presented at the meeting.

All NPC lines have been further differentiated to forebrain neuronal cultures that stain positive for MAP2, beta-III tubulin, CTIP2, TBR1, CUX1, and SATB2. Preliminary morphological analyses indicate that 3q29del neurons display increased neurite branching and shorter primary neurites at 2 weeks post-differentiation (wpd). Additionally, CTIP+ neurons at 4wpd display somewhat simplified neuronal complexity. Transcriptomic and proteomic analyses of 3q29del neurons are ongoing. These preliminary results suggest that haploinsufficiency of multiple 3q29 genes impinges on key neuronal pathways, impairing development and maturation.

---

The most common human genomic rearrangement is a 3 Mb deletion on chromosome 22q11.2, occurring once in every 4,000 live births. The 22q11.2 deletion syndrome is associated with variety of maladies with particularly high risk to schizophrenia and childhood-onset neurodevelopmental disorders. Yet, it is unclear how the deletion acts to manifest the high risk for these presumably cerebrocortical phenotypes, and how much could be learned from these disorders by studying this high impact regulatory variant. To gain insight into these questions, we performed RNA sequencing in human induced pluripotent stem cells (hiPSC), neuronal progenitors (NPs) and post-mitotic excitatory neurons derived from 49 donors, of which 20 carried the 22q11.2 deletion. We were able to detect a statistically significant reduction in gene expression of genes located within the deletion region across all three cell stages (FDR<5%) where the deletion explained ~50% of variance in the RNA abundances. The majority (89%) of the differentially expressed genes were located outside the deletion and was mostly cell-stage specific, suggesting that the regulatory effect of the 22q11.2 deletion changes with progression of neuronal development. We then turned our attention to genes that were differentially regulated by the stem cells and early NPs. We found that the differentially expressed genes in these early developmental stages had more than expected protein-protein interactions with genes that have been previously linked with early-onset neurodevelopmental disorders ( $p=0.046$ ). However, this enrichment was not present in neurons. We next asked whether gene variants in the differentially expressed genes contribute disproportionately to the heritability of common neuropsychiatric traits and disorders. We found that variants in up-regulated genes in neurons from deletion carriers were significantly enriched for heritability particularly for schizophrenia ( $p=4.2 \times 10^{-6}$ ). Finally, the 22q11.2 deletion using CRISPR was sufficient to induce the directionality of effects observed in the patient collection. Together, these results suggest that the 22q11.2 deletion has a regulatory effect on pathways that converge with the polygenically defined schizophrenia in neurons, and with genetic variants implicated in early neurodevelopmental disorders in progenitors.

## PgmNr 3162: Exonic resequencing of the genes encoding the ionotropic glutamate receptors of kainate subtypes in patients with schizophrenia.

---

Schizophrenia is a chronic debilitating mental disorder with a high genetic component in its etiology. The ionotropic glutamate receptor kainate type plays a critical role in regulating the synaptic transmission and the functions of various synaptic receptors. Genes encoding the ionotropic glutamate receptors of kainate subtypes can be considered as the candidate genes of schizophrenia. There has been growing debate that rare mutations in synapse-associated protein genes are rare and may contribute to parts of the pathogenesis of schizophrenia in certain patients. This study aims to identify the rare and pathogenic mutations of the glutamate ionotropic receptor kainate type subunit (GRIK) gene family members in patients with schizophrenia. We resequenced the exon regions of 5 genes (*GRIK1*, *GRIK2*, *GRIK3*, *GRIK4*, and *GRIK5*) in 420 unrelated patients with schizophrenia using ion semiconductor sequencing method. We identified several protein-disrupting mutations in patients with schizophrenia, and *in silico* analysis showed that some of these mutations were damaging or pathological to the protein function. Notably, we identified one frameshift deletion (*GRIK1*:c.70\_71delTT) in one schizophrenic patient and two heterozygous nonsense mutations (*GRIK2*:c.898C>T; *GRIK4*:c.1024C>T) in two patients with schizophrenia. The *GRIK1*:c.70\_71delTT mutant was predicted to change the reading frame (*GRIK1*<sup>Phe24fs</sup>), resulting in a completely different translation from the original GRIK1 protein. The *GRIK2*:c.898C>T mutant was predicted to cause the stop codon in codon 300 of the GRIK2 protein (*GRIK2*<sup>Arg300Ter</sup>). The *GRIK4*:c.1024C>T mutant was predicted to cause the stop codon in codon 342 of the GRIK4 protein (*GRIK4*<sup>Gln342Ter</sup>). Because, these three protein-disrupting mutations were absent in the ExAC dataset and 1517 healthy controls from Taiwan BioBank, we presumed these three rare mutations are schizophrenic-associated variants. The study suggests that the GRIK genes harbor rare pathogenic mutations in certain patients with schizophrenia, supporting rare coding variants may contribute to the genetic architecture of schizophrenia. Future studies using cells or transgenic mouse models carrying these mutations are necessary to understand the functional consequence of the GRIK gene family mutants *in vitro* and *in vivo* and, most importantly, to elucidate whether and how they contribute to the etiology of schizophrenia.

## PgmNr 3163: Alternative splicing: Non-canonical isoform REEP6.1 exhibits tissue-specific function.

Alternative splicing plays a role in increasing the complexity of gene products in eukaryotic cells. However, knowledge about the extent that the sequence complexity is translated to function complexity among tissues remains limited. For example, it is largely unknown whether isoforms that are expressed in a tissue-specific manner correlate with their tissue-specific functions. Previous studies from our lab have linked a deficiency in Receptor Expression Enhancer Protein 6 (*REEP6*) with retinitis pigmentosa (RP), an inherited retinal disease. Two isoforms of *REEP6* have been identified: both are conserved in mice and humans. While the canonical isoform, *REEP6.2*, is expressed broadly in many organs, the non-canonical isoform *REEP6.1* is expressed mainly in rod photoreceptor cells. Here, we investigated whether *REEP6.1* has retina-specific functions that cannot be substituted by *REEP6.2*. *REEP6.1* contains a 27-amino-acid region encoded by Exon 5 of the *REEP6* gene. *Reep6* exon 5 deletion mice (E5 mice) have been generated, which eliminates the *Reep6.1* isoform while leaving the *Reep6.2* isoform unchanged. Phenotypes of different *Reep6* genotypes, including *Reep6*<sup>E5/+</sup>, *Reep6*<sup>E5/E5</sup>, *Reep6*<sup>E5/-</sup>, with *Reep6*<sup>6+/-</sup> and *Reep6*<sup>-/-</sup> serving as positive and negative controls respectively are characterized. *Reep6*<sup>E5/E5</sup> mice showed a moderate retinal degeneration phenotype while *Reep6*<sup>E5/-</sup> mice showed a phenotype as severe as the complete knock-out (*Reep6*<sup>-/-</sup>). In parallel, we performed rescue experiments by overexpressing *Reep6.1* and *Reep6.2* cDNA in *Reep6*<sup>-/-</sup> mice. We found the *Reep6.2* is less efficient than *Reep6.1* in rescuing the retinal defect. Taken together, our results indicate that the retina specific isoform of *Reep6* plays a distinct function from the canonical isoform, providing critical information for further investigation of its function in the retina, as well as future development of therapy.

## PgmNr 3164: Novel compound heterozygous, nonsense variants p.L150\* and p.Y3565\* of the *USH2A* gene in a Chinese pedigree links to Usher syndrome type IIA.

### Authors:

---

**Purpose:** Usher syndrome includes a group of genetically and clinically heterogeneous autosomal recessive disease with retinitis pigmentosa and hearing deficiencies. The relationships between the Usher syndrome-caused genes and the resultant Usher syndrome phenotypes in the patients are highly variable. **Methods:** In the present study, an Usher syndrome Chinese family was recruited, targeted next-generation sequencing, Sanger sequencing, and segregation analysis were fulfilled. The expression profile was analyzed. Functional effects of the pathogenic variants for *USH2A* were analyzed. **Results:** We revealed novel, nonsense compound heterozygous variants c.T449G (p.L150\*) and c.T10695A (p.Y3565\*) in the *USH2A* gene, which showed co-segregated with the disease phenotype causing Usher syndrome type IIA in our Chinese pedigree. The p.L150\* variant produced truncated small protein with losing almost all functional domains of *USH2A*; whereas the p.Y3565\* variant is located in one of the fibronectin type 3 domains with losing several fibronectin type 3 domains at the C-terminus of *USH2A* by producing truncated protein. We found that the *USH2A* mRNA was high expressed in the retina of the eye and this protein was highly conserved by comparing *H. sapiens* *USH2A* to eight other species. **Conclusion:** This is the first to reveal two novel, pathogenic compound heterozygous variants c.T449G (p.L150\*) and c.T10695A (p.Y3565\*) in the *USH2A* gene in a Chinese family with Usher syndrome type IIA, thereby expanding *USH2A* mutation spectrums. Our discoveries can help understand molecular pathogenesis including RP and Usher syndrome type IIA, developing strategies of diagnosis, therapy and genetic counseling in this Usher syndrome type IIA disease. **Funding:** The project was funded by the National Natural Science Foundation of China (31701087, 30371493, and 81672887).

## PgmNr 3165: Submicroscopic 13q32.1 deletions causing congenital microcoria modify the regulatory landscape of neighboring genes.

**Purpose.** Congenital microcoria (MCOR) is a rare autosomal dominant disease characterized by unreactive pinhole pupils lacking iris dilator muscle (DM), iris transillumination and primary open angle glaucoma (POAG; > 30%). Previously, we reported 13q32.1 deletions as the cause of the disease. *GPR180* and *TGDS* were consistently altered, but the loss of either gene individually does not cause MCOR. We propose that MCOR is due to the modification of the regulatory landscape of the region which encompasses *dct* involved in iris pigmentation, *Sox21* that regulates the expression of *Pax6* involved iris development and *Abcc6* playing a role in the maintenance of the intraocular pressure (IOP), the increase of which is a major determinant of POAG. The purpose of the study was to assess this hypothesis by analyzing mice carrying deletions of variable size within or around the minimal MCOR deletion (35KB).

**Results.** Heterozygous animals carrying the 35 Kb deletion, presented with moderate, yet statistically significant, reduction in pupil diameter. RNAseq analysis revealed deregulation of a single neighboring gene, *Sox21*. The gene displayed ectopic expression in the iris, starting before the formation of the muscle during embryonic life, through to adulthood. Ablation of insulators within the MCOR deletion had no effect on neighboring genes. ChIPseq-H3K27Ac data identified two iris *Dct* enhancers upstream the deletion that might interact with *Sox21*. 4C analysis from the viewpoint of 2 kb surrounding *Sox21* showed the presence of ~1Mb TAD at the MCOR locus and that *Sox21* interaction extend from *Dct* through to *Uggt2*. TAD organization did not change dramatically in MCOR mice. Combined analysis of RNAseq and ChIPseq datasets revealed the deregulation in MCOR irises of two *Sox21* targets, including a protein known to play a major role in the maintenance of IOP.

**Discussion.** Here, we show that MCOR deletions alter the regulatory landscape of 13q32.1 in the iris. The ectopic *Sox21* expression in the developing iris likely changing the fate of the progenitors that should give rise to the DM. We suggest that in the absence of their endogenous targets (*Tgds* and *Gpr180*), *Dct* enhancers might activate *Sox21* more efficiently by altering promoter competence or by

reducing genomic distances within the TAD. Finally, we propose that POAG in MCOR patients might be secondary to the deregulation *Sox21* instead of *Abcc6*.

## PgmNr 3166: Mutations in the functional amyloid PMEL lead to pigmentary glaucoma.

---

Pigmentary glaucoma (PG) is the most common secondary glaucoma making it a major cause of blindness worldwide. Recently, we have reported that mutations in the melanosome structural protein premelanosome protein (PMEL) underlie PG, the first known genetic cause of this form of blindness in humans (Lahola-Chomiak et al., 2018). Functional analysis of non-synonymous PMEL missense mutations found in patients revealed 7/9 mutations displayed defects in proteolytic cleavage and/or melanosome fibril formation. CRISPR-Cas9 disruption of the homolog *pmel* in zebrafish caused profound pigmentation defects and glaucoma-like phenotypes further supporting PMEL's role in PG. However, the mechanism by which PMEL mutations cause glaucoma is yet to be elucidated. PMEL is a rare protein that forms functional amyloid fibers at normal physiological conditions; indeed PMEL fibers constitute the scaffold in melanosomes upon which melanin is synthesized and deposited. We hypothesize that PMEL mutations are gain-of function mutations that switch PMEL from a functional to a pathological amyloid. In the eye, the trabecular meshwork located in the anterior segment is the primary drainage route of aqueous humor. We now show that PMEL-containing cellular debris is phagocytosed by ocular trabecular meshwork cells which may compromise cell survival. As loss of trabecular meshwork cells results in IOP homeostasis deregulation, these findings could reveal one of the initiating steps of pigmentary glaucoma pathogenesis.

## PgmNr 3167: *CPH1*, a new gene for dominant optic atrophy.

---

Hereditary Optic Neuropathies (HON) are genetically heterogeneous diseases. HON can be isolated, affecting exclusively the retinal ganglion cell, or syndromic. HON are linked to genes coding proteins with a major role in the mitochondrial function. Our purpose is to characterize a new gene causing HON, called CPH1.

Whole-exome sequencing (WES) method was used to characterize the genetic cause of a new form of Dominant Optic Atrophy associated with a maculopathy. Sanger sequencing was used to verify the mutations. Then, we used fibroblasts to characterize mitochondrial dysfunction in patient cells.

WES analysis was performed on several members of a very large family with a dominant optic atrophy (DOA) and a photoreceptor anomaly in the central part of the retina. A dominant mutation was identified in a candidate gene called CPH1. This gene encodes a protein involved in the mitochondrial function. We then screened *CPH1* in a large cohort of DOA families and found additional mutations. Our results on patients' fibroblasts show that CPH1 protein expression is decreased compared to controls, whereas the mRNA level of CPH1 remained unchanged. To uncover the structural features underlying CPH1 mutations, we determined CPH1 crystal structure. Structural analysis suggests that mutations cause a disarrangement crucial motif of the protein. Using patient fibroblasts, we validated that CPH1 variant destabilizes the protein and affects mitochondrial function. We used morpholinos and CPH1 RNA mutant to model the disease in zebrafish. First results show defect in eye development in mutant fish.

These results suggest that CPH1 is a novel gene associated with dominant optic atrophy. Mechanistic study indicated that the mutation in this gene involves severe mitochondrial dysfunction.

## PgmNr 3168: Loss of function variants rs1971050, rs10038177 and rs10038058 of *WDR36* are not associated with primary open angle glaucoma in a Cameroon population.

### Authors:

F. Mbacham<sup>1,4</sup>; Y. Bilong<sup>1,2</sup>; A. Nomo<sup>1,2</sup>; H. Dongmo<sup>3,6</sup>; C. Tah<sup>3</sup>; J.C. Katte<sup>1,5</sup>; W. Mbacham<sup>1,3,6</sup>; E. Sobngwi<sup>1,3,5</sup>; B. Assumpta<sup>1,2</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Faculty of Medicine and Biomedical Sciences, University of Yaounde 1, Cameroon; 2) Ophthalmology Unit, Gynecologic-Obstetrics and Pediatric Hospital, Yaounde, Cameroon; 3) Biotechnology Center, University of Yaounde 1, Cameroon; 4) Institut Supérieure des Sciences et de la Santé, Université des Montagnes, Banganté, Cameroun; 5) National Obesity Center, Yaounde Central Hospital, Cameroon; 6) Faculty of Science, University of Yaounde 1, Cameroon

In primary open angle glaucoma (POAG), the most common form of glaucoma in people of African origin, it is established that retinal ganglion cells are lost due to apoptosis. Loss of *WDR36* (OMIM 609669) function has been shown to result in activation of the p53 stress- response pathway, a key regulator of apoptosis. However, there is controversy surrounding its contribution in the pathogenesis of POAG. We aimed to establish association between rs1971050, rs10038177 and rs10038058, *WDR36* gene polymorphisms and POAG. We assessed 798 glaucoma medical records and a selected 209 POAG cases were further reduced to 87 participants eligible for inclusion. Out of these, we got through to 20 participants residing in Yaounde, 16 of whom were included and 4 not included (denied to participate). Ten more from daily consultations were enrolled. A total of 26 cases completed the study and 19 controls were matched for age and gender. Dried blood spots on whatman filter paper grade 3 were used for DNA extraction by the Chelex method. Polymerase chain reaction (PCR) was conducted with two sets of primers on rs1971050, rs10038177 and rs10038058 followed by restriction fragment length polymorphism (RFLP) using restriction enzymes *AluI* and *ApoI* to determine the genotypes. Digestion of rs10038177 revealed in the POAG group C/T (7.7%) and T/T (92.3%) and in the non POAG group C/T (10.5%) and T/T (89.5%) genotypes. Digestion of rs10038058 revealed G/A (11.5%) and G/G (88.5%) genotypes in the POAG group and in the non-POAG group G/A (10.5%) and G/G (89.5%) genotypes. Heterozygote and homozygote mutant genotypes were thus expressed in both groups for rs10038177 and rs10038058. Only the homozygous mutant form of rs1971050 was evidenced in both groups of our study population T/T (100%). There was a non-significant clustering of the heterozygous genotype of rs10038177 C/T ( $p = 0.5$ ) with the advanced glaucoma disease process. Correlation tests showed no significant association of single nucleotide polymorphisms (SNPs) rs1971050, rs10038177 or rs10038058 with POAG ( $OR = <1.0$ ,  $p = 1.0$ ). In conclusion, advanced glaucoma clustered with the heterozygote mutant form of rs10038177 and may request greater sample size and other dependent associated genes to be investigated. Homozygous mutant genotypes of rs1971050, rs10038177 and rs10038058 may not be associated with the disease process of primary open angle glaucoma. **Key words:** POAG, *WDR36*, SNP, *AluI*, *ApoI*.

## PgmNr 3169: Role of archaic APOBEC3 genes in population-specific virus-host interactions.

Human chromosome 22 codes for seven APOBEC3 (A3) enzymes, four of which, A3D, A3F, A3G, and A3H have antiviral activities. These enzymes can inhibit retroviruses such as HIV-1 by hypermutating cDNA cytosine nucleobases or by other deaminase-independent mechanisms. Our multi-omics studies suggest that A3G and A3H are the main sources of viral hypermutation in non-African and sub-Saharan African populations, respectively. We found that the dominant A3H allele in sub-Saharan Africa has a significant sequence similarity to the Neanderthal/Denisovan A3H gene. In contrast, the dominant A3G allele outside Africa shares significant sequence similarity with the Neanderthal/Denisovan A3G gene. Taken together, these data suggest that both modern sub-Saharan Africans and non-Africans have inherited their ability to hypermutate retroviruses from archaic humans. It is possible that exposure to ancient retroviruses were positively (and independently) selected for these two genes in different human populations.

## PgmNr 3170: Mouse chitinases have no synergistic effects on degradation of chitin.

### Authors:

M. Kimura <sup>1,2</sup>; T. Umeyama <sup>1</sup>; S. Wakita <sup>1</sup>; K. Okawa <sup>1</sup>; M. Masayoshi <sup>1</sup>; F. Oyama <sup>1</sup>

---

Humans and mouse express two active chitinases, chitotriosidase (Chit1) and acidic mammalian chitinase (AMCase). Chit1 and AMCase have been implicated in various pathophysiological conditions such as chronic inflammatory diseases. Chit1 is increased in individuals with Gaucher disease, atherosclerosis disease and Alzheimer's disease. AMCase is increased in individuals with mouse models of asthma. However, the contribution of mammalian chitinases to the pathogenesis of these diseases and the physiological condition remains to be determined. *Serratia marcescens* express high levels of chitinases, Chitinase A (*Serratia* ChiA), Chitinase B (*Serratia* ChiB) and Chitinase C (*Serratia* ChiC). *Serratia* ChiB is a well-studied bacterial chitinase and structurally similar to the mammalian chitinases. It has been reported that *Serratia* ChiA and ChiB have synergistic effect on the chitin degradation. Mouse Chit1 and AMCase are expressed in monocytes and macrophages. Although Chit1 and AMCase co-exist in various tissues and cells, where the potential synergic functioning of these enzymes have not been determined. We determined combinatory effects of Chit1 and AMCase in natural chitin substrates using by fluorophore-assisted carbohydrate electrophoresis (FACE) method. Our results show that Chit1 and AMCase have no synergistic effect under physiological conditions. Thus, Chit1 and AMCase function independently in any tissue regardless of the pH or the substrates, in contrast to observations regarding some bacterial chitinases.

## PgmNr 3171: Comparision of functional properties between human and mouse chitotriosidase enzymes.

Chitin is a polymer of  $\beta$ -1, 4-linked *N*-acetyl-D-glucosamine (GlcNAc), and is an integral component of the exoskeletons of crustaceans and insects, the microfilarial sheaths of parasites and the fungal cell walls. Although mammals do not produce chitin, two active chitinases, chitotriosidase (Chit1) and acidic mammalian chitinase, have been identified in mouse and human. Chit1 has attracted considerable attention due to its increased expression in individuals with different pathological conditions such as Gaucher disease, chronic obstructive pulmonary disease (COPD), Alzheimer's disease, atherothrombosis, diabetes mellitus and cystic fibrosis. Thus, Chit1 may play important roles in many pathophysiological conditions and can be used for biomarkers monitoring the disease state. In this study, we directly compared the enzymatic properties between human and mouse Chit1 proteins using artificial and natural chitin substrates by combination of the colorimetric analysis and fluorophore-assisted carbohydrate electrophoresis (FACE) method. The chitinolytic activity of human Chit1 is higher than that of mouse Chit1. Furthermore, human Chit1 exhibited much higher transglycosylation activity over mouse counterpart. These results suggest the functional differences of human and mouse Chit1 proteins *in vivo*.

## PgmNr 3172: Production of chitooligosaccharides from chitin and chitosan by mouse acidic mammalian chitinase.

### Authors:

C. Takasaki; S. Wakita; F. Oyama

**Affiliation:** Department of Chemistry and Life Science, Kogakuin University, 2665-1 Nakano, Hachioji, Tokyo, Japan

---

Chitin is a polysaccharide composed of  $\beta$ -1,4-glycosidic linked *N*-acetyl-D-glucosamine (GlcNAc). It functions as the major structural component of exoskeleton of crustaceans and insects, microfilarial shells of nematodes, and cell walls of fungi. Chitin is partially deacetylated by chemically or enzymatically and becomes chitosan. Although humans and mice do not synthesize endogenous chitin and chitosan, they produce two active chitinases, chitotriosidase and acidic mammalian chitinase (AMCase). AMCase has attracted considerable attention because AMCase levels are altered in various diseases such as asthma, allergic inflammation, gastric cancer, ocular allergy and dry eye syndrome. In addition, polymorphisms of AMCase have been shown to be associated with bronchial asthma in humans. Mouse AMCase mRNA is predominantly expressed in the stomach. Recombinant AMCase and its catalytic domain had the highest activity at pH of around 2.0, when it produces primarily dimer of GlcNAc [(GlcNAc)<sub>2</sub>] with lower activities at more neutral pH (pH 3.0~7.0). Several recent reports have indicated that chitooligosaccharides derived from both chitin and chitosan possess biomedical activities including anti-tumorigenic and anti-inflammatory effects. It still remains elusive whether AMCase can produce chitooligosaccharides. Here, we report that AMCase produce chitooligosaccharides from chitin and chitosan. AMCase produced more (GlcNAc)<sub>2</sub> from  $\beta$ -chitin than  $\alpha$ -chitin. It is been known that  $\alpha$ -chitin and  $\beta$ -chitin differ in their degree of deacetylation (DD). Thus, we next examined the degradation products of chitosan with 69%, 73%, 84% and 95% DD by AMCase. AMCase degrade chitosan substrates up to 84% DD. In response to increase of DD, the amounts of products were decreased, and 94% DD chitosan remained undetected. These results indicate that AMCase can degrade chitin and chitosan and produce chitooligosaccharides.

## PgmNr 3173: Expression and characterization of chitinases in crab-eating monkey, a non-human primate.

---

Crab-eating monkey is one of the important nonhuman primate animal models in basic and applied biomedical researches. Chitin is a polymer of *N*-acetyl-D-glucosamine. Although mammals do not produce endogenous chitin, they express two active mammalian chitinases, acidic chitinase (CHIA) and chitotriosidase (CHIT1). Because the levels of expression of these chitinases are increased under many pathological conditions such as Gaucher disease and mouse models of asthma, both chitinases may play important roles in the pathogenesis. Moreover, CHIA can function as a protease-resistant major glycosidase under the gastrointestinal conditions. Here, we investigated the expression of chitinases in crab-eating monkey. Expression level of CHIA mRNA was high in monkey stomach. CHIT1 mRNA was highest in the lung among other monkey tissues. When the chitinolytic activity was measured using monkey stomach and lung extracts, they showed strong chitinolytic activities. Then, we measured the chitinolytic activity of *E. coli*-expressed monkey CHIA and CHIT1 enzymes to clarify their respective enzymatic function. The highest activity of both chitinases was detected at pH 5.0. In addition, we also detected robust chitinolytic activity of CHIA under strong acidic condition to neutral condition. These results indicate that crab-eating monkey CHIA possess distinctive properties for biomedical purposes in various organ.

## PgmNr 3174: Studying functional *de novo* mutations linked to autism spectrum disorders in *Drosophila* using an overexpression screen.

---

Autism Spectrum Disorders (ASD) encompasses a complex spectrum of neurodevelopmental disorders. Sequencing efforts reveal a highly heterogeneous genetic component to ASD. In our lab, we work to uncover molecular pathways involved in neurological diseases by testing functionality of human disease associated variants in *Drosophila*. Currently, we are testing *de novo* ASD-associated missense mutations identified in the Simons Simplex Collection, a cohort of 2500 simplex families where one child has non-syndromic ASD. From the collection, we selected 300 variants in 237 genes for functional studies in *Drosophila*. We generated loss-of-function (LOF) gene trap alleles that express GAL4 in the pattern of the fly gene of interest (T2A-GAL4 lines) in order to determine if the variant has functional consequences *in vivo*. With the 126 MiMIC T2A-GAL4 lines and 214 UAS-human cDNAs we have made thus far, we have been performing high-throughput phenotypic analysis and rescue experiments (see poster by Andrews et al). In parallel, we are over-expressing reference or variant human cDNAs to assess phenotypic consequences. This is a quick method for analyzing functionality of the variant to identify if the ASD variant behaves as a LOF (reference causes phenotype but variant does not) or a gain-of-function (GOF, variant causes phenotype but reference does not) allele. We are expressing the reference and variant cDNA using three different drivers (ubiquitous, wing-specific, and eye-specific) and scoring for lethality or phenotypes such as reduced wing size, abnormal wing veins, or rough-eyes. Thus far, we have tested 56 reference and 60 variant cDNAs using this approach, and we have observed a LOF effect in 26.7% (16 variants) and a GOF effect in 1.7% (1 variant) of the variants tested. By using this overexpression approach to understand variant function, we have identified several interesting candidates for further study including *GRK4*, *MINK1*, *PC*, and *SOGA3*. We have also identified a variant in *TSC2*, a known ASD gene, to be a LOF allele, which supports our method to screen for ASD candidate genes. We are currently dissecting our hits for their role in neural development using additional human genetic data sets as well as *Drosophila* genetic toolkits. This screen allowed us to quickly probe the function of hundreds of uncharacterized variants in ASD candidate genes and provides a framework to study the function of these genes in neural development.

## PgmNr 3175: Single-cell RNA sequencing analysis identifies knockout-specific and conserved immune cell subsets in *Clec16a* knockout mice.

### Authors:

M. Bakay <sup>1</sup>; M. Gonzalez <sup>1</sup>; B. Strenkowski <sup>1</sup>; F. Mafra <sup>1</sup>; R. Pandey <sup>1</sup>; H. Hakonarson <sup>1,2</sup>

*CLEC16A* is genetically linked with many inflammatory and autoimmune diseases. Its implication in these diverse diseases suggests that *CLEC16A* could be a critical regulator of aberrant autoimmune responses, however the exact mechanism of its action is still largely unknown. To investigate the role of *CLEC16A* in autoimmunity we generated an inducible ubiquitous *Clec16a* knockout (KO) mouse. The global *Clec16a* KO mice exhibit a complex phenotype: immune dysfunction, weight loss, and neurodegeneration. Recently we demonstrated that loss of *CLEC16A* in immune cells leads to an abnormal mitophagy, cell death and immune dysfunction.

Here, we performed single-cell RNA sequencing of immune cells isolated from peripheral blood of nine mice combined into three sample sets (*Clec16a* KO control-vehicle and control-tamoxifen), using the standard 10x Genomics method. The Seurat package in R was used to analyze data and visualize results. After QC, 23,455 cells were characterized from three separate conditions (11,243 from *Clec16a* KO, 5,849 from control-vehicle, 6,363 from control-tamoxifen). Ingenuity Pathway Analysis was used for further assessment of gene function. Automated clustering generated 19 distinct cell clusters. Cells were identified into one of the known cell populations based on canonical gene markers in each cluster. The transcriptional profiles of these individual cells enabled us to identify 19 clusters. Based on canonical gene markers in each cluster we identified 13 of them, with 6 still pending for characterization. For two the most prevalent subtypes (T, B) and also NK-cells, we observed clear separation between cells derived from KO and controls. The specific subset of CD8<sup>+</sup> T cells was preferentially enriched in blood of *Clec16a* KO versus vehicle and tamoxifen treated control (9.4%, 6.4 and 6.5%, respectively), the only subset with very limited number of differentially expressed genes (DEGs), total of 38. Next, we identified signature genes for each cluster and DEGs between KO and control for each known cell subtype. Only a small portion of DEG (~10%) was down-regulated and included genes involved in iron homeostasis signaling. The most significant up-regulated genes were involved in oxidative phosphorylation and cellular signaling. Mitochondrial dysfunction was in a top of tox list, followed by NRF2-mediated oxidative stress response. These result provide additional support for the direct involvement of *CLEC16A* in regulation of mitochondrial function.

## PgmNr 3176: Tissue specific compensatory regulation of gene expression associated with copy number variants in *Danio rerio*.

---

Copy number variants (CNVs) refer to the loss or gain of copies of a DNA region within the genome. While some CNVs enrich the diversity of an organism and play a role in species evolution, CNVs may also be linked to certain diseases such as neurological disorders, early onset obesity, and cancer. CNVs can affect gene expression sometimes leading to disease by direct overlap of the gene or by indirect effects (outside the gene location). These indirect associations may be the result of CNVs containing regulatory elements such as miRNAs. *Danio rerio* (zebrafish) is an excellent model organism for human development as well as disease. Zebrafish share 70% of genetic similarities with humans with 84% of genes associated with human disease also found in zebrafish. Additionally, zebrafish genomes contain a large amount of variation with 14.6% of the zebrafish reference genome being variable. This level of variation is more than four times the percentage of reference genome sequence covered by similarly common CNVs in humans and makes this organism an interesting model to investigate the effects of CNV on gene expression as well as how cells may compensate for these effects. This study seeks to compare CNVs, miRNA expression levels and gene expression levels within the kidney and liver of zebrafish. Array comparative genomic hybridization was used to determine CNV regions in 30 adult Tubingen zebrafish while expression arrays were used to measure gene expression as well as miRNA expression in kidney and liver in these same 30 fish. Expressive quantitative trait loci (eQTL) analysis (linear regression model in R) was used to explore how CNVs may affect gene expression and the regulatory role played by miRNAs. eQTL analysis was performed for cis associations with a 1-Mb (megabase) window upstream and downstream from the transcription probe midpoint to CGH midpoint. This analysis found less than 100 associations in the kidney and over 800 associations in the liver. Around 40% of associations in both tissues were negative (increased copy number – decreased expression, decreased copy number – increased expression) and most associations were indirect where the gene was not overlapped by CNV. Ongoing analyses with these associations will investigate gene functionality including immune function and potential disease susceptibility impacted by CNVs and the compensatory regulation carried out by the cell through mechanisms such as miRNAs.

## PgmNr 3177: Combing ACMG criteria with deep learning algorithms to classify VOUS mutations in genetic sequencing for rare diseases.

---

Contradictory evidence in functional classification of genetic variation based on the American College of Medical Genetics and Genomics (ACMG) guidelines has been a frequently seen issue. Based on analysis of 140,883 genetic variation in the Human Gene Mutation Database (HGMD), benign classification BP1 (2.99%) and BS2 (0.74%), were identified among variants met criteria to be classified as likely pathogenic/pathogenic. PM1 is commonly observed among variants classified as benign (28.45%), while PM2 and PM1 are commonly identified among variants met criteria to be classified as likely benign (48.91% and 42.95%, respectively). In most cases, these variants were re-assigned as VOUS (variants of uncertain significance) and medical genetic geneticist must review the results with patient medical history cautiously to reach a conclusion. Deep learning architectures such as deep neural networks (DNN), recurrent neural networks (RNN) and convolutional neural networks (CNN) have been applied to multiple biomedical fields, including drug discovery/toxicology tests, medical imaging analysis and bioinformatics. We applied deep learning model for the most common type of monogenic diabetes, maturity onset diabetes of the young type 3 (MODY 3), with HGMD reported variants in HNF1A gene as cases and likely benign/benign variants as controls in training data, the ACMG criteria service as the feature vectors to predict the confident score of VOUS variants. In this study, we demonstrated that deep learning algorithm could be applied to weight ACMG criteria then further differential VOUS variants for well-known genetic diseases.

## PgmNr 3178: Whole genome sequence analysis of *Mycobacterium tuberculosis* from Morocco.

---

Drug-resistant tuberculosis (TB) remains a major challenge to global health and to healthcare in Morocco. In 2017, a total of 30897 cases of TB were recorded in Morocco, of which 1.8 % were multidrug-resistant TB (MDR-TB). Extensively drug-resistant TB (XDR-TB) occurs at a much lower rate, but the impact on the patient and hospital is severe. Current diagnostic methods such as drug susceptibility testing and targeted molecular tests are slow to return or examine only a limited number of target regions, respectively. Whole genome sequencing (WGS) has been shown to provide a rapid and comprehensive view of the genotype of the organism, and thus enable reliable prediction of the drug susceptibility phenotype within a clinically relevant timeframe. In addition, it provides the highest resolution when investigating transmission events.

To characterize the genetic determinants of resistance to antituberculosis drugs, we performed a whole genome analysis study on clinical isolates of *Mycobacterium tuberculosis* from different part of Morocco. A mutation rate analysis was followed by a spoligotyping determination for a phylogenetics SNP basec analysis. In addition to mutations in established and recently described resistance-associated genes, novel mutations were discovered for resistance to fluoroquinolones, ethambutol with lower concentration. This study shows that the majority of MDR and pre XDR strains belong to the Euro-American LAM9 sublineage while all the susptible strains belong to the haarlem H4. In addition all strains shared more than 360 SNP's, however uniq SNP's among MDR-TB and susptible strains suggested a higher genomic diversity among the LAM9.

Our findings provide an improved understanding of MDR-TB in Morocco, potentially significant in achieving the goal of precision medicine with respect to MDR-TB prevention and treatment.

## PgmNr 3179: Identification and functional characterization of a novel *ENAM* mutation in the signal peptide region in an autosomal dominant hypoplastic amelogenesis imperfecta family.

Amelogenesis Imperfecta (AI) is a rare hereditary condition that results in developmental enamel defects, affecting the quality and/or quantity of enamel. The affected suffer from early tooth loss, eating difficulties and dental pain. Formation of enamel (amelogenesis) starts from ameloblasts secreting proteins that gradually thicken extracellular layer. ENAM is one of key matrix proteins in amelogenesis. We recruited a three generation family with a unique form of rough hypoplastic AI. The enamel shows irregular local hypoplastic area in all teeth. The affected enamel was not only thin but also hypomineralized based on reduced contrast with dentin. Pedigree analysis suggested autosomal dominant inheritance. Whole exome sequencing of the proband revealed a novel *ENAM* missense mutation (c.101T>C). This mutation would change leucine to proline at 34 codon position in the signal peptide region (39 amino acids). Sanger sequencing confirmed perfect segregation of this mutation with affected status in this family. Short N-terminal segment (42 amino acids) was amplified and cloned into pEGFP-N1 vector. PCR mutagenesis was performed to introduce the identified mutation. HEK293T cells were transfected with wild type and mutant vectors. Cell lysate and culture media were collected and western blot was performed to compare protein level of wild type and mutant vectors. It confirmed that secretion of mutant protein is greatly impaired. Confocal microscopy showed co-localization of ER marker with mutant protein, indicating ER retention. These results will not only expand mutational spectrum of the *ENAM* but also improve our understanding of molecular pathogenesis in AI.

**Keywords:** amelogenesis imperfecta; hypoplastic; whole exome sequencing; ENAM; confocal microscopy

---

**Background:** Vaccines have enormous impact on global health, but their protective efficacy varies between individuals, and we have limited understanding of the immune mechanisms responsible. Systems vaccinology can be applied to model the variation in immune response to vaccines, but few studies thus far have examined the influence of host genetics. **Methods:** We consider in vivo response to pandemic influenza H1N1/09 vaccine (Pandemrix), in a previously-recruited cohort of 178 UK adults (Sobolev et al. 2016, DOI: 10.1038/nr.3328). We integrate matched genetic, transcriptomic (pre-vaccination, day 1 post-vaccination, day 7 post-vaccination), and vaccine-induced antibody response data (pre-vaccination, day 63 post-vaccination). **Results:** 1481 genes were differentially expressed post- vs. pre-vaccination (FDR<0.05, abs. log<sub>2</sub>FC>1). Coexpression gene modules related to innate immunity were upregulated at day 1 (e.g. monocyte and dendritic cell modules). Modules related to adaptive immunity were upregulated at day 7 (e.g. cell cycle and plasma cell modules). At 4630 genes, we find cis-eQTLs that influence post-vaccination gene expression (LFSR<0.05), of which 1894 are vaccine-response eQTLs, where the eQTL effect size differs pre- vs. post-vaccination. A subset of these vaccine-response eQTLs affect differentially expressed genes, and genes with expression that correlates with antibody response. For example, *ELL2* (MIM 601874), a gene involved in B cell antibody production, has upregulated expression at day 7 (FDR=8.2e-10, log<sub>2</sub>FC=2.2) that correlates with antibody response (p=0.04, r=0.31), and is modulated by a day 7-specific eQTL (LFSR=0.03). **Discussion:** By integrating longitudinal transcriptomic and antibody response data with matched genetic data, we identify loci where host genetics impacts immune response to Pandemrix. We are now performing colocalization of our vaccine-response eQTLs with independent QTL studies (e.g. in vitro stimulated immune cell subsets) and associations from GWAS of immune-mediated diseases. This will allow us to pinpoint cellular contexts and shared mechanisms through which these genetic effects on immune response manifest—we expect to present these additional results at the meeting.

# **PgmNr 3181: Gene-level, allele-specific and total read count-based mixed effects model improves power and speed for cis-QTL mapping, fine-mapping, and prediction.**

---

An increasing number of studies measure RNA-seq and other molecular traits with allele-specific (AS) reads. However, most methods do not take full advantage of the information provided by the combination of total and AS reads. Although there have been efforts to unify total and AS reads, they tend to be computationally intensive and are typically not used in large-scale studies such as GTEx with several hundred samples. In addition to QTL mapping, multi-SNP models for building prediction models and fine-mapping have become increasingly important for post-GWAS analyses approaches such as PrediXcan and COLOC. However, to our knowledge, there are no multi-SNP methods that take advantage of AS observations.

The gain in speed and power is achieved by using a linear mixed effects model combining total and gene-level AS read counts. Key features of our approach are 1) the use of a random effect to directly model the common environmental conditions to which both copies of the person's haplotypes are subjected; 2) a second random effect to account for the noise around the expected fraction of AS reads given the individual's heterozygosity; 3) the borrowing of information across the gene body using gene-level AS counts that are calculated using phASER.

We implement the single-SNP version of the method for QTL-mapping. To fit the multi-SNP model for prediction, we develop a penalized likelihood-based algorithm. Furthermore, to make our framework compatible with existing fine-mapping tools, which assume independent observations, we perform a whitening procedure on the three observations of each individual. Finally, we apply the methods to GTEx RNA-seq data to study the cis-regulation of gene expression.

We applied our methods to RNA-seq of 670 whole blood samples in GTEx version 8 data. Our eQTL mapping method (mixQTL) was more than 10 times faster and more powerful than existing methods such as WASP and RASQUAL. Compared to GTEx standard eQTL calling pipeline results, mixQTL was more powerful while maintaining the type I error calibration. Furthermore, our multi-SNP method showed better performance in identifying causal variants both in simulations and real data.

We present here a suite of fast and powerful methods that improve cis-eQTL mapping, fine-mapping, and prediction by taking full advantage of total and AS counts available in many large-scale studies. We demonstrate the type I error calibration and superior power using both real and simulated data.

---

Large-scale genome sequencing is poised to provide an exponential increase in the discovery of disease-associated mutations, but the functional interpretation of such mutations remains a major challenge. Here we identify deletions of a regulatory sequence (intestine-critical region, ICR) on human chromosome 16 that cause inherited severe and intractable congenital diarrhea in affected infants from seven families of Jewish Iraqi origin. Transgenic mouse reporter assays show that the ICR robustly activates tissue-specific transcription *in vivo* during development of the gastrointestinal system. Targeted deletion of the ICR in mice caused symptoms recapitulating all major aspects of the human condition. Guided by the gastrointestinal *in vivo* activity pattern of the ICR, we performed transcriptome analysis in the developing gut of mouse embryos, which identified a neighboring unannotated open reading frame (*Percc1*) whose expression was lost in ICR knockout animals. Targeted deletion of *Percc1* in mice recapitulated the phenotypes observed in ICR deletion mice and patients, whereas an ICR-driven *Percc1* transgene rescued all phenotypes found in ICR knockout mice. Taken together, our results uncover a novel human gene critical for intestinal function and underscore the need for targeted *in vivo* studies for interpreting the growing number of clinical genetic findings that do not affect known protein-coding genes.

## PgmNr 3183: Evaluating variants of unknown significance with CRISPR-engineered human-yeast ortholog complementation.

Most catalogued human genetic variants lack any functional characterization. These variants of unknown significance pose a dilemma for the diagnosis of human diseases whether they are hereditary disorders arising from germline mutations or cancer with somatic alterations. Moreover, without any substantive functional characterization, it remains difficult to determine the phenotypic consequences of most human genetic variation, be it polymorphism, rare variant or mutation. There are a limited number of high throughput methods for functional characterization of human variants. To address this challenge, we are using a novel CRISPR yeast genome engineering technology to study variants of unknown significance – our study focuses on the functional complementation of specific human yeast gene orthologs. Notably, some human genes provide complementary function to their yeast ortholog which has been deleted or reduced in expression. We are leveraging this functional ortholog complementation for parallel evaluation of human variants in human genes. Specifically, we are focused on complementing yeast genes that are essential or non-essential. For this study, we identified four essential yeast genes with their human orthologs provide complementation of lethal growth defects. These human genes have germline mutations that lead to a variety of genetic disorders. First, human gene orthologs are engineered for approximately 300 coding variants. To knockdown endogenous yeast genes, we rely on a yeast strain that has stable integration of gRNAs specific to over 1,117 essential genes and 514 genes required for robust growth. Among this set of human genes include NSHDL, a gene where germline mutations cause congenital hemidysplasia with ichthyosiform erythroderma and limb defects (CHILD). To identify germline variants, we used resources such as gnomAD and ClinVar. Using structural prediction information or CADD scores, we ranked up to 300 variants that are introduced into the human gene, eliminate the yeast ortholog expression and then these strains are tested for perturbations in growth. Subsequently, we determine which human variants affected growth. Our approach holds the possibility of enabling rapid, efficient and highly parallel functional characterization of human genetic variants.

## PgmNr 3184: A mix pool of iPSCs from hundreds of genetically different donors for multiplexing genetic studies.

Genome wide association studies (GWAS) have been used to discover variants associated with a plethora of traits and diseases. Fine mapping and validation of the variant is not straightforward as manipulation of the genome of a human individual in-vivo is not feasible. However, with the invention of induced pluripotent stem cells (iPSCs), we can reprogram human adult cells into iPSCs and differentiated them to a plethora of adult tissue types for testing in-vitro. Therefore, we can create iPSCs from carriers as well as non-carriers, differentiate and test whether the genetic effect discovered in GWAS can be replicated in-vitro. To enable such studies, one would require a very large collection of individual iPSCs that have whole-genome sequencing data as well as a method to reprogram all of them into iPSCs in a feasible and cost effective manner. Here, we describe our approach for achieving just that. We use lymphoblastoid cell-lines (LCLs) from both the 1000 Genomes Project and Personal Genome Project where whole-genome sequencing data is available for every donor. By pooling together a large number of LCLs from many different donors (>100 donors), we reprogrammed the mixed pool of LCLs into iPSCs by nucleofection of the Yamanaka factors. We found that the LCLs do become adherent and expressed stem-cell markers. To determine to what extent the individual donor LCLs were successfully reprogrammed, i.e. donor diversity, we employed our method which uses cell sorting, DNA sequencing and an EM-algorithm to predict relative donor proportion. The method does not require single-cell or exogenous DNA barcodes but exploits SNPs as natural barcodes for individual donors. Using the method, we found that the majority of LCLs were successfully reprogrammed into iPSCs. We then proceed to determine if the iPSCs are indeed pluripotent by performing directed differentiation into the 3 different germ layers, i.e. ectoderm, mesoderm and endoderm. Using the same method, we determined the donor diversity for each of the 3 germ layers and discovered that the majority of donors iPSCs can be differentiated into all 3 germ layers. Finally, we applied our method to test for genotype specific effects of inducing pluripotency as well as exiting pluripotency from the mixed pool. In summary, we describe a method that enables the multiplex reprogramming of LCLs into iPSCs and they become a valuable resource for testing and validating genotype specific effects discovered in GWAS.

## PgmNr 3185: Vulnerability to stress: The moderating role of *HOMER1* gene in gene x environment interaction.

Early life experiences and stress events play a crucial role in future development and affect future orientation as well. Future orientation is the way individuals tend to think about the future which includes planning, goal-setting and delay-discounting. The present research aims to explore whether *HOMER1*(rs7713917) polymorphism can moderate relationship between early life stress and future orientation. 14,675 Chinese Han people involved in the current study, in which were 8267 female (56.3%). Future-Oriented Coping Inventory and Adolescent Self-Rating Life Events Checklist were fulfilled by participants, and DNA was collected to test polymorphism of *HOMER1*. The results indicated that genotype of *HOMER1* rs7713917 was not associated with future orientation( $\beta = -0.01$ , 95% CI = [-0.18, 0.18],  $t = -0.04$ ,  $p = 0.969$ ), early life stress was negatively associated with future orientation ( $\beta = -1.42$ , 95% CI = [-1.60, -1.25],  $t = -15.75$ ,  $p = 0.000$ ), and that *HOMER1* polymorphisms moderated this association ( $\Delta R^2 = 3.3\%$ ,  $F[5, 14619] = 99.64$ ,  $\beta = -0.18$ , 95 %CI = [-0.36, -0.01],  $t = -2.06$ ,  $p = 0.039$ ). Specifically, individuals with AA genotype and in high early life stress expressed higher future orientation compared with those with in low chronic stress. In contrast, individuals with GA/GG genotype displayed lower vulnerability to environmental changes. Then we separated samples into 3 groups according to their type of hometown to check the interaction effect ( $\Delta R^2 = 5.6\%$ ,  $F[5, 2229] = 26.41$ ,  $\beta = -0.61$ , 95 %CI = [-1.08, -0.16],  $t = -1.27$ ,  $p = 0.204$ ), and found the same mode in town group, but found no associations in city ( $\Delta R^2 = 3.2\%$ ,  $F[5, 9140] = 60.22$ ,  $\beta = -0.18$ , 95 %CI = [-0.36, 0.09],  $t = -2.06$ ,  $p = 0.039$ ) and countryside groups ( $\Delta R^2 = 2.7\%$ ,  $F[5, 3284] = 17.99$ ,  $\beta = -0.02$ , 95 %CI = [-0.38, 0.34],  $t = -0.10$ ,  $p = 0.920$ ).

## PgmNr 3186: Generation and *in vivo* characterization of human *NOTCH* transgenes to study the functional impact of disease-associated variants in *Drosophila*.

---

Notch signaling is a well-studied signaling pathway that is conserved throughout metazoan evolution. While the *Drosophila melanogaster* genome encodes a single Notch receptor, the human genome encodes four paralogs (*NOTCH1-4*). Variants in human *NOTCH* genes have been found to cause diverse Mendelian disorders and have been identified in various types of cancer. Some Notch related diseases in human are thought to be caused by loss-of-function alleles (amorphs or hypomorphs), whereas others are considered to be due to gain-of-function alleles (hypermorphs, antimorphs or neomorphs). Classification of *NOTCH* mutations into different functional classes has primarily been performed using mammalian cell-based signaling assays *in vitro* or knock-in mouse models *in vivo*. However, considering the number of newly identified missense variants found in human *NOTCH* genes is increasing at a rapid pace due to utilization of whole-exome sequencing in clinical settings, a higher-throughput assay system to experimentally determine the functional consequence of disease associated *NOTCH* variants *in vivo* is crucial.

To this end, we first generated a series of transgenic constructs and *Drosophila* lines that allow the expression of full length human *NOTCH1-4*. Intriguingly, these transgenes were unable to activate Notch signaling in flies, and *NOTCH1* even seemed to act in a dominant negative manner. Because human NOTCH proteins might not be compatible with fly Notch ligands, Delta (DLL1-4 in humans) or Serrate (JAG1-2 in humans), we next generated a series of transgenic lines that can function in a ligand-independent manner. Interestingly, ligand-independent NOTCH1 and NOTCH2 were able to strongly activate Notch signaling in flies, with NOTCH3 and NOTCH4 having reduced strengths. These results suggest that the intracellular domains of human NOTCH proteins have the ability to functionally interact with Mastermind (MAML1-3 in humans) and Suppressor of Hairless (RBPJ in humans) to activate fly Notch signaling *in vivo*. We are currently continuing to introduce several disease-linked NOTCH1 and NOTCH2 mutations into these constructs to assess their functions. This system will provide a platform for analyzing human *NOTCH* variants that affect the intracellular domain systemically and efficiently *in vivo*.

## PgmNr 3187: Genetic manipulation of zebrafish is a powerful tool to determine the pathogenicity of holoprosencephaly mutations.

Holoprosencephaly (HPE) is the most common malformation of the forebrain in humans. It is classified anatomically by the degree of separation of the eye field and telencephalon into discrete left and right structures. Its phenotypic spectrum is broad and can range from mild craniofacial features to the extreme of severe microcephaly, cyclopia and a proboscis. Both strong autosomal dominant driver mutations, in a handful of key developmental genes, as well as modifying environmental and genetic factors are considered likely factors to explain this phenotypic variability.

Therefore, from a set of 330 HPE probands evaluated using a targeted capture panel of 150 developmental genes we selected variants in a number of known or suspected HPE genes, both published and un-published, for zebrafish assay development. Our ultimate goal is to annotate specific disease-associated individual variants and to look for any associated co-morbid genetic modifiers present in the same family.

For example, we recently employed a sensitive assay of human *FGF8* variants in zebrafish to demonstrate that the spectrum of isoforms of FGF8 produced by alternative splicing can provide key insights into the genetic susceptibility to human malformations. In addition, we described novel mutations in the FGF core structure that have both subtle and profound effects on ligand post-translational processing and biological activity. Finally, we solved a case of apparent digenic inheritance of novel variants in *SHH* and *FGF8*, two genes known to functionally co-regulate each other in the developing forebrain, as a simpler case of FGF8 diminished function. We now extend these investigations to include nearly a hundred non-synonymous variants in *SHH*. Here we show that the application of functional testing brings considerable clarity to the genotype/phenotype analysis and affirms many of the original pathogenetic assertions. Direct variant testing in zebrafish ultimately extends, and often replaces, pathogenicity determinations made bioinformatically.

Advances in genomics has transformed our ability to identify the molecular cause of rare diseases. Yet for most candidate genes, we lack insight into their biological function, how mutations identified in patients affect them, or what therapies could be useful. Model organisms (MOs) represent powerful experimental systems to confirm the pathogenicity of gene variants, characterize the gene's biological function, and identify potential therapies. For these reasons, the Canadian RDMM Network ([www.rare-diseases-catalyst-network.ca](http://www.rare-diseases-catalyst-network.ca)) was established in 2014 to catalyze and fund connections between clinicians discovering new disease genes and researchers able to study equivalent genes and pathways in MOs.

The RDMM Network has created a rapid and direct pathway from gene discovery to functional characterization studies in MOs. The central resource of the RDMM Network is a web-based Canadian directory of MO researchers ('the Registry') built to facilitate identification of suitable collaborators for applying clinicians. As of June 2019, more than 500 researchers have registered over 6,500 genes of interest. With the aid of the computational inference built into the Registry, this translates to the coverage of close to 7,500 human genes. RDMM uses a committee process to identify and review potential clinician-MO researcher matches and approve \$25,000 CAD in catalyst funding. Since 2014, we have made 84 connections and funded 98 functional characterization studies. Besides the scientific insights into the molecular mechanisms of rare disease and possible novel therapies, these collaborations also lead to high impact papers, long-term collaborations, and external grants.

Leveraging on the success of the first four years, last year we expanded the impact and reach of the RDMM Network: we established international linkages with emerging similar networks in Europe, Australia, Japan and the United States. To facilitate further community uptake and adaptation of the concepts we established, we have made the RDMM Registry portable, customizable and linkable with other instances, and our committee processes freely available.

The Canadian RDMM Network continues to expand its utility by adopting policies and processes to support global collaborations irrespective of the software used. In so doing, we will continue to create meaningful collaborations between clinicians and MO researchers, generate new knowledge, and

advance rare disease research locally and globally.

## PgmNr 3189: Defining the missing heredity and phenotypic diversity associated with oculocutaneous albinism.

---

Oculocutaneous Albinism (OCA) is a recessive disorder characterized by reduction of skin, hair and eye pigmentation. OCA occurs with an average world-wide incidence of ~1 in 17,000. OCA individuals are at higher risk for UV-induced skin cancers and a complex set of developmentally-mediated visual impairments, and present with diverse clinical severity. While two definitive OCA mutation alleles are predominately identified in *TYR* (OCA types 1A and 1B) or *OCA2* (OCA type 2), a small number of cases can be attributed to mutations in *TYRP1*, *SLC45A2*, *SLC24A5*, *C10orf11/LRMDA*, or a linkage region on 4q24. Most critically, 20-50% patients remain without identification of biallelic mutations after traditional exon-based screening for these six known OCA genes. This suggests potential coding-variation in novel loci, or aberrant splicing or non-coding cis-regulatory variation at known OCA genes may contribute to the missing heredity and diverse clinical presentations observed in OCA patients. To better define the molecular mechanisms underlying OCA, we are sequencing over 400 OCA proband individuals and associated family members, at coding, intronic, and cis-regulatory regions of six OCA genes and 31 genes identified by pigmentation GWAS. We are using custom capture, short-read sequencing, in which we defined the non-coding cis-regulatory regions from a catalog of DNase1-HS data (derived from primary melanocytes, immortalized melanocytes, melanoma tumors, and retinal pigment epithelium) and from H3K27Ac ChIP cis-regulatory elements we have identified under conditions of MAPK activation and inhibition in 501mel melanoma cells. In addition, we have included regions encompassing SNPs in linkage disequilibrium with SNVs identified from our melanocyte expression quantitative trait (eQTL) dataset, generated from RNA-Seq analysis of 106 primary melanocytes. This dataset identifies eQTLs for 4997 genes expressed in the melanocyte lineage. Here we find over 73,000 eQTLs for 128 genes associated with visible pigmentation-related phenotypes, including 156 and 684 eQTLs for *TYR* and *OCA2*, respectively. Our family, trio-based analysis and interrogation of coding, and non-coding sequence, will better define the molecular spectrum of OCA mutations, facilitate assessment of non-coding DNA variation function, and allow for the subsequent systematic evaluation of the molecular mechanisms underlying both missing heritability and phenotypic variation observed among OCA patients.

## PgmNr 3190: ClinVar variants in Rhesus monkey (*Macaca mulatta*).

Nonhuman primates provide unique and remarkably informative animal models for a wide range of human diseases and biomedical questions. In neuroscience, infectious disease, endocrine function and reproductive biology, developmental psychobiology and other aspects of biomedical research, nonhuman primates continue to play an indispensable role. Human genetic research has identified specific genes that influence a variety of human diseases, but for many pathogenic mutations, non-primate models fail to adequately model the human condition. We are documenting naturally occurring genetic variation in research colonies of rhesus macaques (*Macaca mulatta*), the most widely used nonhuman primate in biomedical research, and have produced Illumina whole genome sequence data for 537 animals, identifying more than 72 million unique single nucleotide variants (SNVs). Among those variants there are 339,699 unique missense variants affecting 19,929 protein coding genes, 94.4% of the genes annotated in the rhesus genome. This large pool of naturally occurring variation provides an outstanding and mostly untapped resource for the development and exploitation of spontaneous highly translational genetic models of human disorders. To evaluate the potential impact of this standing genetic variability, we downloaded the ClinVar database of human genetic variants and using the liftOver tool determined the orthologous base in the rhesus genome. We find 509 pathogenic or likely pathogenic variants from ClinVar that are also polymorphic in the macaques, pointing directly to hundreds of novel genetic models. Of those 509, 46 are pathogenic variants in autosomal dominant diseases (based on ClinVar records), making these immediate candidates for validation by Sanger sequencing and detailed phenotypic characterization of carriers. The dominant mutations include documented causes for cardiomyopathy, cancer, hypercholesterolemia, Angelman Syndrome and others. Given the significance of primates for studies of neurobiology, we investigated the potential relevance of the 509 shared pathogenic missense variants and found 65 are predicted to influence brain or neurological function. These analyses demonstrate that naturally occurring variation segregating in NIH funded colonies of nonhuman primates constitutes a unique, valuable and largely unexploited opportunity for rapid development of highly translatable animal models of numerous significant public health problems.

Blood plasma proteins play an important role in immune responses, including cytokine signaling, the complement system and the acute-phase response. Variability in plasma protein levels is observed in the general population, and has been partly explained by both genetic and non-genetic factors, including age and sex. Quantitative Trait Loci (pQTLs) collectively involving more than 1,597 plasma proteins have been recently reported. However, previous studies of genetic determinants of plasma protein levels have lacked an exhaustive control of the concomitant blood cell composition which may act as a confounding factor.

Here we evaluated plasma protein levels across 400 unrelated healthy individuals of Western European ancestry stratified by sex, and by age across two decades (20-29 and 60-69 years) from the *Milieu Intérieur* population-based cohort. 297 proteins were quantified by antibody-based multi-analyte profiling using Luminex technology in a clinically certified laboratory. More than 5.2M single-nucleotide polymorphisms were assessed following genome-wide DNA genotyping and imputation. Non-genetic variables considered in the analysis, included cell counts of major immune cell types measured by blood tests and standardized flow cytometry as well as 188 lifestyle and biochemical factors.

A total of 704 significant associations involving 131 proteins and 75 non-genetic factors were identified. Consistent with previous studies, age, sex, body-mass index and glomerular filtration rate were among the factors with the highest number of associations. In addition, a total of 46 proteins were associated with specific blood cell fractions including erythrocytes, platelets, neutrophils, lymphocytes and eosinophils. After controlling for these covariates, we detected 101 and 12 pQTLs acting in *cis* and *trans* respectively, collectively associated to 93 plasma protein levels (False Discovery Rate adjusted p-value <0.05). These results replicate between 51% and 77% of the plasma proteins evaluated with QTLs previously reported. Moreover, we identified an additional set of 29 plasma proteins whose expression levels are under genetic control. Overall, genetic factors, followed by blood cell fractions, showed a larger contribution to variable plasma protein levels than age and sex. Our study highlights common human polymorphisms that may modulate immune phenotypes on

the basis of altered plasma protein levels.

## PgmNr 3192: Inference of target genes regulated by open chromosome regions in human brain.

The spatial and temporal gene expression involves in interaction between transcription factor (TF) and cis-regulatory element (CRE), abnormality of which plays a causal role in many human diseases. GWAS has identified thousands of SNPs related to complex diseases; however, most of them are in noncoding regions. Translating GWAS discoveries to biology requires linking CREs to their target genes. CREs in which GWAS loci are located are often distant to their target genes, making it nontrivial to link CREs to their target genes. Assay for Transposase-Accessible Chromatin (ATAC-seq) can assay genome-wide open chromatin profiling, providing opportunities for studying regulatory elements. Previous quantitative trait loci (QTLs) studies have indicated that accessibility of open chromatin regions and gene expression can be regulated genetically. Our preliminary data show overlaps of QTLs for open chromatin regions (chromatin accessibility QTLs - caQTLs) and gene expression (eQTLs), implying their co-regulation by same genetic variants, motivating us to identify open-chromatin-region-gene pairs leveraging the genetic sharing.

In the brainGVEX project of PsychENCODE, we assayed matched multi-omics data, including whole-genome sequencing (WGS), RNA-seq, ribosome profiling (Ribo-seq), ATAC-seq and proteomics, in frontal cortex samples from over 400 individuals. In this study, we first trained an elastic-net model to identify variants associated with a gene's expression, and then used the variants to predict ATAC-seq peaks in 200kb window centered the gene's transcription start sites (TSS). An ATAC-seq peak with non-zero coefficients for at least one variants, is considered to link to this gene. In the preliminary exploration, we focused on the 149 genes that have both eQTLs and caQTLs; these genes have a median of 27 ATAC-seq peaks and 46 variants to predict their gene expression. Among these genes, we identified 77 genes (47.7%) that have linked ATAC-seq peaks, of which a median of 6 variants was included in the predictive models. The median of R<sup>2</sup> is 0.18 for peak-gene pairs, comparing to the 0.02 of the non-relevant peaks. The preliminary results show the potential of our method to identify ATAC-seq peaks and their target genes, and we are using Hi-C data in public datasets to further validate our results. We will expand the analysis to whole genome and interpret their biological meanings in SCZ combing the data from GWAS.

## PgmNr 3193: Elucidating the role of mRNA splicing in disease pathogenesis.

Up to 70% of disease-associated genetic variants do not have apparent effects on gene expression levels. This suggests that a large fraction of functional variants may disrupt gene regulation through alternate mechanisms, such as mRNA splicing. We have shown previously that mRNA splicing is a primary mechanism that links genetic variation to disease. Several studies have underscored this point by identifying splicing quantitative trait loci (sQTLs) in linkage disequilibrium with GWAS hits for a number of diseases, including Type 2 diabetes, Alzheimer's disease, and schizophrenia. This suggest that SNPs affecting splicing have the potential to be casual variants underlying a substantial number of disease-relevant GWAS hits. However, there exists no comprehensive analysis of the regulatory mechanisms by which genetic variation affects RNA splicing in a large number disease-relevant tissues. Therefore, we investigated the impact of genetic variation on mRNA splicing in 53 tissues from the Genotype-Tissue Expression (GTEx) project. Using LeafCutter, we mapped thousands of sQTLs in each tissue individually and quantified that 80% of splicing events and 95% of sQTL are shared across all tissues.

One limitation of sQTL analysis is that it is often difficult to disentangle the mechanisms by which SNPs affect splicing to contribute to disease. For example, SNPs can affect splicing by strengthening or weakening the sequence or recognition of splice sites and splicing regulatory elements, which can result in aberrant protein products and cause disease. Our hypothesis is that SNPs that increase disease risk through splicing likely do so by reducing splicing accuracy, resulting in the production of a number of non-functional mRNA transcripts. Therefore, we devised a novel strategy to detect non-functional transcripts produced as a result of error-prone splicing (i.e. 'noisy' splicing), mapped thousands of noisy splicing QTL (noisy sQTL) in disease-relevant tissues from GTEx, Depression Genes and Networks (DGN), and the CommonMind Consortium, and checked for associations between these non-functional transcripts and disease risk (e.g. for autoimmune, neurodegenerative, and cardiovascular diseases) by performing mRNA splicing imputation followed by splicing transcriptome-wide association studies (TWASs).

Our results provide the field with a better understanding of the molecular mechanisms underlying sQTL activity and effect size variability in the context of disease.

The clinical application of genomic data is reliant upon robust, curated associations between locus, genotype, mechanism, and disease phenotypes.

Several groups provide resources for variant annotation to aid interpretation, but each of these use different terminology to describe inheritance, allelic requirement, and both structural and functional consequences of a variant. There is considerable discrepancy in the derivation and application of these terms.

The Gene Curation Coalition (GenCC), includes members of Clinical Genome Resource (ClinGen), DECIPHER, Gene2Phenotype (G2P), Transforming Genetic Medicine Initiative (TGMI), Genetics Home Reference (GHR), Genomics England PanelApp (PanelApp), Online Mendelian Inheritance in Man (OMIM), and Orphanet. Together, this group is working to harmonise approaches to ensure gene-level curated resources are comparable and interoperable, and use standardized terms for mode of inheritance, allelic requirement, genetic consequence, functional consequence, and mechanism of pathogenicity. This will allow these international groups to most effectively work together to provide consistent and useful resources for the community, including guiding the formation of gene panels for disease-targeted testing and genomic analysis.

Here we present an approach to standardize terminology for characterization of disease-gene relationships to facilitate harmonized curation, and support variant interpretation within the

ACMG/AMP framework.

Terminology used by all GenCC members and partners was reviewed. Terms for allelic requirement and inheritance coalesce around human phenotype ontology (HPO) terms, while terms for gene, transcript and functional consequence coalesce around sequence ontology (SO) terms. Use of these standardized terms will facilitate assessment of which variant classes are likely to be disease-relevant (e.g. to apply PVS1) and assessment of relevance of functional evidence, to determine which ACMG/AMP rules are applicable.

In addition to streamlining disease-gene curation and facilitating interpretation of variants in established disease-gene pairs, this standardized terminology will aid in assessment of novel potential disease-gene or disease-variant relationships. For a previously unseen variant, we usually understand the genetic consequence, but not (directly) functional effect. Similarly we may not know the precise mechanism for a disease or variant, but can interpret likely disease-relevant variant classes.

## PgmNr 3195: The functional impact of structural variation in the human brain.

Structural variants (SVs) are an important source of genetic diversity and have been linked to many diseases. However, their contribution to molecular traits in the brain and its impact on neurodegenerative diseases remains unknown. The AMP-AD consortium provides an extensive collection of multi-omics data that allow us to identify SVs and characterize their functional impact. This includes deep whole-genome sequencing (WGS) from 1860 subjects from four aging cohorts (ROS/MAP, MSBB and Mayo Clinic). Here, we developed a rigorous pipeline integrating six different SV discovery tools plus merging and genotyping strategies to identify a total of 169330 high confidence SVs, present in at least one cohort, and 44919 SVs shared amongst all cohorts. While majority (~63k) SVs were also identified in 1KGP and gnomAD-SV, we also detected ~22k novel SVs in our dataset, suggesting potentially pathogenic variants. We identified previously known SV at *MAPT* locus and identified several novel associations to neuropathology traits. By integrating RNA-seq data from different brain regions, we mapped *cis* expression quantitative trait loci associated with SVs (SV-eQTLs). We identified a total of 945 SVs altering the expression of 1336 genes (FDR<0.05) in the dorsolateral prefrontal cortex (DLPFC) tissues from ROS/MAP, of which 5 SVs were tagged by GWAS SNPs related to neurodegenerative diseases. In Mayo Clinic and MSBB, we identified respectively 907 and 576 genes altered in at least one brain region, of which 6 and 10 SVs tagged by neurodegenerative GWAS SNPs like, for example, a known 157kb duplication in *KANSL1* (*MAPT* locus) that overlaps with a variant (rs2732703) associated with Alzheimer's Disease and a novel 56kb deletion affecting *HLA-DRA* and that overlaps with a variant (rs115641444) associated with Autism spectrum disorder and schizophrenia. Additionally, we found reproducible SV-eQTLs for 147 genes across all cohorts (including *C4A*, *ERAP2*, *GBP3*, *KANSL1*) that promoted widely varying levels of expression changes in the brain. In order to validate the SVs, we have generated targeted (*MAPT* locus) PacBio long-read sequencing data. We are now testing the impact of common and rare SVs on protein levels, splicing, histone acetylation, and methylation of DLPFC. Overall, we present the most comprehensive map of structural variation in aging cohorts, providing a valuable resource for understanding the functional impact of SVs in neurodegenerative and neuropsychiatric diseases.

## PgmNr 3196: Characterization of circulating cell-free miRNA signatures in cystic fibrosis.

### Authors:

**Introduction:** In cystic fibrosis (CF), dysfunction of the cystic fibrosis transmembrane conductance regulator (CFTR) protein, due to *CFTR* gene variants, results in a multisystem disease. Clinical heterogeneity seen among patients with the same *CFTR* genotype presents a major therapeutic challenge. Increasing evidence from transcriptome profiling studies suggests that several cellular microRNAs (miRNAs) act as regulators of gene expression and influence CF disease progression. However, their abundance and functional relevance in CF extracellular milieu remain poorly understood. We utilized microarray profiling to identify cell-free miRNAs differentially expressed between CF and non-CF subjects.

**Methods:** Plasma was extracted from peripheral blood of 5 CF and 5 non-CF subjects. Total RNA was then isolated from each sample and subjected to microarray profiling with Affymetrix miRNA 4.0 microarray. Labelling, hybridization, washing, and scanning was performed according to the manufacturer's recommendation. Microarray datasets were assessed for quality using Transcriptome Analysis Console. The Robust Multi-Chip Analysis (RMA) was utilized for background correction and normalization. The high-quality data were then mapped to miRbase mature miRNA annotation (v20) and differential expression analysis performed with Partek Gene-Specific Analysis algorithm. Cell-free miRNAs differentially expressed between CF and non-CF subjects with at least 2-fold difference (FDR<0.05) or more were prioritized for functional analysis.

**Results:** Analysis of the microarray dataset revealed that several miRNAs were abundantly expressed in CF. Among the key miRNAs significantly (FDR<0.05, log<sub>2</sub> FC<sup>3</sup> 2) differentially expressed between CF and non-CF subjects were members of the let-7, and 103/107. Using in silico methods we identified the top-ranked validated targets were genes involved mostly in miRNA biogenesis and gene expression, and signal transduction pathways were the most significantly (p<0.05) enriched pathways.

**Conclusion:** Cell-free miRNAs play a crucial role in several biological processes and are proven biomarkers for many diseases. Our results suggest their aberrant expression may be clinically in CF.

## PgmNr 3197: Carriers of rare protein-coding variants in *AS3MT* have reduced arsenic metabolism efficiency.

Exposure to inorganic arsenic in drinking water is a global health hazard, affecting >200 million individuals worldwide. Common variation in the 10q24.32 region, containing the arsenic methyltransferase (*AS3MT*) gene, is associated with arsenic metabolism efficiency (AME) and arsenic-related diseases. Findings from familial aggregation studies suggest AME has substantial unexplained heritability, which may be attributable to rare variants. The key role of *AS3MT* in arsenic metabolism and the established association of 10q24.32/*AS3MT* common variants with AME makes *AS3MT* a strong candidate gene for rare variant studies of AME. We generated targeted sequencing data for the coding regions of *AS3MT* (and ~25 additional genes with posited roles in arsenic metabolism) for three arsenic-exposed cohorts: Health Effects of Arsenic Longitudinal Study (HEALS, n=2,343), Strong Heart Study (SHS, n=873), and New Hampshire Skin Cancer study of squamous cell carcinoma (NHSCC, n=666). We measured AME as the percentage of arsenic in urine that is dimethylarsinic acid (DMA), the end metabolite in a series of reduction and methylation reactions (catalyzed by *AS3MT*) that act to detoxify arsenic. We conducted gene-level association tests of the collective effects of rare protein-altering variants (MAF<0.01) in specific genes on DMA% using the SKAT-O R package. We applied MetaSKAT to calculate the combined effect of rare protein-coding variants on AME across all cohorts. All analyses adjusted for common SNPs in *AS3MT* known to be associated with DMA%. In HEALS, we identified three genes showing evidence of association with DMA%, *AS3MT* (P=0.005), *GSTO1* (P=0.05), and *SFR1* (P=0.04). In SHS, we observed associations for *AS3MT* (P=0.04) and *SLCOB1* (P=0.02), and in NHSCC, an association was observed for *GSTO1* (P=0.05). In the meta-analysis, only *AS3MT* (P=0.03) was associated with DMA%. Across all cohorts, the *AS3MT* gene-set primarily included singletons and doubletons, which were all missense mutations with the exception of one stop-gained mutation. Collectively, carriers of rare variants in *AS3MT* had low DMA% compared to non-carriers. Protein-coding *AS3MT* variant rs11191439 was excluded from gene-based tests due to high MAF (0.05, 0.15, and 0.07 for HEALS, SHS, and NHSCC, respectively). This variant showed an inverse association with DMA% across all cohorts (p<0.05) indicating it reduces AME. In summary, we provide evidence that rare variants in *AS3MT* affect AME in multiple populations.

## PgmNr 3198: Non-additive genetic effects on gene expression modulated by cell heterogeneity in whole blood.

Thousands of genetic variants have been reported to influence blood cell counts, with implications for disease risk. However, our understanding of gene expression regulation in specific blood cells types and its relationship with disease remains unclear. To investigate the cell specific nature of gene expression and its additive and non-additive regulation, we quantified cell counts and RNAseq data in whole blood in 915 individuals from 35 pedigrees, including 390 parent-child trios and 180 parent-child duos. Almost all genes (99.8%) are significantly associated with at least one cell count, from 910 genes associated with basophils to 16,679 genes with lymphocytes. Next, we compared heritability ( $h^2$ ) estimates of gene expression before and after controlling for cell counts. Since cell type abundance is heritable, we expected cell counts to contribute to the genetic component of expression, decreasing  $h^2$ . However, we observed a significant increase (mean  $h^2 = 0.192$  to  $h^2 = 0.201$ ,  $P\text{value} = 4.36e-05$ ) suggesting most genetic effects on expression are mediated by other processes, with cell composition playing an important role in the environmental component.

To investigate non-additive regulation, we first looked genetic effects dependent of cell composition (cell-type x genotype interactions) and found 1,311 significant interactions in 636 genes across the 14 cell types. For 11 genes, we found evidence for multiple loci interacting with different cell types, suggesting multiple cell-specific regulatory elements. Secondly, we investigated whether parent-of-origin effects were also influenced by cell-type abundance. Focusing on known imprinting genes ( $N=195$ ), we looked for SNPs that would act in a parent-of-origin dependent manner (PO-eQTL) and also interact with cell-type composition. We detected 30 genes with PO-eQTLs and cell-types interactions. For 16 genes, the same or a nearby eSNP ( $R^2 > 0.8$ ) were significant for both effects, including genes such as *SNURF* (lymphocytes and neutrophils), *NOTCH3* (monocytes), and *CAST* (basophils).

In conclusion, we show the influence of genetic variation on gene expression in a specific tissue is combinatorially affected by factors such as cell composition and allelic inheritance: considering these factors together may be crucial to understanding the mediating role that gene expression plays between genetics and disease.

## PgmNr 3199: Predicting the effects of SNPs on transcription factor binding affinity.

GWAS have revealed that 88% of disease associated SNPs reside in noncoding regions. However, noncoding SNPs remain understudied, partly because they are challenging to prioritize for experimental validation. To address this deficiency, we developed the SNP effect matrix pipeline (SEMpl). SEMpl estimates transcription factor binding affinity by observing differences in ChIP-seq signal intensity for SNPs within functional transcription factor binding sites genome-wide. By cataloging the effects of every possible mutation within the transcription factor binding site motif, SEMpl can predict the consequences of SNPs to transcription factor binding. This knowledge can be used to identify potential disease-causing regulatory loci.

# PgmNr 3200: The molecular basis and genetic control of local gene co-expression.

---

Gene regulation is an essential component of cellular function. Many Eukaryotic genes are not randomly distributed across the genome, but rather form clusters and tend to be expressed together. Indeed, nearby genes often show high expression correlation across individuals, defining co-expression domains (CODs). Recent studies highlight the existence of a complex network of structural and regulatory domains orchestrating the organised expression of nearby genes (Delaneau et al. 2019 Science 364(6439)). However, the full prevalence of local gene co-expression and their genetic control are yet far from being understood.

Here, we developed a novel unbiased method to identify groups of nearby genes (within 1Mb) that are co-expressed, and detect CODs genome-wide using RNA-seq data from large populations (e.g. >200 individuals). As a proof of concept, we identified 2556 high-confidence CODs (FDR 1%) using RNA-seq data from 358 human lymphoblastoid cell line (LCL) samples from the Geuvadis dataset. These CODs comprise 8885 (52.5%) out of 16907 protein-coding and lincRNA genes expressed in LCLs, demonstrating that local gene co-expression is highly prevalent.

Next, by integrating various ChIP-seq and Hi-C datasets, we functionally characterized CODs by studying their chromatin structure and local regulatory element activity. For instance, analysing Hi-C data for LCLs, we found that the region surrounding the transcription start sites of co-expressed gene pairs are often found interacting together, inclusive for genes that are >500Kb apart, evidencing the importance of chromatin 3D structure in gene co-expression.

Importantly, we further explored how co-expressed genes may be co-regulated by identifying expression Quantitative Trait Loci (eQTLs) for more than 70% of the LCL CODs, and investigating how eQTL effects propagate through the co-expressed genes. Notably, we applied our novel approaches to identify and compare thousands of CODs across 48 distinct human tissues present in the GTEx dataset, allowing us to study in-depth the tissue-specificity of gene co-expression and their co-regulation by genetic variants.

The systematic identification and characterisation of CODs and the study of the pleiotropic effects of eQTLs are of crucial importance to deepen our understanding of the regulatory mechanisms underlying gene expression and the functional impacts of eQTLs, ultimately allowing us to fine-map the effects of genetic risk factors involved in complex traits.

## PgmNr 3201: Enhancer domains predict gene pathogenicity and inform complex disease gene discovery.

**Authors:**

Wang<sup>1,2</sup>; D.B. Goldstein<sup>1,2</sup>

[View Session](#) [Add to Schedule](#)

**Introduction:** Non-coding regulatory elements, such as transcriptional enhancers, are critical for the precise spatiotemporal regulation of gene expression. While enhancers have been shown to harbor common and rare variants associated with human disease, applying enhancer information to prioritize and discover disease genes remains a major challenge due to difficulties in identifying damaging non-coding variants and affected genes.

**Methods & Results:** Here, we demonstrate that the genes with larger cognate enhancer domains have greater importance in development and disease. This relationship is sufficiently strong that a machine learning classifier trained using only distal enhancer features predicts disease genes with accuracies comparable to or better than commonly-used metrics of gene constraint, including pLI, LOEUF and RVIS. Further, the relationship persists even after controlling for promoter conservation and genic constraint.

We investigated factors contributing to the biological basis for this relationship. We found that disease-relevant genes with large cognate enhancer domains are subject to both increased purifying selection and are buffered against disruptive regulatory variation due to enhancer redundancy. These genes are depleted for eQTLs and less affected by rare variants in their regulatory regions.

**Broader perspective:** To illustrate the practical consequences of this relationship on disease gene discovery, we focused on the problem of identifying causal disease genes from GWAS studies. We show that candidate causal genes at GWAS loci have larger enhancer domains, suggesting that causal disease genes may be harder to detect than bystander gene signals at the same loci. Collectively, these results provide insights into the identification of disease genes, as well as the disruption of gene regulation by regulatory variants.

## PgmNr 3202: Haplotype based expression quantitative trait loci mapping.

**Authors:**

R. Hofmeister; O. Delaneau

[View Session](#) [Add to Schedule](#)

**Affiliation:** Computational Biology, University of Lausanne, Lausanne, Waadt, Switzerland

---

Expression Quantitative Trait Loci (eQTLs) are genetic variations that affect the expression levels of genes. Considering that genes usually have multiples eQTLs, it is likely that nearby genetic variants contribute together to the variation in expression level, especially when affecting transcription factor binding sites or interactions between regulatory elements. Current studies mainly focus on the effects of individual genetic variants in the vicinity of genes but lack in identifying whether multiple variants can act synergistically as part of haplotypes.

In this work, we investigate whether using haplotype data instead of genotype data at specific variants can help to dissect eQTL signals. To this aim, we use a Hidden Markov Model (HMM) that clusters haplotypes into a small set of K 'founder' haplotypes and provides per-individual dosages for these that continuously vary along the genome in function of the underlying linkage disequilibrium structure. Then, we run linear regressions to test the resulting dosages for association with the expression at nearby genes (1Mb). This effectively builds a statistical test at the haplotype level that is run per-variant and that automatically accounts for the joint effects with surrounding variants. Finally, we used a Likelihood Ratio Test (LRT) to identify genes for which the underlying haplotypic structure better explains the variation in expression levels compared to genotypes alone, as typically done in standard eQTL analysis. This helps to unravel genes impacted by combination of variants (i.e. haplotypes) without having to define these combinations a priori.

Using the RNA-seq and genotype data for 358 individuals from the Geuvadis study, we first show that our clustering captures blocks of high linkage disequilibrium that closely match those defined in the HapMap project, thereby validating our clustering approach. Then, by running our association tests, we find evidences that ~20% of the eQTLs originally reported in the Geuvadis study can be better explained by haplotypic effects. Finally, we show how our approach can help to better characterize the genetic architecture of eQTLs by focussing on few particular genes for which we provide original and informative visualizations.

Overall, we believe that our method is well suited to determine whether an eQTL signal is of genotypic or haplotypic origin and constitutes a useful addition to the toolbox for fine-mapping eQTL effects.

## PgmNr 3203: Manual curation of homozygous predicted loss-of-function variants in 125,000 exomes reveals 1,752 human genes tolerant to inactivation.

### Authors:

E. Seaby<sup>1,2</sup>; M. Singer-Berk<sup>1</sup>; E. England<sup>1</sup>; D. Rhodes<sup>1,3</sup>; N. Watts<sup>1,2</sup>; M. Solomonson<sup>1,2</sup>; S. Baxter<sup>1</sup>; Q. With an increasing number of individuals undergoing diagnostic next-generation sequencing, there is a clear need to accurately delineate pathogenic variants from benign variation. Predicted loss of function (pLoF) variants, including stop gained, essential splice, and frameshift variants, are on average rare and deleterious, with many known to cause severe Mendelian disease through gene inactivation. On the other hand, some genes are tolerant to complete inactivation without severe phenotypic consequences; accurate curation of homozygous pLoF variants can expand our understanding into the biology of these genes. Given the rarity and deleteriousness of most true LoF variants, pLoF variants are enriched for mapping, genotyping and annotation errors; and therefore careful filtering and manual curation is required to remove such errors and identify probable LoF variants.

Using data from the aggregation of 125,748 exomes from human sequencing studies into the Genome Aggregation Database v2.1 (gnomAD), we extracted pLoF variants present homozygously in at least one individual. These variants were further filtered through the application of stringent Loss-Of-Function Transcript Effect Estimator (LOFTEE) criteria to distinguish high confidence pLoF variants from annotation artifacts. Additionally, variants in exons that do not show evidence of expression in adult tissue were removed (pext score < 0.1). To remove additional sequencing and annotation artifacts undetected by bioinformatic approaches, we applied deep manual curation to these 3,385 homozygous pLoF variants spanning 2,166 genes to identify high-confidence genes tolerant to human gene knockout, using a novel custom-built curation portal. We developed systematic criteria for pLoF variant filtering based on likely technical errors, rescue events and transcript errors.

This deep curation process resulted in 2,469 homozygous pLoF variants (73%) passing curation filters, resulting in a list of 1,752 high-confidence genes that are likely tolerant of human biallelic inactivation in the general population and that will be publicly released. This list of LoF tolerant genes was significantly depleted of essential genes (OR = 0.10, p-value =  $1.54 \times 10^{-17}$ ) and LoF constrained genes (p-value =  $4.48 \times 10^{-193}$ ). These results highlight a fraction of human coding genes that can

likely be deprioritized in disease gene discovery studies and highlight potential therapeutic targets tolerant of human inactivation.

## PgmNr 3204: Genetic influences and negative selection signatures on human blood metabolites in the Japanese population.

Blood metabolites are important biomarkers of aging and complex traits, including diseases. Genetic variations which influence their levels in the blood are known for some metabolites. In this study, we conducted a quantitative trait loci (QTL) analysis of targeted metabolome in the Japanese population to construct a comprehensive database of such QTL and to clarify the functional roles of associated genetic variants. A total of 131 soluble metabolites in plasma were measured by gas chromatography-mass spectrometry (Shimadzu GCMS-QP2010 ultra) for 8,314 healthy individuals enrolled in the Nagahama Study. Among them, 4,888 individuals had been genotyped and for those we imputed 10,499,485 genetic variants using 1000 Genomes Phase 3 v5 as a reference panel. These imputed genotypes were then used for the further analyses. Batch effects of metabolome measurements were corrected using a smoothing spline approach. We identified signals with genome-wide significance ( $p < 5.0 \times 10^{-8}$ ) in 132 chromosomal loci of which 52 were not previously reported. Eleven loci showed an association with more than one metabolite, and 24 loci showed pleiotropic associations with clinical phenotypes. Conditional analysis of each QTL showed that there were more than one association signals in 30 loci, which comprised a total of 51 independent QTL signals ( $p < 1.0 \times 10^{-5}$ ). The correlation of genome-wide genetic effects was different ( $p < 0.05$ ) between Japanese and Europeans for ten metabolites. We also found that significantly higher numbers of QTL genetic variants were classified as loss of function (4.0-fold,  $p = 2.3 \times 10^{-3}$ ) or non-synonymous substitution (5.0-fold,  $p = 2.6 \times 10^{-25}$ ), as compared with MAF- and chromosome-matched randomly chosen SNPs. This showed intriguing contrast with the results of disease GWAS in which susceptibility genetic variants are frequently located in regulatory regions. Finally, we tried to identify negative selection signatures of the genetic effects on metabolites by using a Bayesian mixed linear model (MLM) method. We found multiple metabolites showing significant selection signals, suggesting that these metabolites affect the fitness of individuals. In this context, they could be potential candidates for disease-related biomarkers.

## PgmNr 3205: Nuclear genetic control of human mitochondrial RNA modification and its role in complex disease.

---

RNA modifications affect the stability and function of RNA species, regulating important downstream processes. Modification levels are often dynamic, varying between tissues and individuals, although it is not always clear what modulates this variation or what impact it has on biological systems. Here, we quantify variation in RNA modification levels at functionally important positions in the mitochondrial genome across 11,552 samples from 39 tissue/cell types and find evidence that modification levels impact mitochondrial transcript processing. We identify novel links between mitochondrial RNA modification levels in whole blood and genetic variants in the nuclear genome, including missense mutations in *LONP1* and *PNPT1*, as well as missense mutations in *MRPP3*, *SLC25A26* and *MTPAP* that associate with RNA modification levels across multiple tissue types. Genetic variants linked to modification levels are also associated with blood pressure and breast cancer, and we find that variation in both mitochondrial RNA modification and gene expression levels are associated with intermediate cardiovascular phenotypes, suggesting a role for these processes in complex disease.

## PgmNr 3206: Profiling the expression, regulation, and network connections of lncRNAs across human tissues.

### Authors:

---

Recent studies cataloguing lncRNA genes have expanded our understanding of this heterogeneous group. However, it is still difficult to distinguish functional lncRNAs from those that are byproducts of surrounding transcriptional activity. To identify potential hallmarks of biological function, we used GTEx v8 data to profile the expression, regulation, and gene network connectivity of lncRNAs across 49 tissues.

Compared to expression-matched coding genes, lncRNAs displayed highly tissue-specific patterns of both gene expression and expression quantitative trait loci (eQTLs). The testis, brain, skin, and blood had the highest numbers of tissue-specific expressed genes and eGenes. Fewer lncRNAs had eQTLs compared to expression-matched coding genes, at ~50% versus ~75%, respectively. However, out of all eGenes, similar proportions of lncRNAs and coding genes (~25%) had independent associations with >1 eVariant.

Outlier expression analysis identified 942 lncRNAs for which at least one individual was a multi-tissue outlier. Of these, 301 were tissue-specific lncRNAs; 110 of these were expressed in unexpected tissues at TPM >0.5 in the outlier individual. Of note is *AC025219.1*, for which there were multiple over-expression outlier individuals that all had the same rare (<1%) variant at the gene's transcription start site, highlighting the potential for rare variants to modulate lncRNA tissue specificity.

We built co-expression networks for each of the GTEx tissues. To interpret these networks, modules were annotated based on similarity to gene expression signatures of cell types and cell compartments. Overall, lncRNAs were less connected in their assigned modules than coding genes. However, there were examples of modules involving lncRNAs with high intra-module connectivity, such as epithelium modules in the lung, small intestine, colon, and vagina.

We assessed novel lncRNA-trait associations through colocalization of GWAS and lncRNA eQTLs. We found 4843 instances of significant lncRNA colocalization events (PP > 0.5). Of these, 3562 had a lncRNA PP at least 0.3 higher than any coding gene within +/-1Mb. Integrating network modules with these colocalization events identified compelling disease-associated lncRNAs, such as *C6orf3* for psoriasis and *LINC01475* for IBD.

This work provides a hypothesis-generating resource to interrogate individual lncRNAs, as well as to systematically discover and annotate novel functional lncRNAs with cell-type and human trait relevance.

## PgmNr 3207: Machine learning using nonlinear stacking method for predicting long non-coding RNA and enhancer transcription from genome sequence.

Genome-wide association studies (GWAS) have found many non-coding single nucleotide variants (SNVs) associated with human complex traits. So far, catalogs of expression quantitative trait loci (eQTL) have provided plausible and novel interpretations of GWAS findings in a cell-type dependent manner; however, eQTL for lowly expressed non-coding RNAs including enhancer RNAs is poorly understood due to the lack of large-scale studies measuring them. Here we show that, by using only genome sequence surrounding transcriptional start site (TSS) as input data, machine learning (ML) can predict cell-type specific expressions of promoters and enhancers (as a binary “on-off” switch) in Cap Analysis of Gene Expression (CAGE). We designed ML models by combining deep convolutional neural networks (from sequence to epigenetic features, using publicly available pre-trained models) and binary classifier using gradient boosting trees (from epigenetic features to transcription probabilities). We leveraged the transcriptomes of 347 major human cell-types and tissues from the Functional Annotation Of the Mammalian genome (FANTOM5). We trained the ML models with the use of the autosomal promoter and enhancer expressions profiled by CAGE except for chromosome 8 and tested the accuracy using those on chromosome 8. As a result, ML models using  $\pm 100$ -kb sequences from TSS showed high accuracy to predict transcription (mean ( $\pm$  SD) area under the ROC curve (AUROC) =  $0.83 \pm 0.22$  (n = 347)). Notably, 295, 125, and 152 among the 347 models achieved AUROC > 0.7 for divergent-lncRNA, intergenic-lncRNA, and enhancer peaks, respectively. We further explored false positive signals and found that 31-70% of these CAGE peaks were actually expressed according to the profiles of nascent elongating RNAs. These findings indicated the uniqueness of our ML models to predict expressions of unstable, lowly expressed non-coding RNAs. Finally, we calculated effects of SNVs on proximal promoter transcription and found high concordance between the predicted effects on gene-level expressions (aggregated promoter-levels) and known eQTL effects (e.g., increased probability by 10% achieved ~90% of the direction accuracy in the blood model). Collectively, these findings indicate the potential use of our ML models to efficiently investigate genetic architecture for non-coding transcripts without additional population studies.

## PgmNr 3208: A map of single cell *cis*-eQTLs in human brain tissue.

---

Genome-wide association studies have identified thousands of genetic variants that are associated with several diseases. However, the causal genetic variants and underlying mechanisms for many of these associations remain unknown. In order to identify relevant variants that can impact in central nervous system (CNS) cell types, we performed expression quantitative trait loci (*cis*-eQTLs) analysis in single-cell RNA-seq (scRNA-Seq) data from prefrontal cortex tissue. The scRNA-seq data was previously generated from post-mortem human brain samples from the ROSMAP dataset (Mathys *et al.* 2019). To perform eQTL analysis, we leveraged scRNA-seq from 80,000 cells from 39 donors (21 with AD pathology, 18 controls) and genotypes called from Whole Genome Sequencing. Gene expression was measured by averaging the normalized expression per gene per donor and per major cell type (and also within subtypes). We identified from 12 to 316 significant genes ( $FDR < 0.1$ ) in eight cell types, of which excitatory neurons (230) and oligodendrocytes (316) had the most genes with *cis*-eQTLs followed by microglia (69). For the most part, the number of *cis*-eQTLs per cell types correlates well with number of cells per each cluster. Of these, 66% of *cis*-eQTLs were not detected at bulk tissue level, suggesting a substantial proportion are specific to a cell type. We subsequently performed *cis*-eQTL analysis on 34 subpopulations within major cell types. This resulted in several *cis*-eQTLs that were only present in specific subpopulations including *IFITM2* ( $P = 1.15 \times 10^{-7}$ ) and *MEF2C* ( $P = 1.23 \times 10^{-4}$ ) in microglia1, a cluster associated with AD and damage-associated microglia. Although we are underpowered, we identified one novel *cis*-eQTL (*FUS*) colocalized with both Alzheimer's and Parkinson's disease loci (rs1549299;  $P = 8.5 \times 10^{-5}$ ) and several *cis*-eQTLs (nominal  $P < 10^{-3}$ ) in microglia that colocalized with AD risk alleles (*FCER1G*, *PILRB*, *SLC24A4*, *MEF2C* and *MS4A4A*), consistent with emerging narrative of the role of microglia in AD. We also identified *cis*-eQTLs colocalized with AD risk alleles in astrocytes or oligodendrocytes, suggesting non-myeloid contribution to AD cells. We are in the process of replicating these eQTLs in an independent cohort ( $n = 107$ ) with isolated primary microglia. However, a larger dataset is needed to fully uncover effects of genetic variation on gene expression in subpopulations, which in turn, will help in elucidating the contribution of distinct cellular subsets in CNS diseases.

## PgmNr 3209: Intronic deletions that reduce the minimal distance between 5' splice-site and branchpoint define a pathogenic class of splice variant.

---

A precise genetic diagnosis is the single most important step for families with genetic disorders to enable personalized and preventative medicine. In addition to genetic variants in coding regions (exons) that can change a protein sequence, abnormal pre-mRNA splicing can be devastating for the encoded protein, inducing a frame-shift or in-frame deletion/insertion of multiple residues. Non-coding variants that disrupt splicing are extremely challenging to identify. Stemming from an initial clinical discovery in two index Australian families, we define 25 families with genetic disorders caused by a class of non-coding splice variant due to intronic deletions. These pathogenic intronic deletions spare all consensus splice motifs, though critically shorten the minimal distance *between* the 5' splice-site (5'SS) and branchpoint. The mechanistic basis for abnormal splicing is due to biophysical constraint precluding U1/U2 spliceosome assembly, which stalls in A-complexes (that bridge the 5'SS and branchpoint). Substitution of deleted nucleotides with non-specific sequences restores spliceosome assembly and normal splicing; arguing against loss of an intronic element as the primary causal basis. Incremental lengthening of 5'SS-branchpoint length in our index *EMD* case defines 45 - 47 nt as the critical elongation enabling (inefficient) spliceosome assembly. The 5'SS-branchpoint minimal length mechanism, not currently factored by genomic informatics pipelines, is relevant to diagnosis and precision medicine across the breadth of Mendelian disorders and cancer genomics.

## PgmNr 3210: Tissue and individual variability of regulatory variant effects and the role of transcription factors.

The GTEx Consortium has identified thousands of genetic regulatory variants in *cis* (*cis*-eQTLs) that affect gene expression in multiple tissues. Over a third of GTEx eQTLs are active in most tissues, often with varying effect sizes, but the molecular mechanisms of cross-tissue eQTL effect size variability are poorly understood. Since eQTLs are enriched in transcription factor binding sites (TFBS), we developed a model of eQTL effect size as a function of transcription factor (TF) levels across tissues.

We investigated mechanisms of tissue variability of eQTL effect size in the GTEx v8 dataset (838 individuals with WGS, 15,201 RNA-seq across 49 tissues). We first examined the correlation of eGene expression with eQTL absolute effect size across tissues and identified 1,864 expression-correlated eQTLs at a 5% FDR, with 51% positive and 49% negative correlations. This shows that expression level and genetic regulatory effect are not independent phenomena. We then proceeded to correlate TF activity with eQTL effect size across tissues. We find that over a third of all tested eQTLs correlate with the activity of at least one TF, and we find an enrichment of the relevant TFBS overlap among the TF-correlated eQTLs.

Furthermore, we examined patterns of cross-individual variability of eQTL effect size within each GTEx tissue, using eQTL effect sizes measured from allelic expression data. We find that these patterns support our hypothesized cross-tissue TF regulators but also discover novel potential TF regulators that are not observable in the cross-tissue data. We validate our cross-tissue and cross-individual findings by analysis of allelic binding in ENCODE ChIP-seq data.

We highlight an interesting example of PU.1 regulation of a *LIPA* gene eQTL that colocalizes with a GWAS signal for coronary artery disease, and we provide data from functional experiments that support this hypothesis.

Our results provide a basis for identifying regulatory mechanisms of eQTL activity and for understanding eQTL effect size variability in the context of TF activity. This has major implications for future work investigating context-specific mechanisms of GWAS loci and their effects on human phenotype and disease.

## PgmNr 3211: Transposable element mediated rearrangements are prevalent in human genomes.

Transposable elements comprise more than half of the human genome, yet their roles in genomic instability remain poorly understood. Structural variants between two distinct repetitive sequences are termed Transposable Element Mediated (TEM) rearrangements, and differ from transposon insertion and deletion events. The vast majority of TEM events are between homologous repeats, and they are prevalent when examined throughout primate evolution. Due to the nature of their breakpoints, TEM events are challenging to detect using short-read whole genome sequencing. We implemented a multi-tool (Lumpy, Delly, GROM, and Manta) approach on three extensively characterized trios of individuals from the Human Genome Structural Variation Consortium to identify TEM events in short-read sequencing data. Overall, we found that ~17% of the rearrangements in these genomes were TEM events, in comparison to ~25% mediated by transposable element insertions and deletions. Orthogonal support for almost half of the TEM events was provided by PacBio data. Experimental validation confirmed the fidelity of the calls also present in long-read sequencing data, and our validation for non-supported calls will be used to develop a classifier to better predict true TEM events. Overall, we found 2321 distinct rearrangements across our cohort spanning 8 Mb of the human genome; 134 of these rearrangements may disrupt exons of protein-coding genes. Of the 2321 TEM events, 1475 were absent from the Database of Genomic Variants, and the number of events per trio was consistent with the evolutionary histories of the three populations (Yoruba, Puerto Rican and Han Chinese). We next investigated potential mechanisms of TEM rearrangements. Previous studies indicated selection against *Alu* elements that are separated by <1 Kb and on opposite strands (inverted *Alus*), and proposed that they contribute to genomic instability. Interestingly, the incidence of inverted *Alus* is significantly enriched around the breakpoints of TEM rearrangements. Furthermore, our yeast model of template switching indicates that inverted *Alu* pairs can increase the rate of genomic rearrangements. Our data elucidate a potential role for local genome sequence in the generation of double strand breaks that are then repaired with homologous substrates, show the importance of transposable elements in generating human genomic rearrangements, and implicate inverted repeats in driving local genomic instability.

## PgmNr 3212: Assessing functional assays: A case study of functional data use in variant interpretation using a structured evidence curation framework.

---

Functional assay data represents a powerful tool in the clinical interpretation of sequence variants, necessitating clear standards for the application of such evidence. The 2015 ACMG/AMP variant interpretation guidelines indicate “well-established” *in vitro* or *in vivo* functional studies can be applied as strong evidence for or against pathogenicity (PS3/BS3). However, differences in the application of functional data are a major contributor to discordance in variant interpretation between clinical labs, suggesting that current guidance is insufficient for the consistent evaluation of functional evidence. With the goal of identifying hallmarks of “well-established” assays, we assessed the use of functional data by experts in multiple disease areas through a systematic analysis of assays approved for PS3/BS3 application by six Variant Curation Expert Panels (VCEPs) associated with and approved by the Clinical Genome Resource (ClinGen). To aid in this process, we developed and employed a structured framework for the curation of primary literature cited by VCEPs in their pilot variant interpretation. Through our analysis, we observed variable specification of key experimental parameters: controls, replicates, thresholds, and validation, as well as variation in the satisfaction of these suggested parameters by individual assay instances cited as evidence. We further identified four recurring areas of discordance that may contribute to differences in functional evidence application: (1) methodology for estimating the predictive power of assays, (2) use of functional data from patient-derived experimental materials, (3) unclear recommendations for creation and interpretation of model organism evidence, and (4) limited guidance for conflicting evidence. Overall, this analysis highlights the many factors that require consideration in functional assay evaluation and suggests insufficient guidelines may act as a blockade to uniform curation, particularly in disease areas not yet addressed by VCEP recommendations. To advance the current guidelines, findings from this study are being used to inform the development of guidance for functional evidence application in variant interpretation to improve the accessibility of functional study analysis and to ensure minimum quality standards are met by studies cited as evidence. Furthermore, the framework established in this study is being used to develop a data model to structure functional data evidence in a computable form.

## PgmNr 3213: MicroRNAs that target the tripartite complex CARD14-BCL10-MALT1 and could potentially be targeted to downregulate a psoriasiform response.

### Authors:

J.M. Frost <sup>1</sup>; J.P. Sundberg <sup>2</sup>; J. Krueger <sup>3</sup>; A.M. Bowcock <sup>1,4</sup>

---

We previously performed small RNA sequencing and identified 98 differentially expressed miRNAs and a handful of novel siRNAs in psoriatic versus healthy skin. We also discovered highly penetrant, gain-of-function, dominantly acting mutations within the human caspase recruitment domain family, member14 (*CARD14*) gene that led to the development of PS and PSA. *CARD14* mutations lead to enhanced NF-κB signaling and activation of a subset of psoriasis-associated genes in keratinocytes. This enhanced NF-κB signaling is due to a tripartite complex formed between CARD14-BCL10-MALT1. B cell lymphoma 10 (BCL10) and mucosa-associated lymphoid tissue lymphoma translocation protein 1 (MALT1). The introduction of the de-novo p.E138A alteration into the *Card14* gene of mice leads to features of psoriatic skin including a thickened epidermal barrier and immune cell infiltration into lesions. Moreover, the altered transcriptomes of the skin of p.E138A versus WT mice are very similar to that of human psoriatic skin versus that of healthy controls. Guided by these preliminary data we validated a set of psoriasis specific differentially expressed miRNAs in the skin of human PS patients and that of the p.E138A *Card14* mouse knockin with qRT-PCR. Two PS specific microRNAs, miR-26a-1-3p and miR-30e-5p, were predicted to target *BCL10* mRNA, one of the partners of CARD14 upon activation of NF-κB signaling. We confirmed the interaction of miR-30e-5p with the 3'UTR of *BCL10* mRNAs using luciferase assays (p=0.001) and hypothesize that this miRNA is a regulator of CARD14 signaling that can be targeted to downregulate a psoriasiform response.

## PgmNr 3214: Analysis of TFAP2A-binding events in a cellular model for nonsyndromic cleft lip +/- palate.

### Authors:

J. Welzenbach <sup>1</sup>; K.L.M. Ruff <sup>1</sup>; J. Fazaal <sup>1</sup>; F. Thieme <sup>1</sup>; E. Mangold <sup>1</sup>; M. Knapp <sup>2</sup>; K.U. Ludwig <sup>1</sup>

Non-syndromic cleft lip with or without cleft palate (nsCL/P) is a multifactorial malformation with a prevalence of about 1 in 1,000 livebirths. Despite recent success in the identification of underlying genetic risk factors, the functional effects of the risk variants are poorly understood. In the present study we hypothesize that transcription factor (TF) binding events, that occur in relevant cell types and might be modified in an allele-specific manner, contribute to a further understanding of the pathobiology of nsCL/P. To investigate this, we established cell culture and ChIP-Seq of human embryonic palatal mesenchyme cells (HEPM, ATCC CRL-1486), a cell line obtained from the facial region of a ten-week old female fetus which has been shown to represent a model for the developing and fusing secondary palate.

Based on expression profiling with 3'RNA-Seq, we identified several TFs that are expressed in HEPM cells and for which evidence for an involvement in craniofacial development has been presented. We focused our subsequent molecular work on TFAP2A that has been shown with a clear role in nsCL/P and evidence for which includes *in vivo* knockout models with craniofacial defects. Using a polyclonal TFAP2A antibody we performed ChIP-seq in HEPM, in three replicates. After quality control of sequence data (~40 Mio, incl. input control), data analysis was performed using an in-house pipeline. Overall, we observed about 7,000 peaks, with motif analysis confirming a strong enrichment for the TFAP2A consensus binding within the peaks summits ( $P < 2.04 \times 10^{-4}$ ). We next identified positional overlaps of results from our in-house GWAS within 865 high-confidence peaks, and extracted P-values for association with nsCL/P. We observed 657 SNPs within these regions, none of which showed genome-wide significance. We also observed five SNPs with  $P < 10^{-3}$  which might represent risk variants with lower effect sizes that have escaped detection in GWAS so far. This, however, requires further replication to determine the genuine association. Next we will explore preferential allele-specific binding, using heterozygous positions in HEPM and read coverage in the ChIP-Seq data. Our strategy will shed light on molecular events that are triggered by associated risk variants and help to identify regulatory networks in the developing palate. Furthermore, our study might contribute to an identification of novel risk loci associated with nsCL/P.

## PgmNr 3215: Investigation of microRNA-149-3p in neural crest cells and its role in orofacial clefting.

---

Nonsyndromic cleft lip with/without cleft palate (nsCL/P) is a common facial malformation that occurs during the first weeks of embryonic phase. There is increasing evidence that human neural crest cells (hNCC) are major contributors to craniofacial development as this mesenchymal precursor cell population gives rise to the majority of cranial cartilage and bones. nsCL/P has a multifactorial etiology with a strong genetic component. The majority of associated risk loci, mainly identified through GWAS, map to non-coding regions of the genome. This suggests that a substantial fraction of nsCL/P pathomechanisms are mediated through regulatory effects on gene expression, one mechanism of which might be posttranscriptional gene regulation by micro RNAs (miRNAs). We first generated a catalogue of miRNAs expressed in hNCC, using array-based miRNA profiling of four hNCC samples that had been derived from human induced pluripotent stem cells (hiPSC). This revealed a set of 125 candidate miRNAs which was next integrated with in-house GWAS data on nsCL/P. We identified miR-149-3p as strong candidate for nsCL/P, based on consistent expression in hNCC across replicates and the presence of associated risk variants within its genomic region. To investigate the impact of miR-149-3p on neural crest development, we modified miR-149-3p abundance in hiPSC-derived hNCC through overexpression and inhibition. Expression profiling by RNA-Seq revealed differential expression of a number of candidate genes involved in craniofacial development and nsCL/P, such as *BMP7*. Moreover, using scratch assays, we found that the modification of miR-149-3p significantly affected migration of hNCC, which is one of the fundamental properties of hNCC. Future directions include the characterization of the molecular mechanisms of miR-149-3p target genes *in vivo*, using gene knockdown analyses in zebrafish. Overall, our data suggest that the integration of large-scale genetic data and expression patterns in relevant cell types can help to pinpoint regulatory mechanisms that are involved in craniofacial development and might be related to the etiology of nsCL/P.

## PgmNr 3216: An innovative approach to characterizing longitudinal changes in gene expression that underlie disease progression and translational relevance in a large clinical resource: The path to diabetes.

---

Type 2 diabetes (T2D) is a complex and heritable disease, however the regulatory genetic mechanisms involved in progression to diabetes are largely unknown. We developed a two-stage approach to identify changes in gene expression associated with T2D transition and validate their clinical impact in a large biobank. In the transcriptome discovery stage, we studied longitudinal peripheral blood RNA sequence data from two time points in Hispanic study participants. All subjects had fasting blood glucose (FBG) <126 mg/dl (mean 106.7 mg/dl) at baseline. Twenty-four subjects' FBG transitioned to levels diagnostic of T2D ( $\geq 126$  mg/dl) at follow-up visit (cases) while the other 34 subjects maintained FBG <126 mg/dl (controls). We implemented a novel network methodology to identify genes with effect on transition status and evaluated its predictive performance, using an external comprehensive GWAS repository. In the biobank validation stage, we independently validated the identified set of genes in 23,000 participants from the large biobank at Vanderbilt University, BioVU. Associations of genetically determined expression of identified genes with diabetes-related traits in the electronic health record were used to establish their clinical significance. We identified 17 networks, including one comprising 822 genes with significant effect on transition and in which the connectivity of a gene was significantly correlated with the gene's association with T2D transition ( $p = 3.8 \times 10^{-29}$ ). This network is enriched for known metabolic trait genes identified by GWAS ( $p = 0.013$ ), but also includes novel associations. In this network, *WDFY3* accounted for the most variance, *STX3* exhibited the highest connectivity, and expression changes in *MIR3605*, *ASB9P1*, *NUDT16*, and *MKNK1-AS1* had the highest correlation with transition status. In BioVU, this network was significantly enriched for genes whose genetically determined expression is associated with T2D (enrichment  $p = 0.012$ ) and other metabolic traits in our biobank validation analysis. Importantly, we validated 43 novel gene-level associations with T2D, never reported by previous GWAS. Gene Ontology analysis underscored the importance of chronic inflammation and activated innate immunity in expression changes that occur during development of T2D. In this study we present a novel approach to identify key gene expression changes associated with T2D onset and demonstrate their translational relevance in a large clinical resource.

## PgmNr 3217: Maps of high-resolution chromatin interactions in human pancreatic beta-cells elucidate gene regulatory mechanisms at loci associated with type 2 diabetes.

---

Genome-wide associations studies (GWAS) have identified >400 signals at 250 loci associated with type 2 diabetes (T2D) risk. Yet resolving causal genes at these regions remains a challenge as the majority of T2D-associated SNPs are non-coding and map to regulatory elements across multiple tissues. To identify gene regulatory mechanisms, we mapped physical chromatin interactions in a human-derived pancreatic  $\beta$ -cell line (i.e. EndoC- $\beta$ H1) using next-generation capture-C (NGCC). This method enriches 3C libraries for loci of interest by a factor of 100,000 and yields the highest attainable resolution of physical interaction maps. Moreover, given the importance of  $\beta$ -cells to systemic glucose metabolism, we captured enhancer variants with likely regulatory functions in this cell type. To prioritise these variants, we performed a functional GWAS using summary statistics from the latest DIAGRAM GWAS meta-analysis (900K individuals of European ancestry) and a panel of islet epigenetic chromatin states derived from DNA methylation, open chromatin (ATAC-seq), and histone post-translational modifications (ChIP-seq). We integrated fine-mapping results from this analysis with maps of open chromatin in EndoC- $\beta$ H1 cells, islet eQTLs, and loci previously implicated in  $\beta$ -cell physiology to generate a set of nearly 300 “high priority” SNPs at 59 loci. We applied NGCC to capture enhancers encompassing these variants and identified ~600 significant chromatin interactions which were highly enriched for islet transcription factor (e.g. PDX1, FOXA2, NKX6.2) binding sites (p-values < 0.001). Moreover, 52% of all captured sites physically interact with transcription start sites; some of which corroborate GWAS signals colocalizing with islet eQTL associations (e.g. ADCY5, ZMIZ1). Furthermore, these interactions support putative novel T2D genes regulated by risk-associated variants such as KCNK16. These 3D chromatin interaction maps along with eQTL and epigenetic annotations implicate effector transcripts that promote T2D risk in  $\beta$ -cells and prioritise genes that may serve as therapeutic candidates.

## PgmNr 3218: A map of inflammatory-stimulated chromatin in human pancreatic islets reveals novel mechanisms of type 1 and 2 diabetes risk variants.

The majority of genetic risk loci for type 1 and type 2 diabetes (T1D, T2D) occupy non-coding DNA and affect gene regulation in disease-relevant tissues such as pancreatic islets. Islets occupy a complex and dynamic microenvironment, and the responses of islets to environmental changes during diabetes progression are important mediators of disease etiology. Currently available epigenomic maps, however, do not effectively capture changes in the chromatin landscape of islets upon exposure to disease-relevant environmental conditions. In this study we used ATAC-seq and RNA-seq to map chromatin accessibility and gene expression from a total of 7 primary human islet samples exposed to pro- and anti-inflammatory treatment conditions relevant to diabetes pathophysiology, including glucocorticoids (dexamethasone) and cytokines (IL-1 $\beta$ , IFN $\gamma$ , TNF- $\alpha$ ) in multiple combinations and concentrations. We identified highly dose- and stimulus-dependent changes in chromatin accessibility in stimulated compared to untreated islets that mapped to 4,193 stimulus-responsive sites, transcription factor motifs driving these changes such as IRF/STAT for cytokines and glucocorticoid receptor (GR/NR3C1) for dexamethasone, and target genes and molecular pathways affected by stimulus-responsive chromatin. A majority of stimulus-responsive sites (3,643/87%) had evidence for differential chromatin accessibility on a gradient across glucocorticoid-treated, untreated and cytokine-treated islets. We observed enrichment of genetic variants influencing diabetes risk within stimulus-responsive islet chromatin, and identified fine-mapped diabetes risk variants in stimulus-responsive chromatin including at the *SIX3* and *NFATC2* loci. At *NFATC2*, rs3787186 is likely causal for both T1D and T2D risk, mapped in an islet chromatin site with a gradient of activity across stimuli, had stimulus-dependent allelic effects on islet chromatin in allelic imbalance and gene reporter assays, altered a binding motif for GR and other nuclear hormone receptors, was linked to the *NFATC2* promoter using single cell co-accessibility, and affected *NFATC2* expression in islet eQTLs. Our results provide an expanded catalog of chromatin sites in pancreatic islets upon exposure to diverse, disease-relevant environmental conditions through which we identify a greater breadth of genetic mechanisms and genes underlying diabetes risk.

## PgmNr 3219: Dysregulation of circulating microRNAs in Chinese type 2 diabetes patients with obesity.

### Authors:

**Background:** The incidence of type 2 diabetes (T2D) has increased dramatically in recent decades. Differential expression of microRNAs (miRNAs) in adipose tissues from patients with obesity was reported. While obesity is closely related to T2D, the role of miRNAs in obesity under the physiological condition of T2D remained unclear. In this study, we assumed that circulating miRNAs are markers to measure tissue-specific miRNA expression and sought to identify miRNAs that are differentially expressed in the serum samples from T2D patients with obesity as compared to those without obesity.

**Methods:** This study included 58 Chinese T2D patients. We grouped patients by the standard of China National Nutrition and Health Survey data in 2002, body mass index (BMI)  $< 24$  (kg/m<sup>2</sup>) for non-obese and  $\geq 28$  (kg/m<sup>2</sup>) for obesity. We conducted a two-stage study, with T2D patients without retinopathy as discovery stage (12 obese v.s 20 non-obese) and T2D patients with retinopathy as replication stage (15 obese v.s 11 non-obese). Differential expression was quantified by next-generation sequencing and evaluated by DESeq2 adjusted by age and gender. Finally, we investigated the functional enrichment of target genes of the differentially expressed miRNAs.

**Results:** Three miRNAs were differentially expressed in both two stages ( $p$ -value  $< 0.05$ , LFC  $\geq 2$  or LFC  $\leq -2$ ), including miR-3909, miR-3960, and miR-3656. Their target genes were enriched in calcium signaling pathway, GABAergic synapse, type 2 diabetes mellitus, glycerolipid metabolism and adipocytokine signaling pathway ( $p$ -value  $< 0.05$ ).

**Conclusion:** Our results provided the evidence of three miRNAs as candidates for future mechanism studies. The indicated pathways may shed light on the drug development and clinical practice of weight management in T2D patients.

---

Several associations between metabolite levels and DNA methylation (DNAm) have been reported. However, the relationship between longitudinal changes in metabolite levels and differential DNAm is underexplored. We assessed associations between epigenome-wide blood DNAm and change in blood metabolomics-based variables. For 595 non-diabetic individuals from the Northern Finland Birth Cohort 1966 for whom nuclear magnetic resonance-based metabolomics data were available at both ages 31 (T1) and 46 (T2) as well as concurrent blood DNAm data at T2, we calculated for each of the 228 metabolomics-based variables the average change in level per year between T1 and T2. We used our methylSCOPA software, which enables both longitudinal and multi-phenotype epigenome-wide association studies (EWAS), for single-phenotype EWAS of change residuals – corrected for sex – for each metabolomic variable versus the degree of DNAm for 832,569 markers on the Illumina (San Diego, CA) MethylationEPIC BeadChip. We quality-controlled, residualized, and normalized the DNAm data, mapped genomic locations to CGCh37/hg19, and adopted  $1 \times 10^{-7} / 228 = 4.4 \times 10^{-10}$  as the Bonferroni-corrected  $P$ -value threshold to denote epigenome- and metabolome-wide statistical significance of association between an epigenetic mark and change over time in a particular metabolomic variable. We detected significant association between DNAm status at site cg16904859 (chr1:206,849,995;  $\beta=2.31$ ;  $SE=0.36$ ;  $P=3.2 \times 10^{-10}$ ) and change over time in the level of triglycerides in chylomicrons and extremely large very low-density lipoprotein particles (XXL-VLDL-TG). The cross-sectional association between this epigenetic mark and XXL-VLDL-TG levels at T2 was not significant ( $\beta=0.036$ ;  $SE=0.024$ ;  $P=0.13$ ). cg16904859 also showed epigenome-wide ( $P < 1 \times 10^{-7}$ ) but not epigenome- and metabolome-wide significance of association with the concentrations of total lipids, phospholipids, total cholesterol and free cholesterol in chylomicrons and extremely large very low-density lipoprotein particles as well as with the concentration of these types of particles. In conclusion, using a novel powerful methylSCOPA approach, we demonstrated that longitudinal changes in blood metabolite levels are associated with DNAm.

## PgmNr 3221: Multi-stage genome-wide methylation analysis identifies two novel CpG sites associated with obesity in Korean.

### Authors:

Obesity is a major risk factor of chronic diseases including type 2 diabetes and cardiovascular disease. Recently, with advances in genome-wide association studies (GWASs), more than hundreds of genetic variants associated with obesity-related traits have been identified. However, even though the great success of GWASs, most of the risk factors of obesity still remains unexplained. DNA methylation is a key epigenetic mechanism that is suggested to be associated with obesity and related metabolic mechanisms. Because excessive fat accumulation is caused by a combination of multi-factorial contributions, alternative approaches to finding non-genetic factors can be warranted to explain missing factors.

Here, we performed an epigenome-wide analysis of multi-stages to identify DNA methylation site with significant differences between obese and lean subjects. Furthermore, we examined common methylation sites that are significant between whole blood and adipose tissue. Subsequently, we examined differentially methylated site affecting the expression of the nearby gene. To this end, genome-wide methylation levels were measured in whole blood using the Illumina HumanMethylationEPIC array (EPIC) on 450 participants (phase I) with respective 377 (phase II), and 75 participants (phase III) from two independent cohorts. Furthermore, additional 75 pair of the EPIC array and Illumina HT-12 Gene Expression BeadChip data obtained from adipose tissue of the same participants as those of phase III was used for correlation analysis between CpG and gene expression and between tissue and whole blood.

From the results, 124 differentially methylated obesity CpG sites were reached the statistical significance with FDR <0.05. Particularly, 5 CpG sites of 3 genes, ABCG1, CPT1A and TXNIP related to the lipid metabolism, were also replicated two independent replication stages. Of 5 CpG sites, 2 sites were newly identified. Of the 124 CpG sites, differences in DNA methylation in 55 CpG sites were correlated with expression of 49 genes in fat tissue of phase III ( $|\text{spearman's correlation}| > 0.2$ ; 28 positive and 27 negative correlations). Among those, 19 genes of 22 CpG sites showed significant differences in phase I blood DNA methylation.

In conclusion, we identified two novel CpG sites annotated to CPT1A and TXNIP, protein-coding genes involved in lipid metabolism and homeostasis, providing the functional importance of obesity-specific DNA methylation in the Korean population.

## PgmNr 3222: Subcutaneous adipose transcriptomes reveal an environmentally responsive novel master *trans* regulator, TBX15, controlling a co-expression network with 39 obesity GWAS genes.

Gene-environment interactions contributing to the global obesity epidemic remain elusive. We hypothesized that transcription factors (TFs) context-specifically respond to environmental cues and alter co-expression networks in *trans* in obesogenic tissues. Using Weighted Gene Co-expression Network Analysis (WGCNA), we first discovered a waist-hip-ratio adjusted for BMI (WHRadjBMI)-associated co-expression network utilizing subcutaneous adipose RNA-sequence data (n=335) from the Finnish METSIM cohort. The network contains 39 obesity GWAS genes, including adipose transcriptional regulators, *PPARA*, *PPARG*, and *TBX15*. The *cis* regions ( $\pm$ 500kb from the TSS) of the network genes are enriched for SNPs explaining heritability of WHRadjBMI (enrichment=1.58,  $p=0.011$ , LD Score Regression). To test the significance of this network in response to weight loss, we RNA-sequenced subcutaneous adipose biopsies from morbidly obese Finns of the KOBS cohort both at the time of (n=254) and one year after bariatric surgery (n=168). Of the 347 genes in the WHRadjBMI network, 111 (32%) are differentially expressed (DE) in KOBS, including two TFs, *TBX15* and *HOMEZ*. Notably, *TBX15* has a context-specific *cis*-eQTL, rs1779445, exclusive to the extreme obesity state ( $p=6.7 \times 10^{-6}$ ), which is also a WHRadjBMI GWAS variant in the GIANT cohort (n=224,459). In line with this, previous studies have shown that *TBX15* inhibits adipocyte differentiation and reduces triglyceride accumulation. The context-specific *TBX15 cis*-eQTL rs1779445 is a *trans*-eQTL (nominal  $p<0.05$ ) for 27 (24%) of the 111 KOBS DE genes in the WHRadjBMI network, all of which also have a *TBX15* motif in their promoter (1kb upstream of TSS). Moreover, rs1779445 is associated with the expression principal component 1 (PC1) of these 27 genes in both METSIM and KOBS ( $p<0.015$ ). Using mediation analysis, we found that the rs1779445 effect on PC1 of the 27 KOBS DE genes is mediated through *TBX15* expression (32% total effect mediated,  $p=0.015$ ), context-specifically in the extreme obesity state. Finally, the adipose expression of two key drivers among the 27 genes, *CORO1C* and *MLX*, together with *TBX15* and rs1779445 explain a substantial amount (10.87%) of the variance in WHRadjBMI in METSIM. Taken together, we discovered *TBX15* as a novel adipose master *trans*

regulator that context-specifically mediates the effect of a WHRadjBMI GWAS variant, rs1779445, on a WHRadjBMI-associated co-expression network containing 39 obesity GWAS genes.

## **PgmNr 3223: Systematic characterization of the role of alternative splicing in adipocyte differentiation.**

---

Alternative splicing is a key source of functional complexity in human tissues and is known to play an important role in tissue identity and development. A genome-wide analysis of alternative splicing across human adipocyte differentiation could therefore provide novel insights into both the regulation of adipose tissue development and mechanisms of disease. However, splicing is also a noisy process, which can result in many low abundance isoforms with little or no functional relevance. Therefore, while alternative splicing can have important biological consequences, there is also a need to determine which splicing events are biologically relevant. Here, we used the identification of differential splicing events across adipocyte differentiation to systematically characterize the role that alternative splicing plays in the process and to identify likely regulated splicing events that may be of particular biological importance. We used three replicates of RNA-seq data from four time points spanning from preadipocytes to mature adipocytes to identify differential splicing events between pairs of time points using LeafCutter. We identified 281 significantly differentially spliced clusters, and investigated the regulation of these clusters through the identification of enriched sequence motifs within the clusters that may be associated with splicing regulators. These results provide insights into the role of regulated splicing in adipocyte differentiation, as well as providing a resource to investigate the disruption of alternative splicing during adipocyte development as a potential mechanism contributing to obesity.

## PgmNr 3224: Pro-inflammatory cytokines induce circRNA over-expression in human pancreatic $\beta$ -cells.

---

**Background:** Non-coding RNAs have emerged as essential players in the regulation of gene expression and their dysregulation contributes to various pathophysiological conditions. In the last decade, non-coding RNAs, including microRNAs and long non-coding RNAs have been implicated in pancreatic  $\beta$ -cell dysfunction and death in type 1 diabetes. Circular RNAs (circRNAs) are a newly discovered class of endogenous non-coding RNAs that are formed by non-canonical backsplicing events. In the present study, we profiled circRNAs in human  $\beta$ -cells exposed to pro-inflammatory cytokines to study their possible roles in  $\beta$ -cell dysfunction and type 1 diabetes pathophysiology.

**Methods:** Total RNA from human EndoC- $\beta$ H1 cells treated and non-treated with pro-inflammatory cytokines (INF $\gamma$ +IL-1 $\beta$ ) at 24 and 48h was extracted and circRNAs profiled using Arraystar Human circRNA Array V2. Before labeling and hybridization, total RNA was digested with Rnase R to remove linear RNAs and enrich the samples for circular RNAs. Quantile normalization of raw data and subsequent data processing was performed using limma package in R. Differentially expressed circRNAs were identified using a log2FC cutoff of 1 and adjusted p-value of 0.05. RT-qPCR was used to verify the differential expression of circRNAs. CircRNA/microRNA interactions were predicted using TargetScan & miRanda.

**Results:** A total of 74 and 50 circRNAs were differentially regulated by cytokines at 24 and 48h respectively. Most of the circRNAs were up-regulated (71/74 and 48/50 circRNAs) by cytokines at both time-points. RT-qPCR validation demonstrated that the expression levels of hsa\_circ\_0033184, hsa\_circ\_0000479, hsa\_circ\_0033191, hsa\_circ\_0002938, hsa\_circ\_0053955, hsa\_circ\_0053958 and hsa\_circ\_0002017 were consistent with the results from the microarray analysis. Highly up-regulated circRNAs from the *CRIM1* and *WARS* loci harbored multiple binding sites for miR-320 family (miR-320a, miR-320b, miR-320c and miR-320d). The miR-320 family is highly expressed in human pancreatic islets and one of their targets, p85, plays a critical role in cell growth by increasing Akt phosphorylation.

**Conclusion:** Based on our findings, we suggest that circRNAs play a role in the regulation of  $\beta$ -cell gene expression via modulation of host gene expression and miRNA levels. Further studies are ongoing to identify specific mechanisms by which circRNAs regulate  $\beta$ -cell function in human islets under inflammatory conditions.

---

Poor metabolic control may induce epigenetic changes, which play an important role in the development and progression of diabetic kidney disease (DKD). Most prior studies, however, failed to integrate genotype information into the epigenome wide analysis studies (EWAS) to distinguish genetically and environmentally induced epigenetic changes.

We analyzed genome wide cytosine methylation changes in blood samples of 473 patients with diabetes from the Chronic Renal Insufficiency Cohort (CRIC) using the Illumina EPIC arrays. We adopted adjusted linear mixed effect models to identify methylation probes associated with kidney function. We have catalogued genotype-driven methylation changes by performing methylation quantitative trait (mQTL) analysis. Bayesian co-localization analysis was performed to identify causal genes and variations by integrating GWAS, EWAS, mQTL and eQTL datasets.

We found that methylation level of 1 probe significantly (FDR<0.05) associated with baseline kidney function. Methylation could be an important intermediate to mediate the effect of underlying sequence variations; as genetic variants could explain multiple EWAS associations and most GWAS signals resulted in methylation changes. Integration of genotype, methylation and gene expression data identified novel genes, associated with DKD pathogenesis and indicated an importance of underlying sequence variation.

## PgmNr 3226: Multiple testing correction for longitudinal epigenome-wide association studies (EWAS).

---

**Motivation:** Aberrant DNA methylation (DNAm) has been associated with adverse health outcomes and common diseases; however, unlike genetic markers that are fixed over the lifetime, DNAm can drift over time, varies with age, and is responsive to environmental changes. Longitudinal changes in DNAm are of broad interest, but given the ever increasing number of DNAm sites surveyed using microarrays, measuring them at different time points introduces multiple testing problems beyond those that exist in a static genetic context. We use as a motivating example the longitudinal effect of maternal glucose exposure in utero on DNAm levels in blood throughout childhood.

**Methods:** We simulated datasets of the same size as our motivating epigenome-wide association study according to four underlying longitudinal associations: 1) a persistent effect of the exposure over time, 2) an attenuated effect over time, 3) an effect that does not persist, and 4) no effect. We compared two methods of testing for persistent effects of the exposure: linear mixed effects model for each site (LME) or pre-selecting sites with a correlation between maternal glucose and DNAm at the first time point and then fitting LME models (PS).

**Results:** Across 4000 simulations of each setting with 560 true associations, we found that both methods controlled the false discovery rate (empirical FDR = 0.05). However, pre-selection reduced the number of sites identified as significantly associated by an order of magnitude (LME: 338 persistent, 218 attenuated; PS: 82 persistent, 83 attenuated). Furthermore, in the case of an effect that did not persist, pre-selection found an average of 73 sites significantly associated, while fitting all sites identified an average of 1.

Analysis of maternal glucose associations with DNAm in offspring found three sites at the first time point in cord blood (cg01696984, cg17077845, cg16578923), but none were identified using LME models incorporating data from all three time points (cord blood, ages 3 and 7).

**Conclusion:** If the research question hinges on whether an association with exposure persists over time, pre-selecting with a correlation test will not answer this question. We recommend that pairwise tests with the time point of interest be conducted separately from the longitudinal analysis in order to find both persistent effects and effects that resolve with time. Our data suggest that the effect of maternal glucose on DNAm in cord blood does not persist into childhood.

---

Diabetic kidney disease (DKD), as characterised by progressive development of proteinuria and loss of renal function, is a common complication of diabetes. DKD is the most common cause of end-stage renal disease, wherein individuals require renal replacement therapy. Increasing evidence suggests that epigenetic alterations, including DNA methylation, are involved in the development and progression of DKD. This investigation compared methylation profiles between individuals from the British Isles with type 1 diabetes (T1D) and DKD to individuals with T1D and no evidence of renal failure, to identify potential methylation-based biomarkers of DKD.

Using the Zymo EZ DNA methylation kit to bisulphite treat the blood-derived DNA and the Infinium HD Methylation Assay, MethylationEPIC BeadChips (Illumina), the methylation status of >850,000 CpG sites on gene bodies, promoters and CpG islands were determined for 492 individuals with T1D. Of these, 241 individuals had DKD and 251 controls had no evidence of renal disease. Cases and controls were matched carefully for ethnicity, sex, age and duration of diabetes. DNA obtained from each individual was treated consistently, with standard quality control and bioinformatic analyses conducted.

Methylation data was analysed using Partek Genomics Suite v7.0. A total of 486 CpG sites had significantly different levels of methylation in cases compared with controls ( $p \leq 10^{-8}$ ). The top-ranked gene, *FKBP5* ( $p = 1.23 \times 10^{-23}$ ) contained several significantly associated CpG sites and has previously been linked with T1D, ageing and CKD. Additional significant genes included *BCL2* and *PSD3*, and both have been previously linked to diabetes. High concordance ( $r^2 = 0.994$ ) between duplicate samples ( $n = 7$ ) was observed. Pathway analysis revealed Notch signalling with the greatest enrichment score (16.96) where  $p = 4.29 \times 10^{-8}$ .

We previously reported results for methylation sites differentially regulated in individuals with T1D with and without renal disease using Illumina's HumanMethylation450K BeadChip and HumanMethylation27K BeadChip arrays. The *FKBP5* gene demonstrated different methylation levels in the 27K, 450K, and now EPIC arrays with a consistent direction of methylation change. This research confirmed earlier loci for DKD, adds new information on previously unexplored regions of the

methylome, and identified new associations demonstrating blood-derived methylation signatures may serve as minimally invasive biomarkers of DKD.

## PgmNr 3228: Whole-blood transcriptome analysis in longitudinal change in BMI.

Body mass index (BMI) is the most commonly used measure to evaluate body fat content and further obesity. BMI is associated with numerous comorbidities including type 2 diabetes, fatty liver disease and cardiovascular disease. We performed a whole-blood transcriptome analysis to detect expression changes in two time points in relation changes in BMI. We used population based subsamples of the Finnish Dietary, Lifestyle, and Genetic determinants of Obesity and Metabolic syndrome (DILGOM) (n = 518 in 2007, n = 297 in both 2007 and 2014). At first, we performed a whole transcriptome association analysis for BMI at baseline using 518 samples. We observed that 186 transcripts were significantly (The Benjamini and Hochberg false discovery rate, FDR < 0.01) associated with BMI. We continued analysis choosing individuals (297) who had follow up data from BMI and transcriptome measurements in 2014. We observed that 19 transcripts of those 186 associated with the alteration of BMI. Those 19 transcripts contained among other things *PLEK2*, *RANBP10* and *COX7C* and *CA1* genes involving PI3K/AKT signaling, agents acting on the renin-angiotensin system, AMPK enzyme complex pathways, O<sub>2</sub>/CO<sub>2</sub> exchange in erythrocytes including metabolism, respectively. Our results provide novel insights which genes is actually regulated when change in BMI is observed.

## PgmNr 3229: Identification of *CFTR* *cis*-regulatory variants.

### Authors:

Although, more than 2000 mutations have been discovered in *Cystic Fibrosis Transmembrane conductance Regulator (CFTR)* gene, some patients with cystic fibrosis or *CFTR*-related disorders (*CFTR*-RD) have incomplete genotypes or present extreme phenotypes. Development of chromatin conformation study techniques has identified several long-range regulatory elements as involved in this control expression. The objective of this project is to study the involvement of 'cis-ruption', that is the dysfunction of a *cis*-regulatory element, in cystic fibrosis and *CFTR*-RD (*Congenital Bilateral Absence of Vas Deferens*, CBAVD).

In a homogeneous group of 25 CBAVD patients carrying only one F508del mutation, 17 *cis*-regulatory regions of *CFTR* gene were sequenced. By comparing to European population, some variants display a frequency significantly different. In particular, one variant located in *cis*-regulatory region of intron 21 encompassing an important transcription factor binding site HNF1a, is 40 times more frequent in this group. Enhancer tests are realised to measure the effect of the intron 21 region on the activity of *CFTR* promoter in intestinal and airway cells. By combining the enhancer of intron 21 and the enhancer of intron 11 (strong enhancer described in intestinal cells), a strong cooperative effect is observed on the *CFTR* promoter activity in intestinal cells. These two enhancers have common transcription factors binding sites. The insertion of the variant of interest into intron 21 showed a strong decrease of *CFTR* promoter activity in intestinal cells. This variant inhibits the cooperative effect between enhancers of intron 11 and 21, and could affect the recruitment of regulatory elements, such as HNF1a or EP300.

In conclusion, 6 potential regulatory variants have been identified in CBAVD patients carrying a F508del mutation. In particular, one variant strongly reduces *CFTR* promoter activity the cooperative effect between enhancers of intron 11 and 21 and could affect the recruitment of regulatory elements in intestinal cells.

## **PgmNr 3230: Encode and single cell transcriptomics analysis of the developing pituitary gland: Insight into cell fate specification.**

The ENCODE project has discovered regulatory elements in more than 250 cell lines and 150 tissues. This ambitious project integrates histone modification patterns, DNA accessibility, DNA methylation, transcription factor binding and RNA expression data to identify regulatory elements. This information is critical for understanding development and disease pathogenesis. The pituitary gland has not yet been analyzed by ENCODE, and it is essential for producing hormones that regulate growth, homeostasis, and reproduction. We have concentrated on mapping elements that emerge as pituitary progenitors develop into thyrotropes, the cells that secrete thyroid stimulating hormone (TSH), which regulates thyroid gland function. These cells represent only 2-5% of the cells in the adult pituitary gland, which presents a challenge for analysis. We used two immortalized cell lines that represent pituitary progenitors and TSH-expressing thyrotropes. To identify the set of transcription factors, cis-regulatory elements, and epigenetic marks that differ between these lines, we used the Assay for Transposase-Accessible Chromatin with sequencing (ATAC-seq) and Cleavage Under Target and Release Using Nuclease (CUT&RUN) for histone marks and binding of the lineage-specific transcription factor POU1F1. We identified putative regulatory elements for the hormone subunit genes of TSH and critical thyrotrope-signature genes. We validated them by transient cell transfection and confirmed a subset in transgenic mice. Motif enrichment analysis implicated several consequential transcription factors in thyrotrope function. To relate these findings to cells in intact pituitary glands, we collected pituitaries from newborn mice (postnatal day 7) with genetically-marked thyrotropes. We used fluorescence activated cell sorting to enrich for thyrotropes and conducted single-cell transcriptomics using the 10X genomics platform. This analysis revealed transcription factors that were concordant with the cell line analyses, suggesting their role in thyrotrope maintenance, and factors specific to the cell line analyses, suggesting their role in thyrotrope development. This data extends the ENCODE analysis to an organ that is critical for growth and metabolism, and it could be valuable for understanding genetic causes of pituitary dysfunction.

## PgmNr 3231: Genome-wide identification of epigenetic changes associated with 17 $\alpha$ -ethynylestradiol (EE2) exposure in the fathead minnow.

17 $\alpha$ -ethynylestradiol (EE2) is widely used estrogenic chemical present almost ubiquitous in aquatic environments throughout the United States and some other countries. Acting as an endocrine disrupting compound, EE2 can disrupt hormonal homeostasis, leading to developmental disorders, cancer and other diseases. Exposure to EE2 is known to induce expression of vitellogenin, a precursor protein of egg yolk normally only expressed in female fish, in male fish. However, the underlying epigenomic changes associated with vitellogenin induction and phenotypic changes (e.g. feminization), are not well understood. This study was designed to gain insights into such underlying epigenetic regulation mechanisms by evaluating genome-wide DNA methylation changes in CpG sites using the reduced representation bisulfite sequencing (RRBS). Taking advantage of the new and highly contiguous genome reference assembled in house, we used the fathead minnow as the model organism to identify CpG methylation changes before and after exposure to EE2. In our experiment, two groups of male fathead minnow fish, each with 16, were exposed 2.5ng/L and 10ng/L EE2 for 48 hours, respectively. In addition, another two groups not exposed to EE2 were used as control groups: one male group for negative control and the other female group for positive control. We then obtained RRBS data of both liver and brain tissues of all individuals. We assessed and compared CpG methylation changes immediately after EE2 exposure in both male liver and brain tissues. We also compared methylation CpG patterns after 7-day and 14-day depuration of EE2 to find if these methylation changes are temporary or potentially long-lasting. This was done separately for liver and brain tissues. Overall, we found that a limited number of CpG regions were subjected to significant methylation changes after 48-hr EE2 exposure in male liver tissue, and the number of affected CpG sites and their methylation level changes were even smaller in male brain tissue. Such epigenetic changes also exhibit dose-dependent effects with larger changes associated with a higher exposure dose. Our initial results show that CpG-sites methylation were changed quickly after EE2 exposure and stayed for a long time after depuration of EE2, indicating EE2 effects could be potentially long lasting. We are getting more detailed results including specific genes/regions associated with methylation changes, which will also be presented.

## PgmNr 3232: DNA methylation associated with kidney function identifies shared and ethnic-specific loci.

---

Epigenetic alterations such as changes in DNA methylation (DNAm) influence gene expression and regulation, and may contribute to chronic kidney disease (CKD) risk. CKD, defined by chronically low levels of estimated glomerular filtration rate (eGFR), is more common among individuals of Hispanic and African ancestry in the U.S, though the reasons for these differences are unknown. We use data from 2705 participants (833 African, 433 Hispanic, 1439 European ancestry) from the multi-ethnic Women's Health Initiative to examine associations between kidney function (eGFR) and DNAm patterns in whole blood. DNAm beta values obtained using Illumina 450K beadchip arrays were BMIQ-normalized and combat-adjusted for technical covariates. Epigenome-wide association studies (EWAS) were run in ethnic-stratified data using a linear model with robust standard errors adjusting for age, smoking, and study-specific variables, principal components of ancestry, and cell type composition. We meta-analyzed results across ethnicities using inverse-variance weighted methods. At a Bonferroni corrected significance level of  $p < 10^{-7}$  we found 28 differentially methylated positions (DMPs) across ethnicities, 18 of which are located in gene-coding regions and 10 of which are located in non-coding regions. Analyses within ethnicity for African, Hispanic, and European ancestry resulted in 14, 21 and 12 unique DMPs respectively. Enrichment analysis of the top 333 eGFR-associated DMPs across all ethnicities ( $p < 10^{-4}$ ) using eFORGE shows significant association of these sites with H3K4me1, an enhancer-associated mark, across a range of tissues, including mesenchymal embryonic stem cells and IPS cells. Further, these DMPs show a significant association with transcription factors (TF) motifs, *PAX1*, *HNF1B*, *POU2F1*, *SOX7*, *MAZ*, and *CDX2*, which are strongly implicated in developmental pathways including kidney. eFORGE-TF analysis shows that 12 of the top 333 DMPs overlap or are located close to *MAZ* motifs ( $q = 0.021$ ). In summary, DMPs found to be significantly associated with levels of eGFR, a measure of kidney function, show significant overlap with TF motifs involved in kidney development, and dysregulation of these sites may in turn mediate disease risk. Further examination of ethnicity-specific DMPs may elucidate differences in kidney disease risk across ancestries.

## PgmNr 3233: Assessment of DNA methylation on kidney function traits by developing and applying an EWAS workflow.

The estimated glomerular filtration rate (eGFR) is the most common measure of kidney function and used to define and stage chronic kidney disease (CKD). Results of recent GWAS on kidney function implicated gene regulatory mechanisms. To get insight into the link between DNA methylation and traits related to kidney function, we conducted fixed-effects inverse-variance meta-analyses of epigenome-wide association study (EWAS) based on Illumina arrays with DNA methylation assessed from whole blood using samples of up to 35 cohorts from diverse ancestries.

The discovery stage of this project included up to 22,347 individuals for the EWAS on eGFR, 11,458 samples for the urinary albumin-to-creatinine ratio (UACR), and 12,479 individuals for serum urate levels. Associations that reached a 5% alpha level after Bonferroni correction for the number of sites tested per trait ( $p < 1.1E-07$ ) were taken forward for replication in up to 11,258 independent samples. Analyses were conducted using linear regression of the proportion of methylated DNA (beta values) on the trait adjusting for sex, age, white blood cell composition, technical factors, and known trait-specific correlates.

We developed and established a workflow for standardization and quality control of EWAS including automated harmonized generation of variables for pre-analysis data checks, an intra- and inter-study quality control pipeline of the EWAS results that systematically checks both methylation data and association results for consistency. By applying the BACON method, no inflation or bias of the test statistics was observed. In the replication stage, 72 out of the 117, one out of the 12, and 104 out of the 140 CpG sites for eGFR, UACR and serum urate, respectively, passed a  $FDR < 0.05$ . Nine of the 18 associations of a former EWAS on eGFR passed that FDR in the current EWAS. Novel sites passing the replication stage FDR for eGFR included *ZFHX3* and *WDR73*, two loci which were associated with kidney function in a recent GWAS of 1 million individuals. Subsequent analyses will include a detailed annotation of the associated sites, assessment of differentially methylated regions, and analysis of causality between DNA methylation and the associated traits.

These results will improve our understanding of the regulatory mechanisms of kidney function traits by highlighting novel pathways on the epigenetic level, and thus open new avenues on prediction and

potential treatment of CKD.

## PgmNr 3234: Genome-wide DNA methylation profiling identified genes involved in COPD severity.

---

Chronic Obstructive Pulmonary Disease (COPD), a heterogeneous disease of the lungs, is the third leading cause of death worldwide. Multiple factors including genetic and epigenetic changes have been associated with the development of COPD. Numerous research groups have been studied altered DNA methylation profiling in COPD versus normal controls, but little is known about the epigenetic mechanisms underlying the DNA methylation changes according to the severity of COPD. In this study, we profiled genome-wide methylation differences between 50 patients with non-severe (GOLD 0 ~ II) COPD and 53 patients with severe (GOLD III, IV) COPD using Infinium MethylationEPIC BeadChip. Raw methylation data were quantile normalized with the R package (minfi). CpG sites with detection p value > 0.01 were regarded as failed and were assigned as missing values. The RnBeads was used for the analysis of methylation array data and DMP (Differentially Methylated Probe) identification. The Homer (v.4.7) software was used for the annotation of probes and assessment of the distribution of methylation probes across genomic features. In total, 425 significant DMPs were identified (Beta value Difference > 5%,  $P < 5.00 \times 10^{-2}$ ) in severe-COPD, and the majority of these DMPs were located in the promoter, 5'UTR, and exonic regions. There were 198 hyper-methylated and 227 hypo-methylated DMPs. Among them, a previously reported COPD genes, *TBX5*, *NOTCH4*, and *PTEN*, were observed. Previously hyper-methylation of *TBX5*, a member of a phylogenetically conserved family of genes involved in the regulation of development, was reported to be associated with COPD. Similarly, we observed hyper-methylation near *TBX5* in severe-COPD compared to those of non-severe group. We then used the DAVID database v6.8 to examine the functional annotation of genes. Genes with DMPs were enriched in KEGG pathways such as AMPK signaling pathway ( $P = 3.28 \times 10^{-4}$ ; *PPP2R1B*, *HNF4A*, *ACACA*, *CREB3L2*, *PFKP*, *PPP2R5E*, *PPP2R2C*, and *RPTOR*), and PI3K-Akt signaling pathway ( $P = 1.00 \times 10^{-3}$ ; *PPP2R1B*, *SGK2*, *TNXB*, *FGF7*, *CREB3L2*, *ITGB5*, *PPP2R5E*, *THBS2*, *PTEN*, *PPP2R2C*, *BRCA1*, and *RPTOR*). Taken together, our findings provide insights for understanding methylation patterns in severe COPD and novel predictive methylation markers for COPD severity.

## PgmNr 3235: HIV-induced epigenetic regulation: Analysis of methylation and RNA-seq data revealed apoptosis-related genes involved in HIV infected T lymphocyte.

It has been shown that both the methylation and gene expression play roles in HIV-host interplay. In this study, to further investigate the relationship between HIV infection and patterns of genome-wide methylation and gene expression, we performed MeDIP-seq and RNA-seq for five T cell lines and each cell line contained HIV+ and control samples. Within differentially expressed genes (DEGs) between HIV+ and control samples, the top enriched pathways included “cell apoptosis”, “primary immunodeficiency” and “inflammatory response”. Eighteen up-regulated and eight down-regulated DEGs were shared by four cell lines. Moreover, on average, 1,736 differentially methylated regions (DMRs) were found between HIV+ and control samples for each cell line. DMRs were significantly enriched in promoter and exon regions. Moreover, transcription factor binding motifs were also found to be significantly associated with methylation alterations, suggesting that DNA methylation might influence the binding of transcription factors with DNA during HIV infection. The top enriched pathways of DMR-associated genes were “ubiquitin-dependent protein catabolic process” and “GTPase activator activity”. Besides, 635 genes were also involved in the crosstalk of methylation and expression, out of which *ATP1B1*, *CAMK2D*, *GRIN2A*, *MAPK10*, *CACNA1C* and *F2R* were shared by more than two cell lines and enriched in “cAMP signaling pathway” and “cell apoptosis”, which affects HIV replication and infection. To validate our results, we selected the well-known apoptosis related genes for further analysis by qPCR, western blot and bisulfite sequencing. Results showed that all of them were successfully validated. Consistent with sequencing result, luciferase assay showed that the activity of *ATP1B1* and *GRIN2A* promoter were significantly decreased in the presence of Tat or Rev. Result of Annexin V assay revealed that knockdown of *CAMK2D* and *MAPK10* could reduce the apoptotic cells, implying their roles in apoptosis during HIV infection. This study provided comprehensive picture about changes at either transcriptional or epigenetic level for T cells in response to HIV infection. The identified candidate genes in this study may provide insights in treatment and diagnosis of AIDS in the future. This study broadens our understanding on the mechanism of HIV/AIDS and provides a resource about dynamic changes at the transcriptome and epigenetic levels during HIV infection.

## PgmNr 3236: A novel role for a long noncoding RNA in STAT signaling contributing to allergic asthma.

### Authors:

Allergic asthma is characterized by airway hyperreactivity to a type 2 immune response; release of cytokines (IL-4, IL-13) lead to STAT6 phosphorylation & airway inflammation. Airway epithelial cells undergo distinct morphological changes following type 2 cytokine exposure, however the molecular events regulating these alterations are not well understood. Long noncoding RNAs (lncRNAs) are non-protein-coding transcripts with an increasingly reported diverse set of functions and cell type-specificity. Despite evidence of immune regulation, few lncRNAs have been functionally identified in the airway. In this study, we aimed to identify differentially expressed lncRNAs following IL-13 stimulation and assess their potential functional role in airway epithelial cells and type 2 immunity. Cultured primary human bronchial epithelial cells (HBECs) under air-liquid interface (ALI) conditions stimulated with vehicle or IL-13 from 8 individual donors were analyzed via RNA-seq. We identified a significantly induced lncRNA, *WFDC21P*, previously reported to prevent STAT3 dephosphorylation in dendritic cells (DC) and regulating consequent DC function. Additional exposure to IL-6 in HBECs, the prototypical cytokine to induce STAT3 phosphorylation, led to a reduction of *WFDC21P* expression back to basal levels. Similar to DCs, we found *WFDC21P* localization is cytoplasmic in HBECs via subcellular fractionation and FISH. Based on these preliminary observations, we posited *WFDC21P* regulates STAT phosphorylation and signaling in HBECs. To test this hypothesis, we used a bronchial epithelial cell line (HBEC3-KT) and dCas9 technology to overexpress *WFDC21P*. Flow cytometry assessed levels of phosphorylated (P)STAT. Overexpression of *WFDC21P* led to increased (P)STAT3 basally and with IL-13 stimulation. Interestingly, *WFDC21P* overexpression led to mildly decreased (P)STAT6 levels following IL-13 (30 minutes), a previously unreported finding. RNA-seq of HBEC3-KTs overexpressing *WFDC21P* following IL-13 stimulation (24 hours) identified robust changes in expression of known STAT6 and STAT3 target genes, such as *CCL26* and *SOCS1*. Current studies are focused on analyzing this RNA-seq data and characterizing *WFDC21P*'s effect on differentiated HBECs and airway cell-type specificity via single-cell RNA-seq. Our studies reveal a novel and cell type-specific role for *WFDC21P*, with further analysis leading to a better understanding of mechanisms governing allergic asthma and airway homeostasis.

---

Genetic studies have revealed that susceptibility variants for autoimmune diseases are over-represented in regulatory elements of memory CD4<sup>+</sup> T cells. Understanding how genetic variation affects gene expression in T cells at key physiological states is essential for deciphering the mechanisms that lead to autoimmunity. Studies have analyzed genetic regulatory variation genome-wide in resting T cells and in a limited number of genes and cell states in activated T cells. However, an understanding of the dynamics of *cis* regulatory variation along multiple physiological states during T cell activation is lacking. Here we characterized the dynamics of genetic regulatory effects at eight time points during memory CD4<sup>+</sup> T cell activation with high depth RNA-seq in healthy individuals. We identified 186 genes with dynamic allele-specific expression, where the balance of alleles changes over time. These genes were four fold enriched in autoimmune loci. We found pervasive dynamic regulatory effects within six HLA genes, particularly for a major autoimmune risk gene, *HLA-DQB1*. Each *HLA-DQB1* allele had one of three distinct transcriptional regulatory programs. Using CRISPR/Cas9 genomic editing we demonstrated that a single nucleotide variant at the promoter is causal for T cell-specific control of *HLA-DQB1* expression. Our study in CD4<sup>+</sup> T cells shows that genetic variation in *cis* regulatory elements may affect gene expression in a lymphocyte activation status-dependent manner contributing to the inter-individual complexity of immune responses. It underscores the importance of studying the function of HLA class II genes in T cells, and ascertaining the evolutionary and disease risk aspects of regulatory variation of HLA genes independent of their protein-coding variation. Overall, we show a successful strategy that can be used in other biological systems for uncovering new context-specific regulation of genes with key roles in complex disease.

## PgmNr 3238: Defining regulatory variants for SLE susceptibility using an integrative post-GWAS functional genomic framework.

---

Multiple association studies have uncovered numerous genetic associations for systemic lupus erythematosus (SLE), an autoimmune disease with a strong genetic component. However the identity of the true causal variants linking their target gene(s) are largely unknown. The objectives of this study were to identify SLE susceptibility variants and their linked susceptibility genes by leveraging expression, epigenetic and 3D interaction data from five immune cell types.

We performed a comprehensive analysis using reported SLE loci, immune cell-specific gene expression and 3D chromatin interaction datasets to define predisposing variants and their target genes. We collated 346 reported genomewide significant SLE variants and 14,483 correlated ( $r^2 > 0.7$ ) variants to define 122 independent signals. We identified 91 deleterious coding SNPs (48 independent signals; CADD > 12.37), including SNPs at *PDHB* and *PXK* that significantly affected expression of *RPP14* in B cells, and further 10,132 eQTLs correlated with 879 genes in monocytes, neutrophils, CD4+T, CD8+T, and B cells. We identified eQTLs in gene promoters, and in enhancers (from promoter-enhancer interactions) for 204 genes. Overall, cell-specific target genes were overrepresented in 169 immune related pathways including Interferon gamma signaling ( $P = 7.09 \times 10^{-15}$ ). Additionally, 14 target genes from 12 independent signals exhibited aberrant isoform ratios, including *SYNGR1* where rs61616683 risk allele increased 7-fold expression of non-sense mediated decay transcript.

By leveraging immune cell expression, epigenetic information, and 3D interaction data, we identified functional SNPs and SLE genes at 77 independent SLE signals. The 90.3% of functional SNPs collocated with enhancers, followed by promoters, and by deleterious SNPs. Together, we identified 204 target susceptibility SLE genes from 69 loci expressed in immune cell types that were overrepresented in immune pathways.

## PgmNr 3239: Hypomorphic *TNIP1* expression in SLE: A cumulative effect of all risk variants on the *TNIP1* SLE risk haplotype.

### Authors:

1) Genes and Human Disease Research Program, Oklahoma Medical Research Foundation, Oklahoma city, Oklahoma.; 2) Department of Pathology, University of Oklahoma Health Science Center, Oklahoma City, OK, USA

### Background:

GWAS, large-scale replication, and fine-mapping studies identified *TNFAIP3 interacting protein 1* (*TNIP1*) as a strong SLE susceptibility locus shared across multiple ethnicities. Fine mapping identified two independent *TNIP1* SLE risk haplotypes associated with reduced *TNIP1* expression. In this study, we aimed to functionally characterize the SLE risk variant(s) driving the hypomorphic *TNIP1* expression in the SLE risk haplotypes. *TNIP1* rs10036748 risk allele was previously implicated in other autoimmune diseases and cancers. We investigated the potential role of rs10036748 and 10 additional SLE-associated *TNIP1* SNPs predicted to have functionality based on RegulomeDB and ENCODE data.

### Methods:

We evaluated allelic effects on nuclear factor binding and enhancer function using EMSAs and luciferase transactivation assays, respectively, in immune cells stimulated with or without PMA/Ionomycin (P/I). Affinity DNA pull-down assays, Western blotting (WB), and ChIP-qPCR were used to identify proteins with allele-specific binding to the rs10036748 SNP.

### Results:

Bioinformatic data identified EGR1, DEC1, and CREB1 as nuclear proteins predicted to bind rs10036748. EMSAs revealed reduced nuclear protein binding to the rs10036748 risk allele, relative to non-risk, in Jurkat, EBV B, and THP1 cells irrespective of P/I stimulation. Affinity DNA pull-down and ChIP-qPCR suggest that impaired binding was due, in part, to reduced DEC1 binding; EGR1 and CREB1 binding trended but were not significant. Despite reduced nuclear protein binding, the rs10036748 risk allele enhanced luciferase transactivation suggesting an enhancer, rather than a repressive effect on *TNIP1* expression.

To identify additional variants that may explain the repressive phenotype of the *TNIP1* haplotype, we strategically screened the remaining 10 SLE risk variants for functional relevance using EMSAs and luciferase transactivation assays. We observed a complex locus with several SLE risk variants contributing to often conflicting cell type-specific and/or stimuli-dependent changes in nuclear factor binding and enhancer activity.

### Conclusion:

Functional analyses of risk alleles in the *TNIP1* SLE risk haplotypes suggest a complex regulation at the *TNIP1* locus, exhibiting cell-type specificity, stimulation dependency, and allele-specific binding and enhancer activity. Decreased expression of the *TNIP1* risk haplotype may be the result of a cumulative effect of multiple functional risk variants.

## PgmNr 3240: Chronic lymphocytic leukemia (CLL) risk is mediated by multiple enhancer variants.

---

Over 90% of the disease-associated single-nucleotide polymorphisms (SNPs) identified by genome-wide association studies (GWASs) are located in noncoding regions of the genome. It is increasingly recognized that noncoding risk variants play regulatory roles in mediating target gene expression, which often involves the alteration of local chromatin accessibility, histone modification, transcription factor (TF) binding affinity, and chromatin interaction. In CLL, we and others have identified 41 risk SNPs by GWAS. However, for the vast majority of the risk loci, the casual variants and the mechanism of casualty remain unknown. This study systematically analyzed 15 CLL risk loci located across 10 different chromosomes. To first map the gene regulatory regions, we uniformly processed chromatin accessibility data (n=24), ChIP-seq data for histone modifications (n=210), TFs and other DNA-binding proteins (n=99). These public epigenetic data were generated in lymphoblastoid cell lines, various blood cell types, lymphoma patient biopsies and cell line. We also sequenced 14 ChIP-seq libraries for H3K4me3, H3K4me1, H3K27ac and H3K27me3 in CLL. Comparing the 15 index SNPs from the CLL risk loci and their correlated variants ( $r^2 \geq 0.5$  in the EUR ethnic group) to the regulatory regions annotated above revealed that candidate casual variants were all located in enhancer regions, including eight in super-enhancers. Using the reference epigenomes generated by the Roadmap Epigenomics Project in other cell and tissue types, we found in nine of the cases that the H3K27ac signals were highly enriched in immune cells. At 13 of the risk loci, we identified strong evidence for the association of candidate casual variants with allelic imbalance in ChIP-seq signal, alteration of TF binding motifs, or both. Furthermore, enhancers covering four of the risk loci were found to be transcribed into noncoding enhancer RNAs (eRNAs) in primary B cells and lymphoblastoid cell line GM12878; eRNAs are proposed to play a role in modulating promoter-enhancer interactions. Finally, using public Hi-C, capture Hi-C and ChIA-PET data in lymphoblastoid cell lines and/or 17 primary blood cell types, we identified 15 target genes for all the risk loci, including seven that encode TFs. Notably, five of the genes are known to play a role in CLL and another seven genes in other lymphomas. Together, our analyses have illustrated multiple mechanisms underlying the pathogenic roles of risk variants in CLL.

## PgmNr 3241: Studying enhancer activity of hQTLs in human SLE by massively parallel reporter assay.

**Introduction:** Genome-wide association studies have identified > 100 risk loci associated with the genetic susceptibility of systemic lupus erythematosus (SLE); however, identifying and functionally characterizing the causal variants involved in disease pathogenesis has been a laborious, inefficient, and resource-intensive task. Our lab previously integrated epigenetic and genotypic data from SLE patient-derived EBV-transformed B cells to identify and prioritize variants that induce allelic imbalance in the magnitude of histone post-translational modifications, i.e. histone quantitative trait loci (hQTLs). In this study, we applied a massively parallel reporter assay (MPRA) to confirm the allele-specific transcription regulation attributed to hQTLs.

**Methods:** We designed a 67,034 MPRA library that contains ~ 35,000 SNPs. We included: 1) the most significant hQTLs from our previous study; 2) non-hQTLs located on shared haplotypes; 3) autoimmune disease index SNPs; 4) eQTLs that interact with the hQTLs via 3D loops; 5) strong proxies of each SNP; 6) location controls; 7) random controls. 19bp indexes were added by PCR. The final MPRA library was transfected into 3 SLE EBV B cell lines, two replicates per cell line. After 24h culture, RNA was extracted to synthesize cDNA. Sequencing libraries were constructed by PCR with Illumina adapters and sequenced using Novaseq S2 flow cell.

**Results:** 61,446 (91.7%) oligos were tagged with at least one unique molecular index. 7933 (13.17%) SNPs demonstrated transcription regulatory activity. 280 (3.68%) SNPs demonstrated differential allelic expression between the reference and alternate alleles; the majority were hQTLs or SNPs looping to hQTLs. Importantly, hQTLs had the highest proportion (7.66%) of variants demonstrating allelic specificity relative to all other variants (0-4%). Among the most significant allelic specific hQTLs were known SLE risk genes: BLK, LRRRC16A, and IKZF1.

**Discussion:** We confirmed the transcriptional regulatory activity of hQTLs in SLE EBV B cells by MPRA. This study facilitates functional prioritization of hQTLs that demonstrate the most convincing and reproducible allele-specific influences on gene expression. Future study will focus on repeating the MPRA in cell lines of different lineage. We will also perform 3D chromatin topology assays to identify allele-dependent effects of hQTLs on chromatin regulatory networks to understand how hQTLs modify gene expression and SLE pathogenesis.

## PgmNr 3242: Altered DNA methylation profile in placentas from pregnant women with sickle cell disease.

**Introduction:** Sickle Cell Disease (SCD) constitutes a group of genetic pathologies that have as common characteristic the presence of hemoglobin S. The pregnancy of women with SCD is accompanied by an increased incidence of pain episodes and several systemic complications. Furthermore, placentas from these pregnancies present a series of abnormalities and dysfunctions, but little is known about genetic regulation in these tissues. Studies have shown that the placenta may suffer changes in its DNA methylation profile in the presence of maternal diseases. Thus, we have investigated if the DNA methylation profile is altered in placentas from pregnant women with SCD compared with placentas from healthy pregnant women.

**Methods:** We analyzed pregnant women: 8 with sickle cell anemia (SCA), 8 with hemoglobinopathy SC (HbSC) and 7 healthy individuals (control group). After childbirth, the placental tissue was collected and submitted to DNA extraction, bisulfite conversion and hybridization in the methylation BeadChip. We used *minfi* package for data normalization and technical correction. Probes located in SNPs and in the Y and X chromosomes were excluded. To analyze the differentially methylated positions (DMPs) we considered  $\beta$ -values  $\geq 15\%$  and applied Linear Models together with Empirical Bayesian approach implemented in *limma* package; the p-values were adjusted (adjP) by the Benjamini-Hochberg. The same criteria were applied to select differentially methylated regions (DMRs).

**Results:** The comparative analysis between SCA and control groups revealed 57 DMRs, of which 50 different genes were identified. The analysis between HbSC and control groups detected 106 DMRs, of which 87 different genes were identified. Among the most significant DMRs, some genes can be highlighted in the SCA group: *PTGFR*, *LHCGR*, *HOXD-AS1* and *GALR2*, which are involved in apoptotic process, cellular response to gonadotropin, cell proliferation and multicellular organism development. Considering the HbSC group, we highlight the *HLA-L*, *SEC31B*, *MARC2* and *GPR83* genes, which are involved in immune system process, protein transport, oxidation-reduction process and signal transduction.

**Conclusions:** SCA and HbSC pregnant women demonstrated altered DNA methylation profile in the placental tissue in comparison to the control group, suggesting that SCD can affect DNA methylation in placentas and potentially could contribute to placental dysfunction or fetal diseases.

## PgmNr 3243: Studying chromatin accessibility in human SLE at single-cell resolution.

---

**Introduction:** Systemic lupus erythematosus (SLE) is a complex autoimmune disease arising from genetic and environmental factors. While the influence of many genetic risk loci on SLE has been well-described, the mechanisms responsible for SLE pathogenesis are poorly understood. Epigenetics provides a route through which genetic variation can influence chromatin accessibility and affect downstream gene expression. To understand how context-specific epigenetic changes are displayed between SLE patients and healthy controls, we applied a novel technique, single-cell combinatorial indexing assay for transposase accessible chromatin with sequencing (sciATAC-seq), to peripheral blood mononuclear cells (PBMCs). This enables us to study SLE-specific chromatin accessibility changes within the context of individual immune cell compartments.

**Method:** PBMCs isolated from 45 SLE patients and 50 controls were fixed using 0.1% paraformaldehyde and treated with transposase to attach specific adaptor index pairs. Eight samples were pooled and re-distributed into six 96-well plates with 20 cells per well. A unique PCR primer pair was added to each well. Following amplification, DNA from each cell was tagged with unique barcode combinations, then sequenced on the Illumina NextSeq platform. Cell-specific ATAC reads were demultiplexed and quantified by custom software.

**Results:** On average, 1,346 cells were sequenced per sample with a total of 398,973 accessibility sites detected. Reference bulk ATAC assays were used to assign 12 different blood cell types. Chromatin accessibility was significantly altered by SLE status at 19,944 locations dispersed throughout the genome. The proportion of differentially accessible (DA) regions unique to a given cell type ranged from 12% (CD8<sup>+</sup> T-cells) to 50% (monocytes), demonstrating high cell-type specificity. Genotyping data from our cohort was integrated to identify 7,308 genetic variants with significant allelic imbalance (aiQTLs), 74% of which are present in DA chromatin regions. Genes nearest to aiQTLs are enriched for genes related to interferon- $\gamma$  response, prioritizing these loci as genetic interfaces to the epigenetic circuitry in SLE autoimmunity.

**Discussion:** Our ability to differentiate subpopulations of immune cell types through sciATAC-seq allows us to determine changes in chromatin accessibility as a result of SLE, and identify genetic influences which may contribute to this epigenetic modulation, in a cell-type-specific manner.

HIV-1 must overcome host antiviral restriction factors for efficient replication. We hypothesized that elevated levels of bone marrow stromal cell antigen 2 (*BST-2*), a potent host restriction factor that interferes with HIV-1 particle release in some human cells and is antagonized by the viral protein Vpu, may associate with viral control. Expression levels of *BST-2* mRNA were measured using a real-time PCR assay and protein levels were validated by Western blotting. The expression level of *BST-2* showed an association with viral control within two independent cohorts of Black HIV infected individuals ( $r=-0.53$ ,  $p=0.015$  and  $r=-0.62$ ,  $p=0.0006$ ). DNA methylation was identified as a mechanism regulating *BST-2* levels, where increased *BST-2* methylation results in lower expression levels and associates with worse HIV disease outcome. We further demonstrate the ability to regulate *BST-2* levels using a DNA hypomethylation drug. Our results suggest *BST-2* as a factor for potential therapeutic intervention against HIV and other diseases shown to involve associate with *BST-2*.

## PgmNr 3245: DNA methylation features predict HIV frailty and mortality.

### Introduction:

Veterans Aging Cohort Study Index (VACS Index) is a component measure that is associated with disease progression and mortality in HIV-infected population. DNA methylation features associated with VACS index may be biomarkers for predicting HIV clinical frailty and mortality.

### Methods:

DNA methylome (DNAm) in peripheral blood from 1,150 HIV-infected men was profiled using the Infinium Human Methylation 450K BeadChip (450K) (training set) or the Infinium Human MethylationEPIC BeadChip (EPIC) (testing set). All individuals were grouped as a high frailty group (VACS index score  $\geq 50$ , N= 228), and low frailty group (VACS index group  $< 50$ , N= 916). In the training set, we pre-selected DNAm probes associated with VACS index for the feature selection process. We applied four machine learning methods (random forest, XGBoost, Support Vector Machines and GLMNET) to develop prediction models for the VACS index. In each method, 10-fold cross validation was performed. The best performing model was evaluated in the testing set using Area Under the Curve (AUC) and balanced accuracy, which is a better accuracy measurement in an unbalanced sample. To test whether the selected probes were collectively associated with mortality, we constructed a DNAm score by the sum of DNAm beta values weighted by effect size. DNAm score for each individual was normalized by using averaging DNAm score within the low frailty group. All individuals were assigned into high or low DNAm score groups. Cox proportional hazards model on ten-year mortality was estimated by comparing high versus low DNAm score groups.

### Results:

A panel of 113 DNAm features was selected from the training set to predict VACS index. The 113 probes showed AUC 0.835 (95%CI: 0.792, 0.879) and a balanced accuracy of 0.693 in the testing set. Among four models, random forest outperformed the other three methods. Furthermore, DNAm score (high vs. low) developed using this panel was significantly associated with mortality with hazard ratio of 2.04 (95%CI: 1.37, 3.02), adjusting for age, race, viral load, HIV treatment, smoking and CD4 count.

### Conclusion and General Impact:

We identified a panel of DNA methylation features that is predictive for HIV frailty and mortality. The DNAm profile of the VACS index may provide new insights into the mechanisms of HIV progression.

## PgmNr 3246: Epigenome-wide association study of immunoglobulin E levels using high-resolution DNA methylation profiling.

Asthma displays important phenotypic heterogeneity. Allergy features, mediated by Immunoglobulin E (IgE) levels, define a major endophenotype of asthma. The identification of differentially methylated CpG sites (DMC) or regions (DMR) associated with IgE levels in asthmatics may bring further insight into asthma heterogeneity.

High-resolution methylome data in regulatory elements of immune cells obtained by MethylC-Capture Sequencing (2.8 million CpGs after quality control) were analyzed in association with IgE levels in 599 blood samples from asthmatic subjects of the Epidemiological study on the Genetics and Environment of Asthma (EGEA). A binomial mixed model was fitted for each CpG, considering the proportion of methylated reads weighted for sequence read coverage as the dependent variable and log(IgE) as predictor while adjusting for age, sex, smoking and proportions of leucocytes. Associations reaching a  $P$ -value  $\leq 10^{-4}$  ( $N=317$  DMCs) were followed-up in 194 subjects from the Medical Research Council for Eczema (MRCE) study. The results from the two datasets were meta-analyzed using the inverse variance-weighted average method.

Meta-analysis of EGEA and MRCE results identified a DMC at chr21:45628025 associated with IgE at genome-wide significance ( $P=8.5 \times 10^{-9}$ ). The DMC maps to an immune-cell specific distal regulatory element 20kb downstream of *ICOSLG* gene. In addition, we found suggestive associations ( $P < 5 \times 10^{-6}$ ) at 13 other loci. Further investigation of DMRs, based on combining spatially correlated DMC  $P$ -values, showed that out of 15 DMRs detected in EGEA, the one replicating in MRCE included *ICOSLG*.

This study identified a novel IgE-associated DMC, nearby *ICOSLG*, a gene encoding the ligand for the T-cell specific cell surface receptor ICOS, which acts as a costimulatory signal for T-cell proliferation and cytokine secretion. This gene is of major biological relevance for allergy but has not yet been reported by genome-wide studies of allergic diseases.

Beryllium exposure can lead to the development of chronic beryllium disease (CBD), an occupational lung disease characterized by granulomatous inflammation. Exposure first leads to T cell sensitization detected in the peripheral blood of genetically susceptible individuals; in some of these sensitized (BeS) individuals, beryllium-specific oligoclonal CD4+ T cells migrate to the lung and drive alveolar inflammation and CBD, while others do not develop this response. Despite well characterized genetic and environmental risks, the progression from BeS to CBD is poorly understood. Epigenetic mechanisms may explain variable disease phenotypes among those with similar exposure and genetic profiles. Our group has profiled DNA methylation and gene expression in whole bronchoalveolar lavage (BAL) cells and BAL-isolated CD4+ T cells from CBD and BeS patients. Cells were isolated from BAL collected from 30 CBD and 30 BeS individuals. DNA and RNA were extracted and assayed using Illumina HumanMethylation EPIC BeadChips and Agilent SurePrint G3 microarrays. Differentially methylated regions (DMRs) and differentially expressed genes (DEGs) were assessed using linear models adjusting for age, sex, and lymphocyte percentage. CD4+ T cells were isolated from BAL from a further 13 CBD and 13 BeS patients to confirm signals from whole BAL. Methylation was assayed again using EPIC BeadChips, while RNA was polyA-enriched and sequenced using the Illumina NovaSeq 6000.

89 DMRs and 121 DEGs were identified between CBD and BeS, and were found to be enriched for chemokine receptor activity, tumor necrosis factor receptor binding, T cell aggregation, cell-cell adhesion and other signatures of abnormal T cell physiology. Signatures of cytotoxicity, such as upregulation of multiple granzyme genes (GZMA, GZMM, GZMH), unexpected in Th1 cells seen in disease, indicate a possible functional role for DNA methylation in driving the inflammatory response observed in disease. These DNA methylation/gene expression changes will next be tested for association with disease in CD4+ BAL cells. Top hits in promoter and enhancer-associated CpG islands will be validated and functionally altered through dCas9-mediated epigenetic editing to observe effect on cellular phenotype. Multiple genes and pathways that are dysregulated in CBD have been identified and offer future potential targets for biomarker development, therapies, and further study.

## PgmNr 3248: Genetic variation in cis-regulatory domains and trans-regulatory hubs of immunity.

---

Genome-wide association studies have identified a large number of genetic variants that are associated with common diseases. However, the phenotypic effects of genetic variants are generally small and determining the causal effect at the molecular level may be challenging. Recently, several research groups, including our own, have used functional genomics data from a population to infer the effect of genetic variation on the structural and functional units in the human genome. In particular, we recently reported the discovery of cis-regulatory domains (CRDs) in LCLs from the inter-individual correlation among regulatory elements (Delaneau et al., Science 2019).

Building on this approach, we set out to investigate the cell-type specificity of CRDs using data from the BLUEPRINT Consortium, which include histone ChIP-Seq and RNA-Seq data from up to 200 individuals in neutrophils, monocytes and T cells (Chen et al., Cell 2016). Using this framework, we were able to call CRDs across the three immune cell types and found that a majority of them were cell-type specific. When looking at fraction of CRDs under genetic control (i.e. CRD-QTLs), we found that more than 60% of CRDs in monocytes and neutrophils were genetically controlled both with respect to their overall activity but more interestingly to their interactions (structure). We next integrated the CRD annotation with gene expression and investigated the regulation of gene expression via CRDs. We found that up to 40% of the CRDs were associated with at least one gene in a given cell type. Moreover, CRD-gene associations were generally specific to a single cell type, as only about a third was shared from one cell type to another. To characterize the impact of CRDs on gene regulation, we studied co-expression of gene pairs and their relative position to associated CRDs. We found that the fraction of co-expressed genes associated with the same CRD was strongly enriched, suggesting that CRDs may be functional units of coordination of gene regulation. In addition, we also noticed that co-expressed gene pairs associated with a CRD were mostly located within the boundaries of the CRD itself. Current analysis extends to trans regulatory hubs (TRHs) and the degree of tissue specificity of these trans interactions. Together, this study highlights the generalized role of CRDs and TRHs across 3 immune cell types and reveals mechanisms of cell-type specificity based on interactions between genes and regulatory domains.

## PgmNr 3249: eQTL fine mapping by CRISPR-Cas9 genome editing with single-cell clones and CROP-seq.

---

Precision identification of causal variants that are responsible for disease risk is one of the major challenges in interpretation of the molecular basis of genome-wide association signals, the majority of which are located in the non-coding regions of loci and are thought to influence phenotypes by altering gene expression. We describe two approaches to fine map causal variants within credible intervals using moderate-throughput CRISPR-Cas9 mediated gene editing in monoclonal HL60/S4 cells. The first approach uses Fluidigm nano-scale PCR to profile individual clones with confirmed short deletions of candidate eSNPs in 8 autoimmune-disease associated eQTL peaks. Although significantly decreased expression was detected at the *CISD1* locus, substantial alterations in expression of non-targeted genes was observed in the same clones. Power calculations using a linear mixed model simulation study based on observed sources of experimental variance indicates that 80% power to detect at least 1 standard deviation unit after disruption of one of ten SNPs in an eQTL credible interval requires 8 replicates of each clone; with more complex models and relaxed sources of technical error, this approach was judged to be infeasible to fine map most eSNPs. Subsequently, we have begun to evaluate pooled lenti-CRISPR screening by CROP-seq on the 10X Genomics single-cell RNA sequencing platform. We targeted 67 SNPs, approximately 20 each in *CISD1*, *DAP* and *PARK7* eQTLs, along with controls, and contrasted GFP and puromycin-based selection of transduced cells. A novel targeted PCR method was used to obtain nearly 100% assignment of guide RNAs to cells, also revealing unexpectedly high multiplicity of infection that is not apparent from the raw scRNA-seq traces. This multiplicity facilitated fitting of a multivariate linear regression model contrasting all targeted SNPs at each locus, leading to identification of at least one SNP in each gene with significant alteration of the target expression. Variation in cell cycle and metabolic state that arises in the genetically uniform cells in the 10 days after transfection affects gene expression that must be controlled for in the analysis. Efforts to replicate this approach in primary lymphocytes also will be reported, and we will discuss the potential utility of CROP-Seq for fine mapping causal variants in eQTL credible intervals.

## PgmNr 3250: Transcriptional signatures of psychosocial experiences reveal GxE effects in leukocyte gene expression of children with asthma.

### Authors:

J.A. Resztak <sup>1</sup>; A.K. Farrell <sup>2</sup>; H.E. Mair-Meijers <sup>1</sup>; A. Alazizi <sup>1</sup>; S. Zilioli <sup>2</sup>; R.B. Slatcher <sup>2</sup>; R. Pique-Regi <sup>1</sup>; F. Luca <sup>1</sup>

Environmental effects such as psychosocial experiences have been demonstrated to affect the epigenome and transcriptome and ultimately affect human health. Psychosocial factors include intrapersonal processes like emotionality, interpersonal social relationships, and broader structural environments like neighborhoods and socioeconomic status. Psychosocial stress affects cortisol levels that in turn affect gene expression in immune and inflammation-related pathways, which can exacerbate the severity of symptoms of diseases such as asthma. Allergic asthma is a chronic disease characterized by inflammation of the airways and hyperreactivity to allergens, with higher severity and morbidity rates in populations with health disparities associated with their environments. Genetic studies have identified transcriptional dysregulation in immune cells in blood circulation as an important component of underlying asthma heritability.

To identify transcriptional signatures of psychosocial experiences that may affect asthma symptoms, we analyzed 23 psychosocial variables and 16 asthma traits in leukocytes from an ethnically-diverse sample of 119 youth from Detroit, MI. We identified significant transcriptional signatures of 9 psychosocial and 4 asthma variables. We found considerable sharing of transcriptional signatures between asthma and psychosocial experiences: e.g, the transcriptional signature of self-disclosure was significantly associated with those of several measures of asthma: lung functioning (normalized FEV1,  $r=.30$ ,  $p=.001$ ), nightly asthma symptoms ( $r=.22$ ,  $p=.02$ ) and asthma severity ( $r=.38$ ,  $p<.001$ ). Gene co-expression network analysis identified 12 modules significantly associated with both measures of psychosocial experiences and asthma symptoms (10% FDR), including modules enriched for genes in the type I IFN, AP1, TNF and interleukin 10, 4 and 13 signaling pathways.

Using eQTL mapping on an expanded sample of 149 individuals, we identified 4,669 eGenes (FDR = 10%), 1,355 of which have not previously been detected in GTEx blood data. Using the transcriptional signatures as environmental proxies, we identified 117 interaction eQTLs, including 93 with psychosocial environments, thus demonstrating that negative psychosocial experiences in humans can contribute to interindividual variation in gene expression.

These results demonstrate that social genomics approaches in humans can uncover potential molecular mechanisms underlying health disparities.

## PgmNr 3251: Linking candidate GWAS (IBD) non-coding variants to genes using chromatin conformation capture assays.

An emerging challenge in the post-GWAS (genome-wide association studies) era is determining the function of disease-causing single nucleotide polymorphisms (SNPs) and linking them to their target genes. This is confounded by the fact that the majority of these GWAS-implicated SNPs (>90%) are in non-coding regions of the genome. Importantly, >60 % of these non-coding variants overlap with regulatory elements like enhancers suggesting that gene regulatory changes contribute to SNP function and disease risk. It is known that enhancers act in a cell and tissue-specific manner and can regulate genes tens or hundreds of kilobases away mediated by chromatin looping and long-range interactions. Thus, our goal is to intersect these disease-associated regulatory SNPs with 3D-genome interactions to identify disease-relevant target genes. From publically-available data sources, we identified and prioritized the most significant IBD (Inflammatory Bowel Disease) GWAS SNPs by integrating statistical significance, replicability, and epigenetic marks such as H3K27Ac, H3K4me3 and CTCF binding, along with DNaseI Hypersensitivity Site maps in relevant cell types. By using multiple chromatin conformation capture (3C) assays such as 4C-seq, PLAC-Seq, EnChIP and Hi-C we show how one regulatory SNP (rs12585310) interacts with the *CDX2* gene nearly ~1 Mb away. We also find that the interaction is cell-type specific and is only present in colonic epithelial cells (Caco-2 and immortalized primary human colonic epithelial cells) and not in other cell types (Jurkat, HS27). We further confirmed the interaction by using the *CDX2* locus as the viewpoint and showing reverse 4C interaction at rs12585310. *CDX2* is a homeobox transcription factor and is known to play a role in gut epithelial cell differentiation and is also a downstream target of inflammatory cytokines. We hypothesize that rs12585310 modulates the expression of *CDX2* leading to changes in epithelial lining of the colon which could alter responses to infection and inflammation. Indeed, single cell Caco2 clones harboring mono-allelic deletion of a 5 Kb region surrounding rs12585310 show reduced expression of *CDX2*. Further validation using CRISPR HDR to generate Caco2 clones with rs12585310 point mutations is in progress.

## PgmNr 3252: Optimal strategies for linking disease-associated SNPs to genes.

---

Although genome-wide association studies (GWAS) have identified thousands of disease-associated common SNPs, these SNPs generally do not implicate the underlying genes. Many strategies have been developed to systematically link regulatory SNPs to the genes that they regulate, but it is currently unclear which of these strategies should be prioritized.

We developed a framework, SNPs to genes (S2G), for evaluating and combining different strategies for linking SNPs to genes. The main idea of S2G is that an accurate linking of SNPs to genes should preferentially link SNPs with large causal effect sizes to constrained genes (high pLI; Lek et al. 2016 *Nature*), which are known to be enriched for common disease heritability. We construct genomic annotations based on SNPs linked to high-pLI genes by each respective strategy, and use stratified LD score regression to assess the contribution to disease heritability of each annotation; we assess this using standardized effect size ( $\tau^*$ ), defined as the proportionate change in per-SNP heritability associated with a 1 s.d. increase in the value of the annotation (conditional on exon, promoter, and MAF annotations) and meta-analyzed across traits. We identify strategies with jointly significant  $\tau^*$  values, which can then be used to weight these strategies.

We applied S2G to GWAS data from 12 independent autoimmune diseases and blood traits (average  $N=345K$ ), evaluating strategies incorporating functional annotations in blood. Top strategies included ABC enhancers (Fulco et al. *bioRxiv*) ( $\tau^*=2.05$ ), ATAC peak-gene expression correlation (Ulirsch et al. 2019 *Nat Genet*) ( $\tau^*=0.89$ ), Roadmap enhancer-gene linking (Liu et al. 2017 *Genome Biol*) ( $\tau^*=0.83$ ), fine-mapped eQTL (Hormozdiari et al. 2018 *Nat Genet*) ( $\tau^*=0.82$ ), and promoter capture Hi-C (Javierre et al. 2016 *Cell*) ( $\tau^*=0.57$ ) ( $P=10^{-15}$ - $10^{-6}$ ; all 5 strategies Bonferroni-significant in joint model). Simple strategies based on 100kb windows around each gene or on closest gene were less informative ( $\tau^*=0.30$  and  $\tau^*=0.06$ , respectively; both non-significant in joint model). The combined S2G strategy increased the strength of cell-type-specific signals in partitioned heritability analyses of the 12 traits using differentially expressed gene sets (Finucane et al. 2018 *Nat Genet*) ( $\tau^*=0.98$  vs.  $\tau^*=0.34$  for the default strategy based on 100kb windows around each gene) ( $P=10^{-33}$  vs.  $P=10^{-25}$ ). Our results highlight the benefits of combining different strategies for linking SNPs to genes.

## PgmNr 3253: DNA methylation changes are associated with particulate matter 2.5 exposure in SLE patients.

---

Systemic lupus erythematosus (SLE) [152700] is an autoimmune disease with heterogeneous clinical manifestations. Epigenetic changes, including DNA methylation, have been implicated in SLE; specifically, differences in methylation have been associated with auto-antibody and lupus nephritis status. A prior study showed that closer residential proximity to highways was associated with hypomethylation of 3 CpG sites in the *UBE2U* gene in SLE patients. In this study, we examine the association of particulate matter 2.5 (PM<sub>2.5</sub>) levels on the day of blood draw with DNA methylation in a cohort of SLE patients from the California Lupus Epidemiology Study (CLUES). PM<sub>2.5</sub> levels were estimated by Sonoma Technology from air pollution concentrations based on geocoded residential locations. Concentrations of PM<sub>2.5</sub> fell between 1.8 and 25.9 µg/m<sup>3</sup> (SD = 3.3) with all subjects' exposure classified as either "Good" or "Moderate" according to the Air Quality Index (AQI). DNA methylation was measured using the Illumina HumanMethylationEPIC BeadChip for 271 unique subjects of White, Hispanic, African American, and Asian ethnicities. Noob background subtraction with dye-bias correction as well as quantile normalization were conducted in *minfi*. CpG sites with high detection p-values, cross-reactive probes, and CpG sites potentially measuring SNPs were removed for a total of 748,793 CpG sites for analysis. We first conducted an analysis for differentially methylated position (DMPs) using *limma* linear models with empirical Bayes variance shrinkage, adjusting for age, sex, current smoking status, current medication use, estimated cell-type proportions from *ReFACTor*, and genetic ancestry. Preliminary results showed 17 DMPs (after FDR correction) associated with PM<sub>2.5</sub> exposure, 16 of which were hypomethylated. These CpG sites mapped to genes including *TTC17*, *SGCB*, *CCDC26*, *AFF3*, *KCP*, *VGLL4*, *CNTN2*, *NPHP4*, and *GAPVD1*. We then conducted an analysis of differentially methylated regions (DMRs) using *bumphunter*. One region located 900bp upstream of *KLRC3* was significantly differentially methylated after FDR correction. Given the previous findings in the *UBE2U* gene, we also conducted a candidate DMP analysis for the 21 CpG sites on the EPIC chip which map to *UBE2U*; however, no CpG sites reached statistical significance. These results suggest for the first time that there is differential methylation with increased PM<sub>2.5</sub> exposure in SLE patients.

## PgmNr 3254: Interleukin-6 genetic polymorphisms correlate to DNA methylation and cytokine expression in Kawasaki disease.

**Background:** Kawasaki Disease (KD) is a febrile disease of children complicated with coronary artery lesions (CALs). Its incidence in Taiwan is 69/100000 under age 5 and ranks the third after Japan and Korea worldwide. Higher incidence rates in Japanese, Koreans, Han Chinese, and even Asian Americans indicate that genetic factors correlate to KD susceptibility. Activation of numerous immunologic factors such as T cells, cytokines and adhesion molecules, and delayed apoptosis of leukocytes characterize the acute stage and may contribute to the pathogenesis of KD.

Histopathological investigation of the coronary arteritis has revealed that activated T cell-dependent processes characterized by transmural infiltration of activated T cells occur with accumulation of CD8<sup>+</sup> T cells in vascular lesions. Because abnormal immune activation and inflammatory cytokines might contribute to KD, exploration of associated molecules using genetic approaches might shed light on the underlying pathogenic mechanisms. We hypothesized that the etiology of KD might be multifactorial, programmed by genes of inflammasome, immune brake, and cytokines.

**Methods:** We genotyped 670 KD patients (150 with CALs) by using the iPLEX sequenom MassARRAY assay including BCL2, IL6, IL10, PDCD1, PDL-1, Siglec5, Siglec9, STAT3, STAT5b, TNFSF10. Distributions of genotypes and alleles were compared to those of 1517 controls released from Taiwan Biobank using  $\chi^2$  test. P values were corrected for multiple comparisons. Plasma cytokine levels in KD patients were measured using ELISA kit.

**Results:** Alleles rs2069840C ( $P=0.024$ , OR 1.50) and rs1800796C ( $P=0.03$ , OR 1.20) of the IL6 gene conferred susceptibility to KD. Alleles rs2069840C ( $N=520$ ,  $P=0.009$ , OR 1.61) and rs1800796C ( $N=514$ ,  $P=0.015$ , OR 1.23) were more frequent in KD patients without CALs compared with controls. Plasma IL6 levels after IVIG treatment were lower in patients with allele rs2068840C than those with allele rs2069840G.

**Conclusions:** We detect significant association between the IL6 gene and KD. Alleles rs2069840C and rs1800796C conferred risk of KD. Plasma IL6 levels after IVIG therapy were associated with the

allele types of the IL6 gene. IL6 rs1800796 genotypes have been reported to be related to DNA methylation in IL6 promoter region. We speculated that methylation may play a role in KD susceptibility and plasma IL6 levels.

## PgmNr 3255: 3D promoter-open chromatin connectomes in human immune cells yield insight into cell-specific gene regulatory architectures and the genetic basis of multiple autoimmune diseases.

---

Genome-wide association studies (GWAS) have identified ?hundreds of autoimmune disease-associated loci; however, localization of causal variants at these loci, plus the corresponding genes and tissues impacted, have not been determined. To date, there has been a lack of systematic analyses across multiple disease-relevant immune cell types to give a comprehensive view of autoimmune disease etiology. To address this unmet need, we performed high-resolution, promoter-focused Capture C coupled with ATAC-seq to characterize the genome-wide open chromatin-promoter connectomes of 9 primary human immune cell types, including monocytes, naïve CD4+ T cells, naïve B cells, germinal center B cells, T helper-1 (Th1), Th2, Th17, regulatory (Treg) and follicular helper T cells. We found that comparative open chromatin landscapes across these immune cell types largely reflect their hematopoietic origin, indicating that development and differentiation are major forces shaping immune gene regulatory landscapes. Intersecting these open chromatin landscapes with maps of genome-wide promoter interactions revealed the full *cis*-regulatory architectures of >20,000 genes in each cell type. Comparison of these connectomes across cell types identified lineage-specific gene regulatory architectures, revealing the structural basis of cell-specific control on gene transcription. Exploiting these connectomes for variant-to-gene mapping successfully connected 979 putative causal variants at 65% of autoimmune GWAS loci to 1,291 putative effector genes enriched for functional categories such as interferon signaling and T helper cell differentiation. We found that open regions harboring a single GWAS locus commonly contact different genes in distinct cell types, suggesting combinatorial diversity in disease-associated gene regulatory networks. For example, the open proxies at T1D locus 'ITGB7' contact *ITGB7*, *AAAS* and *PFDN5* in most immune cells, while they connect to *PRR13* specifically in germinal center B cells. In addition, some effector genes (*CSF2*, *REL*, *IKZF3*) implicated by open variants through 3D regulatory connectomes were shared by multiple

autoimmune diseases, while others (*FOSL1* for Crohn's, *STAT6* for psoriasis) were specific to a disease. These open chromatin-promoter connectomes reveal both shared and lineage-specific gene regulatory architectures across immune cells, and provide a rich resource for variant-to-gene mapping to understand the genetic basis of autoimmune diseases.

# PgmNr 3256: The transcriptional mosaic of escape from X-inactivation across immune cell-types, individuals, and twin pairs.

## Authors:

A. Zito; A.L. Roberts; J.S. El-Sayed Moustafa; K.S. Small

[View Session](#) [Add to Schedule](#)

**Affiliation:** Department of Twin Research & Genetic Epidemiology, King's College London, London SE1 7EH, UK

---

X-chromosome inactivation (XCI) balances the chrX dosages between 46,XX and 46,XY mammals. In a female diploid cell, one X is silenced (Xi) while the other is active (Xa). In humans, over 15% of genes escape XCI, and escape has been linked to sexual dimorphism in gene expression, autoimmunity and cancer incidence, and phenotypes in X-aneuploidies. Heterogeneity of escape across individuals and disease-relevant cells may modulate disease predisposition. The extent of variability in escape and the influence of genetics and environment on escape are not well known. Here, we use RNAseq and DNAseq to study escape in LCLs (N=136), fat (N=14), skin (N=30) samples, and purified monocytes, B and T-CD8<sup>+</sup> cells from a monozygotic twin pair. All samples exhibited skewed XCI, as this enables to distinguish silent from escape genes. We quantified escape (EscScore) by combining the gene's allele-specific expression with the sample's XCI-skew; values range from 0 (no escape) to 1 (fully escape). In line with the average Xi/Xa expression ratio (Tukiainen *et al*, 2017), we classified genes with EscScore  $\geq 0.35$  and  $< 0.35$  as escapees and silenced, respectively. EscScore discriminated between different XCI classes (Balaton *et al*, 2015). The fraction of genes escaping XCI varied from 15% in LCLs to 34% in fat and 44% in skin. 21 genes exhibited tissue-specific escape like *DMD*, *FHL1*, *CD99L2*. Some genes show complex patterns; *DDX3X*'s escape is highly variable in LCLs across individuals, but not in other tissues, indicating a strong individual and tissue-specific component in the regulation of escape. 50 genes exhibited consistent escape limited to one tissue (e.g *IRAK1* in LCLs, *JPX* in fat), and 60 genes variable escape across both individuals and tissues (e.g *KDM6A*, *TIMP1*). Overall level of escape in an individual varied between immune cell types ( $P < 10^{-15}$ ), with highest escape in T-CD8<sup>+</sup> cells. We identified 16 novel immune cell type-specific escapees like *FMR1* and *MAGT1* (T-CD8<sup>+</sup>), *MTCP1* (B-cells). We did not detect escape in monocytes. Thus, Xi regulation differs between myeloid and lymphoid lineages and between lymphoid cells in an individual. We found higher rates of discordant escape in dizygotic (30%) than monozygotic (24%) twins, suggesting that escape has heritable and environmental components. Within an individual, XCI escape generates a complex transcriptional mosaicism whose regulation may modulate the immune system and impact translational approaches of immuno-therapies.

## PgmNr 3257: Single-cell and neuronal network alterations in the fragile X syndrome.

### Authors:

---

Our cognitive abilities depend to a large extent on the normal development and functioning of the neuronal networks in the brain. Genetic abnormalities that disturb the establishment of physiological neuronal connectivity lead to a variety of disorders, of which Fragile X syndrome is an important example. Fragile X syndrome is a frequent cause of autism and intellectual disability and it is caused by the absence of the Fragile X mental retardation protein (FMRP), mostly due to promotor hypermethylation. The function of the underlying gene has been extensively studied, and FMRP quickly became recognized for its pivotal role in many cellular processes, including translation, RNA transport, and stability. However, despite over 20 years of research, it still remains elusive how the loss of FMRP affects brain connectivity. Abnormalities in both excitatory and inhibitory transmission have been reported in Fragile X syndrome and an altered balance between excitation and inhibition has been hypothesized to underlie the clinical consequences of absence of the protein. Over the past decades, FMRP research focused on abnormalities both in glutamatergic and GABAergic signaling. However, direct proof of this theory has not been provided as yet. Using *Fmrp* knockout mice, we studied an in vitro model of cortical microcircuitry and observed that the loss of FMRP largely affected the electrophysiological correlates of network development and maturation but caused less alterations in single-cell phenotypes. The loss of FMRP also caused a structural increase in the number of excitatory synaptic terminals. Using a mathematical model, we demonstrated that the combination of an increased excitation and reduced inhibition describes best our experimental observations during the ex vivo formation of the network connections. Our study demonstrates that loss of *Fmr1* in neurons results in impairments at multiple levels of circuit organization, largely involving both excitatory and inhibitory transmission and to a much lesser extent single-cell excitability. These alterations manifested themselves in complex forms at the network level, indicating that any therapeutic intervention might require timely and precise pharmacological modulation of synaptogenesis and of synaptic transmission during network formation in order to recover the WT phenotype in vitro.

## PgmNr 3258: Dysregulation of the chromatin remodeling-associated proteins in *Fmr1* KO2 mouse testes: A role of *Fmrp* in mouse spermatogenesis.

### Authors:

R. Zong; K. Shelly; D. Nelson

[View Session](#) [Add to Schedule](#)

**Affiliation:** Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, Texas

---

Fragile X syndrome (FXS) results from loss of *FMR1* function. In addition to cognitive impairment, men with FXS also have enlarged testes (macroorchidism) and produce sperm with only premutation length alleles despite the presence of full mutations in other tissues. *Fmr1* KO male mice show macroorchidism but are fertile. The mechanism(s) responsible for these findings remain elusive, but selection in sperm precursor cells may explain the absence of sperm carrying full mutation alleles. We utilized two mouse models, *Fmr1* KO2 and mosaic *Fmr1* deletion (produced by incomplete conditional KO using tamoxifen-inducible Cre recombinase in cells marked with Rosa-Tomato/GFP), to identify dysregulated *Fmrp* targets in testis and study spermatogenesis.

In testes from *Fmr1* KO2 mice, we found reduced levels of histone H3meK9 along with reduction of the H3K9 methyltransferase, EHMT1, mRNA for which has been found in *Drosophila* to be an FMRP target. We also found enhanced levels of HDAC1 and developmental stage dependent alterations in Protamine1 levels. Several proteins altered in brain were unchanged in testis (MAP1B, MMP2, MMP9), while GluA2 levels were reduced in both testis and brain. Staining testes with hematoxylin and DAPI showed unusual DNA staining in elongated spermatids in the absence of FMRP, and PSA cytoplasmic staining under light microscopy also suggests abnormal morphology. Analysis of mosaic testes and the sperm produced is ongoing and will allow quantification of these effects and determination of the cell specificity for presence of FMRP.

Our results are consistent with a model in which dysregulation of chromatin remodeling factors in the absence of FMRP plays a role in both the enlarged testes and the unusual sperm production in full mutation males through altered histone H3 methylation. This role for FMR1 in testis has potential implications for its function in CNS cells and suggests potential pathways and targets that might be targeted with small molecule therapies.

## PgmNr 3259: Molecular diagnosis of Prader-Willi syndrome and Angelman syndrome by MS-MLPA.

**Authors:**

B. Kim; J.A. Lee; M.W. Seong; S.S. Park

[View Session](#) [Add to Schedule](#)

**Affiliation:** Department of Laboratory Medicine, Seoul National University Hospital, Seoul, Republic of Korea

---

Prader-Willi syndrome (PWS) and Angelman syndrome (AS) are rare genetic disorders which are caused by a deletion on 15q11-q13, uniparental disomy of chromosome 15, or an imprinting defect. However, the methylation analysis, a standard method for diagnosis of PWS/AS cannot distinguish these entities. The aim of the study was to confirm the utility of methylation specific multiplex ligation-dependent probe amplification (MS-MLPA) as a diagnostic tool.

We performed MS-MLPA with DNA samples from 93 patients (45 PWS, 24 AS, 24 patients with negative results) requested for methylation-specific polymerase chain reaction (MS-PCR) for the diagnosis of PWS/AS. We compared the results of both assays.

MS-MLPA showed 100% sensitivity, specificity, and concordance rate to diagnose PWS and AS. Among 45 PWS patients, 26 patients (57.8%) had a deletion of 15q11-q13 and the others (42.2%) had maternal UPD 15 or imprinting defect. Seventeen out of 24 AS patients (70.8%) had a deletion of 15q11-q13. The other 7 patients (29.2%) had paternal UPD 15 or imprinting defect.

MS-MLPA has clinical significance for the diagnosis of PWS/AS and it is superior to MS-PCR in that it can classify the mechanism of the diseases.

## PgmNr 3260: Cryptic transcription is associated with age in mammalian stem cells.

**Authors:**

B. McCauley <sup>1</sup>; L. Sun <sup>1</sup>; W. Dang <sup>1,2</sup>

[View Session](#)[Add to Schedule](#)**Affiliations:**

---

Aging is a multifaceted process that challenges organisms with stresses resulting from the dysregulation of cellular processes. Unsurprisingly, given how tightly regulated it is under normal conditions, transcription is one of the key pathways disrupted during aging. Indeed, dysregulation of transcription contributes to the activation of transposable elements, the loss of cellular identity, and decreased stem cell potency with age. Our previous work identified intragenic cryptic transcription (CT) as a novel type of age-associated transcriptional dysregulation that limits the lifespan of yeast and worms. Continuing this work, we show for the first time that CT increases with age in mammalian stem cells. Increased CT is associated with disrupted chromatin structure, particularly with the reduction of H3K36me3, a histone modification known to inhibit CT throughout eukaryotes. We propose that an age-associated reduction in H3K36me3 in actively transcribed gene bodies drives disruption of chromatin structure in these regions, resulting in an open chromatin state. This open chromatin state is permissive for the entry of RNA Pol II, which can then initiate transcription from within the gene body. These aberrant cryptic transcripts may contribute to the pathological load of mammalian aging.

# PgmNr 3261: Horizontal transfer of whole mitochondria restores tumorigenic potential and dihydroorotate dehydrogenase function after respiratory recovery of mtDNA deficient cancer cells.

Recently, we showed that p cancer cells devoid of mitochondrial DNA (mtDNA) recover tumour formation ability after acquisition of host mtDNA (1). In order to restore respiration, mtDNA moves between cells in whole mitochondria (2). This process is gradual, and mitochondrial respiration is recovered at tumour formation onset. While it is now clear that recovery respiration is essential for tumour formation, there are several unanswered questions, such as: i) what happens in the grafted cells before tumour starts to form; ii) why respiration recovery is needed for tumour formation and progression, and iii) what is the functional link of respiration to tumour growth.

To further explore the mechanisms underlying mitochondrial transfer between cells, we prepared cell lines from 4T1 p cells on different days after grafting, and found that at the time when tumour starts to form, respiration was largely restored. Using our unique sublines, we documented the complex machinery needed for respiration recovery. This includes gradual increase in mtDNA level of homoplasmic host polymorphism, followed by binding of mtDNA-processing enzymes to its regulatory domain, replication and transcription of mtDNA, and increased expression of components of respiratory complexes, resulting in full respiration recovery. In addition, we found that pyrimidine biosynthesis, supported by the respiration-linked enzyme dihydroorotate dehydrogenase (DHODH), is required to overcome cell cycle arrest observed in non-/low-respiring cells. The reason being that respiration recovery, which is necessary for tumour cell proliferation allowing for tumour formation and progression, is associated with efficient *de novo* pyrimidine synthesis. This pathway is dependent on the mitochondrial inner membrane enzyme DHODH, implying the role of complex III and complex IV in coenzyme Q redox-cycling. We propose that re-activation of DHODH, a rate-limiting enzyme in the *de novo* pyrimidine synthesis, is the key event for triggering tumour growth following horizontal transfer of mitochondria into mtDNA-compromised cancer cells and that it is intimately linked to mitochondrial respiration (3).

In conclusion, we propose that DHODH is a critical link between *de novo* pyrimidine synthesis and respiration, and that it is a promising target for a broad-spectrum cancer therapy.

---

**Objective:** To summarize the clinical and genotypic characteristics of mitochondrial epilepsy in children, and to improve the understanding of it.

**Methods:** Retrospectively analyzing and following up the mitochondrial epilepsy of genetic diagnosis from October 2011 to December 2018 in the Department of Neurology Beijing Children's Hospital Affiliated to Capital Medical University.

**Results:** A total of 62 cases. 42(67.7%) focal motor seizure, 20(32.3%) generalized tonic clonic seizure, 16(25.8%) status epilepticus, 14(22.6%) myoclonic seizure, 33(53.2%) had two or more seizure types. 29 cases(46.8%) MELAS, 11 cases(17.7%) Leigh syndrome, 6 cases combined oxidative phosphorylation deficiency, 5 cases MERRF, 4 cases Alpers syndrome. 26 cases(41.9%) MT-TL1 gene mutation(m. 3243A>G), 8 cases(12.9%) mitochondrial complex ? gene mutation, 7 cases(11.3%) mitochondrial ammonia acyl tRNA synthase gene mutation, 4 cases mitochondrial DNA polymerase gene mutation. 24(55.8%) were medically refractory epilepsy in 43 followed up.

**Conclusion:** Focal motor seizure is the most common seizure type. MELAS is the most common clinical phenotype. M.3243A>G is a hotspot mutation. The genes that encoding mitochondrial complex ?, mitochondrial ammonia acyl tRNA synthase and mitochondrial DNA polymerase are major disease genes.

## PgmNr 3263: Exploring the relationship between mitochondrial DNA copy number and gene expression.

Mitochondria are important for cellular function, playing critical roles in energy metabolism, signaling, and apoptosis. Mitochondrial DNA copy number (mtDNA-CN) is a proxy for mitochondrial function and has been associated with cardiovascular disease (CVD), overall mortality, and other morbidities. However, the molecular mechanisms that underlie these associations are still unknown. Using the Genotype Tissue Expression Project (GTEx), we aimed to interrogate the biochemical pathways that link mtDNA-CN and disease by examining the relationship between mtDNA-CN measured in whole blood and gene expression.

We estimated mtDNA-CN from whole genome sequencing data in GTEx (N=139), adjusting for neutrophil count, hematopoietic cell count, age, and cohort with a linear model. Effects for age and neutrophil count on mtDNA-CN were consistent with published literature, supporting the reliability of our mtDNA-CN metric.

We then tested for associations between adjusted mtDNA-CN and gene expression in blood, correcting for genotyping principal components, sex, and surrogate variables generated from transcript counts. Although no associations passed Bonferroni correction, the top hits included genes linked to mitochondrial function, such as mitochondrial phosphate carrier SLC25A23 ( $p=2.43e-05$ ) and coenzyme Q binding protein COQ10A ( $p=9.72e-05$ ). Additionally, 36 out of 37 mitochondrially encoded genes were positively associated with mtDNA-CN, of which 14 were nominally significant ( $p<0.05$ ). Gene ontology enrichment analysis of associated genes revealed enrichment for CREB phosphorylation ( $p=1.90e-07$ ), glucagon signaling in metabolic regulation ( $p=6.82e-05$ ), and muscle contraction ( $p=6.59e-07$ ).

After expanding this analysis to 47 additional tissues, several genes were nominally significant in multiple tissues, most notably brain, muscle, and thyroid tissue. These genes include the mitochondrial transporter SLC25A411, the pseudogene RPS2P46, and the scaffolding protein DLG3. DLG3 and RPS2P46 have not been previously associated with mitochondrial function, and thus may identify novel functional pathways. These results strengthen the link between mtDNA-CN and mitochondrial function. They also suggest that mtDNA-CN measured in blood may reflect processes occurring in other, more disease-relevant tissues, strengthening the rationale for measuring mtDNA-CN in blood as a biomarker for complex aging-related diseases.

The contribution of epigenetic regulation by histone acetylation is being increasingly recognized as a cause of genetic diseases. Notably, variants in several lysine acetyltransferase genes, such as *KAT6A* and *KAT6B*, have been identified in individuals with neurodevelopmental disorders characterized by intellectual disability and malformations. *KAT5* (previously named *TIP60*) encodes a lysine acetyltransferase involved in gene expression, DNA repair, chromatin remodeling, apoptosis and cell proliferation, but it remains unclear whether this gene is mutated in any genetic diseases. Here, we describe three individuals with *de novo* likely pathogenic missense variants in *KAT5* that affect three highly conserved residues with one at the chromodomain (p.Arg86His in the longest isoform) and two at or near the acetyl-CoA binding site (p.Cys402Ser and p.Ser446Ala). All three individuals have cerebral malformations, seizures, global developmental delay or intellectual disability, and a severe sleep disorder. Histone acetylation assays with purified mutant proteins demonstrated that the variants decrease or abolish the ability of native *KAT5* protein complexes (NuA4/TIP60) to acetylate the histone H4 tail in chromatin. In conclusion, *KAT5* variants cause histone acetylation deficiency with likely transcriptional dysregulation of multiples downstream genes, thereby leading to a neurodevelopmental syndrome with sleep disturbance and facial dysmorphisms.

## **PgmNr 3265: Implementation of clinical genomic DNA methylation testing for patients with neurodevelopmental presentations and congenital anomalies.**

**Authors:**

B. Sadikovic

[View Session](#) [Add to Schedule](#)**Affiliation:** London Health Sciences Centre, Western University, London, Canada

---

Conventional genetic testing of patients with neurodevelopmental presentations and congenital anomalies (ND/CA), i.e., the analysis of sequence and copy number variants, leaves a substantial proportion of the patients unexplained. Some of these patients have been shown to carry DNA methylation defects at a single locus (epi-variants), while others can exhibit syndrome-specific DNA methylation changes across multiple loci (epi-signatures). Here, we investigate the clinical diagnostic utility of genome-wide DNA methylation analysis of peripheral blood in unresolved ND/CA patients and present early data from clinical testing in three clinical laboratories in North America and EU. We generated a computational model enabling concurrent detection of 20+ syndromes, and 30+ genes using peripheral blood DNA methylation data with full accuracy. We demonstrate the ability of this model to resolve patients with uncertain clinical diagnoses, some of whom had VUS's in the related genes. We show that the provisional diagnoses can be ruled out in many of the cases, some of whom are shown by our model to have other diseases initially not considered. We demonstrate by applying this model to ND/CA patients without a previous diagnostic assumption and separate assessment of rare epi-variants in this cohort, we can identify patients with syndromic genetic disorders, imprinting and trinucleotide repeat expansion disorders, and patients with rare epi-variants, a portion of which involved genes clinically or functionally linked to the patients' phenotype. This study demonstrates that genomic DNA methylation analysis can facilitate the molecular diagnosis of unresolved clinical cases, and highlights the value of epigenomic testing in the routine clinical assessment of patients with ND/CA.

## PgmNr 3266: Comparative whole genome DNA methylation profiling in Costa Rican nonagenarians with and without dementia: Further evidence for a role of *PM20D1* .

Alzheimer's disease (AD) is a complex disorder in which different genetic and non-genetic factors have been shown to play a role. Multiple genetic variants can increase the risk of developing AD, but there are also protective variants which play a role in the genetic architecture of the disease. Individuals of advanced age without signs of dementia are very useful in the search for protective variants, but such samples can be hard to find. The aim of this study is to identify differentially methylated regions (DMRs) in the genomes of a sample of cognitively healthy individuals and a sample of individuals with dementia, with the distinctive feature that all individuals are over 90 years of age. We studied 32 nonagenarians from Costa Rica, 11 with dementia consistent with AD (mean age 95, SD=3.4), and 21 cognitively healthy individuals (mean age 95, SD=3.4). We compared whole genome DNA methylation profiles from blood of both samples, using the Infinium MethylationEPIC BeadChip. Two different approaches were used in order to identify differentially methylated regions (DMRcate and Bumphunter). We found a total of 11 DMRs between both groups, in which 7 genes are located. Five genes were hypomethylated in the sample with dementia, and 2 were hypermethylated. These genes are involved in cell cycle regulation, embryogenesis, synthesis of ceramides, and migration of interneurons to the cerebral cortex. The gene *PM20D1* was found to be hypermethylated in the sample with dementia, which is consistent with previously reported results for AD. An association of *PM20D1* with AD has been reported in the literature, where the gene was found to be a methylation and expression QTL. The hypothesis is that a higher expression of *PM20D1* can protect against AD and that loss of this expression is a risk factor for AD. This idea is supported by our results, where the group with dementia has potentially lost the *PM20D1* protection present in the cognitively healthy nonagenarians, due to promoter hypermethylation.

## PgmNr 3267: Variant-to-gene mapping for Alzheimer's disease using 3D genomics in an activated microglia human cell line.

Genome wide association studies (GWAS) have revealed many loci for Alzheimer's disease (AD). However, GWAS report genomic signals and not the precise localization of effector genes, with eQTLs making strong inferences to only a subset of such loci. Chromatin conformation-based techniques that detect contacts between distant regions of the genome offer an opportunity to understand GWAS signals that principally reside in non-coding regions, thus likely influencing regulatory elements. AD, as many other neurological disorders, is characterized by chronic activation of microglia, the resident immune cells of the brain. We leveraged a massively parallel, high resolution Capture C based method to simultaneously characterize the physical genome-wide interactions of all human promoters in a human microglia cell line (HMC3). We first generated ATAC-seq open chromatin maps in the same cell line to 'fine-map' informative (i.e. open) proxy single nucleotide polymorphisms (SNPs) ( $r^2 > 0.7$ ) for each of 45 AD independent sentinel SNPs reported to date, yielding 25 candidate SNPs for 13 of these loci. By querying our Capture C promoter 'contactome' data, we observed loops to "open" promoters relevant to two of the original GWAS loci (*ABCA7* and *CASS4*). Interestingly, none of these contacts involved the nearest gene, which is commonly assigned to a locus by the GWAS community. Next, we performed a similar set of experiments in the interferon- $\gamma$  activated microglia cell line, a more relevant context for AD. Activation was confirmed by increased expression of both CD45 and CD68 and a change in morphology. ATAC-seq revealed 4401 differentially open chromatin regions, ~17% of which resided near promoters of coding genes. Pathway analysis indicated that these genes were involved in pathways relevant to immune activation, such as death receptor signaling, antigen presentation, TREM1 and interferon signaling. While chromatin interactions at the two previous loci were preserved, we also observed loops for 3 new loci (*CELF1*, *FERMT2* and *KAT8*) in the activated microglia. Interestingly, the *FERMT2* gene was recently implicated in brain  $\alpha\beta$  deposition. In conclusion, we identified putative candidate effector genes for five AD GWAS loci in a human microglial cell line. Follow-up functional studies are required to validate these findings, and further efforts in other relevant cell types could shed light on additional loci.

## PgmNr 3268: Epigenome-wide association study across multiple cognitive domains identifies a role of DNA methylation patterns in *CLDN5* on cognitive decline.

---

Cognitive decline is the clinical hallmark of dementia; however, the brain epigenetic signature of cognitive decline is unclear. Hence, we performed a brain epigenome-wide association study of cognitive decline in 636 participants from the Religious Order Study and Rush Memory and Aging Project (ROS/MAP). We repurposed DNA methylation (Illumina HumanMethylation450) profiles of the dorsal lateral prefrontal cortex to assess decline in five cognitive domains (episodic memory, perceptual speed, perceptual orientation, semantic memory, and working memory). To analyze epigenetic associations across these five cognitive domains in a powerful way, we used the Gene Association with Multiple Traits (GAMuT) test, which is a gene-based association test of multivariate phenotypes that exploits potential pleiotropy and accounts for trait correlations. We found an epigenome-wide significant association (Bonferroni threshold:  $3.44 \times 10^{-6}$ ) between methylation sites in the *PI4KA* region and cognitive decline ( $p\text{-value} = 1.32 \times 10^{-6}$ ), which was robust to adjustment for cell type proportions ( $p\text{-value} = 2.38 \times 10^{-6}$ ). Further inspection revealed this association was primarily driven by association with declines in episodic ( $p\text{-value} = 1.62 \times 10^{-6}$ ) and working memory ( $p\text{-value} = 9.49 \times 10^{-8}$ ). Fine-mapping of the *PI4KA* region identified *CLDN5* as the most significant gene and the gene most likely to be functional. Within *CLDN5*, the strongest association was found with the CpG site cg16773741. Higher levels of methylation in *CLDN5*, which corresponded with lower gene expression levels, were associated with faster cognitive decline, suggesting a protective role of *CLDN5* expression on cognitive decline. Methylation in this region was also associated with the degree of pathology in Alzheimer's disease assessed by Braak stage in ROS/MAP and in 66 independent frontal cortex samples.

## PgmNr 3269: Expanded GGC repeats in human-specific *NOTCH2NLC* gene modulate the neuronal toxicity associated with Alzheimer's disease.

---

Neuronal intranuclear inclusion disease (NIID) is a slowly progressing neurodegenerative disease characterized by eosinophilic intranuclear inclusions in the nervous system and multiple visceral organs. GGC repeat expansion within the human-specific *NOTCH2NLC* gene was recently shown to be the genetic cause of NIID-related disorders. Given the phenotypic overlap between NIID and other neurodegenerative disorders, such as Alzheimer's disease (AD) and Parkinson's disease, we screened a cohort of AD patients and identified multiple affected individuals with expanded GGC repeats, suggesting that the expansions in *NOTCH2NLC* could also contribute to AD pathogenesis. *NOTCH2NLC* is one of the three human-specific NOTCH2-related genes (*NOTCH2NLA*, *NOTCH2NLB* and *NOTCH2NLC*) in 1q21.1, highly expressed in the brain and thought to be involved in the evolutionary expansion of the human brain. We analyzed the expression of these three paralogs and found that *NOTCH2NLC* displays the highest expression in the brain among these NOTCH2 paralogs. Interestingly, while the expression of *NOCTH2NLB* only displays modest changes in human prefrontal cortex during aging, the expression of *NOTCH2NLC* increased significantly with age. Thus, the increased expression of expanded GGC repeats during aging could cause neurodegeneration. To further determine whether expanded GGC repeats could contribute to AD pathogenesis, we crossed GGC repeat transgenic flies with the flies expressing either APP/BACE1 or Microtubule-associated protein Tau (MAPT), and found that the expression of expanded GGC repeats could enhance the toxicity induced by Abeta and Tau. These results together suggest that the expanded GGC repeats in the human-specific *NOTCH2NLC* gene could contribute to AD pathogenesis.

## PgmNr 3270: Genome-wide 5hmC dynamics during human organoid development and its dysregulation in Alzheimer's disease.

Epigenetic modifications on cytosine residues, such as 5-hydroxymethylcytosine (5hmC), undergo dynamic changes in the developing brain, and their aberrant regulation is known to be associated with numerous neurological diseases. Studies have identified abnormal 5hmC patterns that differ in postmortem brains of Alzheimer's Disease (AD) patients versus healthy brains. However, the dynamic regulation of 5hmC during early development and how that contributes to AD pathology remains unexplored. AD is a neurodegenerative disease characterized by extensive memory loss and cognitive impairments. Evidence suggests that key changes occur during neural development long before the onset of AD pathology. Despite considerable efforts, the molecular mechanism underlying AD pathogenesis, particularly during early brain development, remains elusive. Brain organoids derived from healthy and AD patients provide a unique opportunity to study brain development at the cellular and molecular levels. We have cultured forebrain organoids derived from healthy humans and *PSEN1* mutated, early-onset AD patients to model the human AD brain. Our AD organoids show accumulation of phosphorylated Tau and Ab plaques after 60 days in culture, and replicate 5hmC alterations as previously reported in AD postmortem brains. Using 5hmC-capture coupled with high-throughput sequencing, we analyzed the 5hmC landscape across several organoid developmental timepoints in healthy controls. As a result, differentially hydroxymethylated regions (DhMRs) in organoids cultured for 56 days (D56) versus embryoid bodies showed depletion at regions associated with pluripotent processes (cell adhesion and chemical stimulus detection). Additionally, D56 DhMRs were shown to be enriched at regions pertaining to nervous system development, neurogenesis and differentiation. Comparing AD organoids to their matched control organoids, we found substantial 5hmC alterations at known AD-risk genes: *APP*, *CNTNAP2* and *FRMD4A*. Significant differentially expressed genes identified by RNA-sequence analysis and our identified intragenic DhMRs from these organoid samples were shown to be enriched for neuronal development and differentiation pathways. These findings suggest that early epigenetic dysregulation of the 5hmC landscape during neuronal development may predispose AD pathogenesis, which could lead to the understanding of molecular mechanisms underlying this devastating disease, allowing for early intervention treatment options.

## PgmNr 3271: Non-coding regulatory landscape of Alzheimer's disease variants using GWAS of 63,926 individuals.

### Authors:

Y.Y. Leung; P.P. Kuksa; C.-Y. Lee; Y.-F. Chou; A. Amlie-Wolf; G.D. Schellenberg; L.-S. Wang

[View Session](#) [Add to Schedule](#)

**Affiliation:** Penn Neurodegeneration Genomics Center, Department of Pathology and Laboratory Medicine, University of Pennsylvania, Philadelphia, Pennsylvania.

Genome-wide association (GWAS) studies identified various genetic variants that are associated with the risk of late-onset Alzheimer's disease (LOAD). Most of these genetic signals affect regulatory elements outside coding genes such as transcriptional enhancers and noncoding RNAs, and due to linkage disequilibrium (LD), top reported variants may not be causal but are just correlated with truly causal variants, which remain to be identified.

We used our INFERNO (INFERring the molecular mechanisms of NOncoding genetic variants) tool (<http://inferno.lisanwanglab.org>), which integrates GWAS data with hundreds of functional genomics datasets to identify causal noncoding variants underlying GWAS association signals and their affected regulatory elements, tissue contexts, and target genes. INFERNO uses the COLOC method to identify colocalized GWAS and target gene eQTL signals overlapping enhancers in matching tissue classes and characterizes co-regulatory networks of targeted long noncoding RNAs.

We identified 1,358 significant variants ( $p < 5 \times 10^{-8}$ ) in the largest LOAD GWAS meta-analysis study to date (21,982 cases and 41,944 controls). We pruned significant variants into independent signals (281 LD blocks) by European LD and expanded these into 2,441 candidate causal variants. While only 3.5% of all candidate variants were in coding exons, 5.9% overlapped FANTOM5 enhancers, 66.2% overlapped Roadmap enhancers, and 58.4% overlapped transcription factor binding sites (TFBS). 3.4% of all the candidate causal variants overlapped with FANTOM5, Roadmap enhancers, and were disrupting TFBS. A subset of variants affected non-coding RNAs: 4.1% overlapped 12 classes of small RNA across 185 tissues/cell types using DASHR2 annotation (<http://dashr2.lisanwanglab.org>). 25% of eQTL signals colocalized with GWAS signals, spanning all 44 GTEx tissues, 67% of which were supported by enhancer overlaps in the matching tissue categories.

The target genes of the eQTL and colocalized genes were strongly enriched (corrected  $p < 0.05$ ) in Gene Ontology enrichment analyses, confirming amyloid-beta clearance, tau protein binding, immune response as top candidates. Interestingly, the analyses also revealed lipoprotein particle receptor binding and regulation of metabolic process as potential mechanisms for LOAD. These analyses support the utility of INFERNO for inferring the molecular mechanisms underlying noncoding GWAS signals in common complex diseases.

## PgmNr 3272: Hypermethylation of mitochondrial tRNA p9 sites in the cerebellum of Alzheimer's disease and progressive supranuclear palsy patients.

### Authors:

T. Silzer; G. Pathak; N. Phillips

[View Session](#) [Add to Schedule](#)

**Affiliation:** Graduate School of Biomedical Science, UNT Health Science Center, 3500 Camp Bowie Blvd, Fort Worth, Texas.

---

**Background.** Mitochondrial dysfunction has been implicated in a many age-related disease pathologies, and post-transcriptional sequence modifications in mitochondrial RNA (mtRNA) have been correlated with mitochondrial function. One of the most significant modifications is methylation of mitochondrial transfer RNAs (mt-tRNA) at their 9<sup>th</sup> position ("p9 sites") which alters the efficiency of translation and protein synthesis. The involvement of mt-tRNA modifications on risk for age-related neurodegenerative disease has not been previously explored.

**Purpose.** The purpose of this study was to determine if altered post-transcriptional modification rates to mt-tRNA p9 sites are associated with risk for neurodegenerative disease.

**Methods.** RNA-seq and SNP data was analyzed from cerebellar tissue of 266 Caucasian subjects including elderly controls, Alzheimer's disease (AD) patients, progressive supranuclear palsy (PSP) patients, and pathological aging. Data were obtained through the Synapse data repository and were collected by the Mayo RNAseq Study (Dr. Nilüfer Ertekin-Taner, Mayo Clinic, Jacksonville, FL; with multi-PI U01 AG046139 by Golde, Ertekin-Taner, Younkin, Price). Methylation was inferred from heteroplasmy in mtRNA measured using VarScan. PCA was conducted using EIGENSOFT. Gene-based GWAS was executed in FUMA. Gene expression significantly associated with p9 methylation was determined using Fisher's exact test, and gene set overrepresentation tests were conducted using PANTHER and MAGMA.

**Results.** Average rate of heteroplasmy at each of the 11 p9 sites was compared between control and case groups. Gene-based GWAS identified *SLC28A3* as being significantly associated with p9 methylation. Expression of 5300 genes was also found to be significantly associated with p9 methylation. GO overrepresentation testing using SNP and gene expression datasets displayed significant enrichment for several cellular processes, with overlap for mitochondrial-related compartments/processes.

**Concluding Remarks.** Post-transcriptional modification of mtRNA occurs under normal, non-pathologic states and alteration p9 site methylation of mt-tRNAs is associated with AD and PSP. Here we show similarities in mitochondrial profiles of AD and PSP, suggesting analogous disease pathologies in cerebellar tissue. Targeting mt-tRNA methylation may prove to be a viable therapeutic approach for deficits in mitochondrial function.

## PgmNr 3273: Plasmatic microRNA signature in Friedreich's ataxia: Preliminary findings from a Brazilian cohort.

---

Friedreich’s Ataxia (FRDA) is the most common hereditary ataxia worldwide with estimated prevalence between 2 to 0.13:100,000 in Caucasians. It’s caused by a homozygous GAA expansion in the first intron of the *FXN* gene located at chromosome 9q21.11. As a result, there is a dramatic reduction in the expression of the mitochondrial protein frataxin. It leads to the cardinal manifestations of FRDA: early onset progressive ataxia and sensory deficits. Dysphagia, dysarthria, subtle cognitive dysfunction, cardiomyopathy and diabetes are also often found. MicroRNAs are well known for their ability to regulate gene expression and lately, have been explored as potential biomarkers for several neurodegenerative diseases. One way to obtain miRNAs that can be used for this purpose is extracting them from peripheral blood plasma, not only because of its known stability, but also for its accuracy in real-time phenotypic alterations. Up to now, there are very few studies looking at plasma microRNAs in patients with FRDA. In this study, we recruited a Brazilian cohort of FRDA patients and extracted miRNAs from plasma samples, then submitted all 48 small-RNAs samples (24 patients and 24 healthy controls) to an RNA-seq (Illumina platform). Our preliminary analysis using DESeq2 (shrinkage estimation for dispersions and fold changes to improve stability and interpretability of estimates; Benjamini-Hochberg procedure for adjusted  $p < 0.05$ ) showed that at least 3 miRNAs were downregulated (hsa-miR-26a-5p, hsa-miR-30b-5p, hsa-miR-423-3p) and 2 were upregulated (hsa-miR-15a-5p, hsa-miR-20a-5p) when comparing patients with healthy controls. Two of them (hsa-mir-15a-5p and hsa-mir-26a-5p) already known to be targeting *BDNF* gene, that its reduced protein levels are associated with ataxic conditions. Further technical validation utilizing qPCR is the next step of this study. Financial support: CNPq, CAPES and Fapesp fomentation.

## PgmNr 3274: Methylation of alpha synuclein intorns in a cohort of Sudanese patients with Parkinson disease.

Alpha-synuclein (*SNCA*) is a critical risk gene for Parkinson's disease (PD) with mutations reported to cause parkinsonian syndrome in both sporadic and familial forms of it. We found that Methylation of *SNCA* intron 1 was reduced in DNA from Sudanese PD patients, suggesting an epigenetic role in *SNCA* expression in PD. The novelty of this study in the region suggests further screening of PD patients from Sudan as well as all over Africa.

Recent findings emerging from human genome sequencing efforts have highlighted genes encoding chromatin regulators, particularly histone modifiers, as the genetic basis of developmental syndromes and cancers. Covalent histone modifications play a key role in developmental transcriptional plasticity required for cell fate specification. Converging lines of investigation implicate mono-ubiquitination of histone H2A (H2Aub1) as a pathogenic mechanism of developmental disorders. H2Aub1 is an evolutionarily conserved post-translational modification associated with polycomb transcriptional repression. ASXL3 is a component of the polycomb repressive deubiquitinase (PR-DUB) complex, which deubiquitinates H2Aub1. *De novo* dominant truncating variants in *ASXL3* (*Additional-sex combs like 3*) have been identified as the genetic basis of Bainbridge Ropers Syndrome (BRS), with truncating variants result in elevated H2Aub1 and altered transcriptional regulation. To understand epigenomic alterations and early development defects, we used CRISPR/Cas9-mediated genome editing to generate clinically relevant truncating variants in a novel mouse model of BRS. Constitutive loss of *Asx13* results in highly penetrant developmental heart defects and perinatal lethality. *Asx13*<sup>-/-</sup> mice display congenital cardiac hypertrophy and septal defects. To understand the role of ASXL3-dependent epigenomic changes, we have generated human induced pluripotent stem cell (iPSC) lines from BRS and healthy individuals that are differentiated to a cardiomyocyte fate. Transcriptomic and epigenomic analysis implicate a role for ASXL3 in both human and mouse cardiac development, the mechanisms of which is species specific and not a direct phenocopy. These findings underscore the importance of ASXL3 in polycomb transcriptional repression during heart development.

## PgmNr 3276: Investigating the role of aberrant methylation in developmental and epileptic encephalopathies.

**Background:** The developmental and epileptic encephalopathies (DEEs) are a group of severe disorders characterized by developmental delay and intractable seizures. Advances in genomic testing technology have accelerated gene discovery in DEE; in the clinical setting, a genetic diagnosis can now be made in up to 40% of patients. However, more than 50% of patients with DEEs remain without a genetic diagnosis despite state-of-the-art genetic testing. Methylation represents an epigenetic modification of DNA that does not change the underlying DNA sequence but can impact gene expression. We hypothesize that a subset of DEEs, where the cause remains unknown using conventional sequence-based analysis, harbors rare DNA methylation abnormalities that affect gene expression and cause DEE. We predict that pathogenic aberrant methylation will be due to an underlying DNA defect.

**Methods:** We are using Illumina Infinium MethylationEPIC Kit to evaluate methylation of 850,000 CpG sites in 400 probands to identify differentially methylated regions (DMRs) compared to controls. Bioconductor tools are used to identify rare regions with extreme methylation using a sliding window approach. We will validate DMRs and perform segregation analysis to determine inheritance, prioritizing *de novo* DMRs. For *de novo* DMRs, we will perform regional or genome sequence analysis, repeat analysis and copy number studies to identify underlying DNA defects, prioritizing DMRs near known DEE genes.

**Results:** We have phenotyped 400 individuals with DEEs for whom a molecular diagnosis has not been found after sequencing at least 104 DEE genes. We have completed methylation arrays for 96 samples and developed a pipeline to identify outlier individuals with putative DMRs. Analysis and downstream testing are ongoing.

**Conclusion:** Based on studies in a similarly sized cohort of individuals with neurodevelopmental disorders, we predict that 5-10% of unsolved DEEs will be due to rare methylation abnormalities. Though there are rare examples of epilepsy-related disorders due to methylation defects, to our knowledge, this will be the first genome-wide screen for methylation abnormalities in a cohort of individuals with DEE. This study will enhance our understanding of the molecular and genetic mechanisms of epilepsy, improve diagnostics and provide new avenues for therapies for people and families living with DEEs.

## PgmNr 3277: Loss of Dnmt3a dependent methylation in inhibitory neurons impairs neural function through a mechanism that impacts Rett syndrome.

Methylated cytosine is a major effector of epigenetic gene regulation. In the brain, the DNA methyltransferase, Dnmt3a, "writes" a unique methylation pattern that introduces non-canonical non-CpG methylation (mCH) in neurons during a critical phase of maturation. Despite its apparent importance to brain function our understanding of the mechanism of postnatal gene regulation via Dnmt3a methylation is in its infancy. One clear methylation "reader" involved is methyl CpG binding protein 2 (MeCP2). To gain a foot-hold into this novel epigenetic pathway, we set out to determine if MeCP2 is the brain's only reader for Dnmt3a dependent methylation. We compared two lines of mice, lacking either Dnmt3a (the "writer") or MeCP2 (the "reader") in GABAergic inhibitory neurons, at the behavioral, physiological and molecular levels. We found that loss of either the writer or the reader causes overlapping as well as distinct sets of features from the behavioral to the molecular level, with the loss of Dnmt3a causing global loss of mCH and a small subset of mCG sites to drive more severe neurological dysfunction and more widespread transcriptional alterations. These data indicate that MeCP2 is responsible for reading only part of the Dnmt3a dependent methylation pattern in the brain and lays the foundation to elucidate novel readers involved in neuron maturation that may impact neuropsychiatric phenotypes.

## PgmNr 3278: Role of chromatin remodeling protein CHD2 in neurodevelopmental disorders.

Pathogenic variants in *CHD2* are associated with autism spectrum disorder, intellectual disability, and epilepsy in humans. Chromodomain helicase DNA binding protein 2 (CHD2) is a chromatin remodeler associated with sites of active transcription. To better understand the role of CHD2 in human neurodevelopmental disorders we utilized CRISPR/Cas9 to create heterozygous disruptions of *CHD2* in human induced pluripotent stem cells (iPSCs). To examine the effect of *CHD2* disruption in neuronal development, we converted these iPSC lines into neuronal progenitor cells (NPCs), cortical excitatory neurons (CENs), and cerebral organoids (COs). mRNA sequencing revealed that *CHD2*<sup>+/-</sup> NPCs exhibited an upregulation of genes involved in neuronal differentiation and a downregulation of genes involved in proliferation. *CHD2* disruption also lead to misregulation of other epilepsy genes. Immunofluorescence, proliferation assays and single-cell RNA-sequencing on COs are in process to examine cell type specific changes that occur upon *CHD2* deficiency in human neurons.

## PgmNr 3279: Altered chromatin accessibility in KAT6A syndrome.

The organization of the chromatin landscape plays a crucial role in many cellular processes through accessibility of transcription factors and regulation of gene expression. Histone acetyltransferases are chromatin remodelers that acetylate specific lysine (K) residues and may change cells' expression profiles when disrupted. Mutations lysine acetyltransferase 6A (*KAT6A*, also known as *MOZ* and *MYST3*) causes a rare Mendelian disorder with variable features including intellectual disability, speech delays, microcephaly and gastrointestinal disorders. While *KAT6A* is known to affect chromatin structure by acetylating H3K9 and other lysine residues, the mechanism by which *KAT6A* causes disease is unknown. Here, we use the Assay for Transposase-Accessible Chromatin using Sequencing (ATAC-seq) to identify regions of closed and open chromatin in a pilot study using *KAT6A* syndrome patient-derived fibroblasts from 4 patients compared to 2 control samples. Raw paired-end fastq files were mapped using the BWA MEM algorithm, peaks were called using MACS2. Downstream analysis was performed with DASTk, a toolkit for ATAC-seq analysis. We found that *KAT6A* patients have on average 52.3% more open regions compared to average control samples, however, there are 30.3% fewer bases included within those regions, suggesting that there are more peaks, but that these peaks are, on average, smaller. We also identified transcription factor (TF) binding sites that are more available in *KAT6A* patients (*KLF4* and *MAZ*), and those that are less available (*SP1*) in *KAT6A* syndrome patients compared to controls. Further integration with RNA-seq data suggests that these factors may identify gene-regulatory mechanisms downstream of *KAT6A* histone modulation and will integrate our identification to identify differential RNA expression from matched patient-derived fibroblasts. Understanding the gene regulatory aspects can identify underlying mechanisms controlled by *KAT6A* and will broaden our understanding of how mutations to chromatin modifiers directly alter nuclear organization.

## PgmNr 3280: DNA methylation in two pairs of discordant monozygotic twins for ADHD by Illumina MethylationEPIC BeadChip microarray.

---

Attention deficit hyperactivity disorder (ADHD) is characterized by inadequate levels of hyperactivity/impulsivity and/or inattention and is one of the most common neurobehavioral disorder diagnosed in childhood. ADHD affects around 5% of school children worldwide and, in most cases (50-80%), the disorder persists during adolescence and adulthood. Due to its high heritability (estimated at 76%), it is known that the etiology of ADHD is strongly influenced by genetic factors. However, the genetic architecture of ADHD is not clear. Behavioral genetic studies have demonstrated that genetic influences play a role in the etiology of ADHD. However, it is very important to study whether epigenetic factors, such as DNA methylation, are related to the etiology of ADHD. Thus, performing the DNA methylation profiles of monozygotic twins are an important tool for studying the role of epigenetic factors in ADHD. Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR) was used as a reference for the diagnosis. DNA was extracted from blood lymphocytes from two pairs of monozygotic twins. Each pair of twins was composed of two boys: one with ADHD and one with neurotypical development. The first pair with 12 years old and the second pair with 09 years old. Then, DNA methylation assays were performed using Illumina MethylationEPIC BeadChip. Arrays data were treated and analyzed using specific packages in the R environment. Some Bioconductor packages were used to obtain a list of statistically significant probes, considering  $p < 0.05$ . Thus, we identified differentially methylated probes in the comparison between the two boys with ADHD and the two boys without ADHD. Probes were annotated according to the data provided by Illumina using the genome hg19 reference. Our results suggest that DNA methylation profiles may present significant differences between monozygotic twins discordant for ADHD. Therefore, we emphasize the importance of investigating DNA methylation in more cases of ADHD discordant twins in order to verify if the differences found in this study are, in fact, relevant for the development of ADHD.

## PgmNr 3281: DNA methylation patterns associated with cyanogenic cassava exposure in Sub-Saharan Africa.

---

Cassava is an innately cyanogenic, fibrous tuber that serves as the predominant food source for impoverished regions throughout Sub-Saharan Africa. If sufficiently processed, cassava can be safely consumed; however, failure to do so causes sub-lethal exposure to cyanide through the diet and epidemics of konzo. Konzo is a neurological disease that is characterized by the sudden onset of irreversible spastic paraparesis or paralysis. It has been classified by the World Health Organization as having the highest case-fatality ratio of any disease associated with exposure of chemicals through the food supply. Children and women of child-bearing age appear to be more vulnerable, and familial clusters of disease occur for reasons that have yet to be elucidated. Even with the same homogenous diet of poorly processed cassava, only up to 10% of the population is typically affected by konzo. As such, we hypothesize that the pathophysiology of konzo is mediated by changes to the DNA methylome in response to sub-lethal exposure to cyanogenic cassava.

This study investigates the global DNA methylation differences in individuals exposed to cyanogenic cassava that develop konzo compared to age-matched healthy controls from the same outbreak zones. We showed that there were 118 differentially methylated loci between those affected by konzo and healthy controls. Notably, 80% of the differentially methylated loci were hypomethylated compared to controls. Genes represented by these loci are enriched for biological processes, including neuronal cell death, oxidative stress, cellular detoxification, and epigenetic regulation, which are directly relevant to konzo presentation and cyanide metabolism. This study provides the first analysis of the durable DNA methylation differences attributed to sub-lethal cyanide exposure through diet and reveals disruption of biological processes that may underpin the etiology of konzo.

## PgmNr 3282: Transgenerational disruptions in DNA methylation and gene expression by ancestral folate supplementation.

The central nervous system (CNS) has limited ability to heal and regenerate after injury. Folate is crucial in enhancing axonal regeneration in CNS systems after sharp injury, potentially by influencing the abundance of heritable environmentally sensitive molecular substrates, such as DNA methylation. We have shown that folate-induced axonal regeneration and DNA methylation in the spinal cord following sharp injury is dose-dependent and persists through 4 generations of untreated progeny, depicting a transgenerational epigenetic inheritance. These findings led us to hypothesize that DNA methylation may influence inheritance of the axonal regeneration phenotype. In order to test this hypothesis, we collected spinal cord tissue that was distal to a sharp injury from adult F3 male rats derived from an F0 lineage exposed to daily injections of folic acid or a vehicle control beginning three days before breeding and continuing until the pups were weaned. Genomic DNA from these tissues was profiled by whole genome bisulfite sequencing to examine an average of 22.7 million CpG dinucleotides. This approach found 1,636 folate-related differentially methylated regions (DMRs), and ~86% ( $N = 1,411$ ) were hypomethylated. Pathway analysis of the DMR-associated genes revealed gene enrichments related to axon and neuronal processes, such as *axonogenesis* and *neuron-projection guidance*. RNA sequencing was conducted on RNA from these same tissues to find differentially methylated candidates linked to altered gene regulation. Three genes particularly relevant to the axonal regeneration process that exhibited both folate-related differential methylation and expression were *Rxrb*, *Syn2*, and *Dscam*. These transcripts have well defined roles in regeneration, including cell-fate commitment, neuronal apoptosis, and dendritic extension, respectively. Together, these data support that folate supplementation leads to transgenerational inheritance of DNA methylation alterations and subsequent gene expression changes resulting in enhanced axonal regeneration of injured spinal cord axons. These findings are of particular interest as manipulations of modifiable substrates (*i.e.*, DNA methylation levels) are likely to provide insights into injury mechanisms and novel treatment targets for individuals suffering from spinal cord (and brain) trauma or disease.

Cerebral white matter hyperintensities (WMH) are an indicator of cerebral small vessel disease, a major risk factor for vascular dementia and stroke. DNA methylation (DNAm) may contribute to the molecular underpinnings of WMH, which are highly heritable. We aimed to identify individual CpGs and differentially methylated regions (DMRs) associated with WMH, to investigate their genetic control and to identify potential regulatory variation at known WMH genetic loci using DNAm. We included 6,019 middle-aged to elderly individuals from 11 population-based cohorts, who were free of dementia and stroke and were of African (AA) or European (EA) descent. In each cohort, association between WMH volume and each CpG was tested within ancestry using a linear mixed model, adjusted for age, sex, total intracranial volume, white blood cell count, technical covariates, smoking, body mass index and blood pressures. Meta-analyses were performed within ancestry and in the total sample. We identified DMRs using region-based p-values accounting for spatial correlations among CpGs. Finally, we performed colocalization analyses of methylation quantitative trait loci (mQTLs) and WMH-associated genetic loci using a Bayesian method. No individual CpG reached epigenome-wide significance, but suggestive novel associations were

identified with cg17577122 (*CLDN5*,  $P=2.39E-7$ ), cg24202936 (*LOC441601*,  $P=3.78E-7$ ), cg03116124 (*TRIM67*,  $P=6.55E-7$ ), and cg04245766 (*BMP4*,  $P=3.78E-7$ ). Gene set enrichment analyses implicated pathways involved in regulation of cell development and differentiation, especially of endothelial cells. We identified 11 DMRs (Sidak-adjusted  $P<0.05$ ) including two mapping to blood pressure-related genes (*HIVEP3*, *TCEA2*). We identified 14 DMRs in EA, including one mapping to a stroke gene (*SH3PXD2A*), and 17 DMRs in AA, including 3 mapping to 3 BP genes (*MCF2L*, *PLEC*, and *TM9SF2*). Genes mapping to DMRs were enriched in biological processes related to metabolism and transport of lipoprotein. Finally, the colocalization analysis provided evidence that 4 GWAS loci (2p16, 7q32, 14q32, and 6q25) colocalized with mQTLs.

In conclusion, we identified novel epigenetic loci associated with WMH, which may provide new clues about pathogenesis. We also show evidence for the colocalization of WMH genetic associations and differential DNAm.

## PgmNr 3284: CpG methylation signature define human temporal lobe epilepsy and predict drug-resistant.

### Authors:

B. Xiao; W.B. Xiao; H.Y. Long; L.L. Long; L. Feng

[View Session](#) [Add to Schedule](#)

**Affiliation:** department of neurology, Xiangya Hospital Central South University, Changsha, China

### Purpose—

Based on genome-wide DNA methylation profiling, machine learning methods were applied to screen and verify CpG sites as biomarkers of temporal lobe epilepsy (TLE) diagnosis and drug resistance prediction, providing a new idea for precision treatment of epilepsy.

### Methods—

We initially conducted 450k and 850k methylation chips to detect the DNA methylation of TLE and healthy control in peripheral blood; 450k data were screened for differentially methylated sites, Least Absolute Shrinkage and Selection Operator scored the importance of features, and Support Vector Machine modeled different number of feature combinations, and the optimal model was selected for cross-validation in 850k. The TLE group can be divided into drug-responsive and drug-resistant group, and the same method was used for drug-response related CpGs screening and validation. Furthermore, a Nomogram comprising methylation score and clinicopathological data was generated to establish TLE drug resistance prediction model.

### Key Findings—

As a result, eight CpGs were identified (cg25838818, cg27564766, cg07782795, cg09383187, cg09293614, cg09270525, cg09197288, cg08664849), yielded a sensitivity of 71%, a specificity of 73%, and an accuracy of 77%, with an area under the curve (AUC) of 0.81 to detect TLE. Six CpGs were identified (cg15999964, cg08768218, cg11954680, cg17706086, cg21761639, cg26119877), yielded a sensitivity of 77%, a specificity of 71%, and an accuracy of 73%, with an AUC of 0.79 to distinguish drug-responsive from drug-resistant patients. TLE drug resistance prediction model established by Nomogram included hippocampal sclerosis pathology, epilepsy course, methylation score.

### Significance—

This study introduced a methodological framework to screen and validate biomarker, and demonstrates the ability to use machine learning as a potential clinical tool for epilepsy diagnosis and drug-resistant prediction after more comprehensive validation.

## **PgmNr 3285: Expression of hnRNP A2/B1 suppresses rCGG repeat-mediated neuronal toxicity associated with fragile X-associated tremor/ataxia syndrome in a RAN translation-independent manner.**

---

FXTAS (Fragile X-associated tremor/ataxia syndrome) is a neurodegenerative disorder in aged premutation carriers with 55–200 CGG repeats in the 5'UTR of fragile X mental retardation gene (*FMR1*). Two mechanisms have been proposed for FXTAS: RNA toxicity and non-AUG-initiated (RAN) translation toxicity. Expanded CGG repeat RNA is reported to sequester proteins such as Pur $\alpha$  and hnRNP A2/B1 (heterogeneous nuclear ribonucleoprotein A2/B1), thereby blocking them from performing from their proper function. Recently, polyglycine-containing protein (FMRpolyG) generated by RAN translation of the expanded CGG repeats was shown to be toxic to cells. Here, we have generated a transgenic mouse line that expresses hnRNP A2/B1 in Purkinje cells, and we have crossed this line with the FXTAS mouse model that we generated previously. We found that the expression of hnRNP A2/B1 can ameliorate the Purkinje cell loss and locomotor deficits induced by the expression of the expanded CGG repeat. Gene expression analyses further confirmed the molecular rescue by hnRNP A2/B1 in the FXTAS mouse model. Surprisingly, pathological analyses revealed that the distribution and number of FMRpolyG inclusions were unchanged in the rescued mice. Furthermore, using a FXTAS cell culture model, we observed a similar suppression of rCGG repeat toxicity by hnRNP A2/B1 without altering the distribution and number of FMRpolyG inclusions. These results together suggest that hnRNP A2/B1 has an important neuroprotective function by alleviating RNA toxicity, and FMRpolyG is not essential for the rCGG repeat toxicity associated with FXTAS.

## PgmNr 3286: Cell type, genetic content and presence of the 3'UTR influence TREM2 promoter activity.

---

Genetic variation in triggering receptor expressed on myeloid cells 2 (TREM2) is associated Alzheimer's disease (AD) and plays a role in neuroinflammation in AD mouse models. Little is known about how the expression of TREM2 is differentially regulated. In the human brain, TREM2 mRNA is differentially expressed in multiple brain regions and human cell types. We hypothesized that trans-acting factors present in certain cell types modulate TREM2 regulatory element activity. Therefore, TREM2 expression or promoter activity will differ according to tissue or cell type. The objectives were to demonstrate that: 1) Cerebrospinal fluid (CSF) and plasma sTREM2 levels are elevated in AD. 2) Cell line, hippocampus and cerebellum TREM2 protein expression varies by tissue type. 3) TREM2 promoter region genetic variants and 3' UTR influence to TREM2 promoter reporter expression in certain human cell lines. Human DNA, plasma and CSF samples were obtained from the Cleveland Clinic Center for Brain Health Aging and Neurodegeneration Biobank. Post-mortem brain samples were obtained from the University of Washington Alzheimer's Disease Research Center. CSF and plasma soluble TREM2 (sTREM2) were evaluated using a custom capture sandwich immunoassay. Brain TREM2 was analyzed by Western blot. PCR amplification of genomic DNA was performed using TREM2 primers located outside of the promoter or 3'UTR region. TREM2 PCR products were cloned into a Luciferase reporter constructs. A transient transfection using these reporter constructs was performed in human cell lines. CSF sTREM2, but not plasma, levels were marginally higher in carriers of the AD GWAS rs7748513 risk allele suggesting that TREM2 genetic variation might influence gene expression depending on tissue type. Post-mortem brain and multiple human cell lines also showed differential expression by tissue or cell type. TREM2 promoter + 3'UTR reporter levels showed differential expression depending on genetic content of the promoter in human neuronal SHSY5Y cell lines. TREM2 promoter reporter inhibition in the presence of the TREM2 3'UTR was cell type specific. This inhibition was lost in the presence of genetic variants located in the TREM2 promoter region suggesting that SHSY5Y cells contain inhibitory factors that target this region. This finding is important because it will allow us to identify factors that regulate TREM2 expression and therefore potentially modulate neuroinflammation in AD.

## PgmNr 3287: *HLA-DRB1\*1501* gene expression is modulated by rs4959030 (A) in multiple sclerosis patients.

Multiple sclerosis (MS) is the most common chronic immune-mediated disorder of the central nervous system (CNS) in young adults, characterized by demyelinating lesions that occur across time and space. Multiple large-scale genome-wide association studies (GWAS) have identified over 200 risk variants related to MS; however, all identified risk variants together could only explain ~28% of the sibling recurrence risk. Only *HLA* locus (e.g. *HLA-DRB1\*15:01* allele, *HLA-A\*02* allele) has been repeatedly verified to be associated with the pathogenesis of MS. The role of *HLA* genes in autoimmune diseases has been largely studied in terms of MHC antigenic specificity; yet, much less is known about how these genes are transcriptionally regulated. We hypothesized that the aberrant epigenetic regulation in MS patients may contribute to the pathogenesis of this disease. Here, we recruited 246 MS patients and utilized both whole-exome sequencing (WES) and ImmunoArray genotyping to maximally interrogate the intragenic and intergenic regions of the genome in a cost-effective manner. Both technologies combined identified over half a million SNVs, in which 70.1% and 20.8% of those SNVs located within the intragenic and intergenic regions, respectively. Our pathway enrichment analysis confirmed the complexity of MS pathogenetic mechanisms. Additionally, epigenetic profiling further provided a deeper understanding of potential transcriptional dysregulatory mechanisms in MS. Specifically, we identified rs4959030, which is located within a super-enhancer region nearby *HLA-DRB1* gene, as a potential risk SNV that can modulate the expression of *HLA-DRB1\*1501* through the disruption of transcription factor PU.1 binding motif. We further confirmed the computational prediction with quantitative real-time PCR in whole blood of 30 MS patients. We found that the expression of *HLA-DRB1* was, indeed, decreased by 30% ( $P = 0.0002$ ) when patients have homozygous high-risk allele (A) in comparison to that of homozygous low-risk allele (G). This finding highlighted the importance of understanding epigenetic regulation in MS and may open up new possibilities in personalized health care for MS patients.

## **PgmNr 3288: Is Down syndrome an example of multiple mechanisms of gene dose Dysregulation at Critical Region (DSCR) on chromosome 21? A neurogenomics approach.**

The classical etiological interpretation on Down syndrome (DS), is an aneuploidy caused by a complete, or occasionally partial, triplication of chromosome 21 resulting in a complex and variable phenotype which compromise the structure and function of brain. However no many approaches look for a different explanation about the complexity of its neurological phenotype. The objective of the present study was to analyze the dysregulation of dose in genes located at Down Syndrome Critical Region (DSCR) along of several structures of brain. The searching of DNA microarrays experiments with Down syndrome brain samples in the GEO Data Set of NCB, produced one which fit on our experimental design; it contains data of global gene expression in 11 structures of brain cortex, hippocampus and cerebellum from patients with Down syndrome and their euploid controls. We calculated DS/Control ratio of 40 DSCR genes from the intensity log2 values obtained of the selected DNA microarray experiment. Differential transcriptional profiles, lead us to postulate that three main different mechanisms of DSCR gene dose dysregulation in brain are contributing to partially explain the Down neurophenotype. These mechanisms include: unbalance of the gene dose (triplication and/or single expression); under and over expression, and gene amplification. Our results support the hypothesis of complex spatial and temporal mechanisms regulate the gene dose imbalance in the brain of Down syndrome.

## PgmNr 3289: Screening Alzheimer disease serum for long noncoding RNA biomarkers.

---

Long noncoding RNAs have become the fastest growing class of biomarkers in genomics research. They have been demonstrated to play roles in normal development mechanisms as well as pathological processes, such as cancer, autoimmune diseases and neurodegenerative diseases. In order to find new and relevant biomarkers for Alzheimer's Disease, we designed an approach to quantify changes in expression of long noncoding RNA targets from patient serum. We purified cell free RNA from a portion of each serum sample, and found that the majority of samples did have low amounts of RNA, although a few were too degraded for further analysis. Using a one-step pre-amplification reverse transcription qPCR strategy, we screened for differential expression of long non coding RNAs proposed to be associated with inflammation and epigenetics. Alzheimer's Disease is proposed to be a disease of inflammation, and disease states are often the result of epigenetic dysregulation. Of the 145 unique long noncoding RNAs screened, we identified four with a greater than two fold expression change over healthy controls that were deemed significant ( $p < 0.05$ ) by ANOVA, and had normal sample distributions by the Shapiro-Wilks normality test. All four of these lncRNAs (AC093323.3, BDNF-AS, H19 and HAR1B) are linked to epigenetic processes.

## PgmNr 3290: Chromatin interaction map elucidates regulatory relationships in human interneuron-like progenitors that are associated with atypical Rett syndrome.

Gene regulatory elements such as enhancers dynamically regulate gene expression in a tissue-specific manner. However, the transcriptional regulatory elements during human inhibitory interneuron differentiation and their role in neurodevelopmental disorders are unknown. Here, we generated gene regulatory element maps of human inhibitory-like interneurons derived from embryonic stem cells (H9-ESC), permitting large-scale annotation of previously uncharacterized interactions of regulatory elements that associated with neurodevelopmental disorders. Using histone modification marks of active enhancers (H3K27ac, ATAC-seq), we identify neuronal progenitor enhancers that are associated with cell-specific gene expression (RNA-seq), especially of neuronal transcription factors. Using genome architecture mapping (GAM), we determined the chromatin interactions of regulatory elements and their potential targeted genes. Furthermore, chromatin interactions in *FOXP1* locus unraveled promoter-enhancer looping that likely associated with atypical Rett syndrome. Using *in vivo* enhancer assay, we identified 8 enhancers in the *FOXP1* locus with activity patterns that resembled *FOXP1* expression. Using CRISPRCas9 genome editing, two *FOXP1* enhancers were deleted (but not the *FOXP1* gene body) and showed significant reduction in *FOXP1* expression and alteration of cell proliferation in human cell line. Furthermore, a microdeletion proximal to *FOXP1* encompassing these neuronal *FOXP1* enhancers was found in patient with atypical Rett syndrome, supporting the role of *FOXP1* enhancers in this syndrome. Our study provides a framework for understanding the impact of non-coding regulatory elements during inhibitory interneuron differentiation, and highlights novel mechanisms underlying neurodevelopmental disorders.

## PgmNr 3291: Transcriptomic analyses in a diverse ancestry cohort implicate convergent immune related pathways in Alzheimer disease.

Macdonald Foundation Department of Human Genetics, University of Miami, Miami, FL; 3) Department of Population & Quantitative Health Sciences, Case Western Reserve University, Cleveland, OH; 4) Cleveland Institute for Computational Biology, Cleveland, OH; 5) Maya Angelou Center for Health Equity (MACHE) / Wake Forest School of Medicine, Winston Salem, NC; 6) Universidad Central del Caribe, Caguas, Puerto Rico; 7) Clinica de la Memoria, San Juan, Puerto Rico; 8) Universidad Central del Caribe, Bayamon, Puerto Rico

**Background.** Our group and others have recently expanded genomic studies of Alzheimer disease to individuals of diverse ancestries, however, identification of downstream effects on gene regulation is lacking, particularly in under-represented groups such as African Americans (AA) and Caribbean Hispanics from Puerto Rico (PR). Understanding these transcriptomic effects is critical in discovery of both ancestry-specific and convergent functional mechanisms in AD. In this study, we analyzed the protein coding transcriptome from peripheral blood collected from 76 PR (39 AD, 37 controls), 234 African American (AA) (115 AD, 119 controls), and 241 non-Hispanic Whites (NHW) (121 AD, 120 controls).

**Methods.** Total RNA was extracted from peripheral whole blood, sequenced to 40 million paired-end 100bp reads, and analyzed with a standard bioinformatics pipeline. Linear regression models were used to test differentially expressed genes between cases and controls within each ethnicity adjusting for covariates including age, ascertainment centers, sex, and sequencing batch as required. Gene Set Enrichment Analysis of Gene Ontology and KEGG gene sets were used to identify underlying biological pathways.

**Results.** Using the criteria of adjusted p-value  $\leq 0.05$ , a total of 761 (518 up-regulated, 243 down-regulated), 419 genes (291 up-regulated, 127 down-regulated) and 490 genes (353 up-regulated, 137 down-regulated) were differentially-expressed between AD and controls in the PR, AA, and NHW datasets, respectively. Interestingly, only 25 genes (18 up-regulated, 7 down-regulated) were differentially expressed in both PR and AA, 16 genes (15 up-regulated, 1 down-regulated) were commonly differential in AA and NHW, and no genes were differentially expressed in both PR and NHW. Despite the generally unique set of differentially expressed genes, pathway analysis revealed that adaptive and innate immune response pathways were enriched in all three groups.

**Conclusions.** These results support the hypothesis that there is genetic heterogeneity for AD across

ancestral groups, but suggest convergent underlying processes. Further evaluation of genetic modulation of specific transcriptomic changes using ancestry-aware methods will uncover underlying mechanisms of the genomic regulation of AD pathophysiology.

## **PgmNr 3292: The expanded GAA triplet-repeat in Friedreich ataxia establishes a mutation-specific differentially methylated region (FRDA-DMR) that is predictive of *FXN* gene silencing and reactivation.**

### **Authors:**

S.I. Bidichandani; L. Rodden; K. Gilliam; Y. Chutake

[View Session](#) [Add to Schedule](#)

---

Transcriptional silencing caused by the expanded GAA triplet repeat mutation in intron 1 of the *FXN* gene is the primary molecular defect in Friedreich ataxia (FRDA). We found that patients who are homozygous for the expanded GAA triplet-repeat establish a region of DNA hypermethylation in its vicinity. This region remains largely unmethylated in non-FRDA controls. The FRDA-specific differentially methylated region (FRDA-DMR) is mutation-dependent as hypermethylation was completely reversed in isogenic cells with the expanded repeat removed. Hypermethylation of the FRDA-DMR was observed in disease-relevant tissues (dorsal root ganglia, cerebellum and heart) of the humanized mouse model of FRDA, and in iPSC-derived FRDA neurons. Analysis of PBMCs from 50 FRDA patients revealed a strong correlation between DNA methylation and *FXN* gene silencing. Small molecule HDAC inhibitors are currently being developed for *FXN* gene reactivation in FRDA. PBMCs from the same 50 patients were tested for response to *ex vivo* HDAC inhibitor treatment, which revealed that lower levels of FRDA-DMR methylation correlated with superior gene reactivation in FRDA. Indeed, the same CpG sites that correlated with *FXN* transcriptional silencing in FRDA were also the best predictors of *FXN* gene reactivation. Repeat-mediated hypermethylation of the FRDA-DMR is a novel epigenetic silencing signal in FRDA.

## PgmNr 3293: Cell type and brain region-specific differential chromatin accessibility analysis in Alzheimer's disease.

---

**Background:** Regions of open chromatin house regulatory elements required to mediate cell-type and tissue-specific gene expression. Studies of human brain have shown that dysregulation of these regulatory mechanisms is associated with Alzheimer's Disease (AD). The majority of previous studies, however, has been conducted using homogenate tissue derived from a single brain region and have included small numbers of AD cases and controls. Here, we present the largest cell type and brain region-specific study of differential chromatin accessibility in AD.

**Methods:** Using frozen postmortem tissue from 209 cases with AD and controls, we performed ATAC-seq to profile chromatin accessibility in 2 distinct populations of cells (neuronal and non-neuronal), isolated by FACS from two different brain regions (parahippocampal gyrus and superior temporal cortex). We characterized epigenetics changes associated with multiple AD phenotype ratings, i.e., clinical dementia rating (CDR), density of neurofibrillary tangles (Braak&Braak score), the average count of senile plaques as well as a linear version of the CERAD criteria. The availability of RNA-seq and whole-genome data for this cohort allowed us to measure the overlap between differentially regulated transcriptome and epigenome signatures and related pathways and also run fine mapping.

**Results:** We observed widespread differences in chromatin accessibility associated with AD phenotype, mostly in neuronal samples. While substantial changes between AD-cases and controls can be seen in both brains regions of interest, parahippocampal gyrus is, in general, more affected than superior temporal cortex. The differentially regulated regions of open chromatin were enriched in neurobiological and disease-related pathways. Finally, by integrating this dataset with whole-genome sequencing data, we identified thousands of new chromatin accessibility quantitative trait loci (caQTLs).

**Conclusions:** This dataset provides a unique insight into molecular mechanisms underlying brain region and cell type-specific vulnerability to AD at different stages of the disease progression. Supported by R01AG050986 and R01AG057440.

# PgmNr 3294: The relationship between subunits of a protein complex and gene co-expression networks in the human brain.

---

**Background:** Protein complexes work synergistically as a basic functional unit within cells. Interactions among the subunits that constitute protein complexes reveal specific regulatory mechanisms critical for cellular function. Protein complexes are currently identified by expensive and time-consuming methods (i.e., two-hybrid screening, mass spectrometry, and glutathione S-transferase pull-down assay). We posit that gene co-expression, which implies coordinate regulation, can be a viable alternative for the study of gene interactions. Recent studies have shown that the subunits of protein complexes express in similar patterns, indicating that gene co-expression networks may reflect gene interaction at the protein level. However, the overall concordance between the subunits of a protein complex and gene co-expression network has not been assessed. The systematic evaluation of the co-expression of protein subunits may help to identify specific genes that work in concert.

**Methods:** We constructed a gene co-expression network by weighted gene co-expression network analysis (WGCNA) using the RNA-seq data from the Genotype-Tissue Expression project (GTEx). Protein complex data originating from CORUM was mapped into gene co-expression networks. We used four other independent datasets to replicate our findings and defined protein complexes co-expressed in the four datasets as stably co-expressed.

**Results:** Of the 2,390 protein complexes in the human brain, 36% were found to contain at least two co-expressed subunits when compared with random modules ( $P < 0.05$ ). In the frontal cortex, 43% of the complexes contained at least two co-expressed subunits. Of those, 243 were stably co-expressed, relating to basic cellular functions such as ribosomal function and PI3K-Akt signaling. When comparing stably co-expressed protein complexes with all other proteins, we found that the protein complex subunits were over-presented in the other proteins. (one-tail t-test  $P = 1.07 \times 10^{-69}$ ). The subunits of 210 stably co-expressed protein complexes, such as the psychiatrically-associated SNARE complex, were differentially expressed in autism spectrum disorder ( $FDR = 4.2 \times 10^{-3}$ ) and schizophrenia ( $FDR = 1.8 \times 10^{-3}$ ).

**Conclusion:** Our study revealed a consistency between protein complexes and gene co-expression networks. The finding that co-expressed protein subunits are differentially expressed in psychiatric disorders suggests a new mechanism for the unraveling of their pathology.

## PgmNr 3295: Gene network analysis reveals unique and shared modules associated with alcohol dependence within the PFC and NAc.

### Authors:

E. Vornholt <sup>1,2</sup>; G.O. McMichael <sup>1</sup>; J. Drake <sup>2</sup>; Z.N. Taylor <sup>1</sup>; V.I. Vladimirov <sup>1,3,4</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Virginia Institute for Psychiatric and Behavioral Genetics, Virginia Commonwealth University, Richmond, VA.; 2) Integrative Life Sciences, Virginia Commonwealth University, Richmond, VA; 3) Department of Psychiatry, Virginia Commonwealth University, Richmond, VA; 4) Lieber Institute for Brain Development, John Hopkins University, Baltimore, MD

---

Excessive alcohol consumption has become a growing public health concern worldwide due to the potential development of alcohol dependence (AD). Prolonged alcohol abuse leads to dysregulation of the mesocorticolimbic dopaminergic pathway (MCL) effectively disrupting executive functioning and the allostatic conditioning of reward response. We utilized a human postmortem brain case-control study design to identify differentially expressed genes (DEG) and co-expressed gene networks associated with AD within two different MCL associated structures, the prefrontal cortex (PFC) and nucleus accumbens (NAc). We used weighted gene co-expression network analysis (WGCNA) to identify gene modules significantly correlated with AD in PFC and NAc and further test whether networks are preserved between the two regions. Finally, a gene ontology analysis was used to reveal the biological pathways of significant AD associated gene networks. Gene expression data from 17 AD cases and 18 matched controls ( $n = 35$ ) were obtained via the Affymetrix GeneChip Human Genome U133A 2.0 (HG-U133A 2.0) array and analyzed using a bidirectional stepwise regression. We identified 1841 and 70 DEG (*FDR adjusted*  $p \leq 0.05$ ) in the NAc and PFC, respectively. Using WGCNA on the nominally significant DEG ( $p \leq 0.05$ ) from each brain region we identified 6 and 3 modules (categorically labeled using conventional colors) which were significantly associated with AD (*Bonferroni corrected*  $p \leq 0.05$ ) in the NAc and PFC, respectively. The network preservation analysis identified some of the significant modules to be highly preserved between NAc and PFC, i.e. the magenta module in NAc ( $Z_{summary\_magenta} = 13.0$ ), while others showed little to no network preservation, i.e. the purple ( $Z_{summary\_purple} = 0.55$ ) and dark orange ( $Z_{summary\_dark\ orange} = 0.83$ ) modules. Gene ontology analyses via DAVID Bioinformatics Resource 6.8 revealed the magenta module is primarily associated with immune response and more specifically metallothioneins (*FDR adjusted*  $p \leq 0.05$ ) whereas the purple and dark orange modules contain genes associated with neuronal cell signaling pathways (*FDR adjusted*  $p \leq 0.05$ ) and cell protrusion (*FDR adjusted*  $p \leq 0.05$ ). The upregulation of immune response mechanisms has been consistently reported to be the result of alcohol neurotoxic effects. More interestingly, these results show that the effects of chronic alcohol use on genes important for neuronal signaling and synaptic growth may be brain region specific.

## PgmNr 3296: Cell-type specific investigation of the methylome and hydroxymethylome in the prefrontal cortex of alcohol dependent patients.

### Authors:

S.L. Clark <sup>1</sup>; R.F. Chan <sup>2</sup>; L.Y. Xie <sup>2</sup>; M. Zhao <sup>2</sup>; K.A. Aberg <sup>2</sup>; E.J.C.G. van den Oord <sup>2</sup>

### Affiliations:

1) Psychology, Michigan State University, East Lansing, MI; 2) Center for Biomarker and Precision Medicine, Virginia Commonwealth University, Richmond, VA

Alcohol dependence (AD) is characterized by compulsive and uncontrolled consumption of alcohol despite its negative effects. Mounting evidence suggests a role for DNA methylation in AD. The brain methylome includes both methylation at CG dinucleotides (mCG) and hydroxymethylation (hmCG). We present a methylome-wide association study (MWAS) of both mCG and hmCG, across cell types in human prefrontal cortex (PFC) samples from 50 AD cases and controls. With a sequencing-based approach, we used optimized MBD-seq and HmSeal-seq protocols to study the near complete mCG and hmCG methylomes. FACS was used to sort NeuN+ (neurons) and NeuN- (mainly glia) nuclei from PFC to generate reference methylomes that, in combination with a deconvolution approach, enabled us to perform cell-type specific MWAS in neurons and glia separately. RNA-seq was performed on the same samples to examine the functional impact of mCG/hmCG on gene expression.

For mCG, in bulk brain tissue, the top findings were located in *GOSR2* ( $p=3.9 \times 10^{-07}$ ) and in a replicated gene associated with alcohol consumption, *AUTS2* ( $p=4.6 \times 10^{-07}$ ). Cell-type specific findings revealed further associations with *AOX1* ( $p=1.6 \times 10^{-07}$ ) in glia and *SMAD4* in neurons ( $p=2.4 \times 10^{-08}$ ). Top findings were enriched for bivalent transcription start sites ( $p=7.3 \times 10^{-04}$ ) and depression-related CG methylation in human PFC ( $p=4.3 \times 10^{-03}$ ).

For hmCG, the top finding in bulk brain tissue was located in *SPAST* ( $p=1.5 \times 10^{-07}$ ). In glia, the top result was located in *ACSS3* ( $p=4.9 \times 10^{-08}$ ) that encode acetyl-CoA synthetase, an enzyme that processes the ethanol metabolite acetate. The top genic finding in neurons was located in the autophagy-related *ATG7* ( $p=5.0 \times 10^{-08}$ ). As autophagy is induced by ethanol exposure, differences in hydroxymethylation may indicate upregulation of autophagy. Top findings were enriched for active transcription start sites ( $p=5.0 \times 10^{-05}$ ) and DNase hypersensitive sites ( $p=7.0 \times 10^{-07}$ ).

The work presented here provides a comprehensive consideration of the methylomic and hydroxymethylomic landscape of AD in human prefrontal cortex. These analyses provide potential mechanisms for confirmed genetic loci previously associated with AD and revealed several potentially novel loci. Preliminary gene expression analyses indicate that several associated genes identified here are differentially expressed in AD cases vs controls.

## PgmNr 3297: Dose and time dependency of the *AHRR* cg05575921 demethylation response in nascent smoking.

### Authors:

K. Dawes <sup>1,2</sup>; E. Papworth <sup>1</sup>; A. Becker <sup>1</sup>; W. Philibert <sup>1</sup>; B. Hundley <sup>1</sup>; N. Hutchens <sup>1</sup>; F. Gibbons <sup>4</sup>; M. Gerrard <sup>5</sup>; R. Philibert <sup>1,2,3</sup>

---

In prior work, we and others have shown that methylation of cg05575921 of whole blood DNA accurately predicts smoking status of adults and is sensitive to nascent smoking. Unfortunately, the dose and time dependency of the demethylation response in nascent is not known. In order to determine this relationship, we interviewed 300 high school sophomores biannually (5 time points) and determined yearly methylation, cotinine and cannabinoids levels annually (3 time points). At intake, 29 subjects reported using tobacco and 39 subjects reported using cannabis at least once in their life with 19 and 11 subjects having a positive cotinine and cannabinoid levels, respectively. At exit, 15 subjects reported using tobacco and 89 subjects reported using cannabis at least once in their life with 52 and 37 subjects having positive cotinine and cannabinoid levels at exit, respectively. The rates of unreliable self-report of tobacco or other nicotine products in those positive for cotinine was 74% at intake and 77% at exit. Those 149 subjects had undetectable cotinine levels at all three time points had cg05575921 methylation of 88.67% at entry and 88.84% at exit, while those 12 subjects who had a positive cotinine levels at all time points had an entry methylation levels of 81.84% and exit levels of 71.31%. In those with reliable levels of self-report the amount of demethylation at cg05575921 was correlated with time and intensity of smoking. We conclude that cg05575921 methylation is a sensitive indicator of nascent smoking and suggest that screening of blood or saliva for changes in cg05575921 could identify smokers in the most malleable phases of smoking.

## PgmNr 3298: Methylation sensitive digital PCR tests for rapidly assessing heavy alcohol consumption and smoking using DNA from blood or saliva.

**Background:** Smoking and Excessive Drinking are the 1<sup>st</sup> and 3<sup>rd</sup> leading causes of mortality in the world. Unfortunately, there are no existing clinically implementable tests for quantifying the extent of either lifestyle factor. In 2012 and 2014, respectfully, we published the first genome wide study of smoking and heavy alcohol consumption (HAC). Herein, we detail the translation of those genome wide findings to easy to perform quantitative digital PCR (dPCR) tests for both smoking and drinking using DNA from blood or saliva from 233 smokers, 143 HAC and 200 controls. **Results:** Using DNA from whole blood, we show that dPCR assessment of methylation at cg05575921 has a Receiver Operating Characteristic (ROC) area under the curve (AUC) of 0.995 for predicting smoking with the amount of demethylation at cg05575921 being proportional to daily cigarette consumption. Similarly, a set of 4 dPCR markers specific for HAC has an AUC of 0.95 using DNA from whole blood. By using a recently described dPCR marker capable of correcting for the cellular heterogeneity in saliva, similar AUC values and dose response curves were seen with respect to cigarette and alcohol consumption using DNA prepared from saliva. **Conclusions:** We conclude that clinically implementable dPCR tools using DNA from blood or saliva can sensitively detect the presence and intensity of both smoking and HAC. Since the methylation signatures for both alcohol and cigarette consumption revert with abstinence, we believe that these easy to perform, rapid digital PCR tools will be useful to clinicians and researchers in assessing and monitoring those enrolled in substance use disorder treatment, employee wellness programs and insurance underwriting.

## PgmNr 3299: Epigenome-wide analysis uncovers a blood-based DNA methylation biomarker of lifetime cannabis use.

---

**Background:** Cannabis, the most commonly used illicit drug in the US, is associated with adverse and beneficial effects. Biomarkers that accurately classify cannabis use would facilitate research on potential health consequences. DNA methylation (DNAm) is an excellent candidate biomarker, yet no blood-based epigenome-wide association studies (EWAS) exist.

**Methods:** We conducted an EWAS using blood-based DNAm data (Illumina 450K) from a case-cohort study within Sister Study, a prospective cohort of women at risk of developing breast cancer (Discovery N=1,730; Replication N=853). We ran robust linear regression models of DNAm by lifetime cannabis (ever versus never) use, adjusting for age, breast cancer, tobacco and alcohol use, technical factors, and blood cell-type proportions. A multi-CpG classifier of lifetime cannabis use was developed using penalized regression of top EWAS CpGs in the discovery sample and validated in the replication sample. We also examined published *cis*-methylation quantitative trait loci (*cis*-meQTLs) for reported lifetime cannabis use-associated SNPs in relation to our EWAS findings.

**Results:** We identified and replicated an association with lifetime cannabis use at cg15973234 (CEMIP): combined  $P=3.3 \times 10^{-8}$ . We found no overlap between published cannabis-associated SNPs ( $P < 0.05$ ) and blood-based *cis*-meQTLs of cg15973234. A 3-CpG classifier of lifetime cannabis use had an area under the receiver operating characteristic curve of 0.79 (95% confidence interval [0.76, 0.82];  $P < 2.2 \times 10^{-16}$ ) in the replication sample.

**Conclusions:** Our findings provide evidence that blood-based DNAm is associated with lifetime cannabis use. DNAm levels at cg15973234 were not associated with reported genetic risk factors for lifetime cannabis use, suggesting that the observed DNAm difference was driven by cannabis exposure.

## PgmNr 3300: Genetic, epigenetic, and pharmacologic influences on gene expression regulation in iPSC-derived neural progenitor cells.

---

Neurodevelopmental programs depend upon dynamic changes in gene expression, but the underlying regulatory mechanisms are poorly understood. We are developing an experimental platform based on iPSC-derived neural cells designed to investigate the relative roles of genetic variation, epigenetics, and pharmacologic treatment on neurodevelopment in vitro. Here we sought to pilot the platform in neural progenitor cells (NPC), with and without treatment with valproic acid (VPA), a commonly used CNS drug and neural teratogen whose impact on DNA methylation remains controversial.

Fibroblasts from 6 unrelated donors were reprogrammed to iPSC, differentiated into NPCs, and treated 4 wks later with 1mM VPA (or medium only) for 5d. DNA and RNA were extracted on day 5. DNA bisulfite-converted DNA was analyzed with the Illumina MethylationEPIC array and Minfi pipeline. Methylation was expressed as percent intensity (B). RNAseq was done using NovoSeq 6000 with 40M, 150 bp, paired-end reads per sample. Mapped reads were variance stabilized and analyzed for differential expression through DESeq2. For each sample, methylation and expression levels were compared in treated and untreated conditions. EnrichR was used for functional enrichment analysis of differentially methylated (DM) or differentially expressed (DE) genes.

The methylation array reliably detected 830,000 CpG sites mapped to 34,440 genes. As expected, there was significant correlation between B values and gene expression ( $r^2=0.06$ ) that increased near the transcription start site ( $r^2 = 0.20$ ) and was not changed by VPA treatment ( $r^2=0.22$ ).

After VPA treatment, 2108 sites in 860 genes were DM and 502 genes were DE at FDR 5%, with only chance overlap at the gene level. Consistent with these results, only 1% of variance in B-values could be attributed to VPA treatment. Functional enrichment analysis of DM genes revealed ectoderm differentiation and axon guidance, while DE genes were enriched for genes previously associated with VPA treatment. There was no overlap.

These results confirm the impact of local CpG methylation on gene expression and support known changes in gene expression caused by VPA exposure. Contrary to some previous findings, we detected no evidence that VPA acts as a widespread DNA demethylating agent in NPCs. iPSC-derived neural cells provide a simple and efficient experimental setup for the investigation of genetic and

epigenetic influences on gene expression regulation during neurodevelopment.

## PgmNr 3301: GWAS of epigenetic age acceleration in AUD reveals a role for *APOL2*.

Studies have shown that individuals with alcohol use disorder (AUD) have a significantly shorter lifespan compared to healthy individuals. Given the potential role of AUD in the aging process, it is important to understand the underlying biological mechanism. We employed Levine's epigenetic clock method to estimate DNA methylation age in 532 participants consisting of 331 AUD and 201 healthy controls recruited in the National Institute on Alcohol Abuse and Alcoholism (NIAAA) at the National Institutes of Health (NIH). We further evaluated effects of heavy, chronic alcohol consumption on the epigenetic age acceleration (EAA) using clinical biomarkers, including LFTs and clinical measures. To further characterize potential underlying genetic variation that contribute to age acceleration in AUD, we performed GWAS on EAA in our sample, including pathway analyses. Relevant top findings were follow-up with in silico eQTL analyses for biological function using the BRAINEAC database. Individuals with AUD showed a 2.22 years of age acceleration compared to controls after adjusting for gender and blood cell composition ( $p=1.85 \times 10^{-5}$ ). This effect became diluted but remained significant after additional adjustment for race, BMI, and smoking status (1.38 years,  $p=0.02$ ). Secondary analyses of AUD endophenotypes showed elevated heavy drinking days, GGT, and ALT were associated with even more severe EAA (all  $p<0.05$ ). The genome-wide meta-analysis of EAA in AUD revealed a genome-wide significant SNP in *APOL2* (rs916264,  $p=5.43 \times 10^{-8}$ ) that was also functional, with the minor allele A associated with increased EAA also affected higher mRNA expression on hippocampus brain tissue ( $p\text{-value} = 0.0015$ ). Taken together, our data show EAA in AUD, and suggest that more severe phenotypes of AUD show even greater EAA. Potential underlying mechanisms might include genetic variation in *APOL2*, a apolipoprotein of the high density lipoprotein family involved in cholesterol homeostasis, that affects accelerated biological aging in AUD.

## PgmNr 3302: Quantifying regulatory effects of schizophrenia-associated variation directly from patient DNAs.

Schizophrenia is a chronic, debilitating, and highly heritable mental illness that affects approximately 1% of the population. The relative absence of protein-coding variants linked with schizophrenia suggests that risk alleles associated with the disease may alter gene expression through perturbing gene regulation. To identify noncoding regulatory variants associated with schizophrenia, we used a population-scale high-throughput reporter assay to quantify the effect of tens of thousands of genetic variants obtained from patient genomes. Specifically, those assays measured the effects of regulatory variants across 104 schizophrenia-associated loci captured from 96 control and 96 schizophrenia patients of Swedish ancestry. Together, the captured regions spanned ~8 Mb of genomic DNA. The assays were performed in the SK-N-SH neuroblastoma cell model. In total, 87,437 variants were evaluated in the schizophrenia patients, including 31,772 rare variants (MAF<0.01). We then tested putative regulatory elements and variants in vivo in the fetal mouse brain, and in vitro via dCas9 epigenome editing in cell culture models. Using this GWAS screening methodology we can quantify the regulatory impact of thousands of disease-associated alleles and predict variants likely to influence gene expression in complex diseases such as schizophrenia.

## PgmNr 3303: Genetic variants affecting chromatin accessibility during human neuronal differentiation.

---

Although genome-wide association studies (GWAS) have identified hundreds of common genetic variants associated with neuropsychiatric disorders, the molecular mechanisms underlying these risk variants are still poorly understood. GWAS risk loci are often in noncoding regions and likely play important roles in gene regulation. In order to determine how genetic variation impacts a measure of gene regulation (chromatin accessibility) during a critical time period of cortical neuronal differentiation, we performed a chromatin accessibility quantitative trait locus (caQTL) in cell-type specific population of human neural progenitor cells and their differentiated, labelled, and sorted neuronal progeny. We cultured neural progenitor cells (n=91 donors) derived from genotyped developing human cortical tissue donors (gestation weeks 14-21), and then differentiated and sorted virally labeled neurons (AAV2-hSyn1-EGFP) after 8 weeks of differentiation (n=66 donors). We then generated chromatin accessibility profiles for both neural progenitor cells and sorted neurons using ATAC-seq. We found global chromatin accessibility profiles are strongly different based on cell-type. We identified 136,714 peaks, of which 27,682 (FDR<0.05 and |log2FC|>1) peaks were differentially accessible between neurons and progenitors. As expected, we observed neurogenesis ontologies enriched in progenitor accessible peaks and also observed a strong enrichment in previously identified *in vivo* peaks. Common genetic variants within differentially accessible peaks in progenitors are significantly enriched in heritability explained for several human neuropsychiatric disorders and cognitive traits, most notably neuroticism, schizophrenia and educational attainment. QTL studies were then conducted on accessible peaks in progenitors and neurons separately. We found 22,892 caQTLs impacting 4,615 peaks in progenitors and 12,623 caQTLs impacting 2,715 in neurons. These caQTLs were highly cell-type specific with 11% of progenitor caQTLs (20% neuron caQTLs) having a significant effect in both cell types. Some caQTLs were useful in suggesting cell-type specific mechanisms of GWAS variants. For example, we identified a neuron-specific caQTL (rs9930307) within an intron of *GRIN2A* is also associated with the risk of schizophrenia. Using these caQTLs, we suggest molecular mechanisms of non-coding risk variants affecting gene regulations in particular cell types during human cortical neuronal differentiation.

## PgmNr 3304: DNA methylation profile of narcolepsy-affected brain and overlapping methylation profile between narcolepsy and multiple sclerosis.

Narcolepsy is a sleep disorder characterized by excessive daytime sleepiness and cataplexy. The loss of orexin- (hypocretin-) producing cells in the lateral hypothalamus (LH) causes the disease. Several genetic factors including *HLA-DQB1\*06:02* have been identified to date; however, the reason for orexin-producing cell loss and the pathogenesis are yet to be uncovered. Epigenetics has been suggested to play a certain role in the pathophysiology of complex diseases. Here we focused on DNA methylation and performed an epigenome-wide association study (EWAS) for narcolepsy and replication analyses with DNA samples extracted from two brain regions; LH (Case N=4, Control N=4) and temporal cortex (TC) (Case N=7, Control N=7). We first estimated proportions of surrogate measures of cell types present in brain using genome-wide methylation data. We found that there was no difference of cell populations between cases and controls both in LH and in TC, while there were significant differences between LH and TC. We then investigated differentially methylated regions (DMRs) of narcolepsy both in LH and in TC respectively. Seventy-seven DMRs were identified in the LH analysis, with the top association of a DMR in the *myelin basic protein (MBP)* region. In contrast, only five DMRs were detected in the TC analysis, suggesting that DNA methylation might be associated with narcolepsy especially in LH that is responsible area for the disease. Further, we developed two new approaches making the best use of the EWAS data; i) Investigation of methylation profiles shared between narcolepsy and other disorders and ii) An integrative analysis of the EWAS and the genome-wide association study (GWAS). The results of the two approaches, which included significant overlap of methylation profiles associated with narcolepsy and multiple sclerosis, indicated that the two diseases might partly share their pathogenesis. These major findings were replicated with independent LH-derived control samples (N=4). Although further replication studies are necessary, the DNA methylation in LH, that is responsible for narcolepsy, might have a certain role in the pathophysiology of the disease.

## PgmNr 3305: Recent stress and DNA methylation on emergent suicidal ideation: An epigenome-wide association study.

---

Suicide is a global public health problem, accounting for over 788,000 lives lost annually. In particular, patients with schizophrenia have a tenfold increase in suicide risk, which contributes greatly to their reduced life expectancy. The presence of suicidal thoughts, or suicidal ideation (SI), provides a robust predictor of future suicide. Thus, schizophrenia patients with newly emergent SI are especially at risk. In order to predict and prevent suicide, it is imperative to identify reliable biomarkers. Studies have shown that suicide is often triggered by recent stressful events. DNA methylation, an epigenetic signaling mechanism, plays a role in mediating gene expression and is sensitive to environmental factors such as stress. The present 3-month longitudinal study examines the impact of recent stress on emergent SI, and investigates the epigenome-wide methylation changes in relation to emergent SI in patients with schizophrenia. In a sample of 4 subjects with emergent SI and 4 subjects without SI, we found that increased recent stress was associated with emergent SI ( $p = 0.047$ ), specifically in the domains of family and interpersonal relationships ( $p = 0.027$ ) and personal health ( $p = 0.00002$ ). Furthermore, we quantified the changes in DNA methylation at 850,000 CpG sites using the Illumina Infinium MethylationEPIC BeadChip, and determined that the CpG site cg06371916 in chromosome 10 was the most differentially methylated site, characterized by hypomethylation of white blood cells of subjects with emergent SI compared to those without SI. Combined, these findings suggest that increased recent stressors is predictive of emergent SI, and that there are variations in DNA methylation at certain CpG sites associated with emergent SI. Further work can be done to investigate the mediating effect of methylation on stress causing emergent SI, in order to better establish molecular biomarkers for suicide prevention.

## **PgmNr 3306: A dynamic transcriptional program of transposable elements mediate cell fate specification and lineage commitment during corticogenesis.**

Human brain development is an extensive process that begins during early embryonic state with the differentiation of distinct cell types from neural stem cells (NSC) in a strictly regulated temporal order. The molecular mechanisms that give rise to NSC fate specification are still mostly unexplored, but noncoding regulatory elements are consistently implicated. We developed and validated a straightforward approach to identify unambiguous genome-wide expression profiles of discrete transposable elements (TEs) using a *de novo* assembly strategy. We set out to investigate the role of TE in the embryonic development of the human cortex at single-cell resolution in an in vitro model of hESC differentiating into cortical neurons over 77 days using RNA sequencing. We found that TEs 1) can be profiled in in vitro models of hESC; 2) play a role in the cell fate decision along the differentiation of human cortical development; 3) regulate target gene expression during neurodevelopment.

## PgmNr 3307: Dysregulation of miR-1271-5p in schizophrenia.

### Background:

While the cause of schizophrenia (SZ) is still unknown, multiple genes have been associated with the condition, at both the genetic and gene expression levels. Particular interest has been given to small non-coding RNAs called microRNA (miRNA). Many miRNA have been found differentially expressed in both peripheral and brain tissues, and several miRNA have been consistently linked to SZ. This study aimed to identify putative miRNA-mRNA interactions in peripheral blood mononuclear cell (PBMC) tissue, and investigate the roles of SZ-associated miRNAs in regulating disease-relevant genes.

### Methods:

We obtained PBMC tissue from individuals with and without SZ. Total RNA was extracted and both miRNA and mRNA sequencing was performed. One downregulated miRNA, miR-1271-5p, was further investigated through overexpression and knockdown in an in vitro neuronal cell culture model using synthetic RNA mimics and inhibitors. Both mRNA sequencing and ribosome profiling were performed to analyse differential transcription and translation.

### Results:

Several miRNAs and genes were differentially expressed in PBMCs in SZ, with an enrichment of upregulated immune-related genes. Several miRNA were negatively correlated with their predicted target genes, including several immune-relevant genes. One miRNA of interest, miR-1271-5p, was downregulated in both males and females, replicating previous findings. In vitro perturbation of miR-1271-5p identified roles in regulating a diverse range of gene networks, including cell membrane and cytoskeletal maintenance, neurodevelopment and neuronal function, as well as several SZ-associated genes including *GRM7*, *SLC1A1*, *HOMER1*, and *RELN*.

### Discussion:

These results add to growing evidence that disruption of miRNA regulation is associated with SZ. Peripherally, miRNA dysregulation may be partially responsible for an increased expression of immune system-relevant genes. We replicated previous findings of miR-1271-5p downregulation in PBMCs in SZ. Interestingly, this miRNA is also known to be a brain-enriched homolog of miR-96-5p, miR-182-5p, and miR-183-5p, all of which are contained within a single miRNA cluster and have known roles in regulating neuronal function. Altered expression of miR-1271-5p in vitro affected gene networks relevant to neuronal function and SZ. Thus, miR-1271-5p may be important to the pathophysiology of SZ through disruption of its target genes both peripherally and in the brain.

## PgmNr 3308: Explore the value of circRNA-miRNA multimolecular regulatory network in the diagnosis of early onset schizophrenia.

---

Schizophrenia (SZ) is a severe chronic mental health disorder with 1% lifetime prevalence and unclear pathological mechanism. At present, the diagnosis and prognosis evaluation of SZ still mainly depends on symptomatic observations, which is likely to cause misdiagnosis and missed diagnosis. Early-onset schizophrenia (EOS) was defined as SZ with onset before 18 years of age and experienced even more severe psychiatric symptoms and worse prognosis. Therefore, exploring objective and readily available biomarkers for EOS has become an urgent matter to be solved.

Here we selected 10 EOS patients and 10 matched controls to identify the differentially expressed (DE) circRNAs and miRNAs in plasma by Illumina HiSeq high throughput sequencing. Based on the interaction between circRNA and miRNA, bioinformatics methods were also used to integrate multilevel indicators of gene regulatory expression and construct circRNA-miRNA centered gene regulatory network for EOS. Further, verification of the specificity and sensitivity of these multilevel indicators will be done in a larger sample.

10 peripheral plasma samples from patients with EOS and 10 matched normal controls were selected to quantify the expression of miRNA and circRNA. 44 miRNAs and 50 circRNAs were showed significant DE level in case ( $P \leq 0.05$  and  $FC \geq 2$ ). Among them, 7 miRNAs and 1 circRNA showed a down-regulation trend in the case group, and 37 miRNAs and 49 circRNAs were up-regulated in the patient group. By using silicon analysis, target mRNAs and DE circRNA-miRNA interaction network was further predicted. Enrichment of the DE circRNAs and miRNAs in KEGG and GO (biological processes and molecular function) pathway were also analyzed. We discovered a significant enrichment of these genes associated with nervous system development ( $P = 4.706 \times 10^{-7}$ ,  $FDR = 0.001$ ), even with neuron projection, Glutamatergic synapse, MAPK signaling pathway and etc.

Our study clearly suggests that multilevel-based molecular network in plasma could be served as a more reliable biomarker for EOS. Although further verification should be done, our exploration is still helpful to complement current diagnostic strategies, even shed light on the pathology of SZ.

## PgmNr 3309: Characterizing differential *cis*-regulatory domains in neuronal epigenome across schizophrenia cases and controls.

---

Genome wide association studies (GWAS) of schizophrenia (SCZ) have revealed that disease-associated variants are mapped to gene regulatory sequences. Moreover, pathway analyses of GWAS-SCZ risk loci have shown the strongest association with histone modifications. Yet, we understand very little about the role of regulatory elements underneath these disease specific signals. For example, how do regulatory elements (REs) coordinate to modulate genes' expressions in schizophrenic patients' brains vs. healthy brains? To answer this question, we profiled histone modifications: histone H3-trimethyl-lysine 4 (H3K4me3) and histone H3-acetyl-lysine 27 (H3K27ac) in fluorescence-activated cell sorted (FACS) nuclei from the prefrontal cortex (PFC) brain regions of 149 SCZ postmortem brains compared to the 145 healthy brains. We estimated the correlation of chromatin peaks across all the individuals' brains to probe the coordination of regulatory elements. We found the neuronal genome was partitioned into ~9,000 neuronal *cis*-regulatory domains (nCRDs) that encompassed distinct patterns of histone marks. A total of 75 nCRDs were identified in SCZ brains that showed differential neuronal dysregulation than the healthy brains. Pathway analyses of differential nCRDs showed association with biological processes such as calcium ions signaling. We then characterized the association of genes with nCRDs, wherein ~50% of the genes were associated with nCRDs within the window of  $\pm 1$  Mb. Annotation of nCRDs, showed clusters of active REs.

Our research work provides unique insight into the role of regulatory elements in modulating the gene expression that might be causal for neuronal dysfunction in schizophrenia. Our PsychENCODE sponsored research provides a resource of genome-wide map of neuronal *cis*-regulatory domains (nCRDs) and schizophrenia specific nCRDs. The disease specific nCRDs can be further explored using chromosome conformation capture technique to study psychosis in animal models to advance our knowledge in schizophrenia. In addition to this, we provide a computational pipeline that translates linear functional genomics assays such as ChIP-seq into three dimensional higher chromatin structures. Supported by NIMH U01MH103392

Gene regulation is crucial to the physiology of human cells and disease risk, but our knowledge of transcriptional regulatory elements in the brain and their contribution to psychiatric disease is limited. As part of the HudsonAlpha Brain TF Project, we are developing a deep resource of regulatory information including thousands of maps of transcription factor (TF) binding using ChIP-seq in 9 brain regions from 4 individuals and neuronal progenitor cells from 4 individuals. In addition to ChIP-seq, we are gathering other valuable data pertaining to gene expression, including RNA-seq, microRNA-seq, Whole Genome Sequencing (WGS), and DNA methylation profiling. This work has yielded rich maps of regulatory elements to facilitate analyses of the molecular effects of genetic variation in the brain and discovery of pathways and regulatory mechanisms relevant to psychiatric disease. Beyond our own analyses, these data will be a resource for other studies.

Here, we show recent progress in optimizing a ChIP-seq pipeline that requires a minimal input of brain tissue to collect data of multiple histone-markers and TFs in post-mortem human brain tissues. We have thus far implemented this pipeline to produce high quality TF binding data across nine brain regions from two individuals using small amounts of tissue, thus maximizing the potential for future experiments on precious samples. In addition, we have generated distinct TF binding maps for neuronal and non-neuronal cell populations isolated from cortex tissue by sorting nuclei based on NeuN signal with flow cytometry. The TF signals produced from sorted nuclei are consistent with expected regulation of genes specific to each cell-type and can distinguish neuronal from glial populations by assessing gene ontology of cis-regulatory regions. Furthermore, this approach distinguishes exclusive epigenetic signatures that are unique to neuronal and non-neuronal cell populations. This technique, when implemented in the resource-building component for TF maps across tissues, will provide an invaluable resource for gene regulation in the human brain.

## PgmNr 3311: Investigating the role of the epigenetic reader *Brd4* in hearing and development of the inner ear.

---

Hearing loss (HL) is the most common sensorineural disorder in humans, with profound congenital HL occurring in approximately 1/500 births. In mammals, sensorineural HL (SNHL) arises from irreversible damage to the sensory hair cells (HC) in the cochlea. Investigating transcriptional regulation in inner ear would help understand the mechanisms involved in sensory HC development, function and maintenance. Recently, genes involved in DNA methylation, histone modification and chromatin remodeling have been associated with hereditary HL. Syndromic forms of deafness, such as autosomal dominant cerebellar ataxia, deafness, and narcolepsy (ADCA/DN) and hereditary sensory neuropathy type IE (HSN1E) have been shown to be caused by mutations in *DNMT1*, important in methylation. In this study, we investigated the role of *Brd4*, a chromatin reader protein that recognizes and binds acetylated histones which are relevant in transcription regulation. To generate the conditional knock-out model we crossed *Brd4*<sup>tm1a(EUCOMM)Wtsi</sup> heterozygous mice with B6.Cg-Tg (ACTFLPe)9205Dym/J to obtain *Brd4*<sup>fl/fl</sup> mice. These were then crossed to B6.Cg-Tg (Atoh1-cre)1Bfri/J mice to obtain conditional expression of Cre in the inner ear to eventually generate *Brd4*<sup>fl/fl</sup>; *Atoh1-cre*<sup>+/-</sup>, *Brd4*<sup>fl/fl</sup>; *Atoh1-cre*<sup>-/-</sup> and *Brd4*<sup>wt/wt</sup> littermates. Auditory brainstem response (ABRs) were recorded and compared to *Brd4*<sup>fl/fl</sup>; *Atoh1-cre*<sup>-/-</sup> and *Brd4*<sup>wt/wt</sup> mice using a Smart EP Universal Smart Box (Intelligent Hearing Systems, Miami, FL) at P21. ABR stimuli were induced as 0.1 ms broadband clicks and 0.1 ms pure-tone pips at frequencies 8, 16 and 24 kHz through 20-100dB intensities. To test the mechanical activity of outer hair cells (OHCs) in the cochlea, distortion product acoustic emission (DPOAEs) were recorded in the mutant mice and compared to controls. The ABR thresholds for click response in *Brd4*<sup>wt/wt</sup> mice were ~ 65dB SPL, ~67 dB SPL in *Brd4*<sup>fl/fl</sup>; *Atoh1-cre*<sup>-/-</sup>, and ~100 dB SPL in *Brd4*<sup>fl/fl</sup>; *Atoh1-cre*<sup>-/-</sup>. As with the pure-tone frequencies, mutant mice had significantly elevated ABR thresholds at P21 (~100dB SPL) compared with control mice. The DPOAE recordings at P21 produced by OHCs in the mutants had reduced amplitudes in 8-16 KHz compared to both control groups but had similar profiles at 24 KHz. Thus, the mutant mice were profoundly deaf, indicating a relevant role for *Brd4* in the postnatal development of HCs. This study has been supported by R01 DC005575 and R01 DC012115 from NIH/NIDCD to Xue Zhong Liu.

## PgmNr 3312: DNA hypomethylation in high myopia: Differentially methylated genes in overrepresented molecular pathways could contribute to high myopia in Polish children.

**Introduction:** High myopia (HM) is an eye disorder characterized by refractive error (RE) greater than -6.0 diopters (D) and axial length (AL) more than 26.0 mm. The etiology of HM is complex and involves genetic and environmental factors. Recently, we have completed the global analysis of DNA hypermethylation in Polish HM children (PMID:30858441). Here, we focus on the aspect of hypomethylation to complement the methylation studies in HM.

**Materials and Methods:** The DNA hypomethylation was assessed based on the results of genome-wide DNA methylation analysis performed on DNA of 18 Polish HM children (aged 4-12 years, RE -6.0 – -15.0 D, AL 26.22 mm – 27.85 mm) and 18 age-matched Polish control individuals. In total, 358 hypomethylated genes, containing 333 CpG dinucleotides with more than 12% difference of methylation level between HM children and controls and FDR p-value < 0.00001, were chosen for overrepresentation analyses of molecular pathways in ConsensusPathDB-human server. Only pathways with p-value ≤ 0.01 and sharing at least five genes with our uploaded gene set were considered.

**Results:** The most hypomethylated CpGs with more than 25% difference in the methylation level between children with HM and controls was located in long intergenic non-coding RNA 1088 (*LINC01088*), erythrocyte membrane protein band 4.1 like 4A (*EPB41L4A* [MIM 612141]), ADAM metallopeptidase domain 20 (*ADAM20* [MIM 603712]), grainyhead like transcription factor 1 (*GRHL1* [MIM 609786]), and WW domain containing oxidoreductase (*WWOX* [MIM 605131]). Enrichment analysis of hypomethylated genes set revealed overrepresentation of genes with even more than 10 shared genes in several pathways, including steroid hormone biosynthesis, phase II - conjugation of compounds, metabolism biotransformation phase I and II, signaling by receptor tyrosine kinases, biological oxidations, intracellular signaling by second messengers, focal adhesion-PI3K-Akt-mTOR-signaling pathway, axon guidance, and miR-targeted genes in epithelium. Signaling by receptor tyrosine kinases, focal adhesion-PI3K-Akt-mTOR-signaling, and axon guidance pathways were also identified in our previous hypermethylation studies.

Conclusions: The observed differences in methylation level of genes of the overrepresented pathways indicate the involvement of methylation aspects in HM etiology.

## PgmNr 3313: Early and progressive hearing loss in a mouse model of Kabuki syndrome.

**Introduction:** Kabuki syndrome type 1 (KS1) is a Mendelian disorder of the epigenetic machinery caused by mutations in *KMT2D*, a gene encoding a histone-modifying enzyme. *KMT2D* is responsible for histone H3K4 methylation especially at enhancers and promoters of genes. We have characterized a mouse model of KS1 (*Kmt2d*<sup>+/ $\beta$ Geo</sup> mice) that demonstrates many KS1 features including growth retardation, craniofacial defects, and immune dysregulation. *Kmt2d*<sup>+/ $\beta$ Geo</sup> mice also demonstrate a disruption of adult neurogenesis in the dentate gyrus and hippocampal memory defects, phenotypes rescued postnatally with agents targeting the epigenetic machinery.

**Objective:** Many of our KS1 patients develop progressive hearing loss requiring intervention with aids or cochlear implants during early childhood. Although the etiology of this hearing phenotype is poorly understood, current clinical dogma states it is caused by repeated ear infections in childhood or anatomic abnormalities. However, in our clinic we have observed individuals with hearing loss in early life without anatomic abnormalities or any history of ear infection. We hypothesize that hearing loss in KS1 is sensorineural due to the loss of *KMT2D* and not recurrent ear infections.

**Methods:** To explore the basis of this hearing loss we phenotyped the *Kmt2d*<sup>+/ $\beta$ Geo</sup> mice by imaging and auditory brainstem responses. We further focused on hair cells by directly testing their function through distortion product otoacoustic emissions (DPOAE) and histology of the sensory tissue.

**Results:** We observe no anatomic abnormalities but we do observe auditory response deficits at onset of hearing in our *Kmt2d*<sup>+/ $\beta$ Geo</sup> mice compared to wild type litter mates. This phenotype becomes progressively worse over time. Interestingly, we observe abnormalities of hair cell function by DPOAE and found outer hair cell death at later ages but not at early postnatal time points.

**Conclusion:** Since we find impaired hearing in early life of *Kmt2d*<sup>+/ $\beta$ Geo</sup> mice, we conclude that loss of *KMT2D* results in sensorineural hearing loss independent of recurrent ear infections common in Kabuki syndrome. These data suggest that conditional, transcriptional, and epigenetic studies prior to hair cell demise could help us understand how the deficiency of a chromatin modifier leads to hearing loss through disruption of epigenetic and transcriptional programs. Furthermore, this offers another quantitative postnatal outcome measure for therapeutic development for Kabuki syndrome.

## PgmNr 3314: DNA methylation of microRNA-coding genes in non-syndromic high myopia.

---

Myopia, commonly referred to as nearsightedness, is one of the most common causes of visual disability throughout the world. It affects more people worldwide than any other chronic visual impairment condition. Ocular tissue gene expression variation, including the dysregulation of MicroRNA (miRNA) genes, may lead to the development of myopia. Blood-based miRNA profiling is being used as a diagnostic tool for multiple diseases. Until, there are no studies thus far to address epigenetic methylation of miRNA genes that may affect the progression of myopia. To elucidate the epigenetic mechanism(s) underlying the pathophysiology of high-myopia, we investigated DNA methylation levels of miRNA encoding genes using the Illumina MethylationEPIC BeadChip array in 50 axial HM subjects and an equal normal of age, gender, sex and ethnic matched controls (aged 4-12 years). The degree of myopia was variable among subjects, ranging from -6 to -15D. Several “R” packages were used to identify the significant CpG targets of miRNA. We have performed bioinformatic analysis by mining the MicroRNA Target Prediction and Functional Study Database (miRDB) to predict the possible genes regulated by the identified methylated miRNAs. We have identified seven significantly differentially methylated miRNAs: miR-6737, miR-636, miR-548H4, miR-548G, miR-423, miR-7704 and miR-2277. All identified miRNAs were found to be methylated at their transcription start site or at the 5’UTR region. One of the differentially methylated miRNAs, miR-548G, targets the paired box 6 (PAX6) gene with high target score. This gene has been identified as a candidate for developing HM. This is the first study of the methylation difference of global miRNA genes in HM cases. The study presents a novel approach to understand the molecular mechanism of HM. Altered methylation of miRNAs detectable in blood may potentially be a sensitive biomarker to detect early risk of HM. Understanding the complex mechanism leads to the potential of using miRNAs as prognostic tools and therapeutic agents for HM.

## PgmNr 3315: Characterization of *GJB2* *cis*-regulatory elements in the *DFNB1* locus.

---

Three-dimensional chromatin organization plays a key role on gene expression. Gene regulation depends on *cis*-regulatory elements which can interact with gene promoter by chromatin loop. Alteration of chromatin architecture and/or *cis*-acting elements can lead to *cis*-ruption disorder. Numerous unelucidated nonsyndromic hearing loss and deafness 1 (*DFNB1*) cases carrying out only one heterozygous pathogenic mutation on Gap Junction Beta 2 (*GJB2*) gene, led to strongly suggest the presence of distant *cis*-regulation.

To analyze chromatin conformation of a large *DFNB1* locus, we performed the 5C technology and showed several chromatin contacts with *GJB2* promoter. Then, to identify potential regulatory elements of the *GJB2* gene, we analysed these chromatin interacting regions with the *GJB2* promoter by reporter test activity and identifying *cis*-regulatory elements which have enhancer action and silencer effect on *GJB2* expression. Moreover, to explore *DFNB1* locus architecture we analysed CTCF (CCCTC-binding factor) binding along *DFNB1* locus by ChIP-qPCR and defined an active domain in which *cis*-acting elements were closer brought to the *GJB2* promoter through chromatin looping. This first study of *DFNB1* three-dimensional chromatin organization allows identification of *GJB2* *cis*-acting elements. Finally, better understand of the molecular mechanisms of *DFNB1* deafness could be important to improve genetic diagnosis of hearing loss, to adapt patients care and to develop small therapeutic molecules.

## PgmNr 3316: A circulating microRNA profile in a laser-induced mouse model of neovascular age-related macular degeneration (AMD).

### Authors:

C. Kiel <sup>1</sup>; P. Berber <sup>1</sup>; M. Karlstetter <sup>2</sup>; A. Aslanidis <sup>2</sup>; T. Langmann <sup>2</sup>; F. Grassmann <sup>1,3</sup>; B.H.F. Weber <sup>1</sup>

---

**Purpose:** Age-related macular degeneration (AMD) is the major cause of severe visual impairment in people over the age of 55 in Western societies. Given that AMD is a complex disease, investigations into its pathomechanism are challenging. Circulating microRNAs (cmiRNAs) have been shown to represent valuable biomarkers for several age-related diseases and can be readily measured in blood, since they are common cargo of exosomes or microvesicles. Dysregulation of cmiRNA expression at defined stages of AMD may point towards molecular pathways involved in its pathobiology and may therefore give rise to novel treatment options. In this study, we aimed to investigate the role of dysregulated cmiRNAs in a laser-induced mouse model of neovascular AMD.

**Methods:** Laser coagulation was used to induce six lesions per eye in six C57BL/6J mice. Blood samples were taken the day before (day 0) and on three defined time-points after laser treatment (days 3, 7 and 14). CmiRNA profiles were determined by Next Generation Sequencing. Results were validated independently by quantitative real-time RT-PCR (qRT-PCR) with samples from an additional mouse cohort with six laser-treated and six control animals. Moreover, we used qRT-PCR to investigate the local expression of miRNAs in the retina and retinal pigment epithelium (RPE)/choroid complex at the same time points, in 12 lasered and 12 control mice, respectively.

**Results:** The cmiRNA levels were analyzed at the four defined time-points in a two-step approach, including a discovery and a validation phase. Accordingly, we identified 10 cmiRNAs to be significantly dysregulated after laser-treatment compared to baseline at least at one time-point ( $p < 0.05$ ). Expression of these 10 candidate cmiRNAs were also analyzed in the retina and the RPE/choroid tissues. In each tissue, seven miRNAs were also found to be dysregulated in laser-treated mice compared to control mice, including five miRNAs being dysregulated in both tissues.

**Conclusion:** We detected 10 cmiRNAs to be differentially expressed in a laser-induced mouse model of neovascular AMD. Nine of these also displayed dysregulation in the retina or RPE/choroid complex. Our data highlight the potential role of cmiRNAs in the pathology of neovascular AMD, and point to the use of cmiRNAs as biomarkers in this disease. This is underpinned by the fact that two cmiRNAs, miR-20a and miR-140, were previously identified in a cmiRNA biomarker study in patients with neovascular AMD.

## PgmNr 3317: Biochemical quantification of pseudouridine in spliceosomal RNAs in relation to snoRNAs expression levels: A panacea to developmental defects?

Messenger RNA splicing is the process of removing introns from pre-messenger RNA and ligating together exons to produce a mature messenger RNA (mRNA) that represents the template for protein translation. Alternative pre-mRNA splicing adds diversity to the proteome and greatly increases its diversity. scaRNAs catalyze 2'-O-methylation or pseudouridylation of specific nucleotides in spliceosomal RNAs. We showed that a reduction in the expression level of scaRNA is associated with alternative mRNA splicing and congenital heart defects. Furthermore, our studies and those of others have demonstrated that scaRNA levels are developmentally dynamic and must be precisely regulated in order to achieve normal embryological development. Messenger RNA splicing is catalyzed by the spliceosome, a complex macromolecular machine that consists of a dynamic set of hundreds of proteins and five small RNAs. Although we assume that methylation or pseudouridylation were the intermediary steps in adjusting alternative splicing we have not yet examined the levels of methylation or pseudouridylation in direct response to changing scaRNA levels. Therefore, we developed a process to quantify pseudouridylation based on modifications of the technique developed by Carlile et al (2015). Here we present an assessment of U/ψ89 in spliceosomal RNA after experimental manipulation of scaRNA1, which directs the pseudouridylation of U89. Many genetic diseases in humans are a consequence of splicing defects often due to mutation in splicing machinery, so developing tools to target the spliceosome to correct splicing represents a novel approach to therapy. However, a complete understanding of the mechanisms that influence spliceosome function must be clearly understood in order to successfully target the spliceosome. ScaRNA expression levels that attenuate biochemical modification of spliceosomal RNAs that consequently fine-tune alternative splicing represents an unappreciated functionally important mechanism that might be amenable to therapy.

## PgmNr 3318: Examining *SRCAP* mutations in Floating-Harbor syndrome: An induced pluripotent stem cell disease modeling approach.

---

Floating-Harbor Syndrome (FHS; OMIM# 136140) is characterized by short stature, delayed osseous maturation, cognitive deficit, and distinct facial dysmorphology. We previously identified heterozygous truncating mutations in the 3' end of *SRCAP* as the genetic cause underlying FHS. We also demonstrated that FHS-causing mutations result in unique and highly reproducible methylation alterations in the peripheral blood-derived DNA of FHS patients. *SRCAP* has been described as having coactivator roles in CREB and CBP-mediated and nuclear (steroid) hormone receptor signaling pathways. It has also been shown to co-precipitate as part of a large chromatin remodeling complex which catalyzes ATP-dependent displacement of the histone variant H2A by H2A.Z. Based on the described roles of *SRCAP*, the clustered nature of our mutations, and our finding that FHS mutations result in genomic methylation alterations, we expect that FHS-causing mutations result in widespread gene dysregulation. To examine the functional consequences of these alterations in cell lineages implicated in the FHS phenotype, we employed an induced pluripotent stem cell (iPSC) disease modeling approach. Patient and gender-matched fibroblast cell lines were reprogrammed into iPSCs using an episomal vector system. Clones were characterized by pluripotency cell surface marker expression, differentiation capability (*in vitro* and *in vivo*), and karyotyping assays. iPSCs were differentiated into neural crest cells (NCCs) using a dual SMAD inhibition approach. Expression of NCC markers p75, HNK-1, and SOX10 demonstrated normal NCC specification for all lines. For downstream analysis, pure populations of NCCs were generated by FACs sorting (p75+/PI-). RNA and transposed-DNA were isolated from the initial fibroblast cell lines, reprogrammed iPSC lines, and iPSC-derived FACs sorted NCCs. From these, a combination RNAseq/ATAC-seq strategy is being used to examine alterations in downstream expression and chromatin architecture. By comparing data between these two technologies, and across three cell lineages, we expect to identify key targets and downstream pathways altered in FHS, which will allow us to better understand the FHS disease mechanism and the dysmorphology seen in FHS in a precise tissue specific manner.

## PgmNr 3319: Chromatin structure changes are more closely associated with adipogenesis than osteogenesis.

**Authors:**

---

Chromatin conformation change has been proved to have close connection with gene regulation mechanism changing in cells, especially during cell differentiation procedures. Mesenchymal stem cells (MSCs) are multipotent and can be differentiated into adipocytes and osteoblasts. While the transcriptomic and epigenomic changes in response to adipogenesis and osteogenesis have been characterized, what happened to the 3D chromatin conformation stabilization is hardly known. Here we induced human MSCs to adipogenic and osteogenic differentiation in vitro. We performed 2k resolution Hi-C experiments in 3 cells and detected cell specific “loop” structures. After integration with RNA-seq, H3K4me1, H3K27ac ChIP-seq and ATAC-seq data, we demonstrate that loop structures are associated with active gene expression in general. However, loops in adipocytes show evidence of harboring adipogenesis related genes with active enhancers, whereas osteogenesis associated genes are more likely to locate outside of loops in osteoblasts. We also marked distal and proximal cell specific enhancers in 3 cells, and by mapping open chromatin landscapes, we proposed different gene regulation patterns between adipogenesis and osteogenesis. At the same time, we also identified associated transcription factors that might play a crucial role in lineage determination. Overall, our study provides a comprehensive view of chromatin structure changes and its associated regulation landscape differences during adipogenesis and osteogenesis.

# PgmNr 3320: Impact of structural variations on human genome topology at the population scale.

## Background

Recent studies have demonstrated the importance of chromatin spatial organization in human health by comparing genomic interaction patterns between normal and abnormal cells. However, no systematic studies were published so far on the variability of 3D chromatin structure in human population of healthy individuals. We combine various types of data from a pool of human lymphoblastoid cell lines and computational modeling to address this lack.

## Results

We extend our previous study on the human 3D genome architecture[1] to account for genome topological variation within population and to gain a deeper insight into mechanisms of gene regulation by chromatin topology

We earlier demonstrated that using genomic interaction data a 3D model of an averaged genome structure which recovers architectural features of the genome can be built[2]. We extended our modeling approach (3D-GNOME) to include information on SVs in recovery of 3D chromatin structures. Our algorithm models individual chromatin loops, meaning that the remodeling effect of a genetic variant disrupting a single pair of interacting genomic segments will be represented in the model.

High-quality ChIA-PET data (combined with data from the 1000 Genomes Catalogue of Human Genetic Variation and from the GWAS Catalogue) enables us to perform genome-wide population-scale analysis at the finest resolution. We show different effects genetic variations have on genome regulation when altering chromatin interaction networks mediated by different protein factors. Our results show a close link between variation in chromatin interaction networks mediated by RNA polymerase II and differential gene transcription[3].

## Conclusions

Altogether, our studies show the critical impact of genetic variants on the higher-order organization of chromatin folding and provide insight into the mechanisms regulating gene transcription at the population scale.

---

Epigenetic changes have a significant impact on human health and disease susceptibility since they play a crucial role in the regulation of important cellular processes. Over the past few years significant progress has occurred in this rapidly advancing field. One of the most stable form of epigenetic regulation is DNA methylation.

Bisulfite sequencing (BS) is considered to be the best method for detecting DNA methylation with single nucleotide resolution. However, the high cost of whole genome BS and the low throughput of amplicon BS are challenges that must be overcome.

Here we present a streamlined workflow which combines optimal bisulfite treatment and targeted bisulfite sequencing. This method utilizes single primer enrichment (SPE) and unique molecular identifier (UMI) barcoding technology. This enables high-efficient, flexible and scalable targeted analysis of DNA methylation from gDNA, FFPE and ccf-DNA samples.

## **PgmNr 3322: Filling in the blanks: Simultaneous imputation of epigenetic profiles using deep neural networks to investigate optimal experimental design in large sequencing studies.**

Biological data can often be represented via multi-dimensional arrays. For example, expression levels may be measured for a set of genes across both tissues and individuals, or a number of different assays may be performed across the genome in many cell types. These data are often plagued by structural missingness; entire rows or columns may be missing if a given assay has not been performed or if a given tissue was not assayable. If these missing entries could be accurately imputed, it would be possible to infer the results of unperformed experiments, such as measurements in difficult-to-assay tissues, like the brain, by using analogous measurements in easier-to-assay tissues, such as whole blood. Unfortunately, imputing these missing entries is difficult, and most previous approaches assume a low-dimensional linear latent structure. Biological data are often highly non-linear, however, and with massive datasets it should be possible to relax these assumptions. Correspondingly, we have developed a method based on deep convolutional neural networks which captures the nonlinear relationships among missing entries and observed values. Further, to leverage the exchangeability inherent in many biological datasets, we train our model using a novel permutation-equivariant scheme. We then apply our method to a number of different real datasets and demonstrate that our method compares favorably to existing methods and baselines. Our results also allow us to elucidate the effect of different missingness patterns on imputation performance, thus informing optimal experimental design in the presence of technical or resource constraints.

## PgmNr 3323: *In vivo* response to respiratory viruses assessed by whole genome methylation sequencing in infants.

The methylation patterns of approximately 28M CpG dinucleotides in our genome provide dense information on gene regulatory circuitries. Whole genome bisulphite sequencing (WGBS) quantitatively captures the methylation state of individual CpGs. Canonically, methylation levels are low (0-3%) at active promoters and intermediate at active enhancers (5-40%). We studied nasal epithelial cells from 100 infants with suspected respiratory tract infections, either being virus-positive (N=9 different pathogens) or virus-negative as defined by clinical testing. We pooled DNA of 10 patients from each viral group and negative controls, and WGBS (30-40x coverage) from each pool was used to characterize virus-specific epigenome response. We used the MethylSeekR Hidden Markov model algorithm to identify active promoters (UnMethylated Regions, UMRs) and active enhancers (Low Methylated Regions, LMRs) in each pool. On average, 80K regulatory regions were observed per cell pool, however, Influenza B (Flu-B) exposed children showed wide activation (hypomethylation), with >100K regulatory regions present and nearly 15K were unique to this virus. On the other end of the epigenomic response, Influenza A (Flu-A) showed only 2K regions (2.4%) uniquely activated. However, the limited Flu-A response indicated relatively specific enrichment of IL4 signaling pathways (GREAT overrepresentation analysis of GO Biological processes, 7-fold enrichment,  $P < 0.001$ ). Nearly 4K regulatory elements were consistently inactivated (hypermethylation) among patients with documented infection vs. negative patients. These regions were enriched among genes in monocyte activation pathways, suggesting that suppression of these gene networks is important for viral colonization in infant nasal epithelium. Furthermore, we observed strong enrichment of asthma associated genetic markers (SNPs from genome-wide association studies) among these commonly inactivated regulatory elements, potentially linking dysregulated viral response to genetic susceptibility for asthma. Altogether, our genome-wide monitoring of infant viral response provides first catalogue of viral species and infection associated host DNA regulatory elements in early childhood. Future assessments of epigenetic variation in these regions in individual patients may reveal epigenetic evidence for viral triggers for childhood disease.

## PgmNr 3324: Social disadvantage, gene expression and depressive symptoms in a sample of African American from the Minority Health - GRID.

### Authors:

A. Gaye <sup>1</sup>; G. Goodney <sup>1</sup>; M. Abbas <sup>1</sup>; R. Quarells <sup>2</sup>; G. Gibbons <sup>1</sup>; S. Davis <sup>1</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) National Institutes of Health, Bethesda, MD, USA; 2) Morehouse School of Medicine, Atlanta, GA, USA

### Background

In addition to individual risk factors and behaviors, health is also affected by a range of socio-economic (SES) conditions often measured as income or level of education. More evidence is needed to advance our understanding of how adverse SES conditions are internalized as psychosocial stressors that are manifested as perturbations in biological systems such as patterns of gene expression within the blood circulation.

### Methods

Adverse social conditions were measured as a composite score, social disadvantage, generated from perceived neighborhood environment, level of education, per-capita family income and wealth. Random Forests was used to investigate the relationship between social disadvantage and gene expression, in the whole blood RNA-seq profiles of 180 African Americans and the mediatory role of stress and depression scales in that relationship.

### Results

A set of 191 mRNA could classify social disadvantage with an area under the curve (AUC) of 0.98. Subsets of those 191 mRNA were related to depression scale, perceived stress scale and financial stress scale. The relationships between social disadvantage and the three psychosocial factors were also established through the questionnaire data. A total of 44 of the 191 mRNAs were reported as differentially expressed between depressive subjects and controls in a study of clinical depression (major depressive disorder, MDD).

### Conclusions

The mRNAs identified are involved in mainly 3 areas related to the brain: brain development/neuroplasticity, neurobehavioral response to chronic stress and neurobehavioral and neurodegenerative diseases. The results suggest that subjects above the threshold of depressive symptoms, measured in the data, are likely exhibit a gene expression signature that corresponds to an increased risk of a clinical diagnosis of depression.

## PgmNr 3325: TDG-mediated epigenetic regulation in retinoic acid signaling during spermatogonial differentiation.

**Authors:**

T. Lee; A. Luk; J. Liao; W. Chan

---

Male fertility is sustained by male germline stem cells (GSCs) known as spermatogonial stem cells (SSCs) that either self-renew or differentiate to progenitors to initiate spermatogenesis. A key question in SSC biology is whether and how epigenetic programs contribute to the cellular identity of SSC and specific gene expression programs for committing self-renewal or differentiation. Active DNA demethylation through 5-formylcytosine (5fC) and 5-carboxylcytosine (5caC) by TDG is essential for mouse embryonic and stem cell development, but its role remains elusive in SSC biology. Therefore, we examined the functional role of TDG in male germ cell development using our recent established germline-specific TDG knockout animal. We found that TDG knockout males expressed a progressive loss of fertility associated with increased PLZF+ undifferentiated spermatogonia and reduced elongated spermatids after 6 months of age. We further traced spermatogonial differentiation using the differentiated spermatogonial cell marker KIT at P8, the initial stage of spermatogonial differentiation and observed that KIT-positive cells were significantly reduced in the knockout testes. To examine the molecular phenotypes of the TDG knockout germ cell, we performed RNA-Seq analysis and revealed altered gene expression of a subset of retinoic acid target genes, including *Stra8* and *Cyp26a1*. Furthermore, we found that the demethylation of *Stra8* during the KIT transition was impaired after depletion of TDG in Oct4-GFP+ undifferentiated spermatogonia. These results indicate that TDG-mediated active demethylation regulates the differentiation of undifferentiated spermatogonia through the coupling of the retinoic acid signaling pathway.

## **PgmNr 3326: Development of programmable CRISPR/Cas9-based histone kinases to link histone phosphorylation to human gene regulation.**

### **Authors:**

J. Li <sup>1</sup>; B. Mahata <sup>1</sup>; I.B. Hilton <sup>1,2</sup>

[View Session](#) [Add to Schedule](#)

### **Affiliations:**

1) Department of Bioengineering, Rice University, Houston, US; 2) Department of Biosciences, Rice University, Houston, US

---

### **Purpose:**

We have built new synthetic biology tools that enable us to synthetically engineer histone phosphorylation at specific locations in human chromatin. Ultimately this will permit precision control of the epigenome and gene regulation and the amelioration of disease phenotypes in human cells.

### **Method:**

Taking advantage of the programmable CRISPR/Cas9 platform, we fused variants of histone H3 kinases to deactivated Cas9 (dCas9) and delivered these fusion proteins to specific genomic regulatory elements in human cells. We used ChIP-qPCR to measure changes in histone phosphorylation and qPCR/RNA-seq to measure changes to the human transcriptome.

### **Results:**

dCas9-based histone kinases activate human genes when targeted to endogenous promoters. This activation is dependent upon intact kinase activity, as the catalytically inactivated fusion proteins fail to activate gene expression. Furthermore, ChIP-qPCR results show that the phosphorylation levels at specific histone residues are significantly increased coincident with gene activation.

### **Conclusion and Discussion:**

Although numerous important studies have demonstrated a correlation between histone phosphorylation and gene activation, direct evidence of a causal relationship has been lacking. Using the CRISPR/dCas9 system, we have provided the first direct evidence that histone phosphorylation activates the expression of human genes. This activation specific to gRNA-targeted loci and requires intact kinase activity. In addition to gene regulation, histone phosphorylation is associated with many critical biological processes, including DNA replication, DNA repair, and the onset of human diseases. Therefore, our new CRISPR/dCas9-based histone kinases expand the ability mechanistically understand and control human genes, and also enable new ways to explore fundamental biological pathways and model human diseases.

## PgmNr 3327: Delving into epigenetics and gene regulation on the ENCODE portal.

The Encyclopedia of DNA Elements (ENCODE) project is an international collaboration of research groups funded by the NHGRI. The main goal of the project is to identify the functional elements of the human genome. The ENCODE portal (<https://www.encodeproject.org/>), established and maintained by the ENCODE Data Coordination Center (DCC), provides unrestricted access to the data generated by the members of the ENCODE consortium and other related projects such as Model organism ENCODE (modENCODE), Model organism Encyclopedia of Regulatory Networks (modERN), Genomics of Gene Regulation (GGR), and Roadmap Epigenomics Project (Roadmap). The DCC develops and updates the data model and uniform processing pipelines that allow transparency and reproducibility of the experimentally collected and computationally generated data. The categories of metadata and their implementation in a structured, machine-readable data model ensure that the users of the ENCODE portal can search and identify related experiments, understand how assays were performed, and track the provenance of the data. Currently the ENCODE portal hosts data from more than 15 thousand datasets, representing experimental results of more than 40 diverse assay types, performed in multiple cell lines and tissues under various conditions. The portal provides free access to over 640 terabytes of raw experimental, processed, and analysis data files with the corresponding metadata.

Richness, diversity, and structure of the data on the ENCODE portal make it an invaluable resource for the scientific community. The presence of curated and standardized experimental results from ChIP-seq, DNase-seq, ATAC-seq, HiC and ChIA-PET assays, that were uniformly processed, makes the portal into a one-stop shop for a chromatin investigator. Here we show how the ENCODE portal can be used as a multifaceted lens for chromatin exploration.

## **PgmNr 3328: Pediatric age acceleration: Potential biomarker for individual differences on the effects of maternal mental health on child development.**

Maternal anxiety is associated with adverse behavioural and socioemotional outcomes that vary markedly at the level of the individual child. There is a need for the development of biomarkers of exposure that reflect variation of this impact at the level of the individual child. Epigenetic clocks, which derive estimates of biological age on the basis of DNA methylation, have emerged as clinically relevant biomarkers that predict adverse health outcomes in adults. Error within more well-established epigenetic clocks ( $\geq 3.6$  years) limits predictive power for understanding child development. A new epigenetic clock specifically designed for use in children, the pediatric clock (error = 0.35 years), has recently been developed and shown to associate with measures of child neurodevelopment. In this project, we used longitudinal DNA methylation data to examine how prenatal and postnatal maternal anxiety scores associated with epigenetic aging in children. All pediatric clock analyses were benchmarked against the conventional epigenetic clock. We hypothesized that increased maternal anxiety would show a corresponding increase in pediatric epigenetic aging and that pediatric clock estimates would provide a more robust association than using conventional epigenetic clock estimates. Generalized linear models indicated an association between increased prenatal maternal anxiety and accelerated epigenetic aging in both the pediatric clock and the conventional epigenetic clock. These analyses highlight the potential for the pediatric clock as a biomarker for variation in effects of maternal prenatal anxiety at the level of the individual child.

## PgmNr 3329: EM-seq enables accurate and precise methylome analysis of challenging DNA samples.

DNA isolated from blood draws (cell-free DNA (cfDNA)) or from archival material like formalin fixed paraffin embedded (FFPE) tissues have advanced the field of cancer genetics. DNA methylation (5-methylcytosines (5mC) and 5-hydroxymethylcytosines (5hmC)) is a key epigenetic factor that plays an important role in cellular processes and it's misregulation results in diseased states like cancer. Advances in the field of sample preparation from biological matrices and genomics have enabled cancer biomarker identification based on methylation profiling.

Bisulfite sequencing is the standard method to detect methylation and has been employed for both targeted and whole genome methylation analysis. However, the chemical based bisulfite conversion of cytosines to uracils also results in DNA damage which subsequently results in shorter DNA insert sizes as well as introducing bias into the data. Hence, analysis of DNA methylation from cfDNA and FFPE DNA is challenging as the DNA is typically of low quality and quantity. Robust biomarker detection relies primarily on the ability to profile methylation accurately. To overcome the drawbacks of bisulfite sequencing, we developed an enzyme based methylation detection technology, called NEBNext® Enzymatic Methyl-Seq (EM-Seq™), that minimizes damage to DNA enabling longer insert sizes, lower duplication rates and minimal GC bias resulting in more accurate quantification of methylation in the sample DNA.

Using EM-Seq, we profiled clinically relevant cfDNA and FFPE DNA from multiple tissue types. Results for these challenging DNA types showed that the EM-Seq libraries had longer inserts, lower duplication rates, higher percentages of mapped reads and less GC bias compared to WGBS libraries. These libraries also identified a higher number of CpGs and the estimated global methylation levels were in good agreement with the absolute levels quantified using LC/MS. In conclusion, EM-Seq libraries have superior sequencing metrics resulting in robust methylation profiling for these types of challenging DNA samples.

## PgmNr 3330: OSCA: A tool for omic-data-based complex trait analysis.

---

The rapid increase of omic data has greatly facilitated the investigation of associations between omic profiles such as DNA methylation (DNAm) and complex traits in large cohorts. Here, we propose a mixed-linear-model-based method called MOMENT that tests for association between a DNAm probe and trait with all other distal probes fitted in multiple random-effect components to account for unobserved confounders. We demonstrate by simulations that MOMENT shows a lower false positive rate and more robustness than existing methods. MOMENT has been implemented in a versatile software package called OSCA together with a number of other implementations for omic-data-based analyses.

## PgmNr 3331: DNA hydroxymethylation levels may explain environment-specific epigenetic changes: An example of smoking-discordant monozygotic twin pairs by more than 10 pack years.

### Authors:

S.J. Lee <sup>1</sup>; E. Kim <sup>2</sup>; H.Y. Shin <sup>2</sup>; J. Kim <sup>2</sup>; S. Li <sup>3</sup>; J. Hopper <sup>3</sup>; J. Lee <sup>1</sup>; J. Sung <sup>1,2</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Institute of Health and Environment, Seoul National University, Seoul, Republic of Korea; 2) Department of Epidemiology, Graduate School of Public Health, Seoul National University, Seoul, Republic of Korea; 3) Centre for Epidemiology & Biostatistics, Melbourne School of Population & Global Health, The University of Melbourne, Victoria, Australia

Unlike genetic influences on DNA methylation (Gen-DNAM), the DNAm specific to environmental exposure (Env-DNAM) is less reproducible, mainly due to the composite and cumulative nature of environmental influences. The authors first hypothesized that the presence of ubiquitous genetic influences further confounds the Env-DNAM of the methylome-wide association studies (MWAS). To test our hypothesis, authors dissected 18,496 smoking-associated epiloci from a large population study into Env-DNAM and Gen-DNAM. 1) Env-DNAM: an MWAS involving 33 smoking-discordant monozygotic twin pairs (MZs) with more than a 10 pack-year difference; and, 2) Gen-DNAM: methylation quantitative trait loci (MeQTLs) for 534 participants. Presumably, pure Env-DNAM, if exists, would evade MeQTL controls but show strong signals in the discordant MZ comparison.

About 21% (3,865 out of 18,496) of the candidate smoking-associated epialleles were under strong MeQTLs, and 842 loci were replicated for the smoking-discordant MZ analysis (Bonferroni corrected  $p < 0.05$ ). A reverse correlation existed between the extent of Gen-DNAM ( $= -\log(p)$  of MeQTL) and Env-DNAM ( $= -\log(p)$  of MZ control) for the same CpG probes. Notably, CpG loci on the *AHRR* (hypo-), *MYO1G* (hyper-) and *F2RL3* (hypomethylated) were the top hits from the MZ analysis with none or weak genetic influences.

We further hypothesized that the mechanisms of the Env-DNAM being initiated by the over-expression of genes, either through active demethylation or through increases in gene copies. We did not find any evidence that the copy number of the CpG sites differs, which negated the possibility that the association might have resulted from gene copy changes. We measured 5-hydroxymethylcytosine (5hmC) levels as a marker of active demethylation, which is indistinguishable from plain methylation (5-methylcytosine, 5mC) in conventional analysis. For hypomethylated loci in *AHRR* (smokers) showed significant decreases in 5hmC, whereas hypermethylated loci in *MYO1G* showed random patterns in 5hmC.

In conclusion, our findings suggest that even with a mild correlation with exposure, genetics may paradoxically comprise a large part of environment-DNAM associations further complicating the complex Env-DNAM; and, for the specific Env-DNAM changes, the active demethylation process of

over-expressed genes might provide one mechanical explanation for the hypomethylated changes.

## PgmNr 3332: A database of experimentally tested regulatory relationships relevant to brain development and disorder.

Disruption in transcriptional regulation during early brain development is implicated in neurodevelopmental disorders. For example, mutations in several transcriptional regulators including TBR1, MYT1L, and CHD8 have been causally linked to autism. Genome-wide regulatory network models reconstructed using high-throughput functional genomics data have immense potential in identifying the transcriptional mechanisms associated with the etiology of neurodevelopmental disorders. Due to the lack of a reliable gold standard dataset of direct regulatory relationships, it is currently difficult to evaluate and effectively utilize these predicted network models. We have undertaken the first large-scale attempt to assemble a database of experimentally tested direct regulator-target relationships with relevance to the developing brain by mining the published literature. For each one-to-one relationship, we establish confidence by finding and integrating multiple lines of experimental evidence obtained from transcription factor (TF) perturbation, TF binding, and reporter gene assays. To date, we have identified more than 1000 direct regulatory relationships involving approximately 200 transcription factors. Curated factors include key regulators of brain development such as PAX6, SOX2, and POU5F1. We estimate that we have captured approximately 25% of all experimentally tested relationships relevant to the development of the central nervous system (CNS). Moreover, most regulatory relationships in our database are supported by at least two independent lines of experimental evidence. More than 100 of the relationships include evidence of specific activity in the embryonic mouse CNS. The results of our curation have highlighted that the research literature is dominated by investigations into a small number of transcription factors. Finally, to demonstrate a use case for this resource, we show that a set of putative targets regulated by Pax6 in the embryonic mouse forebrain, detected by intersecting publicly available ChIP-seq and TF knockout transcriptomic datasets, is significantly enriched for the target genes recorded in our database. In summary, we provide a set of experimentally tested, high confidence regulatory relationships to support the inference of large-scale regulatory networks using high-throughput approaches as well as more reliable investigations into the transcriptional regulatory mechanisms involved in neurodevelopmental disorders.

## PgmNr 3333: Functions and dependency of enterocyte-specific enhancers at the *CFTR* locus.

The cystic fibrosis transmembrane conductance regulator (*CFTR*) gene is a large gene with multiple tissue-specific *cis*-regulatory elements (CREs) located in introns and intergenic regions. Among these are enhancers that recruit transcription factors (TF) governing the cell-type specific expression of *CFTR*. We showed previously that the boundaries of the *CFTR* topologically associating domain (TAD) are conserved among diverse cell types, and are dependent on CCCTC-binding factor (CTCF) and the cohesin complex. Within the TAD, enhancers coordinate the loading of TFs onto the gene promoter by cell-specific looping mechanisms. Here we focus on the interactions and dependency of multiple CREs in one cell type: enterocyte-like intestinal epithelial cells. We removed CREs individually and in pairs and measured the effects on *CFTR* expression by RT-qPCR and locus architecture by circular chromatin conformation capture followed by deep sequencing (4C-seq). Enhancers looping is known to be dependent on CTCF recruitment, though non-CTCF binding enhancers may also impact chromatin structure. We identified a new role for a well-studied non-CTCF binding enhancer in the first intron of *CFTR*, showing it is critical for both chromatin structure and gene expression. Another strong enhancer in intron 11 is essential for enterocyte expression of *CFTR*, but has little impact on locus architecture. Combined deletion of these two enhancers abolished *CFTR* transcription and caused a major reorganization of locus structure. Our data suggest the cooperation of enhancers with different roles in regulating *CFTR* transcription: the first has an active role in modulating chromatin structure but modest enhancer function; the second is a strong enhancer with apparently little independent impact on locus architecture. Current experiments are aimed at elucidating the cooperative mechanism of these two intronic enhancers in intestinal epithelial cells and may have broader application to the function of enhancers genome-wide.

This work is supported by the NIH (R01 HL094585) and CFF (Harris 16G0).

## **PgmNr 3334: Chromatin state annotations across 833 tissue/cell types help annotate thousands of additional GWAS loci.**

Large-scale community projects have generated rich epigenomic datasets, with either broad coverage (hundreds of cell types for some assays) or deep coverage (dozens of assays for some cell types). However, owing to cost, time, sample availability, or limited experiment success rates, it has not always been possible to map every assay in every cell type.

Here, we enhance and complete the matrix of ENCODE datasets to enable integrative analyses of gene regulation and disease mechanism, by aggregating, processing, and imputing 30+ epigenomic assays across 800+ human cell types. These include ChIP-seq on histone marks, chromatin regulators, and DNase-seq, painting a rich picture of the non-coding landscape in each cell type.

We combine the resulting imputed maps with experimentally-observed maps to annotate regulatory elements in each cell type using an 18-state chromatin state model with ChromHMM, including enhancer, promoter, repressed, bivalent, and transcribed regions.

We cluster the resulting regulatory annotations across cell lines to infer functional modules of co-regulated elements, and to distinguish constitutive vs. lineage- and cell-specific regions. We also predict driver motifs and co-regulatory motifs in each cluster based on their enrichment in digital genomic footprints (DGF) and surrounding regions. We prioritize cell types for traits and diseases by evaluating GWAS enrichment in enhancers from both full epigenomes and functional modules. We find that novel epigenomes help prioritize an additional 33% GWAS studies over existing annotations and are the strongest associated samples in 64% of all GWAS with significant enrichments.

Lastly, we characterize transitions between cell types and states by their changes in enhancer, promoter, and repressed modules, and we use these transitions to link enhancers to their target genes using coordinated expression changes, and to predict key transcription factors and chromatin regulators involved in cell fate transitions.

## PgmNr 3335: Isolating protein-occupied open chromatin regions.

Modern technology and recent advances in genomics have given rise to a variety of high-throughput methods that interrogate regulatory function of the human genome. In particular, the advent of techniques that measure open chromatin have enabled the identification of loci of active regulatory elements. These methods, in addition to mapping open chromatin, have been widely used to characterize footprints of transcription factors (TFs). The ability to infer TF binding motifs from footprints is dependent upon the lack of sequencing coverage over the footprint (strength of binding of TF) within open chromatin regions. This presents an unmet challenge for critical TFs that do not associate as strongly or as frequently with their binding sites. Indeed, it has been well documented that some TFs present very clear footprints (e.g. CTCF) while others lack any discernable difference in chromatin accessibility and footprinting techniques for these perform no better than a basic motif match. Here we present an orthogonal open chromatin assay that isolates TF binding footprints to be made into sequencing libraries. Briefly, we use micrococcal nuclease to extensively digest crosslinked chromatin to mononucleosomal size and extract the low molecular weight fragments. These fragments represent protein-occupied open chromatin regions protected from nuclease digestion. Analysis of these regions will allow us to finely map functional units within open chromatin and better understand how these regions are utilized in eukaryotic gene regulation.

---

DNA methylation at CpG dinucleotides is one of the most extensively studied epigenetic marks due to its control of gene expression and critical importance in normal development. With technological advancements (e.g., DNA methylation microarrays and bisulfite sequencing), geneticists can profile DNA methylation at increasingly higher resolutions. However, different DNA methylation profiling platforms differ in their resolutions, hindering joint analysis. We have proposed a penalized functional regression (PFR) model to impute missing-by-design methylation levels and demonstrated the power of our PFR approach: it excelled alternative methods when imputing the Illumina HumanMethylation450 (HM450) BeadChip from the HumanMethylation27 (HM27) BeadChip. Here, we extend our method to impute from HM450 to ~850K CpG sites on the HumanMethylationEPIC (HM850) BeadChip, by ensembling with 4 additional methods, K-nearest-neighbors, logistic regression, random forests, and XGBoost, to further increase imputation accuracy. We analyzed data from two population cohorts measured both by HM450 and HM850: the Extremely Low Gestational Age Newborns (ELGAN) study ( $n=127$ ) and the Posttraumatic Stress Disorder (PTSD) study ( $n=144$ ). We assess three datasets: ELGAN and PTSD separately, and a combined dataset with batch effects corrected via the ComBat R function. The cross-validation results show that there is no uniformly best imputation method across the three datasets, which inspires the use of ensemble method. For example, in the PTSD dataset, the ensemble method achieves the lowest predicted MSE (0.0007) and the highest accuracy (99.97%) compared with individual methods. Specifically, the predicted MSE of the ensemble method improved by 28.5% compared with the second-best method (PFR), by 85.7% compared with random forest. Among all 339,033 EPIC-only CpG sites shared between ELGAN and PTSD after quality control, 289,604 (85.4%) exceeding a threshold of 0.0025 for the probe-level predicted MSE and a threshold of 95% for the probe-level predicted accuracy when dichotomizing DNA methylation level at a cutoff of 0.5. In summary, our data highlight that the ensemble method outperforms all the individual methods when imputing from HM450 to HM850, which will boost power for discovery in subsequent epigenome-wide association studies.

## PgmNr 3337: A pipeline to predict prenatal air pollution exposures using DNA methylation data.

---

DNA methylation has been associated with air pollution such as prenatal exposure to polycyclic aromatic hydrocarbons (PAH), fine particulate matter (PM<sub>2.5</sub>), nitrogen dioxide (NO<sub>2</sub>), etc. As air pollution leave traces on a person's epigenome, it is of interest to use DNA methylation measures to recover exposure history. Using the 432 newborns from the mother/newborn (M/N) cohort of the Columbia Center for Children's Environmental Health (CCCEH) whose cord blood DNA methylation measures using Illumina arrays and pregnancy PM<sub>2.5</sub> and NO<sub>2</sub> are available, we developed a pipeline that identifies cord blood DNA methylation signatures that predict binary (high/low) prenatal exposure to air pollutants. The pipeline starts by randomly splitting the M/N cohort into training (50%) and testing (50%) sets and then selects 500 top ranked CpGs that differ between the high/low exposure groups by two-sample t-test p-values. Random Forest (RF) is then applied using CpGs from the selected 500 CpGs with a grid search increasing number of CpGs ranked by importance measures. The aim is to select the optimal number of informative CpGs that best predict air pollution levels. The procedure was repeated 200 times and the final air-pollution predictor is the RF model with the highest mean area under the receiver operating curve (AUC). This pipeline generated two good (significant prediction with a 95% confidence interval not covering random chance) air pollution predictors, a predictor of high/low NO<sub>2</sub> exposure during the entire pregnancy with 130 CpGs (testing set mean AUC=0.605, 95% CI=(0.517, 0.687)) and a predictor of high/low 3<sup>rd</sup> trimester NO<sub>2</sub> exposure with 160 CpGs (testing set mean AUC=0.602, 95% CI=(0.506, 0.693)). Using an internal validation cohort of siblings of the M/N children, we demonstrated the predictability of selected DNA methylation signatures for NO<sub>2</sub> during these pregnancy periods (entire pregnancy AUC=0.561 (0.525, 0.593), 3<sup>rd</sup> trimester AUC=0.587 (0.553, 0.622)). These results demonstrate that this newly developed pipeline has potential to be used to successfully recover exposure history of air pollutants.

## PgmNr 3338: Transcribed cis-regulatory elements across primates.

---

Unveiling regulatory roles of non protein coding regions within the human genome has been a major challenge in assessment of the impact of genome variations on gene expression underlying physiology and disease states. The FANTOM5 consortium identified promoters and transcribed enhancers by monitoring transcription initiation activities in a wide range of samples consisting of primary cells, tissues, and cell lines (Forrest et al 2014; Andersson et al 2014), by using CAGE (Cap Analysis of Gene Expression) that determine capped-5' ends of RNAs in a nucleotide resolution (Kanamori-Katayama et al. 2011). We subsequently found that only a limited fraction of human cis-regulatory elements, in particular enhancers, have corresponding regions in mouse. The lack of such corresponding regions hinders analysis of cis-regulatory regions from the aspect of transcriptional activity and evolution.

To cope with the problem, we mapped cis-regulatory elements in two species of non-human primates (NHPs), crab-eating macaques (*Macaca fascicularis*) and common marmosets (*Callithrix jacchus*) by using CAGE. We collected more than hundreds of tissue samples from the both species, and found a similar magnitude of promoters and enhancers to human. Our data indicated that a larger fraction of corresponding regions to the human promoters and enhancers are transcriptionally active in the non-human primates than mouse. Our data set provides a unique opportunity to study human cis-regulatory elements from both of the functional and evolutionary aspects.

## **PgmNr 3339: Extent, heritability, and functional relevance of single cell expression variability in highly homogeneous populations of human cells.**

### **Authors:**

---

**INTRODUCTION:** Because of recent technological developments, single-cell assays such as single-cell RNA sequencing (scRNA-seq) have become much more widely available and have achieved unprecedented resolution in revealing cell heterogeneity. The extent of intrinsic cell-to-cell variability in gene expression, or single cell expression variability (scEV), has thus been increasingly appreciated. However, it remains unclear whether this variability is functionally important and, if so, what its implications are for multi-cellular organisms.

**METHODS:** We therefore analyzed multiple scRNA-seq data sets from lymphoblastoid cell lines (LCLs), lung airway epithelial cells (LAECs), and dermal fibroblasts (DFs). For each of the three cell types, we estimated scEV in homogeneous populations of cells; we identified 465, 466, and 291 highly variable genes (HVGs), respectively.

**RESULTS:** These HVGs were enriched with specific functions precisely relevant to the cell types, from which the scRNA-seq data used to identify HVGs were generated---e.g., HVGs identified in lymphoblastoid cells were enriched in cytokine signaling pathways, LAECs collagen formation, and DFs keratinization. HVGs were deeply embedded in gene regulatory networks specific to corresponding cell types. We also found that scEV is a heritable trait, partially determined by cell donors' genetic makeups. Furthermore, across genes, especially immune genes, levels of scEV and between-individual variability in gene expression were positively correlated, suggesting a potential link between the two variabilities measured at different organizational levels.

**CONCLUSION:** Our results support the 'variation is function' hypothesis, which argues that scEV is required for higher-level system function. Quantifying and characterizing scEV in relevant cell types may deepen our understating of normal as well as pathological cellular processes.

## PgmNr 3340: Genome-wide unliganded estrogen receptor 1 (ESR1) binding in human liver.

**Authors:**

J. Collins; D. Ling; D. Wang

[View Session](#) [Add to Schedule](#)

**Affiliation:** Department of Pharmacotherapy and Translational Research, College of Pharmacy, University of Florida, Gainesville, FL, 32610.

---

The estrogen receptor 1 (ESR1) has been implicated in the transcriptional regulation of thousands of genes. Canonically, ESR1 is activated by its ligand estradiol (E2). However, the role of unliganded ESR1 in transcriptional regulation has been gaining attention in the last decade. For example, ChIP-Seq experiments detailing ESR1 DNA-binding sites in breast cancer cells implicated distinct binding profiles for the liganded and unliganded forms of ESR1, and that unliganded ESR1 plays a key role in transcriptional regulation of genes with developmental function (Caizzi et al. 2014; Bojcsuk et al., 2019). Previous results generated in our lab indicate that unliganded ESR1 also plays a role in liver cells, functioning as a major regulator of several cytochrome P450 (CYP) genes (Wang et al., under review). Also, alternative ESR1 isoforms lacking N-terminal and C-terminal motifs known to exhibit altered transactivation and DNA-binding profiles (Flouriott et al., 2000; Hattori et al., 2017) are predominant in liver tissue (Sun & Wang, unpublished). In an effort to improve our understanding of transcriptional regulation by ESR1 in the liver, ESR1 ChIP-Seq was conducted in human hepatocytes and in liver tissue. To differentiate between liganded- and unliganded-ESR1 binding sites, hepatocytes were treated with or without 17beta-estradiol (E2) for 12 hrs. Preliminary analyses indicate approximately 700 ESR1 binding sites shared among all samples and that ESR1 enrichment occurs at proximal promoter regions, the 5'UTR, the introns of genes and intergenic regions. Interestingly, similar to studies in breast-cancer cells, unliganded ESR1 bound to 679 unique sites. Furthermore, in both the liver and E2-treated samples, the Estrogen Response Element (ERE) was identified as an ESR1-enriched motif, but not in the unliganded ESR1 sample. This indicates that in the liver, binding of unliganded ESR1 to DNA may instead occur through interaction with additional transcription factors, as suggested by Bojcsuk et al. (2019) and supported by our previous data (Wang et al., under review). Overall, these results further support a role of unliganded ESR1 in transcriptional regulation in liver. Characterization of ESR1 genomic occupancy and identifying genes associated with differential ESR1 binding will provide insight into the function of ESR1 in liver and its implications in liver drug metabolism and liver diseases.

## PgmNr 3341: Haplotype-specific binding among by transcription factors in human brain tissue.

---

Gene expression variation is crucial to both normal biology and disease, and can be mediated by transcription factors (TFs) binding to cis-regulatory sequences. Genetic variation that alters TF binding can thereby lead to altered gene expression levels. However, finding variants that alter TF binding is a challenge. To characterize the binding patterns of TFs in human brains, the HudsonAlpha Brain TF Project is performing ChIP-seq on up to 100 TFs in 9 anatomically-defined brain regions from multiple donors. This project has also generated other datasets, including RNA-seq and phased genome sequences. We have thus far generated 250 distinct maps of TF binding for 15 TFs. We have analyzed these data to search for variants that alter TF binding. In particular, we used the phased genome sequences to create haplotype-specific reference genomes against which ChIP-seq reads were aligned. We then identified loci in which a donor is heterozygous for one or more variants and there exists a haplotype-specific bias in the number of ChIP-seq reads. As our approach integrated phased genomic variants into a reference genome, we greatly reduced reference-haplotype alignment bias and can also detect the effects of multiple nearby variants in cis. Even after stringent FDR corrections, we find hundreds of cases of haplotype-specific binding in each donor, many of which occurred in promoters. Variants altering TF-binding in one tissue often had consistent effects in other tissues, supporting their sequence-dependent effects on TF preference. Similarly, specific haplotypes frequently showed congruent TF bias across donors, further supporting robustness of our analysis. We intersected these events with the location of TF-binding motifs, and discovered that the production or destruction of a motif frequently had an unexpected impact on binding. We also examined deltaSVM and CADD scores to determine how well these capture TF binding effects. We plan to integrate this data with phased variants in RNA data to identify cases where haplotype-specific binding is associated with a change in mRNA production, and generate a more comprehensive view of genetic effects on gene regulation in human brain.

## PgmNr 3342: Sex differences at the molecular level: Lessons from the human transcriptome.

To understand the basis of organismal sex differences, characterization of sex differences at the molecular level is warranted. Here, we explore the role of sex on a variety of transcriptome-related phenotypes in 44 tissues of the Genotype+Tissue Expression (GTEx) project (v8 release). We performed differential gene expression analysis and identified 12,627 (FDR<0.05) sex differentially expressed genes (sexDEGs) in at least one tissue. Tissue-shared sexDEGs are generally more highly expressed in females and enriched for X-linked genes. Across-tissue meta-analysis (*MASH*, FDR<0.05) identifies 20,023 sexDEGs and higher tissue sharing: sexDEGs shared across all 44 tissues increase from dozens to hundreds, ~93% of which are located on autosomes and distribute non-randomly across the genome. To characterize tissue similarities based on sex-biased gene expression, we compared tissue clusters based on sexDEG effect sizes to those based on transcriptome abundances. Tissues cluster similarly by both metrics, but we observe differences in the strongly supported clustering of immune-rich tissues, which are very similar at the transcriptome level but notably different for sexDEGs. We identify 44 male- and 16 female-specific gene networks across tissues with *BicMix*, including breast sex-specific networks enriched for milk secretion and hormone genes. Overall, breast is the most sex-differentiated tissue. Based on *xCell* cell-type estimates, endothelial and epithelial cells are more abundant in male and female breast, respectively. For cis-eQTLs derived by the GTEx Consortium, we performed a genotype-by-sex interaction test and identified 445 sex-biased eQTLs (sb-eQTLs), ~70% in breast (FDR<40%), of which 24% validate with allelic fold change. More than 50% of breast sb-eQTLs are mediated by cell abundances, suggesting these sb-eQTLs are eQTLs specific to cell types(s) that correlate with sex. To explore sex differences in the genetic architecture of disease, we performed colocalization analysis (*coloc*) between eQTLs and summary statistics from 87 GWASs and identified dozens of sex-biased colocalized loci (PP4>0.5). For HKDC1

and CRLF3, birth weight and breast cancer GWAS signals colocalize with female ( $PP4=0.83, 0.66$ ) but not male ( $PP4=0.07, 0$ ) eQTLs in liver and breast, respectively. Collectively, our integrative analyses provide the most comprehensive characterization to date of sex differences in the human transcriptome, with implications for complex traits.

## PgmNr 3343: Do *Alu* elements in intron affect alternative splicing? Identification of minimum sequence of inducing downstream exon skipping within antisense partial *AluSx* element in a minigene model.

### Authors:

M. Nakama <sup>1,2</sup>; H. Otsuka <sup>2</sup>; Y. Ago <sup>2</sup>; H. Sasai <sup>1,2</sup>; E. Abdelkreem <sup>2,3</sup>; Y. Aoyama <sup>2,4</sup>; T. Fukao <sup>1,2</sup>

[View Session](#) [Add to Schedule](#)

### Affiliations:

1) Clinical Genetics Center, Gifu University Hospital, Gifu, Japan; 2) Department of Pediatrics, Graduate School of Medicine, Gifu University, Gifu, Japan; 3) Department of Pediatrics, Faculty of Medicine, Sohag University, Sohag, Egypt; 4) Education and Training Center of Medical Technology, Chubu University, Japan

**BACKGROUND:** *Alu* elements are known as primate-specific repeats and commonly locate in introns. We have been analyzing effects of *Alu* elements on alternative splicing. We recently reported that antisense *AluSx* inserted in intron 9 affected exon 10 skipping in a minigene model consisting of exons 9–11 of the *ACAT1*, especially when splice acceptor sites are suboptimal (Nakama et al., 2018). Here, we further examined to identify the minimum sequence elements in the intronic antisense *AluSx* affecting RNA splicing in the same model.

**METHODS:** We have a minigene splicing vector consisting of exon 9-intron 9-exon 10-intron 10-exon11 of *ACAT1* in a pCAGGS. An *AluSx* originally from intron 5 of *ACAT1* gene was inserted into intron 10 (-226 bp from the beginning of exon 10) with antisense-direction in the above vector. The *AluSx* consists of two similar, but distinct monomers-the left and the right arms. Hence first we made antisense left arm or right arm constructs separately to examine which arms could affect splicing. We then generated further fifteen deletion constructs. Each expression vector was transfected into SV40-transformed fibroblasts from a patient with *ACAT1* deficiency. RNA was harvested from the transfected cells and was reverse-transcribed by strand-specific primer and oligo(dT) primer. Chimeric cDNAs (fusion of human *ACAT1* with rabbit beta-globin) were amplified.

**RESULTS:** Exon 10 skipping was more effectively observed in the antisense right arm than full-length antisense *AluSx*. Analysis of successive deletion mutants confirmed a minimum sequence element of 23 bp within the right arm. Exon 10 skipping was less effectively observed in the antisense left arm only than full-length antisense *AluSx*. The corresponding region to the minimum sequence element of 23 bp within the right arm was 22 bp in the left arm and also responsible for exon 10 skipping. These two minimum sequence elements in *AluSx* had a character of splice acceptor site sequence.

**DISCUSSION:** We identified minimum sequence elements, 23 bp and 22 bp in the right arm and left arm, respectively, for affecting downstream exon skipping. Especially, the identified sequence in the the right arm was highly conserved in other *Alu* subfamilies and was predicted as new splice acceptor site by *in silico* splicing analysis. Our experiments suggested the intronic antisense-orientation partial *Alu* sequence (just a few dozen nucleotides) triggered a downstream exon skipping.

## PgmNr 3344: An epigenome-wide association study revealed novel epigenetic factors for childhood asthma in East Asians.

Asthma is a heterogeneous disease arise from complex interaction between genetic and environmental factors. To date, numerous genetic factors responsible for asthma have been discovered. However, identifying epigenetic changes, reflecting variation of environmental factors, of asthma is relatively in the early stage compared to those of genetic factors. Moreover, majority of previously reported epigenome-wide association study (EWAS) for asthma were conducted in populations with European ancestry. In this study, we performed EWAS on childhood asthma comprising 41 asthma cases and 29 controls of East Asians (Korean). Asthma cases were diagnosed by physician and controls were selected if no history of asthma. Genome-wide DNA methylation were profiled by using Illumina Infinium HumanMethylation 450K BeadChip. Raw data were quality controlled and quantile normalized prior to further analysis. A two-sample t-test was used to determine epigenetic difference between cases and controls. As a result, four differentially methylated regions (DMR) discovered at  $P < 1 \times 10^{-4}$  near *CDV3*, *ABCB9*, *RNF144B*, and *FOXC1*. Of note, *RNF144B* is known to be involved in Class I MHC mediated antigen processing and presentation. We further assessed DMRs at  $P < 5 \times 10^{-2}$  and performed functional annotation analysis to understand possible biological role of genes closely located near DMRs. Pathway analysis revealed top associated KEGG pathway 'Natural killer cell mediated cytotoxicity' consisting of seven genes: *MICA*, *VAV3*, *PIK3CB*, *FASLG*, *HLA-C*, *PAK1*, and *HLA-E*. Collectively, this study provides valuable knowledge of epigenetic factors for asthma and its possible role in the pathogenesis of asthma.

## PgmNr 3345: RegulomeDB 2.0.

The rapid growth of human genome sequencing has identified a large number of genetic variants present in the human genome relevant to human disease and other phenotypes. The majority of sequence variation is found within the noncoding regions of the genome where it is presumed to affect gene regulatory elements. We have developed a unique web-accessible database, RegulomeDB, which provides integrated knowledge of existing information describing regulatory elements that lie within noncoding regions. The RegulomeDB v1.1 (<http://www.regulomedb.org/>) was originally built from ENCODE and other community data, and has proven to be a useful tool for noncoding variant annotation. Various genomic information, including eQTL, transcription factor binding, chromatin modification and DNA methylation have been integrated into a common database and displayed at nucleotide resolution. Researchers are able to compare variants of their interest to the wealth of information in RegulomeDB, and rapidly gain insight into possible mechanism of gene regulation. In order to keep up with emerging genome sequencing projects and provide an up to date regulome annotation, we have integrated RegulomeDB into the ENCODE portal, as RegulomeDB v2.0 (<https://regulome-master.demo.encodedcc.org/regulome-search/>). We are also investigating improved annotation with new data types and integration of novel, statistical scoring methods. Overall, we expect this unique resource to have wide impact in the biomedical community.

## PgmNr 3346: Heritability of common complex traits is enriched at topologically associating domain boundary regions.

**Background:** The 3D conformation of the genome plays an integral role in regulating gene expression. However, the effects of the interaction between genetic variation and 3D architecture on phenotypes are incompletely understood. On a sub-chromosomal scale, chromatin folds into topologically associating domains (TADs), regions that commonly self-interact, but rarely contact outside chromatin. TADs, and the boundaries between them, modulate gene regulation by restricting interactions of regulatory sequences, like enhancers, to their target genes. Structural variation that disrupts the insulating effects of TAD boundaries has been implicated in rare developmental phenotypes. Smaller-scale variants, like SNPs, also have the potential to disrupt TAD boundaries, but the overall contribution of such variants to phenotypes is not known.

**Methods:** We hypothesized that common genetic variants modulate TAD boundaries' effects in ways that are relevant to complex disease. To investigate the relationship between genetic variants in TADs and boundaries with disease, we performed partitioned heritability analysis. We integrated TADs identified from Hi-C experiments in 37 different cellular contexts and, using stratified LD Score Regression, estimated patterns of heritability for 28 complex phenotypes.

**Results:** We show that heritability of many traits is enriched at TAD boundaries, while heritability is not enriched nor depleted within TADs themselves. Although TAD boundaries are generally conserved among cell types, some are observed in almost all cellular contexts, while others are unique to a single cell type. We find that boundaries seen in multiple cell contexts have higher heritability enrichment than less conserved boundaries. This suggests that common SNPs in conserved boundaries are enriched for functional effects. Indeed, boundaries present across many cell types also have higher sequence conservation. We also observe different heritability enrichment patterns among uniquely cell-specific boundaries.

**Conclusions:** In summary, our work demonstrates enrichment for effects of common variants in TAD boundaries on complex phenotypes. Our results suggest that these variants likely modulate the ability of boundaries to insulate regulatory elements; however, further molecular investigation of their mechanistic effects is needed. Ultimately, our results inform non-coding variant interpretation by quantifying the functional contributions of variants in different 3D contexts.

## PgmNr 3347: GADB: Large-scale, curated functional genomics annotation database.

### Authors:

Large-scale, systematic annotation of genetic variants and genomic regions (SVs, called peaks, etc) generated by different sequencing experiments becomes increasingly important and is a complex part of sequencing-based genomic/genetic analyses. Functional genomic data necessary for systems biology analyses, causal gene analyses, interpretation of GWAS signals are currently distributed across individual data collections such as ENCODE, GTEx, FANTOM5, with no single resource providing centralized, unified annotation information allowing seamless integration, retrieval, comparison of functional datasets across experimental assay types, data types, file formats, etc.

To address this, we built Genomic Annotation Database (GADB) and collected, consistently cataloged and harmonized all genome-wide experiments (>60,000 experiments) from 12 consortia such as ENCODE, FANTOM5, ROADMAP, GTEx, etc. GADB contains annotated collection of >22 billion genomic intervals in >67,000 genome-wide annotation files across >1,100 tissues and cell types annotated using OBO Foundry ontologies which provide a framework for grouping the functional genomics tracks into broader cell and tissue categories.

GADB provides integrated, harmonized, searchable and extensible human functional genomic annotation data collection for genetic and genomic analyses measured by 17 different kinds of experimental assays and >30 data types including xQTL, Hi-C interaction data, epigenetic marks, regulatory elements (enhancers, promoters). All GADB annotation tracks are available in both GRCh37/hg19 and GRCh38/hg38 reference genomes.

All these genomic annotation tracks were systematically annotated with assay type, cell type, tissue category, sample, and other information (21 features) and indexed using GIGGLE (<https://github.com/ryanlayer/giggle>).

On average, each genomic position is covered by 3,000 genomic tracks (>9.5 Trillion bps covered). Following the FAIR principles, we built Spark-based API for querying GADB database. Researchers can use GADB to a) quickly identify relevant experiments and data types in specific tissue contexts for downstream analyses; b) quickly search and retrieve all genomic intervals within the genomic region of interest (>3Billion genomic intervals/sec).

GADB (<http://gadp.niagads.org/>) provides integrated, harmonized, extensible functional genomic data repository allowing for seamless retrieval, comparison across various data sources, tissue/cell types, data types.

## PgmNr 3348: The relationship between telomere length and genome-wide DNA methylation in a Bangladeshi population.

Telomeres are DNA-protein structures that protect chromosomal ends. Telomere length (TL) is a proposed biomarker of biologic aging and of risk for various chronic diseases. DNA methylation (DNAm) also changes with age, and aging is generally associated with increased DNAm at CpG islands and decreased DNAm at non-CpG islands. However, the relationship between TL and genome-wide DNAm has not been extensively studied. In this study, we characterized the association of TL with genome-wide DNAm features and epigenetic aging measures in two cohorts of Bangladeshi adults. DNAm in whole blood was measured at 771,192 CpGs using the EPIC array in the Health Effects of Arsenic Longitudinal Study (HEALS) and 390,810 CpGs using the 450k array in the Bangladesh Vitamin E and Selenium Trial (BEST). After correcting for batch effects, we assessed the association between TL and CpG DNAm using linear models adjusted for age, sex, BMI, smoking status, and cell type composition. We meta-analyzed results from HEALS (n=364) and BEST (n=388) using METAL. Using the DNA Methylation Age Calculator (<https://dnamage.genetics.ucla.edu/>), we computed DNAm age, intrinsic epigenetic age acceleration (EAA) (adjusted for cell type composition), and extrinsic EAA (dependent on changes in cell type composition); and assessed their association with TL.

We identified 100 CpGs that were associated with TL at  $p < 10^{-4}$ . Compared to CpGs not associated with TL, these TL-associated CpGs were enriched in islands and depleted in non-CpG islands ( $p = 0.01$ ). The locational distribution of age-associated CpG differed by direction of association with TL ( $p = 2.9 \times 10^{-5}$ ): negatively associated CpGs (n=75) tended to be located in islands (49%) and shores (32%) while positively associated CpGs (n=25) tended to reside in non-CpG islands (60%). Among HEALS participants, TL was inversely correlated with DNAm age ( $r = -0.21$ ,  $p = 5.2 \times 10^{-5}$ ), consistent with the correlation between TL and age. TL was not associated with intrinsic EAA ( $p = 0.22$ ) but was inversely associated with extrinsic EAA ( $p = 0.02$ ), suggesting longer TL decrease epigenetic age acceleration associated cell type composition.

This analysis revealed that TL was weakly associated with genome-wide DNAm, and these associations with TL were in the opposite direction of age-associated DNAm at CpG islands and non-CpG islands. Additionally, longer TL may be associated with less EAA, suggesting consistency between these biomarkers of aging.

# PgmNr 3349: Landscape of inter-omics interaction of genetic variation, DNA methylation, and gene expression in CD4<sup>+</sup>T lymphocytes, monocytes, and neutrophils.

## Background

Omics, such as genomic variation, DNA methylation (DNAm), and gene expression, are known to interact with each other. eQTL and mQTL (expression-/methylation-quantitative trait locus) are genomic variations that affect gene expression and DNAm, respectively, and eQTM (expression-quantitative trait methylation) is DNAm that affects gene expression. A number of eQTLs, mQTLs, and eQTMs have been reported and information regarding them is available on some databases, which are frequently employed for annotation of signals found through (epi)genome-wide association studies (GWAS/EWAS), with advantages of multi-omics knowledge. Specifically, as profiles of DNAm and gene expression and EWAS signals vary across cell types, inter-omics interactions can also vary across cell types. To address this, we have been working on multi-omics analyses using sorted blood cells with an emphasis on cell type-specificity, and herein, we present results of our multi-omics analyses.

## Methods

CD4<sup>+</sup>T lymphocytes (CD4T) (n = 99), monocytes (n = 99), and neutrophils (n = 94) isolated through fluorescence-activated cell sorting with >95% purity were used in this study. Genotypic data for ~9 million (M) variation sites, DNAm profiles at ~24M CpGs, and gene expression data for ~20 thousand (k) genes were used. To minimize the effect of outliers, we applied filtering strategies on each omics dataset; then, we conducted cis-eQTL, cis-mQTL, and cis-eQTM analyses (cis-proximity: 500kbp). We employed the Bonferroni correction to adjust p-values, and an adjusted p-value of 0.05 was considered statistically significant threshold.

## Results

We analyzed 22M/19M/26M variation-gene pairs, 3 billion/1 billion/3 billion variation-CpG pairs, and 24M/15M/17M CpG-gene pairs, from which we detected 50k/87k/37k eQTLs, 8M/1M/11M mQTLs, and 5k/470/2k eQTMs, respectively (CD4T/monocytes/neutrophils). Among them, 76% of eQTLs, 65% of mQTLs, and 95% of eQTMs were cell type-specific and 3% of eQTLs, 5% of mQTLs, and 0.5% of eQTMs were common across all three cell types studied.

## Discussion

Interactions between omics observed herein differed substantially across cell types suggesting that

multi-omics analyses based on the mixture of heterogeneous cells could lead to important cell type-specific interactions being overlooked. Using the data from our multi-omics interaction analyses, we would be able to infer the functions and consequences of GWAS and EWAS signals more accurately.

## PgmNr 3350: Activity by contact model identifies targets of regulatory variants for smoking and drinking use traits.

---

A recent genome-wide association study for smoking and alcohol use with 1.2 million individuals have identified 406 associated loci. Many of these variants implicated in GWAS are in non-coding regions, which are difficult to interpret. With the advancements in genomic data generating technologies, integrating analysis of multi-omic data types have become an increasingly popular method to improve our understanding of mechanisms behind genotype-trait association. Here we use the recent activity by contact model (ABC) to pinpoint the target gene of active enhancers that potentially harbor GWAS associated regulatory variants. The basis of this model is to identify enhancers in a given cell type based off chromatin accessibility and histone modifications. This is the activity proxy which will be coupled with Hi-C contact data to find the physical interactions between regulatory elements and gene promoters. We have extended this model to the IMR90 cell line and biologically relevant brain tissues, to further understand gene regulation and its role in drinking and smoking. The preliminary application of the model predicted 110,239 and 77,205 enhancers for the IMR90 and prefrontal cortex, respectively. Furthermore, the ABC predicted enhancers were compared to the ChromHMM software that predicts and characterizes chromatin states. For IMR90 and prefrontal cortex, 76% and 65% of the ABC predicted enhancers have enhancer or promoter chromatin state characterizations in ChromHMM. Furthermore, variants associated with three tobacco and alcohol use phenotypes were studied: cigarettes per day (cpd), smoking initiation (si) and drinks per week (dpw). We calculate the enrichment using the ratio of the fraction of genome-wide significant SNPs in the active enhancer region over the fraction of all SNPs in the active enhancer region. We observed 3.1x, 4.2x and 2.8x enrichment for DPW, CPD and SI associated loci in the predicted pre-frontal cortex active enhancers. Enrichment was not seen in IMR90 cell line suggesting that this enrichment is tissue specific. These variants also have ABC quantities greater than the median and implicate target genes based off contact data. In conclusion, our results represent a multi-omic approach to dissect the potential regulatory mechanisms behind smoking and drinking related traits. This method can lead to more targeted experimentation of regulatory variants and their prioritized target genes.

## PgmNr 3351: Characterizing the regulatory architecture of essential genes in the human genome.

The search for essential genes (EG) is the quest to define a minimal set of genes necessary for the survival of a cell or an organism. These genes are known to be more conserved across species, are intolerant to mutations in human populations, are expressed in early development, are enriched for disease genes, and are broadly expressed across tissues. However, the regulatory architecture of this class of genes is not well-understood. In this study, we characterize the regulatory features of genes essential for mouse viability (developmentally lethal, or DL genes), genes essential for viability of human cell lines (CL), and compare these to two control sets of non-essential genes. Specifically, we use publicly available expression and epigenomic datasets to ask if the evolutionary and functional constraint on EGs (DL and CL genes) is also reflected in regulatory constraint. We also try to understand biological differences between cell-line lethality and organismal lethality.

First, we see that DL genes, despite their high levels of expression, are depleted for eQTLs across 49 human tissues. They also have lower variation in gene expression, indicating selection on this set of genes to maintain stability in expression levels. DL genes further show less tissue sharing of eQTLs than CL genes and NEGs. A larger fraction of eQTLs for DLs is found in enhancer and TSS elements compared to other gene classes; this enrichment disappears when we account for the increased enhancer footprint for DL genes. However, we do not see a difference in effect sizes between eQTLs of different gene classes. These results add to the body of knowledge highlighting the important role of enhancers in regulating developmental genes.

Second, using publicly available epigenomic datasets from multiple human tissues, we show that DL genes are enriched for active regulatory elements, and depleted in repressive elements of the genome. In particular, DL genes are most enriched in enhancers, and show significantly less enrichment at TSS elements compared to non-essential genes. In contrast, CL genes show highest enrichment at TSS elements compared to enhancers. CL and DL genes show greater enhancer sharing across tissues, which could explain their breadth of expression.

Through our efforts, we better characterize the regulatory architecture of a set of genes with an outsized role in human disease; these will aid efforts in understanding disease architectures and variant prioritization.

## PgmNr 3352: Contrasting the genetic architecture underlying gene expression levels in European Americans and African Americans: An eQTL mapping study in GENOA.

---

Identifying genetic variants that are associated with gene expression levels, an analysis commonly referred to as expression quantitative trait locus (eQTL) mapping, is an important first step towards understanding the genetic architecture underlying gene expression variation. Most existing eQTL mapping studies have thus far focused on individuals of European ancestry and are noticeably underrepresented in other populations, with a particular absence of large studies in populations with African ancestry. Lack of large-scale, well-powered eQTL mapping studies in populations with African ancestry can both impede the dissemination of eQTL mapping results for benefiting individuals with African ancestry and hinder the comparable analysis for understanding how gene regulations are shaped through evolution. We fill this critical knowledge gap by performing a large-scale in-depth eQTL mapping study on 1,205 African Americans (AA) and 801 European Americans (EA) from the Genetic Epidemiology Network of Arteriopathy (GENOA) study. We identified a total of 422,586 eQTLs in AA and 458,204 eQTLs in EA after controlling for age, gender, population structure and familial relatedness. Among them, only a small percentage of eQTLs (128,915) overlapped between the two populations, highlighting the importance of eQTL mapping in populations with African ancestry. The identified eQTLs from both populations are enriched near transcription start sites and the overlapping eQTLs between populations have consistent effect directions. eQTL harboring genes (eGenes) tend to have higher SNP heritability as well as cis- and trans-SNP heritability compared to non-eGenes. Importantly, eGenes that are common in the two populations tend to be more conserved than eGenes that are unique in one population, which are more conserved than non-eGenes. In addition, through conditional analysis, we also found that eGenes in AA tend to harbor more independent eQTLs than the eGenes in EA, suggesting potentially diverse genetic architecture underlying gene expression variation between the two populations. Overall, our results represent an important step towards revealing the genetic architecture difference underlying gene expression variation between African Americans and European Americans.

## PgmNr 3353: Jointly modeling allele-specific and total expression to identify cis-acting expression outliers in humans.

Non-coding genetic variants can lead to large changes in gene expression and may underly instances of genetic disease. Indeed, a recent study found that individuals with outlier values of total expression ( $|z\text{-score}| > 2$ ) for a given gene harbor an excess of rare variants nearby (Li et al. Nature 2017); however, power to detect expression outliers using total expression is limited and it is challenging to determine whether a particular expression outlier is driven by a cis-acting genetic effect.

We developed a rigorous statistical method to identify rare variant driven outliers by jointly modeling total and allele-specific expression, extending a previous method for identifying quantitative trait loci (WASP: van de Geijn\*, McVicker\* et al. 2015 Nat Methods). By including both total read depth and allele-specific information, we boost power to detect outliers and are able to distinguish between different types of outliers based on model likelihood. The first type, which we are most interested in, is cis-acting effects, where an individual has outlier total expression value and allelic imbalance. The second type is trans-acting effects, where only total expression shows an effect, which could be driven by trans-acting variants or non-genetic factors. Finally, we also identify monoallelic or buffered effects where there is allelic imbalance but no change in total expression. The method directly integrates both total and allele specific RNA-seq count data, taking into account technical effects, overdispersion, and miscalled genotypes (which can lead to false positives).

We applied our method to GTEx RNA-sequencing data from subcutaneous adipose tissue in 350 individuals. We identified 80% more significant expression outliers at 5% FDR (average of 36 vs 20 per individual) with our method, compared to the z-score test for total expression. We then tested whether outliers from each test replicated in visceral adipose tissue from the same individuals using the corresponding test and a nominal  $p\text{-value} < 0.05$ . We replicated 67% of outliers identified by our method, compared to only 23% of outliers identified using the z-score test for total expression. These results indicate that our method provides a powerful approach to detect replicable outliers, even in individual tissues.

## **PgmNr 3354: Gene circuitry mapping assigns validated functional annotation to GWAS non-coding hits: from primary human hepatocytes to culprit disease-associated genes.**

---

Nearly 90% of GWAS hits are in non-coding genomic regions with 57% of these lying in open chromatin regions, suggesting roles in transcriptional regulation. For these variants, the specific functional relevance and impacted genes remain elusive, with most studies currently mapping non-coding variants (NCVs) to genes based on genomic proximity. However, gene transcription is often regulated by enhancer-promoter interactions spanning large distances. We have built a Gene Circuitry Map™ of primary human cells, including hepatocytes, which defines functional cis-regulatory elements, identifies the transcription factors (TFs) that interact with these elements, and elucidates functional long-and short-range enhancer-promoter interactions. Combined with transcriptome-wide analysis of the cellular response to signaling perturbagens, the map empowers the prediction of novel connections between signaling pathways and the transcriptional control of any gene of interest. We used the map to annotate the functionality of NCVs identified in GWAS. To achieve this, 46989 of the 83121 (56%) unique variants in the GWAS catalog (as of 5Apr2019) were mapped into hepatocyte Gene Circuitry regulatory regions, including 7950 (17%) in enhancers or promoters, and 771 (5%) in CTCF chromatin insulator regions (Insulated Neighborhood [IN] boundaries). Also, 41016 (87%) unique NCVs were mapped within INs containing known genes. Next, a focused list of quantifiable liver-specific GWAS traits was compiled encompassing liver function tests (AST, ALT, GGT, bilirubin, prothrombin time), iron regulation (ferritin, iron, transferrin, total iron binding capacity, transferrin saturation), and lipid levels (cholesterol, HDL, LDL, VLDL, triglycerides). Of the 46989 functionally annotated NCVs, 2681 (5.7%) are associated with quantifiable liver traits, out of which 102 (4%) are in known TF motifs, map within INs containing known genes, and map to open chromatin regions defined by ATAC-seq (liver function =14, iron=4, lipid = 84 NCVs). Integration of concordant disruption in motif, transcription binding event and eQTL of a gene in the relevant IN is then poised to deconvolute the pathologic NCV within an LD block. Further experiments are planned to confirm the causal relationship with the downstream gene affected. Our map assigns reliable novel functions to NCVs across the genome, facilitating rapid discovery of disease associated genes and novel mechanisms for their therapeutic management.

## **PgmNr 3355: Better IDEAS: Using epigenetic “fingerprints” to systematically identify disease causal cell types for thousands of traits in the GWAS Catalog and UK Biobank.**

---

Identifying disease causal cell types underlying a genetic association is a crucial step towards understanding disease biology and executing effective target validation experiments. Recent advancements in epigenetic profiling has resulted in a wealth of data that can be leveraged to gain a deep understanding of the genetics of cell type-specific gene regulation. Here, we predicted causal cell types for 1,918 traits in the UK Biobank and 1,098 traits in the NHGRI-EBI GWAS Catalog by matching genetic association signals with cell-type specific gene regulatory elements. We applied Integrative and Discriminative Epigenome Annotation System (IDEAS), a 2D genome segmentation method to annotate regions of the genome with gene regulatory potential in 150 cell types. To estimate the proportion of genetic signal that can be attributed to each cell type for a given trait at locus-level resolution, we developed a method called IDEASpredict that integrates GWAS posterior probabilities from statistical fine-mapping with regulatory elements defined by IDEAS. In contrast to existing enrichment analysis methods, IDEASpredict accounts for the correlation of regulatory events across cell types and estimate the cell types in which causal variants are most likely to be functional.

For traits with more than 10 genome-wide significant loci, we found 20% to have a single cell type explain > 50% of the associated loci, with most of those signals residing in immune related cells. In addition to observing novel and expected enrichments for specific disease-cell type pairs, we also were able to disentangle disease biology for related phenotypes. To illustrate, Crohn's disease had 2x higher enrichment in immune derived cells than ulcerative colitis, while ulcerative colitis had 4x higher enrichment in epithelium derived cells. A comparison between T-cell subtypes for the two traits revealed that while memory T-cells explained 90% of the T-cell related signal for ulcerative colitis, they only explained 18% of the T-cell signal for Crohn's. In summary, we present a new approach to identify cell type-specific enrichments and provide an encyclopedia of cell type annotations at the locus level for 3,016 traits. We expect this approach to substantially improve our ability to take advantage of GWAS to understand complex disease pathobiology and improve the design of in vitro studies to validate prospective therapeutic targets.

## PgmNr 3356: Expression regulatory quantitative trait locus with various functions.

**Authors:**

J. Han; C. Lee

[View Session](#) [Add to Schedule](#)**Affiliation:** Department of Bioinformatics and Life Science, Soongsil University, Seoul, Korea

---

Expression regulatory quantitative trait locus (erQTL) is of a great concern to understand underlying mechanisms of genetic factors for complex diseases. Such a concern has been intensively extended to erQTLs for various kinds of molecular products of genes. The current genome-wide erQTL analysis with transcriptome-wide data revealed cis-acting erQTLs for HLA-DQA1 and MRPL43 by employing a mixed model ( $P < 1 \times 10^{-5}$ ), showing associations with all of the mRNA expression, ribosome occupancy, and protein abundance. Every erQTL was covered by a wide range in strong linkage. In particular, an erQTL was located in a strong linkage at the gene encoding MRPL43. While its minor haplotype increases mRNA expression and ribosome occupancy, it reduces protein level. Further analysis revealed that erQTL was attributed to independent functions of three sequence variants in the locus. One variant may regulate binding affinity of transcription factors. Another variant may change splice site that affect to isoforms of MRPL43. A variant in the isoform with long 3' UTR may strengthen microRNA binding affinity because of its 7-mer seed sequence, which might contribute to the flipped effect from transcription to translation.

Hi-C and chromatin immunoprecipitation (ChIP) have been combined to identify long-range chromatin interactions genome-wide at reduced cost and enhanced resolution, but extracting information from the resulting datasets has been challenging. Here we describe a computational method, MAPS, **M**odel-based **A**nalysis of **PLAC-seq** and **HiChIP**, to process the data from such experiments and identify long-range chromatin interactions. MAPS adopts a zero-truncated Poisson regression framework to explicitly remove systematic biases in the PLAC-seq and HiChIP datasets, and then uses the normalized chromatin contact frequencies to identify significant chromatin interactions anchored at genomic regions bound by the protein of interest. MAPS shows superior performance over existing software tools in the analysis of chromatin interactions from multiple PLAC-seq and HiChIP datasets centered on different transcriptional factors and histone marks. MAPS is freely available at <https://github.com/ijuric/MAPS>.

The Indonesian populations exhibit a striking level of diversity, regional patterns of admixture, and varying degrees of introgression from Neanderthals and Denisovans. Recent studies have characterized the patterns of genetic variation and admixture across the Indonesian islands. Here, we provide a benchmark dataset of molecular phenotypes in Indonesia. We have integrated CpG methylation and RNAseq data from three island populations that capture the major genomic and geographical axes of diversity across the region: Mentawai is representative of the dominant Asian ancestry and Korowai of the regional Papuan ancestry, while Sumba is a near equal mixture of these two ancestries. Moreover, Korowai contains up to 5% of introgressed DNA from archaic Denisovans. Using this approach, we have investigated the between- and within-island variation of two gene regulatory phenotypes: DNA methylation and gene expression. DNA methylation is an epigenetic process that has an essential role in regulating transcription and has been implicated in affecting various complex traits and diseases. Both DNA methylation and gene expression are influenced by environmental and genetic factors, yet little is known about gene regulatory variation at the population level in Indonesia, and how this variation may contribute to important phenotypes, such as immunity.

We report substantial population differences in DNA methylation and gene expression: we identified differentially methylated CpG probes (DMPs) and differentially expressed genes (DEGs) between these genomically distinct populations. We show that the observed variation in gene expression is partially driven by DNA methylation, with the expression levels of 12.6% of the investigated genes

strongly correlating with nearby CpG methylation. These transcriptionally predictive methylated genes partially overlap the DMPs and DEGs between islands. The DMPs, DEGs, and transcriptionally predictive genes were enriched in pathways involved in immunity. Furthermore, we report within-island variation in DNA methylation and gene expression, likely driven by the local environment. Together, these results indicate a causal relationship between genetic variation, DNA methylation, transcription, and immunity, shaped by the environment. These findings have implications to genomic medicine in underrepresented Indonesia, and help us better understand the roles of genomic and environmental effects in shaping molecular and complex phenotypes.

## PgmNr 3359: Novel detection of mitochondrial RNA cleavage sites.

**Authors:**

G. Carbajosa; A. Hodgkinson

[View Session](#) [Add to Schedule](#)

**Affiliation:** Department of Medical and Molecular Genetics, School of Basic and Medical Biosciences, King's College London, London, United Kingdom

---

Human mitochondrial DNA is transcribed as a polycistronic RNA containing multiple genes. To obtain the final gene products, extensive post-transcriptional processing is required, including the cleavage of RNA through the targeting of secondary degree structures by nuclear encoded enzymes. Recent studies have shed some light on the molecular mechanisms underlying these processes, but they are far from completely described, and little is known about whether RNA cleavage sites vary in location and frequency across 'healthy' individuals. We have developed a computational method by which we can infer mitochondrial RNA cleavage sites by assessing the structure of RNA read stacking in standard RNA sequencing libraries, and we apply this to data from over 1000 individuals to infer variation in these processes on the population scale. Using this approach we identify known RNA cleavage sites at gene boundaries, but also a series of events at non-canonical sites that may be driven by post-transcriptional modifications or lead to alternative transcripts that modulate gene expression. By comparing rates of cleavage across individuals with genetic data, we identify common nuclear genetic variation in known RNA processing genes that modulate these processes across individuals (e.g. *MRPP3*), as well as novel roles for genes in mitochondrial RNA cleavage, building a more complete picture of the processes and pathways that ultimately influence mitochondrial function.

## PgmNr 3360: Human enhancers with complex age architectures are more active than enhancers with simple architectures.

### Authors:

S. Fong; J.A. Capra

[View Session](#) [Add to Schedule](#)

**Affiliation:** Vanderbilt University Medical Center, Human Genetics, 2215 Garland Avenue Nashville, TN 37232-0700

Enhancers bind transcription factors (TFs) and regulate gene expression. Variation in enhancer regions can give rise to new gene regulatory functions, but also commonly associates with disease. While evolutionary conservation in protein coding genes is a powerful predictor of variant function, low functional conservation across enhancer landscapes complicates variant interpretation. Thus, new methods for interpreting non-coding variants are needed.

We hypothesize that the age of an enhancer sequence holds information about its function.

Enhancers can be “simple” and consist of a sequence from a single age or “complex” and consist of sequences from different ages—older “core” sequences and younger “derived” sequences—but how age architecture relates to function is not understood.

We explored the relationship between enhancer age architecture and function by integrating sequence alignments from 46 vertebrate species with FANTOM tissue enhancers, transcription factor binding sites (TFBS) from ChIP-seq, and massively parallel reporter assays (MPRAs). Genome-wide, enhancers are enriched in old genomic regions. Over half of current human enhancers occur in sequences from the ancestor of placental mammals, validating previous reports in liver tissue. Sixty-three percent of enhancer sequences[TC1] have simple architectures, while the rest are complex. Both architectures are enriched for GWAS SNPs, but simple have stronger enrichment than complex. However, in MPRAs, enhancers with simple architectures have lower activity than complex enhancers. Within complex enhancers, derived regions have higher activity than older core regions. This supports a model in which the presence of derived regions promotes strong enhancer activity. Indeed, we identify 17 TFs enriched for binding in derived regions. However, derived regions have lower overall TFBS density than simple enhancers and complex cores. Together these results suggest that specific TFs in derived regions promote enhancer function.

Human enhancers have two types of age architectures: simple and complex. These enhancer architectures differ in activity, specific TF binding, and TFBS density. Thus, considering enhancer age architecture may aid interpretations of human regulatory regions, functional targets, and disease variants.

## PgmNr 3361: Genetics of gene expression studies identify RNA polymerase pausing as a regulator of gene expression.

---

Genetic studies of gene expression identify regulators of gene expression. Here we show that RNA polymerase II pausing affects gene expression and can be manipulated to restore aberrant gene expression. DNA-dependent RNA Polymerase synthesizes RNA with punctuated pauses which are coupled to RNA processing and the regulation of transcriptional output. Initially described at the promoters of a few genes, genome-wide studies have found RNA polymerase pausing to be a common feature of transcription in metazoans. To assess the effect of RNA Pol II pausing on human gene expression, in normal cells from different individuals, we determined where RNA polymerase pauses along human genes and the expression levels in the corresponding genes. Using the Precision nuclear Run-On and Sequencing assay (PRO-seq), we isolated nascent RNA with actively transcribing RNA polymerase, then mapped the locations of the polymerases. From the same cells, we quantified gene expression by mRNA sequencing. We found RNA Pol II pauses in a highly regulated manner in promoters and gene bodies. We uncovered a 9-mer motif that signals where RNA polymerase II pauses. Overall, genes with more paused RNA polymerase have significantly ( $P < 10^{-16}$ ) lower gene expression. We then carried out genetics of gene expression analyses and found that RNA polymerase pausing regulates gene expression. Using data from the GTEx consortium, we confirmed that sequence variants in RNA polymerase pause sites are significantly associated with expression levels. In this presentation, we will show how mutagenesis of the sequence motif allows targeted alteration of gene expression and thus provides a promising tool to restore aberrant gene expression in genetic disorders.

## PgmNr 3362: Open chromatin and transcriptome profiling reveal key transcriptional drivers and biological processes in iPSC differentiation to lung epithelium.

Induced pluripotent stem cell (iPSCs) are a valuable tool for studying cell identity, development, and the organization of tissues. Robust protocols are available to differentiate iPSCs into lung epithelial cells at air liquid interface (ALI). This allows for the modeling of human bronchial epithelial (HBE) cell maturation, which is relevant to respiratory diseases such as asthma and cystic fibrosis. The capacity for differentiation of individual iPSC lines and their response to biochemical and/or physical cues influences maturation into functional HBE-ALI cells. Characterization of the developmental program of the stem cells may reveal aspects of critical biological processes and lineage determination. Here we use genome-wide methods to examine the gene regulatory networks that contribute to the differentiation pathways from iPSCs to HBE-ALI cultures. In addition, we compare iPSC-derived ALI cultures with primary HBE-ALI cells from donors to identify functional similarities and divergence between them.

Using cells from six key stages of differentiation we performed ATAC-seq to define the open chromatin landscape and in parallel RNA-seq to document the transcriptome. By intersecting these high-throughput datasets we reveal the dynamic nature of the transcriptional network controlling differentiation. Changes in the accessibility of promoters, intronic, and intergenic *cis*-regulatory elements (CREs) across the genome are apparent from the distribution of ATAC-seq peaks during stage progression. Transcription factor (TF) motif predictions within ATAC-peaks show changes in frequency of the binding sites for key chromatin architectural proteins such as CCCTC-binding factor (CTCF) and of cell-type selective TFs. Among these TFs is ets homologous factor (EHF) that is known to have an essential role in the differentiated functions of the airway epithelium. Gene ontology enrichment analysis of differentially expressed genes (DEGs) indicates upregulation of networks involved in immune function and in organ specification during the progression to HBE-ALI cells. Finally, the comparison with primary HBE-ALI cells illustrates key similarities that are important in airway epithelial cell identity together with significant divergence. In summary we developed a detailed profile of the regulatory landscape governing the differentiation of iPSCs to HBE-ALI that will be of value in optimizing this important human airway model system.

## PgmNr 3363: Incomplete X chromosome inactivation is reflected in complex trait genetics architecture.

X chromosome inactivation (XCI) balances X-chromosomal (chrX) gene dosages between males and females. However, XCI is incomplete: up to 25% genes escape from XCI, i.e., are expressed from both chrX in females. Notably, at escape genes the inactivated X often shows lower expression levels than its active counterpart. While escape from XCI is seen as sex differences in gene expression, its effect on the genetic architecture of complex traits is under debate. Thus far, the statistical models applied to GWAS data to study XCI have not fully incorporated the incompleteness of XCI.

We investigated how XCI is reflected in genetic associations between sexes including models reflecting known XCI biology and using height as a model trait for highly polygenic architecture. To this end, we performed sex-stratified and sex-combined GWAS in the UK Biobank (N=407,343) and compared the male-female effect estimates at the identified 74 lead SNPs on chrX and 2,711 lead SNPs on autosomes.

Unlike the autosomes, where the male and female allelic effects are close to equal on average (coefficient for male-female comparison,  $\beta_{aut}=0.977$ ), chrX is enriched in SNPs with larger female effect ( $\beta_x=0.879$ ,  $P=0.003$  for the difference). Such observation deviates from the full XCI assumption hence suggesting a contribution from ~23% loci that escape from XCI.

To further quantify the degree of escape, we applied a mixture model to cluster the chrX lead SNPs into three groups: full XCI (F-XCI) and no XCI (N-XCI) models and additionally an incomplete XCI model (I-XCI) that accounts for the case where expression from the inactivated X is ~70% lower than active X. In this analysis, less than 1% of the lead SNPs followed N-XCI, i.e. full two chrX dosage in females, an estimate in line with prior expression-based evidence. However, a much larger fraction, 36% (SE=11.4%) of the lead SNPs were explained by I-XCI. This suggests a proportionally larger contribution from loci undergoing escape from XCI (36% vs. 25%) to height genetics. Interestingly, the lead SNP with the highest I-XCI probability is rs1736534 near *ITM2A*, a gene proposed as an XCI escapee.

Our results show that escape from XCI is indeed reflected in the GWAS results of height, and to a larger degree than previously reported. This finding became possible as we explicitly included the biologically motivated I-XCI in our statistical framework. We are expanding these investigations to other complex traits and genetic architectures.

## PgmNr 3364: Investigation of DNA elements regulating the escape of *KDM5C/Kdm5c* from X-chromosome inactivation.

X-chromosome inactivation (XCI) epigenetically silences one X chromosome in every cell in female mammals, but approximately 12-27% of human and 3-7% of mouse X-linked genes escape from XCI and continue to be expressed from both the active and inactive X chromosomes. Mouse escape genes tend to be distributed as singletons while human escape genes often cluster in larger domains, suggesting both promoter-centric and regional mechanisms of escape. We have shown that despite known species differences between escape gene number and distribution on the X chromosome, human escape genes *RPS4X* and *CITED1* stably escape from XCI in multiple tissues of a transgenic mouse model across development. The recognition of human elements necessary for escape from XCI in mouse provides a tractable system to assess additional human genes for intrinsic escape ability, and characterize the critical regions responsible for continued expression from an inactive X.

As the mouse escape gene *Kdm5c* (in a bacterial artificial chromosome, BAC) has also been shown to escape from XCI when integrated at the 5' end of the X-linked *Hprt* gene, we targeted a BAC containing the human homologue *KDM5C* to the same site. *KDM5C* is known to escape from XCI at the endogenous location in humans, and has been implicated in sex differences in intellectual disability and cancer. Surprisingly, RT-qPCR and promoter DNA methylation analyses demonstrated *KDM5C* to be subject to XCI in mouse. To address our primary hypotheses for why *KDM5C* failed to escape, we generated female mouse embryonic stem cell (ESC) models. (1) Escape may require full gene transcription, and the *KDM5C* we integrated in mouse had an artificial transcription stop site; therefore, a BAC without the stop in *KDM5C* was integrated into an ESC line to analyze for escape following differentiation and XCI. (2) The escape element(s) might not have been included in the BAC; therefore a region near the endogenous *Kdm5c*, located in the mouse BAC but not the human BAC, was deleted in mouse ESCs. This region does not impact *Kdm5c* expression in ESCs, so will be assessed for effects on escape upon differentiation and XCI. If neither of these tests reveals an escape mechanism, other BACs containing genes in the human *KDM5C* escape region can be integrated into the ESC model and analysed. Identifying the features permitting escape from inactivation informs our understanding of the regulatory mechanisms of *KDM5C*, as well as broader questions of XCI.

## PgmNr 3365: The people of Khyber Pakhtunkhwa: An ethnogenetic profile of dental anthropology and molecular genetics of northern part of Pakistan.

---

Occupying an area of 101,741 km<sup>2</sup> in northern Pakistan, Khyber Pakhtunkhwa Province (KP) is inhabited by 35.53 million people whose origins have been broadly attributed to ancient Dards and Kushans as well as to recently arrived populations from the west generally referred to as subjects of the Pathan dynasties. A significant sporadic literature is available on the history and culture but the scientific investigation concerning the precise origin, general biology and genetic affinities of the myriad ethnic groups residing in KP have yet to be established. Here we are provide new original information on dental morphology and molecular genetics of some 27 ethnic groups of KP.

Phenotypes were established through the analysis of the dental traits of 15,600 volunteers. Dental casts of the maxillary and mandibular dentitions of every subject selected for an ethnic group, were obtained for the permanent teeth, from at least 75 males and 75 females, which were analyzed for a set of 17 tooth-trait combinations, according to the Arizona State University Dental Morphology System. The dental phenotypes thus established were compared with the available data of 3,185 ancient and living groups scored by the same researcher (BEH). Genotypes were analyzed in a phylogeographic perspective among 4,500 volunteers from 15 ethnic groups using Y-STRs, Y-SNPs and mtDNA markers to reconstruct population history and dynamics into and out of this region. Results obtained for 1,318 HVS haplotypes were assigned to 292 haplogroups out of which 134 (10%) were represented once, 40 (3%) were represented twice and 30 (2.3%) three times. The sequences were aligned and compared with the revised Cambridge reference sequence (rCRS), which showed that the 1,061 DNA samples analyzed for paternal ancestry encompass 10 haplogroups among which haplogroup R1a was the most frequent. Nine other haplogroups (R1b, R2, Q, O3, L, J2, I2a, H, and G2a) were represented with differing frequencies. Principal coordinate analysis plots generated by combining our newly reported data with already published datasets from other world regions showed that the paternal origin of the ethnic groups of KP and adjoining areas can be traced to South Asia, Western Eurasia and Eastern Eurasia, coupled with a very limited contribution from Sub-Saharan Africa.

## PgmNr 3366: A deep learning-based approach for fast and accurate genotype imputation.

---

Genotype imputation is the statistical inference of unobserved genotypes by using haplotypes from whole genome sequencing (WGS) data as a reference. This task is critical to increase power of genome-wide association studies, allowing the identification of causal variants and helping in the interpretation of observed associations. Statistical genotype imputation is a time-consuming task that demands a substantial amount of computational power, large WGS reference panels, and uses stochastic algorithms that do not always converge into the same solution after running multiple replicates. Here we propose a deep learning-based approach that uses a pre-trained inference neural network, allowing the fast imputation of genetic variants with lower computational cost. Our proposed algorithm consists of a sparse denoising autoencoder that automatically learns the linkage disequilibrium structure among genetic variants, identifying latent factors and using them for predicting the unobserved genotypes. Our results show that our imputation autoencoder algorithm has superior computational performance when compared to other state-of-the-art imputation tools such as Minimac4, running genotype imputation more than 12 times faster and maintaining high accuracy across different genotype array platforms (F1 score  $\geq 0.94$ ,  $r^2 \geq 0.92$ ).
